THE CAMBRIDGE
WORLD HISTORY
OF HUMAN
DISEASE

EDITED BY

KENNETH F. KIPLE

Combining recent medical discoveries with historical and geographical scholarship, this volume is the most comprehensive history of human disease since the monumental *Handbook of Geographical and Historical Pathology* by August Hirsch in 1880.

Accessible to laypeople and specialists alike, *The Cambridge World History of Human Disease* explores the patterns of disease throughout the world as well as the variety of approaches that different medical traditions have used to fight it. The work includes contributions from more than 160 medical and social scientists from all over the globe, making it a truly interdisciplinary history of medicine and human disease.

The first four parts trace the concept of disease throughout history. As medicine developed from an art to a science, the idea of disease expanded to encompass not only plagues and epidemics but also maladies connected with genetics, nutrition, and substance abuse. The *History* introduces the reader to epidemiology and immunology and examines the different medical traditions as well as the attempts outside medicine to control disease. Parts V through VII then describe the history of disease in each major region of the world, including an overview of global disease ecology.

The final and largest part offers the history and geography of each significant human disease – both historical and contemporary – from AIDS to yellow fever. Each entry is divided into medical, historical, and geographical sections, and explicit indexes help guide the reader in exploring a topic through a variety of approaches.

Together with its companion *The Cambridge World History of Food* (2000), *The Cambridge World History of Human Disease* provides an extraordinary glimpse of what is known about human health as the twenty-first century begins.

Kenneth F. Kiple is Distinguished University Professor in the history department at Bowling Green State University. He is the author of *The Caribbean Slave: A Biological History* (1984) and, with Virginia King, *Another Dimension to the Black Diaspora: Diet, Disease, and Racism* (1981), both published by Cambridge University Press. He is the editor, with Kriemhild Coneè Ornelas, of *The Cambridge World History of Food* (2000), of the monumental companion to *The Cambridge World History of Human Disease*.

Preface

Over the past few decades or so, scholars and the public alike have been made increasingly aware of the role pathogens have played in shaping the history of humankind – an awareness now underscored by Quincentenary literature and exhibitions, which depict disease as a potent ally of the Spanish explorers and conquerors of the Americas. Certainly the swath that disease cut into the ranks of the Indians, and the chain of events the thinning of those ranks set in motion, constitute a vivid example of the importance of epidemiology in the unfolding of the historical process – a process that quickly spilled over from the Western Hemisphere to influence profoundly events in Africa, Europe, and ultimately the entire globe.

Yet this example, however compelling, can be as misleading as it is instructive when it creates the impression that the forces unleashed by pathogens in the Americas were products of circumstances that render them discrete. In fact, as the pages that follow demonstrate, pathogens have wielded (and are wielding) a similar dramatic and decided power over the history of all peoples everywhere throughout the whole of humankind's stay on the planet.

To make such a demonstration in substantial detail and from many different angles is one of the major purposes of this work. Another is to provide a place to start for others who wish to elaborate a biological dimension for their own research. A final purpose is to encapsulate what this generation knows or thinks it knows about disease and history as an artifact for generations to come.

One of the most striking features of world health today that scholars of those generations (as well as our own) will doubtless struggle to explain is the widely varying differences in infant, child, and adult mortality rates from region to region (as well as within regions) and the causes that generate those rates. In those less developed areas that embrace the majority of the world's population, the diseases that winnow human ranks remain, for the most part, the very killers that brought death to distant ancestors. In the world's more developed portions, however, new maladies of old age, such as heart diseases, cancer, and Alzheimer's disease, have supplanted communicable and deficiency diseases as the greatest outlets of human life.

Such differences confront us with political, economic, social, and certainly moral questions – questions that make the study of health in the less developed world a very pressing matter indeed. For this reason we have endeavored to bring the epidemiological history of that world right up to the present. Yet because of a certain "sameness" in the history of disease of the developed countries we felt no such obligation, but rather permitted these regional treatments to "trail off" and let topical entries such as "Alzheimer's Disease," "Concepts of Cancer," "Concepts of Heart-Related Diseases," and the like continue the story into the twentieth century.

Acknowledgments

This work is the fruit of the Cambridge History and Geography of Human Disease Project that was launched in late 1985. During the six years or so it took to complete, we have accumulated a considerable amount of indebtedness. That incurred by individual authors is acknowledged in their essays. It is my pleasure, however, to acknowledge the indebtedness of the project as a whole to many splendid individuals and institutions.

Funding for the project was provided as needed by various offices on the Bowling Green State University campus from beginning to end. Louis Katzner, Dean of the Graduate School, and Gary Hess, Chair of the History Department, made certain that the project was always staffed by at least one graduate assistant, and often two, on a year-round basis. The History Department also purchased computer equipment for the project including an optical scanner, made an office available for the staff, and provided secretarial service. Indeed, I shudder to think at what stage the effort would still be without Connie Willis, Judy Gilbert, and Phyllis Wulff, who performed a myriad of tasks including the typing of hundreds of letters and retyping of dozens of essays.

In addition, Christopher Dunn, Director of Research Services, helped us struggle with fundraising problems and made "seed money" available, whereas the Faculty Research Committee provided a salary and travel funds during two of the summers spent on the project. Finally, Eloise Clark, Vice President for Academic Affairs, gave us the resources needed to meet our payrolls on two critical occasions.

Seed money from outside the university was awarded to the project in 1986 by Cambridge University Press, the Hoffman–La Roche Corporation, Pfizer Pharmaceuticals, and the Milbank Memorial Fund. These monies were absolutely crucial in the early stages of the project both to launch it and to instill in us some confidence that others besides ourselves thought the effort important. A grant from the Earhart Foundation in 1987 helped to keep the project moving, and in 1988 the generosity of the National Endowment for the Humanities (Tools Division) made available the necessary funds to see it through to completion in late 1990. I am enormously grateful to all of these very fine organizations.

The project was born of discussions with Frank Smith, our editor at Cambridge University Press, and Frank has been extraordinarily supportive of the effort from the very first. That support, however, was much more than just encouragement from the sidelines. Frank was involved with the project's conceptualization; he helped to assemble the Board of Editors, and, on more than one occasion, found authorities to write essays that I had become convinced would go unwritten. To say that without his support this project would have never been realized is merely to state the obvious.

I would also like to acknowledge the considerable effort on our behalf made by copy editors Rosalind Corman and Mary Racine who, under the direction of Sophia Prybylski, were not at all intimidated by the four thousand or so manuscript pages of the project. Rather they scrutinized each and every page, frequently calling us to task, and forcing upon us that last round of writing, checking, and double checking that is so important but so painful. On the other hand, there are those who saved us a great deal of pain, and I am most grateful to some very gifted as well as good-hearted scholars who helped us with the intricacies of accenting, spelling, even rendering languages we had absolutely no compe-

tence in. These are board members Nancy Gallagher and Paul Unschuld; Oliver Phillips of the University of Kansas; and Bowling Green colleagues Ed Chen, Larry Daly, Fujiya Kawashima, and Kriemhild Coneé Ornelas.

Three generations of graduate students at Bowling Green have labored on the project, some for considerable periods of time, checking sources, entering essays into our computer equipment, preparing indexes, and performing countless other chores, including tutoring the rest of us on increasingly complex computer hardware and software. I thank them all. If these individuals were with us for a year or more, we have listed them as the associate editors they, in fact, were. Others who were with us for only a semester appear as assistant editors, but these distinctions are in no way intended to indicate reflections on the quality of the effort they gave us.

Rachael R. Graham has been the only permanent staff member to work on the project, and, as Executive Editor, it is she who has provided the continuity that kept the project from sliding into the abyss of chaos on numerous occasions. She also imposed stylistic continuity on it by reading, with marvelously critical eyes, each of our some 200 entries countless times, researching many of them, and working with the authors to completely rewrite a few. In addition, she corresponded regularly with our authors, and even as I write these words is readying a new caption listing of tables, graphs, charts, and so forth, while at the same time helping me with the latest versions of both of the indexes. It is impossible to express adequately my gratitude for all of her considerable effort and for her unfailing, and contagious, enthusiasm that accompanied it. But I shall try anyway with a simple "Thank you, Rachael." I also thank her husband, James Q. Graham, Jr., for all of his labors on our behalf in acquiring and setting up our various pieces of computer equipment. Finally I thank him for the considerable patience he exercised during years of hearing about the project from both of us and for the very good advice he provided on many occasions, just to prove he was still listening.

I am immensely grateful as well for all of the splendid advice given, and critical reviewing done, by the board members, some of whom, like Philip Curtin and Ann Carmichael, helped to initiate the project. The board members recommended most of the authors for the project, in many cases wrote essays themselves, and read essays in their areas of expertise for scientific and historical accuracy. Because of the nature of that expertise, some, such as

Tom Benedek, Jim Cassedy, Arthur Kleinman, Steve Kunitz, Ron Numbers, Dave Patterson, and Paul Unschuld, were called upon with sufficient frequency to provoke a bit of "testiness." But the collective performance of the entire board constituted a remarkable display of the highest possible standards of scholarship, right to the end when Ann Carmichael, Nancy Gallagher, Ron Numbers, and Guenter Risse more or less cheerfully helped in reading the Name Index. In some cases revisions called for by our board members were not made, or were only partially made. Negotiations with individual authors account for some of these differences, disagreement in the reports of board members account for more, and, on occasion, editorial decisions in our office were the reason. This is all by way of saying that despite the board members' incredible amounts of selfless input, only the authors and I bear final responsibility for the essays in this volume.

This work is, of course, first and foremost the product of those who wrote it, and my admiration for, and gratitude to, our 160 or so authors is boundless. Surely, as experts in their fields with countless other things besides this project to worry about, many of them must have felt sorely put upon by our (occasional) seemingly endless demands on their time. Doubtless this was very often the case for those contributors in faraway countries, when we encountered both technical and linguistic problems of communication as drafts, revisions, advice, criticism, and corrections traveled uncertainly back and forth via telephone, faxlines, and the mail services. Yet even if we tried the patience of many, the complaints have been few, and I thank all of the authors for the tremendous effort that their work represents and the wisdom it contains.

One of the great pleasures of any new project is that it generally brings new friends, and this one brought them by the score. But a project of this magnitude is also likely to bring sadness, and so it did as seven of our authors died while the work was still in progress. The loss of Michael Dols, Wilbur Downs (a board member as well), Lu Gwei-Djen, R. H. Kampmeier, Edward H. Kass, John L. Kemink, and Jerry Stannard was a heavy one for medicine and for its history.

During the course of the project, I also lost one of the best friends any person could hope for, when Miguel M. Ornelas, Director of Affirmative Action and Handicapped Services at Bowling Green State University, passed away. And it is to his memory, and to the memory of our seven colleagues on the project, that I dedicate this book.

Introduction

Between 1860 and 1864, August Hirsch published his monumental *Handbuch der historisch-geographischen Pathologie* in two volumes. In 1881 he finished an introduction to an updated edition, which Charles Creighton translated from German into English. This opus, published by the New Sydenham Society in three volumes, appeared during the years 1883 to 1886 and was entitled *Handbook of Geographical and Historical Pathology*. The *Handbook* represented a Herculean effort to detail the distribution of diseases of historical and geographic interest in time and in place.

Our work represents a similar undertaking, but with a major difference. In the second half of the nineteenth century, the dawn of germ theory, it was still possible (as Hirsch proved) for an individual working alone to produce a compilation of this sort. Today even the contemplation of such an attempt boggles the mind. The Cambridge World History of Human Disease project was launched in 1985 as a collective effort of some 160 social and medical scientists to provide at the close of this century something of what the Hirsch volumes provided at the end of the preceding century. We hope that, like the Hirsch volumes, our own effort will aid future students of health and disease in grasping our present-day understanding of diseases in their historical, spatial, and social dimensions.

Another important purpose of the project is to make available an understandable and accessible history of disease to social scientists and humanists in their many varieties. As historians, geographers, anthropologists, and other researchers have become increasingly aware of the importance of adding a biological dimension to their work, they have found the usual medical tomes, with their unfamiliar terminology and concepts, daunting indeed. We do not, however, ignore the needs of specialists in the many fields our work encompasses. Most of the following essays have been written by specialists, and all have been refereed by one or more of our board members, who are also specialists.

Parts I Through VIII

Part I of the work presents the major historical roots and branches of medical thought from ancient times to the twentieth century, and introduces the reader to the interplay of human migration, epidemiology, and immunology. Some may be interested to learn that despite popular notions about the antiquity of Chinese medicine, it actually trailed behind medicine in the West as a systematic discipline.

Part II deals with concepts of disease in the East and in the West, as well as with concepts of complex physical and mental ailments, the emphasis being on how those concepts have changed over time. As medicine has become more a science and less an art, it has helped to tame yesterday's plagues, which capriciously brought sudden death so frequently to so many. As a result, many now have the questionable privilege of living long enough to develop cancer or heart-related illnesses, which have supplanted infectious disease and malnutrition in the developed world as the most important causes of death. Increasing life expectancy has also contributed to the growth of that branch of medicine that deals with disorders of the mind and that, as Vern Bullough points out, has tended over time to appropriate for itself the right to decide what is deviant in sexual as well as other matters.

Some chapters in Part III deal with the inheritance of disease. Certainly one can inherit genetic diseases

just as one can inherit disease immunities. Some disease immunities are acquired, but even these can be viewed as a heritage of the disease environment of one's birth. Children "inherit" what might be considered special illnesses because of their age, and the heritage of human-modified environments has frequently been famine, illnesses of malnutrition, and illnesses triggered by occupation. In addition, the "heritage" of habits can often produce illness, as is made clear in the essays on substance abuse and tobaccosis (along with those on cirrhosis and emphysema in Part VIII). The remaining chapters of Part III deal with efforts outside mainstream medicine to prevent and control disease; these include public health projects and the rise of chiropractic – a system of alternative medicine.

Part IV is essentially demographic. It focuses on measuring the health of various groups by nutritional status, by morbidity, and especially by mortality. An extremely important contribution of this section derives from the methodological questions that are raised.

The following three parts provide regional histories of disease around the globe from prehistory to the present. Part V concentrates on Europe, the Middle East, Africa, and most of the Americas, whereas Part VI is devoted to Asia. We have employed two types of historical division in these sections – Western idiosyncratic divisions in Part V and the more straightforward (and convenient) divisions of "ancient," "premodern," and "modern" for Asia in Part VI. Part VII completes the regional treatment by presenting a larger picture of changing disease ecologies. In addition to encapsulating the more detailed discussions of Europe, the Americas, Africa, and Asia that appear in Parts V and VI, this section deals with two more geographic areas – the Caribbean and Australia/Oceania. Because of their diversity and relatively small populations, they were omitted from the history sections.

Collectively, the essays in Parts V through VII reveal how much more is known about the history of disease in Europe and the Americas than in the rest of the world. There are a number of reasons for this, but three stand out. One is that anthropologists and other investigators of diseases that afflicted our distant ancestors have been considerably more active in the West than elsewhere. The second is that Western medical observers have historically been more empirically oriented than their philosophically inclined counterparts elsewhere. The third reason is that Western observers have had greater opportunities to observe a greater variety of illnesses. From

the Renaissance onward, increasing urbanization created more and larger breeding grounds for disease in Europe. In addition, the expanded travel of Europeans into the larger world – travel fraught with pathogenic peril – introduced them to still more diseases. All of this seems to have stimulated a compulsiveness in the West to give names to illnesses, which was not shared by medical practitioners elsewhere.

Part VIII discusses the history and geography of the most notable diseases of humankind in alphabetical order, from AIDS through yellow fever. Most essays are divided by the subheadings *definition, distribution and incidence or prevalence, epidemiology, etiology, clinical manifestations and pathology,* and *history and geography.* However, because of the variable nature of illnesses, some essays are organized in a way that is more suitable to the topic under discussion.

In Part VIII readers will encounter some disease entities discussed under archaic names, because they occur with some frequency in historical works. In certain cases we know what disease entity or entities they were intended to describe. The term *catarrh,* for example, was used in the past (and occasionally is still used) to label a variety of conditions that produced an inflamation of the mucous membranes of the head and throat. In other instances, such as chlorosis, which was proabably often anemia, we kept the name because it specifically signifies a "disease" recognized in the past as one that struck mostly young women. However, in the case of other ephemeral diseases such as sweating sickness, typhomalarial fever, and the plague of Athens, we had no choice but to use the archaic terms because to this day we can only guess what they were.

Most of these ailments are found in Hirsch under their now archaic names. He did not, of course, discuss AIDS or other newly discovered, extremely deadly infections such as Ebola virus disease, Lassa fever, or Legionnaires' disease, or illnesses such as Alzheimer's disease that were not recognized as specific clinical entities when Hirsch wrote. Others, however, like poliomyelitis are treated in his work under a different name (in this case, epidemic cerebrospinal meningitis). Indeed, what is striking about a comparison of the illnesses discussed in our volume and those dealt with by Hirsch is how few diseases have disappeared and how few new ones have arisen to take their places in the century that divides the two efforts. Perhaps most striking of all, however, is the change in emphasis. When Hirsch wrote, the world was still ignorant of the causes of

epidemic diseases. Today, it is the chronic diseases such as cancer, Alzheimer's disease, and heart-related ailments about which we are most ignorant.

Indexes, Overlap, and Illustrative Materials

By means of two detailed indexes we have attempted to make the information in this work as useful, and accessible, as possible. The larger, general index provides many cross-references and historical synonyms for diseases. The second index lists proper names and supplies the dates and a brief biographical sketch of all historical figures in medicine mentioned by more than one author. Thus, it is possible to consult an entry on, say, the perception of disease in Asia during the eighth century (Parts I and II); to turn to another entry on the impact of smallpox and other epidemic diseases in eighth-century Japan (Part VI); to read another entry that discusses smallpox as a disease entity and provides its history; to discover something about Edward Jenner in the index of names; and then, using the general index, to trace the course of smallpox over time and around the globe.

The fact that this is possible means that there is some overlap. Yet from the outset it was decided that each essay should stand on its own. Thus, some repetition was not only inevitable but even desirable. Indeed, given the variety of methods and approaches employed by the contributors, what might be thought to be duplication is often scrutiny of a question with different lenses. Still, much overlap has been avoided because of the different approaches. Medical scientists tend to emphasize subjects that social scientists do not, and among the latter, anthropologists, demographers, economists, geographers, and historians all manage to disagree (not always cheerfully) about what is important. The various disciplines have also dictated an uneven deployment of illustrative materials. Geographers use maps; demographers, charts and graphs; anthropologists, diagrams; whereas historians all too often believe that their words are descriptive enough.

Overview

Despite the diversity, some consensus can be gleaned from the essays, and the epidemiological overview presented here is an attempt to highlight some new findings and old answers as well as the many perennial questions that remain unanswered.

Hunter-gatherers and early agriculturalists of the Old World, although hardly disease free, are gener-ally held to have been free of epidemic diseases as well as of many other illnesses now regarded as "diseases of civilization." In fact, there is some agreement that the cradle of many epidemic viral ailments, such as smallpox, was ancient South Asia, which was among the first regions to develop civilizations large enough to support these ailments. From there the diseases traveled east to China and then accompanied Buddhist missionaries to Korea and Japan.

Much evidence suggests that the West was relatively free of eruptive fevers such as smallpox, measles, and rubella until the first millennium A.D., when they finally settled in. These fevers are not mentioned in Greek texts, and as Stephen Ell points out in his study of the disease ecologies of Europe, the military fortunes of the Romans and their enemies do not seem to have been influenced by the kinds of diseases that decimated later European armies – or at least this influence was not felt until very late in the Empire's decline. But at that time, the eruptive ailments had apparently taken root, as is indicated by a change in Roman strategy and by the fate of wave after wave of invaders who enjoyed initial success only to go finally into sharp decline.

It is now clear that leprosy was a serious health problem for Europeans during much of the Middle Ages. Excavations of leper cemeteries leave no doubt that those interred were suffering from that disease and not something else such as yaws, as earlier writers have argued. The reason or reasons for the disappearance of leprosy remain subject to dispute. Some researchers believe that it had to do with the rise of tuberculosis – a disease that provides some immunity to leprosy; others argue that the plague killed so many lepers that the disease itself died out.

As for the plague, a great number of the questions regarding its course in Europe remain unanswered. It is generally accepted that it originated in the Himalayan borderlands between India and China and that the plague of Justinian (542–3), which reached Europe by 547, was in fact bubonic plague. But why it disappeared from Europe for some 800 years remains a mystery. Plague certainly seems to have been active in China during this period. The circumstances of its reappearance are also obscure. Our authors note that it may have reached the West from the Middle East. But the most likely explanation is that a plague epidemic began in China in 1331, found its way to the Crimea by 1346, and then diffused over Europe. Yet how this disease could linger on for centuries, very possibly without a sylvatic focus and with little evidence of widespread

rat mortality, has not been explained. Nor have the circumstances of the eventual disappearance of plague from western Europe in the late seventeenth and early eighteenth centuries been determined. Explanations ranging from a mutation of the bacillus to the rise of strong governments able to regulate trade (and, often by accident, disease) continue to be advanced.

Among scholars of diseases in the Americas, there is a noticeable tendency to accept the notion that much larger Indian populations developed in isolation from the rest of the world than has previously been believed. Indeed, even the now nearly empty Amazon basin was teeming with them. Like the Old World hunter-gatherers, these people were not disease free. Intestinal parasites, a form of tuberculosis that may have become extinct, encephalitis, and hepatitis tormented them along with some kind or kinds of treponemal infection, and in certain locales, such uniquely American ailments as Carrión's disease and Chagas' disease were present. But despite the fact that some populations were dense enough to host them, neither the Old World epidemic diseases, nor malaria or yellow fever, infected the native Americans. If the Indians lacked pathogens to kill them, they seem to have made up for it by violence, because burial sites often reveal that trauma was an important cause of death.

European diseases changed this state of affairs – abruptly in the case of Caribbean Indians, somewhat more slowly in the Inca and Aztec empires, and substantially more slowly among other groups in Brazil and North America. But it is generally conceded that, despite locale, about 90 percent of the population eventually died out before demographic recovery began. Ann Ramenofsky has pinned down at least 13 diseases that arrived in the Americas with the Europeans and Africans during the first two centuries after the discovery of the American continent: viral diseases including influenza, measles, mumps, rubella, smallpox, and yellow fever; bacterial ailments embracing pneumonia, scarlet fever, pertussis, anthrax, and bubonic plague; typhus, whose causative microorganism stands midway between a virus and bacteria; and one protozoal infection – malaria. There is general agreement that, outside of Brazil, smallpox was the most devastating disease, though there is puzzlement as to how a relatively benign disease suddenly became deadly in Europe as well as the Americas in the sixteenth century. But all authors concerned with the matter point out the devastating impact of disease after disease sweeping over a people and the social dislocation caused by the death of adults who normally provided food and care for the young and the old. Malaria is blamed for having depopulated much of the interior of Brazil, which brings us to still other Old World ailments, and to Africa.

If it is generally conceded that Asia was the cradle of many of the illnesses so far discussed (i.e., diseases that probably reached humankind via domesticated animals), there is no doubt that Africa was the cradle of another group of illnesses – those of wild animals and thus diseases that in many instances antedated the human species. These African diseases include some malarial types and other protozoal infections, such as African trypanosomiasis, which first infected our primate predecessors, as well as viral infections such as yellow fever and dengue.

Malaria, of course, has plagued India and China for millennia. But Africans and those of African descent living elsewhere around the globe are almost completely refractive to vivax malaria. This suggests that they have had the longest experience with what is generally believed to be the most ancient of the malarial types to affect humans. Indeed, because black Africans are so refractory to vivax malaria, the disease has disappeared from almost all of sub-Sahara Africa. By contrast, falciparum malaria, which is the most deadly of the malarial types, is also the newest; it too seems to have an African origin (or at least to have plagued Africans the longest), because Africans have by far the greatest variety and highest frequencies of genetic defenses against it.

Nonetheless, falciparum malaria spread out across the Sahara desert to take up residence around the Mediterranean and to become a serious threat in classical times, whereas vivax malaria had diffused much earlier over much of the globe. Vivax malaria doubtless reached the New World in the blood of early Spanish conquistadors, and falciparum malaria in the blood of the first slaves to be imported, if not before. Yellow fever, by contrast, was confined to Africa until the slave trade brought it to the Americas in the mid-seventeenth century. It seems to have begun tormenting European cities only in the eighteenth century, and never became established in Asia despite a plethora of suitable vectors, as well as monkey and human hosts. One possible explanation for the latter is that Asia supports so many other group B arborviruses that there has been no room for another.

In any event, such was not the case in the Americas. Both malaria and yellow fever joined in the slaughter of Indians; in the Caribbean this African

wave of disease, coming hard on the heels of the European wave, almost obliterated them. But African diseases also killed whites, while sparing blacks, who seemed immune to both. These differences in susceptibility suggested to the Europeans that neither Indians nor whites could survive hard labor in warmer regions of the hemisphere. This brought about an accelerated slave trade and, of course, an accelerated flow of African pathogens to the New World. Indeed, much of tropical and subtropical America became more an extension of the African disease environment than of the European, until late in the nineteenth century. Even smallpox arrived from African, as opposed to European, reservoirs.

Whether the Indians gave syphilis to the rest of the world is a question taken up by a number of authors in this work. The biological anthropologists report that the treponemal lesions found in the bones of pre-Columbian Indians are probably not those of syphilis (as previously thought), or at least not of syphilis as we know it today. Moreover, the ability of Indians to resist the disease, which has been taken by some as proof of its pre-Columbian presence in the Americas, can be explained to some extent by the prevalence of pinta and perhaps nonvenereal syphilis – both milder forms of treponemal disease that nonetheless would have provided some cross-immunity. Also, our authors take into account the opinion of European physicians who claimed that the syphilis they saw at the beginning of the sixteenth century was simply a more virulent form of an old disease they had always treated. In view of these circumstances it is tempting to speculate that two treponemal infections, one from the Old World and the other from the New World, somehow fused to become the disease that ravaged Europe for more than a century before becoming more benign.

Somewhere around the beginning of the eighteenth century, Europe's population began to increase and, despite fits and starts, has continued to do so. How much of this growth can be credited to improved nutrition, the abatement of disease, increasing fertility and decreasing infant and child mortality, medical intervention, the growth of nation-states and improved public health, and changes in human attitudes and behavior has long been a subject of considerable debate. Stephen Kunitz believes that all are important factors and that no single one provides a full explanation. Nonetheless, he, along with other authors considering the problem in Asia, does stress the importance of the growth of cities in which diseases could become endemic and thus transformed into childhood ailments.

Meanwhile, from the 1770s onward, the natives of Australia and Oceania were subjected with increasing ferocity to the same trial by disease that had begun almost two centuries earlier in the Americas. And according to David Stannard, the results were similar, at least in Hawaii, where he places the population decline at 90 percent and blames smallpox, as well as other epidemic illnesses and venereal disease, for both increased mortality and reduced fertility. Elsewhere the process was often more gradual and is unfortunately still ongoing in some places, such as Brazil and Colombia.

As the world's cities grew in importance, so did tuberculosis, in both Asia and the West. Our authors leave no doubt about the relationship between urbanization and tuberculosis. Yet the disease began receding while urbanization was still accelerating and long before medicine had acquired its therapeutic "magic bullet." This leaves still another unresolved medical mystery, although it would seem that the explanation lies somewhere within the parameters of improving nutrition and the development of resistance to the illness.

Crowded nineteenth-century cities with poor sanitation and impure water supplies were natural targets for another of the plagues from India – Asiatic cholera. In his essay, Reinhold Speck demonstrates the role of the British army in unwittingly unleashing the disease. He traces each of the pandemics, straightens out the problem of dating one of them, and shows how cholera did much to emphasize the importance of public health and sanitation programs.

The end of the 1800s brought an understanding of the role of vectors in a number of diseases, including malaria and yellow fever, and this along with an increase in the production of quinine permitted the Europeans finally to venture beyond the coasts into the interior of Africa. Tropical medicine became an integral part of colonizing efforts, although as both Maryinez Lyons and K. David Patterson make clear, the initial aim was not so much to help those colonized as it was to preserve the health of the colonizers. Moreover, in modifying environments to suit themselves, the latter inadvertently facilitated the spread of such illnesses as African trypanosomiasis, onchocerciasis, schistosomiasis, and leishmaniasis.

The twentieth century dawned with the principles of germ theory still being digested by the world's medical community. As our authors on Asia and Africa indicate, Western medicine has (perhaps fortunately) not always supplanted local medicine but rather has often coexisted with it. Nonetheless, the effectiveness of Western medicine in combating

trauma and illnesses such as rabies, cholera, typhoid, gangrene, puerperal fever, and yaws was quickly recognized.

Yet Western medicine was completely overwhelmed as influenza became the next great plague to sweep the earth just as World War I was winding down. As Alfred Crosby emphasizes, although the case mortality rate for the disease is low, the disease killed upward of 30 million across the globe, making it perhaps the "greatest single demographic shock that the human species has ever received." Nor did the dying cease after the pandemic was over: As R. T. Ravenholt reveals in his essay on encephalitis lethargica, this illness was a peculiar sequela to the so-called Spanish flu.

After the influenza epidemic, the developed world enjoyed perhaps its first extended respite from epidemic disease since classical times. Medical science made great strides in understanding and controlling infectious illnesses. Because of the emphasis on germ theory, however, the etiologies of nutritional ailments remained elusive for a time, but eventually those of beriberi, pellagra, rickets, and scurvy were unraveled and the role of vitamins discovered. In the tropical and subtropical worlds, Rockefeller programs were launched to rid these regions of long-standing illnesses, and if hookworm disease and yellow fever were not eradicated as had been confidently expected, at least much was learned about their control.

Rickettsial diseases have always been troublesome for armies. Typhus has been credited with defeating Napoleon in Russia, and during World War I the disease killed some 2 million to 3 million soldiers and civilians. But in World War II and its aftermath, important advances were made in combating rickettsial diseases. In addition, new drugs were developed against malaria.

As the authors writing on the ailments of infants and children make evident, the young have historically suffered most from epidemic and endemic diseases. But in the past several decades this has been changed by the development of antibiotics and by accelerated worldwide programs of vaccination. In fact, as Alfred Crosby points out, in his essay on smallpox, one of these programs led by the World Health Organization appears to have ended the career of that disease, which killed so many for so long. Poliomyelitis, which briefly loomed as another of the world's great plagues, was also brought under control by similar programs, although as H. V. Wyatt reminds us, such efforts are not without some risk and the disease lingers in many parts of the world.

Unfortunately, other diseases of the young continue to be prevalent, especially in the developing world, where protein–energy malnutrition, respiratory infections, dysenteries, and helminthic and protozoal parasites, separately and working in concert, kill or retard the development of millions each year. As our specialists make clear, much headway must be made in that world against other potentially crippling ailments such as yaws, leprosy, and ophthalmia. Some malarial strains have become drug resistant, and continued dengue epidemics, carried by the same vectors that spread yellow fever, raise the very real possibility of yellow fever making a comeback in the Western Hemisphere, as it seems to be doing in parts of Africa.

In the developed world, chronic diseases such as cancer, heart-related illnesses, and Alzheimer's disease have supplanted infectious diseases as the important killers, and increasingly the role of genes in the production of these diseases has come under scrutiny. In addition, medicine has concentrated on understanding the genetic basis for such diseases as cystic fibrosis, Down syndrome, epilepsy, favism, hemophilia, Huntington's disease, leukemia, multiple sclerosis, muscular dystrophy, Parkinson's disease, sickle cell anemia, and Tay-Sachs disease. Some of these, such as sickle-cell anemia, favism, and possibly Tay-Sachs disease, are an unfortunate result of the body's evolutionary attempt to protect itself against other diseases.

As this research has gone forward, it has become clear that many other disease conditions, such as lactose intolerance and diabetes, are strongly influenced by heredity. Leslie Sue Lieberman argues that in the latter instance a "thrifty gene" left over from the feast and famine days of our hunter-gatherer ancestors may be at work. Genes also play a vital role in selecting cancer and heart disease victims or even gout patients, although in these cases genetic predisposition can often be modified by behavioral changes – and to that extent these illnesses can be viewed as human made. No wonder, then, that there has been a recent upsurge of concern about the air we breathe and the food and other substances we take into our bodies.

It may well be that environmental factors are bringing us back face to face with epidemic illnesses. For example, as more and more individuals are entering our shrinking rain forests, new and deadly viruses are being released into the rest of the world. In fact, AIDS, which almost certainly originated in nonhuman primates, has become a plague of such proportions that it may eventually be ranked along with

the Black Death, smallpox, cholera, and influenza as among the most disastrous epidemic scourges of humankind. In addition, as Wilbur Downs shows, other extraordinarily lethal viruses such as Ebola, Marburg, and Lassa also lurk in these rain forests and pose a serious threat to us all.

When Hirsch wrote in the preceding century, few understood and appreciated the extent to which humans have created their own disease ecologies and their own diseases by the ways they live and the ways they manipulate their environments. As we approach the twenty-first century, we have finally begun to acquire that understanding. Whether at the same time we have acquired a sufficient appreciation of what we have done is another matter.

Kenneth F. Kiple

PART I

Medicine and Disease:
An Overview

I.1
History of Western Medicine from Hippocrates to Germ Theory

Greece and Rome

Before the fifth century B.C., ancient Greece had physician-seers (*iatromantis*) who combined magical procedures and drug treatments, and wound healers deft at caring for battlefield trauma. Another group of practitioners were engaged in medical dietetics, a tradition that developed primarily in response to the needs of athletes. Ultimately, it encompassed not only questions regarding exercise, bathing, and relaxation, but the regulation of food and drink for all citizens. All of these traditions eventually merged around 500 B.C. into a *techne iatriche,* or healing science, that sought to define its own intellectual approach and methodology. For this purpose, the new medicine adopted a theoretical framework capable of explaining the phenomena of health and illness. The new *techne* was also heavily dependent on clinical observations from which careful inferences and generalizations were derived.

The foremost representative of classical Greek medicine was Hippocrates, a prominent practitioner and teacher who came to personify the ideal Western physician. Within a century of his death in 370 B.C., several unknown disciples wrote nearly 60 treatises, come clinical and some theoretical, on medical subjects differing widely in content and style. This collection of writings, which comprised a comprehensive and rational healing system usually known as "Hippocratic" medicine, emphasized the individual patient. Its practitioners focused exclusively on physical factors related to health and disease, including the immediate environment. Indeed, among the most famous works of the Hippocratic corpus was the treatise *Airs, Waters, and Places,* an early primer on environmental medicine. Another was *Epidemics,* a day-to-day account of certain patients, and a third was *Regimen,* a prescription of diet and life-style conducive to health.

For the ancient Greeks, health was a state of balance among four bodily humors: blood, phlegm, yellow bile, and black bile. Each had a specific bodily source, a pair of fundamental qualities, and a particular season in which it could be produced in excess. The blood, for example, was elaborated in the liver, was hot and moist, and was prone to overflow during the spring. Not only were humors the material and dynamic components of the body, but their ever-imperfect and labile mixture was responsible for a person's psychological makeup, or "temperament," as well as for deficiencies in bodily constitution that created susceptibilities to disease.

Illness thus occurred when the humoral balance was upset either by a lack of proper nourishment or by the imperfect production, circulation, and elimination of the humors. The physician's goal was to restore a healthy balance through the use of diet, rest, or exercise and a limited number of drugs, all capable of aiding the natural healing powers believed to exist in every human being.

This somewhat conservative approach of merely assisting nature and above all not harming the sick characterized the method of Hippocratic physicians. It was congruent with the rather tenuous social position of the early Greek healer, often an itinerant craftsman entirely dependent on his personal reputation because the country lacked an educational and licensing system for medical professionals. Given the elementary state of medical knowledge as reflected in the absence of properly identified disease entities, the demands made of Hippocratic healers were simple prognostications – will the patient live or die? – and ideally some amelioration of symptoms by complementing the healing forces. Unfettered by religious barriers, although coexisting with a religious healing system based on the cult of Asclepius (the god of medicine), the *techne iatriche* prospered within the flexible tenets of humoralism, a cultural system that was widely shared by healers and their patients and that allowed for the gradual inclusion of new clinical observations.

After the death of Alexander the Great in 323 B.C. and the partial dismembering of his empire, Egypt flourished under the rule of the Ptolemies. Alexandria, the chief cultural and commercial center, became famous for its library and museum, attracting manuscripts and scholars from the entire Hellenistic world. In addition to collecting medical literature, scholars such as Herophilus of Chalcedon and Erasistratus of Cos carried out systematic human dissections, identifying structures of the circulatory and nervous systems, the eye, and the female reproductive organs.

Given the limitations of contemporary medical knowledge, as the Hippocratic healing profession began to compete for upper-class patronage serious debates ensued about the value of medical theory and

bedside expertise. Two "sects," the Dogmatists and Empiricists, first became involved in this dispute. The former, led by Praxagoras of Cos, emphasized the need for theoretical knowledge in medicine, especially to establish plausible explanations for the phenomena of health and disease. The Empiricists, under the guidance of Herophilus, revolted against excessive speculation and expressed skepticism about the value of medical theory, placing instead greater emphasis on bedside experience. Two centuries later, a third group of Greek physicians residing in Rome – the Methodists – espoused a simplistic view of bodily functioning and restricted their treatments to bathing, diet, massage, and a few drugs.

In Rome, healing was essentially a popular skill practiced by heads of families, slaves, and foreigners. A lack of regulations and low social status contributed to a general mistrust of physicians. An exception, however, was the respect accorded to Galen of Pergamon of the second century, a well-educated follower of Hippocratic medicine who managed to overcome the schisms of sectarianism. A prolific writer who authored hundreds of treatises, Galen also carried out anatomic dissections and physiological experiments on animals. He successfully integrated his extensive clinical experience, which he acquired mainly as a surgeon to performing gladiators, into his basic theoretical knowledge, providing medicine with a comprehensive system destined to survive for nearly 1,500 years.

Early Christian Era, East and West

After the collapse of the Roman Empire, Western medicine experienced a period of retrenchment and decline. Healing became an important act of Christian charity, a divine gift freely provided within the framework of the new church and not restricted to professional physicians. Given this religious orientation, Christians healed through the confession of sins, prayer, the laying on of hands, exorcisms, and miracles, occasionally performed by saints or church fathers.

In Byzantium, the Christian magical-religious healing flourished side by side with the earlier rational Greco-Roman medicine in spite of frequent tensions, especially because physicians often exacted exorbitant payments for their services. Several of them, including Oribasius of the fourth century, Aetius of Amida and Alexander of Tralles of the sixth century, and Paul of Aegina of the seventh century, compiled and preserved ancient medical knowledge and with their writings made Galen the central medical authority for the next 500 years.

Faced with a growing population and adverse economic conditions, the early Christian church created a number of philanthropic institutions. The provision of shelter and food for the poor and for strangers was extended to several forms of health care in houses called *xenones* (hostels) and more specifically *nosokomeia* (places for the sick). Among the first was an inn built by Bishop Basil around 375 in Caesarea, which was apparently staffed by nurses and physicians. Two decades later similar institutions opened their doors in Constantinople, and thereafter such hospitals proliferated in other major commercial cities of the Byzantine Empire.

In western Europe, monks played an important role in Christian healing as well as in the collection and preservation of medical manuscripts. Whereas Augustinian monks lived a life of isolation and prayer, the followers of Benedict created working communities that cared for their sick brethren as well as visitors and transients. Monasteries such as the cloister of Monte Cassino, founded in 529, and the cathedral schools after the year 800 became heirs to fragments of classical medical knowledge. Many Benedictine monasteries – such as St. Gall (c. 820) – continued both a *hospitale pauperum* for pilgrims and an *infirmarium* for sick monks and novices. Monasteries were constructed along important roads or in surviving Roman towns, notably in southern France and Italy. Sick care was dispensed as part of the traditional Christian good works. By contrast, medical treatment under the supervision of physicians remained sporadic.

Islam

Before the seventh century, Islamic healing consisted merely of a collection of popular health rules, or *hadith*s, known as "Muhammad's medicine" for use by devout Muslims living on the Arabic peninsula. In accordance with basic religious and philosophical ideas, this system was holistic, emphasizing both body and soul. However, as the Islamic Empire gradually expanded, a comprehensive body of Greco-Roman medical doctrine was adopted together with an extensive Persian and Hindu drug lore.

The collection, preservation, and eventual transmission of classical medical knowledge went on for several centuries. Even before the Arab conquest of 636, Nestorian Christians in Jundishapur, Persia, had played a prominent role in safeguarding Greek learning by translating many Greek works into the Syriac language. Later, under Islamic rule, these Nestorian physicians wielded great influence over the early caliphs, conducting searches for additional

Greek manuscripts in the Middle East and directing a massive translation program of scientific texts from Syriac into Arabic.

Islam's political supremacy and commercial networks made possible the collection of medicinal plants from the Mediterranean basin, Persia, and India. The eleventh-century author Abu al-Biruni composed a treatise on pharmacy in which he listed about 720 drugs. In addition, Islamic alchemy furnished a number of metallic compounds for the treatment of disease. Such expansions in materia medica and the compounding of remedies led to the establishment of a separate craft of pharmacy.

In medical theory, authors writing in Arabic merely followed and further systematized classical humoralism. Whereas al-Razi, or Rhazes, of the ninth and early tenth centuries contributed a number of original clinical works such as his treatise on smallpox and measles, the *Canon of Medicine* composed in the early eleventh century by the Persian physician Ibn Sina, or Avicenna, became the leading medical encyclopedia and was widely used until the seventeenth century. Finally, Moses Maimonides, a Jewish physician and prolific author, wrote on clinical subjects and medical ethics.

Islam significantly influenced hospital development, creating secular institutions devoted to the care of the sick. The first *bimaristan* – a Persian term meaning "house for the sick" – was established in Baghdad before the year 803 by Ibn Barmak, the famous wazir of Harun al-Rashid. It was based on Byzantine models transmitted to Jundishapur. Unlike previous and contemporary Christian institutions devoted to medical care, *bimaristans* were private hospitals symbolizing royal prestige, wealth, and charity. Their selected inmates came from all sectors of the population and included mentally disturbed individuals. Operated by a director together with a medical staff, pharmacist, and servants, *bimaristans* offered comprehensive medical care and educational opportunities for students serving apprenticeships. In fact, the hospitals had their own libraries, which contained copies of medical texts translated from the Greek and Syriac.

In addition to providing clinical training, medical education became more formalized. Small private schools offered a flexible curriculum of lectures and discussions, generally under the direction of famous physicians. In recognition of these cultural apprenticeships, the state issued licenses for practicing medicine to students who had successfully completed a course of theoretical and clinical studies. The traditional Islamic *hisbah* system of codes and regulations

designed to enforce law and order according to the mandates of the Koran gradually extended its jurisdiction over multiple healing activities. Physicians, surgeons, bonesetters, and pharmacists were examined by the caliph's chief physician or an appointed inspector before receiving permission to practice. Unquestionably, such official efforts to establish ethical and practical standards for medical conduct and action were important steps in the professionalization of medicine.

Middle Ages

After the twelfth century, medieval medical knowledge in the Occident ceased to be based solely on a number of scattered Greek and Latin manuscripts carefully collected and preserved for centuries in monasteries and schools. A rapidly growing number of classical medical texts, including the *Canon* of Avicenna and clinical treatises of Rhazes, were translated from Arabic to Latin. Nonetheless, the theory of four humors and qualities remained the basis for explaining health and disease. It was supplemented by the notion that an essential or "radical" moisture was needed to ensure proper mental and physical functioning. Based on the natural wetness of bodily tissues, this element played an important role in explaining disease, senility, and death.

The inclusion of medicine in early university studies had momentous consequences. Teachers devised formal curricula and identified a specific body of medical knowledge to be mastered by students. For the first time, physicians could acquire an academic degree in the field of medicine, thus laying claim to greater competency and legitimacy. Among the first schools to offer medical studies was in Salerno, around 985, but the real growth in medical education occurred in the thirteenth century with the founding of three major university centers: Montpellier and Paris in France, Bologna in Italy. Because a medieval medical education stressed theory, rhetoric, and philosophical speculation, graduates acquired an unprecedented degree of prestige and status. In contrast, the practical aspects of healing lacked intellectual standing, and surgery was therefore excluded from university studies. Graduates, in turn, created select medical organizations – often under royal patronage – and worked hard to achieve a monopoly on practice.

Teaching centers became focal points for medical investigations. Human dissection, for example, began at the University of Bologna toward the end of the thirteenth century, prompted by forensic as well as medical considerations: Both lawyers and practi-

tioners were interested in ascertaining the causes of death from foul play or epidemic disease. In 1316, a Bolognese professor, Mondino de Luzzi, wrote the first modern treatise on anatomy. This specific interest was continued at other universities, including those of Padua, Florence, and Pisa. All works on anatomy were designed to illustrate the descriptions of Galen, still the absolute authority on the subject.

In response to repeated and deadly plague epidemics – the first pandemic struck Europe between 1348 and 1350 – northern Italian city-states instituted a series of public health measures designed to protect the healthy elite from the ravages of the disease. Because poisonous miasma was blamed for the humoral imbalance that caused susceptibility to plague, authorities isolated ships whose crews and cargoes were suspected of carrying miasma. The isolation – or so-called *quarantenaria* – necessary to neutralize the offending particles lasted for 40 days. Venice and Ragusa were among the first cities to implement such measures, the former in 1348, the latter in 1377. Burial regulations, the control of water supplies, the cleansing or burning of contaminated possessions – all inaugurated a comprehensive sanitary program widely adopted by other European cities in ensuing centuries.

The emergence during the twelfth century of lay communities in which the principal focus of charitable work was care of the sick can be seen as a response to Europe's growing burden of disease. The Knights of St. John, the Teutonic Knights, and the Augustinian Brotherhood played key roles in this evolution. Hospital foundations, sponsored by the rulers of newly created kingdoms or local bishops, provided the poor, elderly, unemployed, and sick with spiritual and physical care in the form of diet and nursing. The rising prevalence of leprosy after 1200 forced the establishment of nearly 20,000 shelters to separate these stigmatized sufferers from the general population. With the onset of plague after 1348, local authorities set up quarantine stations and pesthouses aimed at isolating those suspected of harboring the disease.

Renaissance

With the revival of classical Greek learning, or humanism, during the Renaissance, Western medicine was profoundly influenced by the replacement of corrupt and incomplete texts with new Latin translations of the original Greek. However, tensions developed between the old learning and contemporary insights into the phenomena of health and disease, some of which had been previously ignored or misun-

derstood. For example, the early-sixteenth-century findings of Andreas Vesalius of Padua, based on meticulous and systematic dissections that established the foundations of modern anatomy in the West, contradicted Galen's descriptions. In fact, Vesalius demonstrated that Galen's findings were based on animal dissections – especially of the barbary ape – instead of human dissections.

Another sixteenth-century attack on classical medicine came from a Swiss practitioner, Philippus von Hohenheim, better known by his adopted name, Paracelsus. His goal was to investigate nature directly and thereby discover the hidden correspondences between the cosmos and human beings. During his many travels, Paracelsus acquired a detailed knowledge of occupational diseases. For example, he observed the ailments contracted by European miners, an unprecedented pathology without adequate classical antecedents. On the basis of his alchemical education and clinical experience, Paracelsus formulated a new theory of medicine based on the notion that the body functioned chemically under the direction of an internal "archeus," or alchemist, responsible for maintaining the proper balances and mixtures. Consequently, cures could be achieved only through the administration of chemically prepared remedies. Paracelsus strongly advocated the use of mercury in the treatment of syphilis, a potentially toxic therapy widely accepted by his contemporaries.

Equally important were the innovations in surgical technique and management of gunshot wounds by the sixteenth-century French surgeon Ambroise Paré. On the basis of new anatomic knowledge and clinical observations, Paré questioned a series of traditional assumptions concerning the treatment of injured soldiers, including venesection, cauterization, and the use of boiling oil. Paré's publications, written in the vernacular, profoundly influenced the surgical craft of his day, replacing ancient methods with procedures based on empirical knowledge.

Seventeenth Century

The classical assumptions of humoralism that had explained human functioning in health and disease for nearly two millennia in the Western world were severely challenged in the seventeenth century. During this century, the body came to be viewed as something like a machine governed by physical principles. This view was expressed by the philosopher René Descartes in a treatise published posthumously in 1662. Cartesian man had a dual nature: a physical body ruled by universal laws of matter and motion, and an immaterial soul or mind – a pure

thinking entity – located in the pineal body of the brain. The body was conceived of as a vast hydraulic network of hollow pipes, moving blood and nervous fluid in the circulatory and nervous systems under the influence of the mind.

Descartes's mechanical theory spawned a mechanical school of human physiology located primarily in northern Italy, where Galileo Galilei, the great physicist, had already established a science of mechanics. Following in Galileo's footsteps, a mathematician, Giovanni A. Borelli, analyzed the phenomenon of muscular contraction and a physician, Sanctorius of Padua, studied metabolic combustion and insensible perspiration.

In England, William Harvey's experimental discovery of the blood circulation, announced in 1628, contributed to the mechanical view of living organisms while discrediting Galen's fanciful hypothesis of a humor ebb and flow. The heart was now viewed as a pump, its chambers closing tightly with the help of valves. Blood was impelled into an intricate system of vessels according to the laws of hydrodynamics and traveled in a close circle through the arterial, venous, and capillary systems.

Not only did Harvey's findings support a mechanistic view of the human organism, but his approach to the theory – which included dissections, animal experiments, and mathematical reasoning – demonstrated the potential usefulness of scientific research in resolving physiological questions. On the basis of the ideas of Pierre Gassendi, a seventeenth-century French philosopher, regarding the corpuscular nature of matter, various British investigators working in concert studied the phenomenon of respiration. By the 1670s, Robert Boyle, Robert Hooke, Richard Lower, and John Mayow had concluded that certain air particles entering the lungs and mixing with arterial blood were essential for all vital functions. At the same time, chemical fermentation studies by Jean Baptiste van Helmont and François de la Boë explained the nature of digestion. Microscopic studies, carried out by Anton van Leeuwenhoeck in Holland using a single-lens instrument with a magnification of about 300 diameters, remained unequivocal.

Although corpuscular dynamics replaced traditional humors and their qualities in the explanation of human physiology, clinical medicine failed to benefit from the new medical theories. Practitioners treating the sick could not readily apply these views to the therapeutic tasks at hand, preferring instead to prescribe their traditional cures by adhering to obsolete ideas of humoral corruption and displacement. Thomas Sydenham, a prominent English physician, urged his colleagues to ignore the conflicting theoretical views, proposing instead the careful study of individual diseases at the bedside. Sydenham's goal was the establishment of complete clinical descriptions of particular diseases, their subsequent classification, and the development of specific remedies for each identified ailment.

Eighteenth Century

In the occidental world, the Enlightenment created an optimistic outlook concerning the role and benefits of medicine. Most contemporary thinkers believed that health was a natural state to be attained and preserved. Society had to be made aware of medical possibilities through the employment of professionals who could deal expertly with all health-related problems. Governments increasingly sought to develop social policies that included the physical well-being of the public. A new medical elite took charge and began to play a more prominent role in European society.

Among the requirements of national power perceived by European authorities was a healthy and expanding population. Greater emphasis was placed on environmental health, infant and maternal welfare, military and naval hygiene, as well as mass treatment of the poorer sectors in newly erected hospitals and dispensaries. Absolutist governments established systems of "medical police." These organizations were responsible for establishing and implementing programs, such as that designed by the German physician Johann P. Frank, to monitor and enforce public and private health regulations from cradle to grave. In Britain, private philanthropy substituted for governmental action in matters of health. Although frequently utopian in its goals, the medical police movement created greater awareness of the social and economic factors conducive to disease. In turn, physicians and reformers were successful in establishing charitable institutions for care of the sick, including mothers and children. Needy ambulatory patients were seen in dispensaries and polyclinics. Although often crowded and a source of contagion, such establishments provided shelter, food, and a modest medical regimen designed to manage illness.

Efforts to control smallpox focused on a practice popular in the Orient: smallpox variolation. The virus, taken from pustules of an active case, was inoculated in healthy individuals on the assumption that this transfer would attenuate the agent and produce only a mild case of the disease in exchange for permanent immunity. In England the procedure was pio-

neered in 1721, but it remained controversial because of its potential for causing full-fledged, often fatal cases of smallpox and thus triggering unexpected epidemics. After the 1760s, however, simplified and safer inoculation methods found popular acceptance, and these were replaced in the 1790s by cowpox vaccination, introduced by Edward Jenner.

On the theoretical front, the eighteenth century became the age of medical systems in the Western world. It was clear that a synthesis of the isolated physical and chemical discoveries of the preceding century into a comprehensive system would be necessary to provide a rationale for and guidance to clinical activities. Spurred by success in the physical sciences, especially Newton's formulation of the laws of gravity, physicians set out to establish principles governing the phenomena of health and disease. Such efforts were as old as medicine itself. However, new models of anatomy and physiology based on Vesalius's dissections and Harvey's experiments, coupled with chemical and microscopic findings, demanded placement into an updated scaffolding.

Most eighteenth-century systematists tended to be prominent academics. As teachers and famous practitioners, they zealously promoted and defended their creations, fueling bitter controversies within the medical profession. System building conferred status and a mantle of intellectual respectability conducive to patient patronage and separation from quacks. Among those who adhered to mechanical concepts in explaining clinical events were the Dutch professor Herman Boerhaave of Leyden and the German Friedrich Hoffmann of Halle. By contrast, a colleague of Hoffmann, Georg Stahl, tried to remedy the apparent inadequacies of iatromechanism by postulating the existence of a vital principle, a soul or "anima," capable of harmoniously directing all mechanical activities in the body and thus ensuring organic unity. Two subsequent systems elaborated by the Scottish physicians William Cullen and John Brown assumed that a properly balanced and stimulated nervous system played a pivotal role in the maintenance of human health.

Efforts to classify diseases were intensified. Nosology, the systematic division of disease entities, prospered side by side with similar taxonomic efforts directed at plants and animals. Physicians such as Carl von Linné (Linnaeus), Boissier de Sauvages, and Cullen established complex classification systems designed to bring order to the myriad symptom complexes found at the bedside as well as to provide guidelines for treatment. Unfortunately, these systems remained highly subjective and dependent on the clinical experience of the nosologist who produced them. Greater accuracy and uniformity were achieved as bedside experiences were linked to structural changes observed at postmortem dissections, an approach pioneered by the Italian physician Giovanni B. Morgagni but not fully implemented until decades later in France.

Nineteenth Century

French Clinical School

Modern Western medicine emerged in France at the Paris Medical School during the first half of the nineteenth century. After the French Revolution, political developments and a new philosophical outlook radically changed the theoretical and institutional bases of medicine. Given the population explosion and urbanization, hospitals became the key locations for medical advances. Housing thousands of poor patients, the Parisian hospitals offered unique opportunities for the observation of a large number of sick individuals.

The French medical revolution was ushered in by an important change in approach. Arguing that it was not necessary to discover the ultimate causes of health and disease, early leaders of the Paris Medical School, such as Pierre J. Cabanis and Philippe Pinel, postulated that physicians could perceive the effects of disease and apprehend the relationships between the disease and the patient, accessible to observation only at the bedside. Thus, only the incontestable truths of sensory perception had validity in any attempt to understand health and disease. These phenomena were too complex and variable to be placed into the straitjacket of a specific medical theory. Stress was to be placed on practical problem solving, with sense impressions providing the only reliable data.

This skeptical empiricism gave rise to a new method: "analysis." Disease was composed of many symptoms and signs, and these confusing combinations appeared sequentially at the sickbed. The most important task was to record the regular order of such manifestations, correlate them with physical signs, and thus recognize simple patterns. Eventually, practitioners would be able to discern specific disease entities and finally classify them. Pinel urged physicians to walk the hospital wards frequently, notebook in hand, recording the hourly and daily progression of illness. The goal was better diagnosis and prognosis based on clinical events.

Emphasis on the physician's powers of observation increased the importance of physical diagnosis and expanded the techniques employed in eliciting physical signs of illness. Until this time, practitioners had relied almost entirely on their patients' accounts to reach a diagnosis. Although the clinical history remained important, French physicians began to apply new methods starting with Jean N. Corvisart's direct percussion in 1808, the employment of a stethoscope by René T. H. Laennec in 1816, and indirect percussion of the body with a plessimeter designed by Pierre A. Piorry in 1826. These procedures were, of course, also based on the premise that certain organs in the patient's diseased body suffered a number of structural changes.

Thus, another fundamental development of the Paris Medical School was pathological anatomy, the study of localized changes in bodily organs accomplished through systematic postmortem examinations of the thousands of patients who died in hospitals. Correlating clinical symptoms and signs with specific organic lesions enabled practitioners to redefine particular disease entities and understand the underlying structural defects. Such clinicopathological correspondences expanded medicine's knowledge of diseases, their effects, and natural evolution. As a corollary, French physicians became more interested in improving their diagnostic rather than their therapeutical skills.

Another tool, the "numerical method," was introduced in 1828 by Pierre C. A. Louis to compare clinical findings and identify through medical statistics general disease characteristics as well as the efficacy of traditional therapies. Although this approach initially raised a storm of protest among practitioners who felt that statistical calculations tended to obscure the significance of individual clinical variations, the method launched a new era of clinical investigation, replacing intuitive and impressionistic decision making at the bedside.

By the mid-nineteenth century, however, the French school lost its undeniable leadership in Western medical practice. Although tremendously fruitful, the clinical approach based on bedside observations and postmortem findings had its limitations. Consciously ignored were questions concerning the causes of disease and the nature of biological events surrounding the phenomena of health and disease. What had been a realistic approach in an era of speculative chemistry and physiology, imperfect microscopes, and nonexistent pharmacological knowledge around 1800 became an anachronism 50 years later. Further answers had to be sought in the laboratory, not just at the sickbed.

German Scientific Medicine

Before the eclipse of the Paris Medical School, German medicine began to emerge from its earlier, speculative period, frequently labeled "romantic." From 1800 to 1825 physicians in the politically divided German states made a serious attempt to establish a "science" of medicine using criteria from the critical philosophy of Immanuel Kant. But their efforts were doomed given the elementary state of knowledge of what we consider to be the "basic" medical sciences: anatomy, physiology, biochemistry, pathology, and pharmacology.

By the 1830s, however, the foundations had been laid for less ambitious but more fruitful investigations into the phenomena of health and disease. The 1834 Prussian–German Customs Union and extensive railroad network brought a measure of economic prosperity to the German states, enabling them to support the reform of their autonomous university system. Armed with an ideology of pure research and lack of concern for immediate practical results, German physicians went to work in academic laboratories and dissecting halls. The emphasis on and prestige accorded to the pursuit of intellectual activities was eagerly supported by the highest authorities, who perceived such scientific enterprises as enhancing national prestige.

Studies in physiology, microscopic anatomy, embryology, as well as comparative and pathological anatomy flourished. One of the key figures promoting these studies was Johannes Mueller, a physiologist searching for the ultimate truths of life behind empirical data. Although his philosophical goals remained elusive, Mueller had trained a whole generation of outstanding German scientists by the time of his death in 1858. They included Theodor Schwann, proponent of the cell theory; Emil DuBois Reymond, and Hermann von Helmholtz, famous for their discoveries in nerve electrophysiology and the physics of vision; Jakob Henle, the founder of histology; and Rudolf Virchow, the founder of cellular pathology. Indeed, these men rejected a general philosophical framework and adopted a purely reductionist viewpoint, attempting to explain all biological phenomena as merely following the laws of physics and chemistry.

Germany's university system played a central role in the development of scientific medicine in the West after 1840. Unlike the near monopoly of

French academic studies in one city, Paris, there were more than 20 institutions of higher learning scattered throughout the German states, each self-governing and intensely competitive. Since degree requirements included the submission of dissertations based on original research, the stage was set for a spectacular increase in scientific activity once the universities had established prestigious professorships and built adequate laboratory facilities. Medical research became a respectable career, made possible by the proliferation of fellowships and assistantships. Successful individuals were rewarded with academic posts and further facilities, leading to a dramatic rise in scientific professionalization and specialization.

Even in clinical disciplines German academics with proper research experience edged out outstanding practitioners. A whole generation of physicians who had trained abroad – especially in Paris – returned with a knowledge of physical diagnosis and pathological anatomy. A new bedside approach combined the French methods with German chemical and microscopic examinations based on a growing understanding of human physiology and physiopathology. Although the first key step of disease description and identification had taken place in Parisian hospitals, German physician-scientists sought to understand the mechanisms that caused pathological changes. Here the laboratory became important for biochemical analyses, microscopic observations, and animal experiments.

The quest for greater diagnostic precision was aided by the design of new tools for visualizing disease. In 1851, Helmholtz described the ophthalmoscope, an instrument capable of directly exposing eye disorders and testing visual acuity. The successful assembly of a laryngoscope by Johann N. Czermak in 1857 permitted inspection of the throat, especially the larynx and vocal cords. Visualization of the esophagus was accomplished in 1868 by Adolf Kussmaul with an esophagoscope, and the bladder came to be observed with the help of the cystoscope, invented by Max Nitze in 1877. Finally, in 1895, Wilhelm C. Roentgen, a physicist, discovered the rays that carry his name. Henceforth, X-ray photographs and fluoroscopes became common features in clinical diagnosis, especially that of chest diseases.

German advances in the basic medical sciences and clinical diagnosis were not matched at the therapeutic level. In fact, a better understanding of disease processes often led to skepticism – even nihilism – regarding possible cures. To be sure, the conceptual advances in understanding disease were impressive and promised further breakthroughs. At the same time, greater technological assistance and diagnostic complexity shifted medical care to hospitals and clinics, significantly raising costs. But the actual practice of medicine remained unaffected. Although the fledgling pharmaceutical industry began to purify a number of traditional remedies and develop a few new drugs, therapeutics lagged. Translating scientific understanding into convincing practical results had to await the development of vaccines, sera, and antisepsis based on a knowledge of bacteriology.

Germ Theory

Since the time of Hippocrates, Western practitioners had blamed factors in the atmosphere for the appearance of infectious disease. A "miasma" composed of malodorous and poisonous particles generated by the decomposition of organic matter was implicated in a broad array of fevers, including plague, malaria, and yellow fever. Speculations about the nature of these miasmatic specks waxed and waned, from Girolamo Fracastoro's *seminaria,* or "seeds of disease," in 1546, to microscopic "worms," or multiplying ferments, *zymes,* proposed by William Farr in 1842. However, physicians remained generally skeptical of theories that implicated microscopic substances in the genesis of complex disease entities. Moreover, their rudimentary microscopes only added to the confusion by revealing myriad objects.

Given the clinical behavior of the most common nineteenth-century diseases such as typhus, cholera, typhoid, and yellow fever, most physicians accepted the notion that they were not directly contagious and could occur only because of specific environmental conditions. This anticontagionist posture was strongly reinforced by political and economic groups that sought to avoid the imposition of costly quarantines. But others argued that certain contagious diseases, such as smallpox, measles, and syphilis, were indeed transmitted by living parasites.

In the 1840s, chemists, including Justus von Liebig, proposed that both contagion and miasma were actually "ferments," consisting of self-reproducing particles of a chemical nature spontaneously generated during the decomposition of organic matter. At about the same time, Henle, a German anatomist, suggested that such particles were actually alive and behaved like parasites after invading the human organism. He believed that the causes of infectious disease could be found by a careful search for these parasites, believed to be members of the plant kingdom. The proof for this causal relation-

ship between disease and parasites was contained in Henle's three "postulates": constant presence of the parasite in the sick, its isolation from foreign admixtures, and reproduction of the particular disease in other animals through the transmission of an isolated parasite.

Thanks to the work of Louis Pasteur, a French chemist, fermentation and putrefaction were shown to be indeed mediated by living microorganisms. In 1857 Pasteur claimed that the yeast responsible for lactic fermentation was such a microorganism. In the early 1860s, Pasteur disposed of the doctrine of spontaneous generation, proving through a series of clever experiments that only by exposure to tainted air would processes of fermentation and putrefaction take place. Microbial life could not exist in any organic medium that had been sterilized and subsequently protected from outside contamination.

With the existence of microscopic germs and some of their actions firmly established, researchers such as Pasteur and the German physician Robert Koch began to study specific diseases. In 1876 Koch published his findings on anthrax, a deadly illness of animals, especially cattle and sheep. He provided the first proof that a specific microorganism could cause a particular disease in an animal. Koch's new techniques for obtaining pure cultures and staining pathogenic bacteria further advanced the fledgling field of microbiology and led to a reformulation of Henle's postulates. According to Koch, three criteria were needed to implicate a particular microorganism in the etiology of a certain disease. First, the parasite must be present in every case of the disease and under circumstances that could account for the clinical course and pathological changes of that disease. Second, this agent should not be present in any other disease as a fortuitous and nonpathogenic parasite. Finally, after being fully isolated from the sick organism and repeatedly grown in pure culture, the parasite should be able to induce the same disease if inoculated into another animal.

The last two decades of the nineteenth century witnessed an unprecedented string of bacteriological discoveries based on the Henle–Koch postulates, including the agents responsible for typhoid fever, leprosy, and malaria (1880), tuberculosis (1882), cholera (1883), diphtheria and tetanus (1884), pneumonia (1886), plague and botulism (1894), dysentery (1898), and syphilis (1905). Whereas Koch and his coworkers devoted much time to the development of

technical methods for cultivating and studying bacteria, Pasteur and his collaborators turned their efforts toward determining the actual mechanisms of bacterial infection and host resistance. By 1900 not only were physicians able to diagnose the presence of specific microorganisms in the human body and hence diagnose an infectious disease, but they possessed some knowledge concerning natural and acquired immunity. In several instances, the latter could be successfully induced, a belated triumph of modern laboratory medicine.

I.2
History of Chinese Medicine

Premedical Health Care

A concern with illness has been documented in China for three millennia; the earliest written evidence extant today on the theoretical and practical consequences of this concern dates from approximately the eleventh century B.C. At that time, and for centuries to come, it was assumed that the well-being of the living – be it related to success on the battlefield, to an abundant harvest, or to physical health – depended to a considerable extent on their interactions with the nonliving members of the community (i.e., with their ancestors). An adherence to specific norms was thought to guarantee social and individual health; transgressions were known to cause the wrath of the dead, who then had to be propitiated with sacrifices. The communication between the living and the nonliving that was necessary to establish the cause of an affliction and to identify an appropriate remedy was recorded on bones and turtle shells, many of which were found in the soil, especially in the province of Henan, earlier this century. Whether the belief in ancestral intervention was supplemented by a pragmatic application of drugs or other empirically valuable means of therapy was not documented in written form at this early time.

Political changes during the first millennium B.C., when the Chou dynasty fell into a period of turmoil with several centuries of civil war, may have been responsible for the rise of a new worldview. Even though a belief in the effect of ancestral curses or blessings on the health of the living has survived in Chinese culture well into the twentieth century, especially among some rural strata of the population, Chou sources indicate a change in emphasis. The physical health and illness of the individual (and, in the case of epidemics, of society) were thought of at this time predominantly as an outcome of successful protection against the possibility or manifestation of an onslaught of not only visible but also invisible enemies (i.e., demons).

In contrast to ancestors, demons, who were not related to specific living persons as deceased relatives, were not believed to desist from harming humans even if they adhered to certain moral principles. Moreover, demons could not be propitiated through sacrifice. Rather, they had to be prevented from entering and harming a human body by means of signs and symbols demonstrating an alliance with superior metaphysical powers, and they had to be removed from the body either through the casting of oral or written spells or with the help of substances designed to kill or chase away (for instance, through their odor) unwanted intruders. Several clues suggest that among the origins of acupuncture may have been attempts to pierce, with symbolic swords and lancets, afflicted, aching body regions thought to be invaded by some outside evil.

Ancestral and demonological notions of health and illness are mentioned here for two reasons. First, they have survived in Chinese culture until the present time as important aspects of the overall system of conceptualized and practical health care, particularly in the treatment of mental and children's illnesses. Second, Chinese medicine, documented since the second century B.C. and developed as a system of ideas and practices based on insights into the laws of nature rather than on metaphysics, still embodies some of the fundamental tenets of these earlier approaches to understanding health and healing, namely an emphasis on cause–effect relationships and a localistic-ontological notion of disease.

Traditional Chinese Medicine

An almost complete afterworld household, closed in 167 B.C., was unearthed from the now-well-known Ma-wang-tui site near Ch'ang-sha in Hunan between 1972 and 1974. This tomb of a noble family had been equipped with virtually everything a deceased person was thought to need in his or her subsequent existence, including 14 manuscripts on various aspects of health care. These manuscripts marked the beginning of documented Chinese medicine and revealed that it was on the verge of breaking away from metaphysical health care. Thus, we may assume that they also reflected the earliest phase in the development of medicine in China, that is, the development of a system of health care beliefs and practices focusing specifically on the illnesses of the human mind and body rather than on human social and individual existence as a whole.

The tomb dates from a period between the second century B.C. and the first century A.D., when Chinese medicine took on its basic shape. This appears to have been a quite dynamic era. As early as the first century, various schools of medical thought had been founded and had already produced diverging ideas. These were compiled under the name of the mythical Yellow Emperor and have become the clas-

sic scripture of traditional Chinese medicine, that is, the *Huang-ti nei-ching* (The inner classic of the Yellow Emperor).

An attempt at systematizing the rather heterogeneous contents of the *Huang-ti nei-ching,* and at drawing diagnostic and clinical conclusions from an assumed circulation of vapors in the human body, resulted in the second major literary work of Chinese medicine, the *Nan-ching,* probably of the first century A.D. This work is also of unknown authorship and was subsequently associated with an earlier (about the sixth century B.C.) semilegendary itinerant physician named Pien Ch'io.

Pharmaceutical knowledge was recorded with astonishing sophistication in a collection of prescriptions found among the Ma-wang-tui scripts named *Wu-shih-erh ping fang* (Prescriptions against 52 ailments) by modern researchers. At about the time of the compilation of the *Nan-ching* (and coinciding with the appearance of the materia medica of Dioscorides in A.D. 65 in the West), Chinese pharmaceutical knowledge found its own literary form when the first Chinese herbal was compiled, which became known by the title *Shen-nung pen-ts'ao ching* (The divine husbandman's classic on materia medica). Its real author is unknown, and like the other works discussed, this classic was linked to a mythical culture hero, Shen-nung, who is also credited with the development of agriculture and markets as well as with the establishment of drug lore.

Basic Perspectives

The Ma-wang-tui manuscripts, the *Huang-ti nei-ching,* the *Nan-ching,* and the *Shen-nung pen-ts'ao ching* are the main sources for our current understanding of the early developmental phase of Chinese medicine, even though the last three may have undergone considerable revisions in later centuries and cannot be considered genuine Han dynasty sources in their entirety. Still, the picture emerging from studies of these sources so far reveals the formation of several complex and multifaceted approaches to health care, all of which were associated with basic social, economic, and ideological changes preceding and following the unification of the Chinese Empire in 221 B.C.

Central to Chinese medicine is its perception of the human organism. Corresponding to the socioeconomic structure of the unified empire, the human organism was described in Han sources as a system of individual functional units that stored, distributed, and processed resources, which were brought into the organism from the outside or were developed within. The individual units were linked through a system of channels, thought to transport resources from one place to another and join the units to the outside world. The terminology used to describe the structure and workings of the organism is largely metaphoric and is based on images from the geographic, economic, and social environment of the Ch'in and Han dynasties in China.

The resources or goods to be passed through the organism were given the name *ch'i* in the *Huang-ti nei-ching.* This term denotes essential vapors thought to be the carriers of life. Similar to the development of ancient European concepts of *pneuma* and *spiritus,* the concept of *ch'i* may have originated from observations of such phenomena as suffocation and "empty vessels" (arteries = *aer tereo* = "carriers of air") in a corpse. The *Huang-ti nei-ching* described a continuous circulation of these vapors through the organism, ascribing greater importance to them than to blood. Illness occurred in an individual organism in the same way that crisis emerged in a complex state economy. This might be because one or more of the functional units failed to fulfill their duties, or were inadequately equipped with *ch'i,* or did not pass *ch'i* on. Also, the transportation system might be blocked, thereby preventing the circulation of resources. All of these problems could be caused by the person concerned – for example, through an unhealthy life-style – or by environmental conditions to which the person was unable to adapt.

The purpose of Chinese medicine, like that of all medicine, is to protect individuals from an untimely loss of health, one of their most essential possessions. According to the *Huang-ti nei-ching,* a life span of 100 years should be considered normal, and as the unknown author concluded, it is only because civilized people are unable to lead healthy lives that they must resort to medicine for help. The prevention and treatment of illness were attempted in Chinese medicine through the two basic approaches of localistic-ontological and holistic-functional reasoning.

An ontological approach views diseases either as abstract hostile entities themselves or as the result of an intrusion of some normally innocuous environmental agent into the human organism. One of the Ma-wung-tui texts suggests the existence of a tangible ontological perspective by relating the notion of small animals (such as worms or insects) entering the body to cause destruction at well-defined locations. This internal destruction was thought to become visible in the failure of bodily functions or in the destruction of external parts of the body that were associated with the internal functional units

affected first. The history of leprosy in Chinese medicine, traceable from Ch'in sources written between 252 and 221 B.C., is one example of the persistence of such ontological thoughts through two millennia of Chinese medical history. It is also a good example of the early ontological notions in China that paved the way for an understanding and acceptance of Western bacteriology, morphological pathology, and, finally, chemotherapy in the nineteenth and twentieth centuries.

In addition to such tangible agents as worms and insects, the ontological perspective views the environment as filled with agents (such as heat, cold, humidity, dryness, and wind) that are essential components of nature and that may turn into "evils" that harm humans upon entering their bodies either in undue quantities or at inappropriate times. "Wind" in particular has remained a central etiologic category in Chinese medicine through the ages, and it is this very concept of wind that demonstrates the continuation and transformation of basic demonological tenets in the history of Chinese medicine. Originally conceived of as a spirit entity, the wind was believed to live in caves and cause harm to humans when it left its residence. Yet in the *Huang-ti nei-ching* there is a shift to the concept of wind as a natural phenomenon active as a result of the movement, through heaven, of a superior spirit named *T'ai-i*. Harm was caused by wind now only if it blew from what were considered inappropriate cardinal directions in the course of the year (as might be expected in an agricultural society) or if it met humans with constitutions susceptible to harm. Then, beginning with the works of Chang Chi in the second to third century A.D., the wind came to be seen solely as an environmental agent, albeit one that could strike humanity and cause a host of illnesses.

In addition to identifiable environmental influences that could change from "normal" (*cheng*) to "evil" (*hsieh*), abstract "evil" or "malicious" (*o*) entities could enter the organism and cause illness. These assaults were thought of not only as invasions of the natural environment into the human body, but also as flare-ups between various functional units within the body itself. If, for instance, *ch'i* normally filling the spleen was exhausted beyond some acceptable degree, agents from the liver might turn evil and invade the spleen to take over its territory. The language used to describe these processes, beginning with Han dynasty sources and throughout the history of Chinese medicine, reflects the experience of the long period of "Warring States" that preceded the unification of the Chinese Empire. Furthermore,

in the same way that troops move through a country from one place to another, the ontological perspective of Chinese medicine assumed that evil intruders could be transmitted from one location in the body to another. Transmission was thought to occur in accordance with clearly defined mutual relationships between the various upper and lower, inner and outer regions of the body. An early example of this thought can be found in the biography of Pien Ch'io compiled by Ssu-ma Ch'ien in 90 B.C.

Closely linked to the ontological perspective of Chinese medicine is a functional view that is recorded in medical literature beginning with Han dynasty sources. This approach to identifying and curing illness is concerned mainly with diagnosing functional disturbances in the human organism, which is considered to be a complex structure consisting of various mutually interrelated functional units. The functional view focuses on processes and on functional relationships among the subsystems constituting the organism, and it assumes that the same illness may affect several functions at the same time.

For example, a specific functional unit may be harmed by wind. There result various pathological conditions, such as aversion to wind or fever, headache, and sweating without external reason. Or the "liver" (seen here not as a tangible organ but as a set of functions) may be marked by a depletion of *ch'i*, which is accompanied by the growth of a shade in one's eyes. Treatment may be directed at the ailment in the liver, or it may be focused solely on the secondary problem in the eyes. Although the first example reminds one of Western categories such as "disease" and "symptoms," the second demonstrates that the terms *illness, disease,* and *symptom* do not entirely overlap in Chinese and Western medicine and should be used only with great care in a comparative context.

The perspectives outlined here did not preclude the realization that one individual organism might be affected at one time by two or more mutually independent illnesses, each of which had to be named and treated separately. To make matters more complicated, one identical cause could result in two simultaneous, yet separate, illnesses. Conversely, two separate causes could bring about one single illness, with each of these situations requiring, theoretically at least, different therapeutic treatments.

Diagnosis

Some of the Ma-wang-tui texts refer to various vessels thought to pervade the body without intercon-

nection. Specific irregularities in the contents and movements of each of 11 such vessels revealed specific illnesses. The *Huang-ti nei-ching,* however, described 12 vessels, or conduits, which were interconnected. This text advocated the feeling of pulses at various locations of the body to examine movement in the individual sections of the vessel circuit and to diagnose the condition of the functional units associated with these sections. Finally, the *Nan-ching* proposed the feeling of the pulses at the wrists only and developed complicated methods for extracting detailed information on the origin, present location, and possible future courses of an illness. In addition, the *Huang-ti nei-ching* and the *Nan-ching* provided ample data on the meaning of changing colors in a person's complexion, of changes in a person's voice or mouth odor, and of changes in longing for a specific flavor. Furthermore, the *Nan-ching* recommended investigations of the condition of the skin of the lower arms and of abdominal palpitations.

These diagnostic methods were described in the literature so that an illness could be discovered and categorized from a theoretical (mainly functional) point of view. Prescription literature, by contrast, did not depend on theory. Rather, it contained listings of very simple and more or less obvious symptoms, such as headache and diarrhea. These were paired with drug prescriptions for their cures.

Theoretical Foundations and Treatment

The most impressive mode of treatment recorded in detail in the Ma-wang-tui scripts is drug therapy. More than 200 active drugs and neutral carrier substances were described, as was a highly developed pharmaceutical technology. Other therapies included massage, minor surgery, hot baths, sexual practices, dietetics, and moxa cauterization, in addition to various magical interventions. Acupuncture was not yet referred to and appeared first in the already mentioned biography of the semilegendary physician Pien Ch'io compiled by Ssu-ma Ch'ien in 90 B.C. Because no earlier documentation of needling exists in China, the origins of acupuncture, possibly the most recent mode of therapy in the history of Chinese medicine, remain unknown.

For about 1,200 years after the emergence of Chinese medicine, until the end of the Song dynasty in the thirteenth century, a dichotomy prevailed between two major currents. One was the so-called medicine of systematic correspondence; the other was pragmatic drug therapy.

The ideology of systematic correspondence appeared almost simultaneously in China and ancient Greece (possibly stimulated by a common origin, the location of which is unknown) around the sixth century B.C., when it became the theoretical underpinning of the functional approach to an understanding of health and illness.

The (most likely older) ontological understanding of illness is based on a recognition of struggle, attack, and defense as normal modes of interaction in nature. Both human behavior and the daily observation of attack and defense among other animals and plants supported this worldview.

In contrast – and this is to be regarded as one of the outstanding cultural achievements of humankind – the ideology of systematic correspondence is based on the concept of harmony as normal, and of a loss of harmony as abnormal, states of existence. Like the ontological notion, the notion of systematic correspondence drew on sufficient environmental and social evidence to be plausible; it gained legitimacy from its emphasis on the regularity of countless natural processes, a regularity that was guaranteed by the appropriate behavior and location of each perceivable phenomenon in a complex network of interrelatedness. It holds that inappropriate behavior jeopardizes this regularity, or harmony, and leads to crisis. This crisis may occur in nature, in the affairs of state, or in the life of an individual, in the last case leading to illness. Hence, this ideology is holistic in that it views both the individual physical/mental organism and the sociopolitical organism as corresponding to identical principles, and "health" is a notion transcending them.

The ideology of systematic correspondence assumes (as this designation by contemporary scholars implies) a relationship of correspondence among virtually all tangible and abstract phenomena in the universe. Phenomena of identical quality are grouped within a category, and two or more categories are linked with one another and interact with one another according to certain natural laws. Various schools emerged within the framework of systematic correspondence, advocating the existence of two (yin and yang) or five (five-phases) categories of all phenomena.

The yin–yang school was based on a perception of the unity of two antagonistic categories of all existence. Day and night are opposites, and yet they form a unity. The same applies to male and female, heaven and earth, summer and winter, above and below, dominating and submitting, and so forth. Beginning in the fourth century B.C., day, male, heaven, summer, above, and dominating were identified as qualitatively identical and were categorized

as yang, their opposites as yin. The *Huang-ti nei-ching* contains more sophisticated groupings into four and six yin–yang subcategorizations, which may have developed in the meantime.

The second school, the five-phases school, recognized five categories of qualitatively identical phenomena, symbolized by five essential environmental elements: metal, wood, water, fire, and soil. These five categories represented phases in the succession, and hierarchical stages in the interaction, of certain phenomena. For example, the liver was associated with the phase of wood, and the spleen was associated with the phase of soil. Wood – for instance, as a wood spade – could move soil; hence, a specific relationship between liver and spleen could be explained as resulting from a potential of the liver to subdue the functions of the spleen.

The *Huang-ti nei-ching* and the *Nan-ching* linked these notions of systematic correspondence with physiology, etiology, and therapy. As a result, the human organism was described as a microcosm of interrelated functional units associated with the more encompassing categories of all being, and hence with the social and physical environment. Not surprisingly, the reasons for maintaining individual health, or for the emergence of illness, closely paralleled the reasons for social and environmental harmony and crisis. The only therapeutic mode within this system of ideas was acupuncture (and to a certain degree dietary means and moxa cauterization).

The *Shen-nung pen-ts'ao ching* contained virtually no references to the concepts of systematic correspondence. Pharmaceutics developed along its own lines from a description of 365 substances in Shen-nung's herbal of the first century, to 850 substances in the first government-sponsored materia medica in 659, to more than 1,700 drug descriptions in the great herbals of the northern Song published from 960 to 1126.

One reason for this dichotomy may be seen in a basic antagonism between Confucian-Legalist thinking and the Taoist worldview. Confucian-Legalist social ideology has dominated Chinese society – with varying intensity – since the early Han dynasty. One of its conceptual foundations is the belief in social order, a social order maintained by the government through law enforcement and education, both of which encourage appropriate legal and moral behavior. The medicine of systematic correspondence was built on identical tenets; health was promised to individuals if they followed a specific life-style congruent with Confucian-Legalist ethics. Needling, moxa, and dietetics were not meant to

rescue the fatally ill, but were seen as stimuli to correct aberrations from a proper path.

By contrast, drug lore promised to rescue individuals from illness regardless of whether they adhered to morality and human rites. From the Han through the T'ang dynasty, the development of pharmaceutics was closely tied to persons affiliated with Taoism. This phenomenon was obviously related not only to the Taoist quest for elixirs and drugs of immortality, but also to the value of drug lore for contradicting the Confucian-Legalist linking of social and individual well-being with an adherence to a morally legitimated life-style and to government-proclaimed laws. Taoists claimed such rites and laws to be the origins of social and individual crisis. Thus, it was only between the thirteenth and fifteenth centuries, in the aftermath of Song Neo-Confucianism, that certain Confucian-Legalist and Taoist tenets were united for a few centuries and that attempts were made to construct a pharmacology of systematic correspondence.

Literature and Specialties

Before the decline of the last of the imperial dynasties at the end of the nineteenth century, Chinese medicine developed on many levels and in many directions. Even though new insights and data were being accumulated virtually all the time, it maintained its original theoretical foundations; perhaps a peculiarity of Chinese medical history is that the concept of obsolescence remained almost entirely alien to it. Indeed, before modern Western thought made an impact, no theory or practice was ever relegated to oblivion as outdated (only in pharmaceutics do some herbals list "drugs no longer in use"). The notion of a dialectic advancement of knowledge or of "scientific revolutions" does not apply to Chinese medicine. In fact, one should speak of an expansion rather than of a progression of knowledge, because the etymology of *progress* implies that something is left behind.

More than 12,000 titles of premodern Chinese medical literature from a period of about 2,000 years are available in libraries in China and other countries today, but not even a handful of these texts have been translated into modern languages in a philologically serious way. Hence, only some very basic historical tenets of traditional Chinese medicine are known in the West, and it is imperative that access to many sources be provided so that comparisons can be made with the history of medicine in other cultures. In this connection, it is important to note that Chinese medicine developed the same specialties as did traditional European medicine. Separate sections in the often very voluminous prescrip-

tion works and individual monographs were devoted to such problems as children's diseases, the diseases of women, skin problems, eye complaints, and throat ailments. The following provide a few examples: The earliest extant title concerned with the diseases of children is the *Lu-hsin ching* (Classic of the Fontanel), of unknown authorship and compiled around A.D. 907, which was presumably based on sources of the fourth century or even earlier. The oldest available text today on women's diseases and obstetrics is the *Fu-jen liang fang* (Good prescriptions for females) of 1237 by Ch'en Tzu-ming. A text, lost now, possibly dating back to T'ang times and indicating the Indian origins of Chinese ophthalmology, is the *Lung-shu p'u-sa yen lun* (Bodhisattva Nagarjuna's discourse on the eyes), and a first monograph on leprosy was published by Hsüeh Chi in 1529 under the title *Li-yang chi-yao* (Essentials of the *li*-lesions). On ailments affecting the throat, the oldest text extant is the *Yen-hou mai cheng t'ung lun* (Comprehensive discourse on vessel [movements] indicating [the condition of] the throat), of unknown authorship and dating from approximately 1278.

Although, as has been stressed, Chinese medicine emphasized an ontological perspective and was quite familiar with localistic notions of illness, only a few dissections were recorded during the imperial age, and surgery was never developed much beyond the knowledge needed for performing castrations. Cataract surgery was introduced from India as early as the T'ang dynasty, but was never really integrated into Chinese medicine or further developed, despite the great number of patients who could have benefited from such operations.

The reasons for such reluctance to explore human anatomy and develop surgery are unclear; also unclear is the reason for the failure to expand certain knowledge that reached an impressive stage at some early time but went no further. An example is the world's first treatise on forensic medicine, the *Hsi yüan lu* (The washing away of wrongs) of 1247 by Sung Tz'u. Although it preceded comparable Western knowledge by several centuries, it remained a solitary achievement, for no author is known to have built upon and improved this work. In contrast, pharmaceutical literature was continuously expanded and amended throughout Chinese history.

The Final Centuries of the Imperial Age

If the Han dynasty was marked by the initial development of Chinese medicine, the Song–Chin–Yüan period was the second most dynamic formative period in the history of Chinese medicine. The attempts by K'ou Tsung-shih, who wrote about the middle of the thirteenth century, by Chang Yüan-su of the twelfth century, and most important by Wang Haogu to create a pharmacology of systematic correspondence signaled a closing of the most decisive rift that had separated the two major traditions of Chinese medicine for the preceding one and a half millennia. At the same time, however, individual schools began to appear, and these initiated an increasing specialization and fragmentation within this unified system – a process that came to an end only in the twentieth century.

The second millennium of Chinese medical history was characterized by the attempts of individual authors to reconcile their own observations and experiences with the ancient theoretical guidelines. One of the first to suggest a reductionist etiology was Liu Wan-su, a twelfth-century physician who proposed that most illnesses were caused by too much heat and who advocated cooling therapies. Chang Ts'ung-cheng, a few decades later, saw the main course of human illnesses as an intrusion of "evil influences," and he founded a school emphasizing "attack and purging" in therapy. His near contemporary, Li Kao, in contrast, thought that most illnesses were a result of a failure of spleen and stomach to perform their presumed digestive functions, and he advocated supplementation of these two units as a basic therapy. None of these schools, or any other of the many opinions published in subsequent centuries, achieved even temporary dominance. Hence, a proliferation of individual perspectives characterized the history of Chinese medicine during these final centuries rather than a succession of generally acknowledged paradigms.

This does not mean, however, that this period lacked brilliance; several authors made contributions to their respective fields that were never surpassed. The *Pen-ts'ao kang mu* (Materia medica arranged according to drug descriptions and technical aspects) of 1596 by Li Shih-chen is a most impressive encyclopedia of pharmaceutics touching on many realms of natural science. It contains more than 1,800 drug monographs and more than 11,000 prescriptions in 52 volumes. In 1601 Yang Chi-chou published his *Chen-chiu ta-ch'eng* (Complete presentation of needling and cauterization) in 10 volumes, offering a valuable survey of the literature and various schools of acupuncture and moxibustion, which is cauterization by the burning of a tuft of a combustible substance (moxa) on the skin (including a chapter on pediatric massage), of the preceding one and a half millennia.

Yet despite such monumental works, the dynamics of Chinese medical history appear to have slowed down subsequently. When in 1757 one of the most brilliant physician-intellectuals of the second millennium, Hsü Ta-ch'un, wrote his *I-hsüeh yüan liu lun* (On the origins and history of medicine), he recorded a deplorable "loss of tradition" in virtually every respect of theoretical and clinical health care.

The work of Hsü Ta-ch'un, who died in the same year, 1771, as Giovanni Battista Morgagni, the author of *De Sedibus et Causis Morborum* (On the seats and causes of diseases), illustrates the fact that traditional Chinese medicine, traditional European medicine, and even modern Western medicine have more basic theoretical foundations in common than is usually believed. Hsü Ta-ch'un, a conservative who was not influenced by Western thought and was a sharp critic of the influences of Song–Chin–Yüan thought on medicine, nonetheless wrote treatises on "intra-abdominal ulcers" and, following a long tradition of military metaphors, compared the use of drugs to the use of soldiers. One may assume that he would have had few difficulties in communicating with his contemporary Morgagni or in understanding Western medicine as it later developed.

Given the internal fragmentation of traditional Chinese medicine and the fact that it contained many of the theoretical foundations of modern European and U.S. medicine, it should be no surprise that the latter was quickly accepted in China early in the twentieth century, a process stimulated by a feeling shared by many Chinese that a decent existence could be achieved only by employing Western science and technology. Only during the past four decades has there been a reassessment of the value of traditional medicine in China.

For decades, traditional Chinese medicine was held in contempt by virtually all prominent Chinese Marxist thinkers. In the 1950s and 1960s, however, it became apparent that Western medicine, with its emphasis on expertise and its many tenets that contradicted those of dialectical materialism, could not be fully integrated into a socialist society, and Chinese medicine was suddenly perceived to be a political tool. Chinese Marxist dogmatists began to point out the antagonism between Western medicine, so-called bourgeois metaphysics, and individualism, on one side, and dialectical materialism and traditional Chinese medicine, on the other. Whereas the complex formulas of traditional Chinese pharmaceutics could not be explained by modern pharmacology, the second law of dialectics as formulated by Friedrich Engels offered a satisfactory theoretical foundation.

Similarly, acupuncture anesthesia resisted modern scientific explanation, but could be understood on the basis of the dialectics of internal contradiction. Since the demise of the Cultural Revolution, such theoretical reinterpretations of traditional Chinese medicine have coexisted in China with Western medicine, with the latter dominant on virtually all levels of health care.

Efforts to preserve Chinese medicine include attempts to select those facets of that heterogeneous tradition that appear to form a coherent system, that are thought to supplement Western medicine, and that are not considered superstitious. Research on the scientific basis of traditional Chinese medicine is being pursued on many levels. Veteran doctors, however, prefer a continuation of traditional Chinese medicine in its own right. Although the dialogue between Western medicine and Chinese medicine goes on, not without tension, the Chinese population turns to both, selecting whatever it considers best for a specific problem.

I.3
Islamic and Indian Medicine

Islamic and Indian medicine originated in distinct cultural traditions but have been in close contact for many centuries. The terms *Islamic* and *Indian* as they refer to medicine do not describe static, idealized, or monolithic systems that can be categorized by referring to the medical texts of a distant golden age. Medical practices in Islamic and Indian cultures were, as elsewhere, eclectic and pluralistic, evolving in response to complex influences that varied according to time and place. This essay briefly traces the origins and the major components of the two traditions and compares and contrasts their institutional responses to the challenges of modern times.

Islamic medicine is based largely on the Greek medical knowledge of later antiquity and is more properly called Greco-Islamic or Galenic-Islamic medicine, reflecting the influence of Galen, whose works dominated medical learning in the eastern Hellenic world. At the time of the Muslim conquests of the seventh century A.D., the major centers of Greek medical learning in the eastern Mediterranean were flourishing.

Because of theological constraints, Greek Orthodox scholars were more interested in the Greek sciences, which included medicine and philosophy, than in literature, historiography, and other humanistic subjects. The Muslim conquerors recognized the excellence of Greek learning, and the Umayyid and Abbasid caliphs subsequently sponsored the translation of a large portion of the available scholarly works into Syriac and Arabic (Ullmann 1978).

The Hellenic culture had in large part been developed in the Near East and was an integral part of the Near Eastern culture inherited by the Muslims. The belief that the Greek sciences were transported from the Occident to the Orient, where they were preserved in Arabic translation until their eventual repatriation by the Occident, is mistaken. The infusion of Greek scholarship transformed the Arabic language and Islamic culture and must be viewed as a major historical process in which Islamic civilization energetically built on the existing Near and Middle Eastern cultures.

The major period of translation spanned the years from the ninth to the eleventh century and was a complex process that drew on several routes of cultural transmission. Even before the Muslim conquest, numerous Greek texts had been translated into Syriac, and many of these as well as a few original medical works written in Syriac were in turn translated to Arabic. The transmission of Greek scholarship into Arabic, which became the learned language, accelerated during the Abbasid era when, beginning toward the end of the eighth century, Harun al-Rashid and his successors sponsored centers of translation and learning in Baghdad. Almost all of Galen's lengthy medical texts were translated by the end of the ninth century, and Greek knowledge had also reached the Islamic world through Persian sources. The Achaemenid rulers of western Iran, who valued Greek knowledge, had founded in the third century A.D. a center of learning at Jundishapur where Greek scholars, captured in war, could work. In the fifth and sixth centuries A.D., Nestorian Christian scholars, persecuted in Greek Orthodox Byzantium, found refuge in Jundishapur, then under Sasanid rule. The Sasanid rulers sponsored numerous translations of Greek medical texts into Pahlevi. In the ninth century many of these Pahlevi texts were in turn translated into Arabic. Finally, the major Indian medical works were translated into Arabic or Persian and were accessi-

ble to Islamic physicians from a relatively early date (Ullmann 1978).

In answer to the often asked question regarding the originality of Islamic medicine, Manfred Ullmann, a specialist in Islamic medicine, has suggested that the question is inapplicable because it is inherently anachronistic. The physicians (hakims) of the Islamic Middle Ages, he observes, were not interested in discovering new knowledge, but rather in developing and commenting on the natural truths learned from the ancients (Ullmann 1978). This view, however, may overstate the case, for within the framework inherited from the Hellenic sciences, the Islamic scholars made numerous discoveries. For example, Alhazen (Ibn al-Haytham), a mathematician who worked in Cairo, used inductive, experimental, and mathematical methods inherited largely from Ptolemaic science to discount Greek and Islamic theories of light and vision and to produce a new, more accurate and intellectually sophisticated theory (Sabra 1972; Omar 1977).

A. I. Sabra (1987) has suggested that scholars study the Islamic sciences as part of Islamic civilization. The question then becomes not whether the Islamic scholars made original discoveries or how the Greek sciences were translated into Arabic and then into Latin, but rather by what process Islamic civilization appropriated, assimilated, and "naturalized" the Greek sciences.

According to the Greco-Islamic medical theories, diseases were caused by imbalances of the four humors of the body: hot, cold, moist, and dry. The matters of the four humors, blood, phlegm, and yellow and black bile, influenced the temperament of individuals. When the balance was upset, the body would become ill. Thus, an excess of blood would produce a sanguine condition, whereas an excess of phlegm would produce a phlegmatic condition, and so forth. The physician's role was to correct the imbalance, perhaps by prescribing foods or medicines with "hot" or "cold" properties or by removing excess blood. This system was essentially secular because it did not ascribe disease causation to supernatural influences. When Greek medical works referred to the Greek gods, Muslim translators simply inserted Allah when appropriate or made the gods historical figures.

Prophetic medicine can be viewed as a "science" that integrated medical knowledge derived from the hadiths, or sayings and traditions of Mohammed and his companions, and local medical customs, magical beliefs, incantations, charms with ideas and con-

cepts drawn from Greco-Islamic medicine. It was, in other words, an effort to incorporate Greek medical knowledge into an acceptable Islamic framework. The authors of prophetic medicine were generally not practicing physicians but *ulama* (specialists of Islamic theological and legal sciences), who worked out "religiously correct" compendia of medical lore. In recent years, many prophetic medical works have been printed and can be purchased in bookstores throughout the Islamic world.

Sufis, or mystics, believed that illness should be treated through prayer or other religious observances and not by medical means at all. In addition, many people believed in astrological influences on disease causation. Astrological medicine was widely practiced, and most astrological manuals had sections giving medical advice (Savage-Smith 1988). The obvious contradiction between natural causation, divine causation, and planetary control of events was never entirely resolved. The late Fazlur Rahman, the noted Muslim philosopher and scholar, while dismissing astrology, confronted the dilemma of the orthodox theological insistence on total reliance on God's will and the necessity of seeking secular medical intervention. He concluded that "the Qur'an's position appears to be that God acts through natural causation and human volition to further His purposes" and that whereas many theologians and Sufi leaders clearly advocated resignation to the will of God at all times, most, when sick, sought medical treatment (Rahman 1987). The average person presumably subscribed to a variety of medical beliefs without great concern for the obvious contradictions. In short, in emergencies, all possibilities were to be tried.

It might be said that over time the difference between Greco-Islamic medicine and daily medical practices resembled the difference between the classical Arabic and the spoken language. One was formal and was carefully studied and developed by savants for scholarly discourse. The other was informal, eclectic, and used for everyday needs.

Only a few of the major Greco-Islamic physicians will be mentioned here, in chronological order, to suggest their varied origins and interests. Mesue (Yuhanna ibn-Masawayh), court physician to four Abbasid caliphs during the late eighth and first half of the ninth centuries, was a renowned clinician and teacher who wrote influential texts on nosology and therapeutics. Joannitius (Hunayn ibn-Ishaq al-Ibadi) was a ninth-century physician who studied in Jundishapur, Basra, and Baghdad. He was proficient in Greek,

Syriac, and Arabic, and was renowned for his excellent translations of Greek medical texts, which secured his place in the history of medicine and of Islamic civilization. He also wrote monographs on ophthalmology and other subjects. His contemporary, Ali ibn Sahl Rabban al-Tabari, who worked for most of his life in Rayy, wrote a compendium of medicine based on the works of Hippocrates, Galen, Aristotle, Dioscorides, and other authors, mostly from Syriac translations. Qusta ibn-Luqa al-Balabakki, who died in 912, practiced in Baghdad and, toward the end of his life, in Armenia. He wrote on the relationship between mind and body, in addition to other medical, philosophical, and mathematical treatises. His famous contemporary, Rhazes (Abū Bakr Muhammad ibn Zakarīya al-Rāzī), was born in Rayy and practiced medicine in Baghdad and at various locations in Iran. He was a noted philosopher and alchemist who compiled the famous medical texts entitled *Kitab al-Mansuri* and *Kitab al-Hawi*. He is best known for his exceptionally precise (but not original) descriptions of diseases such as smallpox and measles. Haly Abbas (Ali ibn al-Abbas al-Majusi), who died in 994, was a physician at the Buwayhid court. He wrote the famous *Kitab al-Malaki*, one of the most concise and well-organized expositions of Greco-Islamic medicine. At about the same time, Albucasis practiced in Cordoba and wrote an encyclopedic study that contained an influential section on surgery based on Greek sources and his own findings. Avicenna (Abu-Ali al-Husayn ibn-Sina) was a polymath who during his checkered career practiced medicine at various locations in Iran. Early in the eleventh century he compiled the famous *Qanun*, a five-volume study dealing with physiology, nosology, etiology, symptomatology and therapy, simple remedies, pathology, and the preparation of compound remedies. This work is a compilation of medical knowledge of the era that was enormously influential in the Islamic world and in the West in Latin translation. He also wrote a book refuting astrology, a "science" held in ill-repute by most of the prominent physicians of the era. Averroes (Ibn Rushd) was twelfth-century Aristotelian philosopher and government official in Cordoba and Marrakesh who wrote a major medical work divided into seven parts dealing with anatomy, dietetics, pathology, nourishment, materia medica, hygiene, and therapeutics. His pupil, Maimonides (Ibn Maymun), was, like Ibn Rushd, born in Cordoba. But he left Spain following Almohad persecution and sought refuge in Cairo, where he became court physician and the official representative of Egypt's large and flourishing Jewish community. Among his medical works

is the famous *Kitab al-Fusul*, which was derived largely from Galen.

Abd al-Latif al-Baghdadi, who died in 1232, was a scientist who demonstrated that simple observation of human anatomy revealed substantial errors in Galen's anatomic descriptions. Also prominent in the thirteenth century was Ibn Nafis, who studied medicine in Damascus and became director of the Mansuri Hospital in Cairo. He wrote *al-Mujiz*, a widely used commentary on Avicenna's *Qanun*. In it he stated his famous theory of the pulmonary, or lesser, circulation of the blood, later proved correct. Finally, Ibn Abi Usaybia should be mentioned. An oculist at the Nuri Hospital in Damascus, he later worked at the Mansuri Hospital with Ibn Nafis. He compiled *Uyun al-Anba fi Tabaqat al-Atibba,* a biography of more than 400 physicians of Greco-Islamic medicine. It remains a major source on the history of Islamic medicine (Ibn Abi Usaybia 1882–4; Brockelmann 1937–49; Ullmann 1978).

These Greco-Islamic medical scholars were a diverse group, among whom were Muslims, Christians, Jews, and Zoroastrians. Persian Muslims probably outnumbered those of other origins. Although nearly all wrote their major works in Arabic, many also wrote in Syriac or Persian, as well as in Hebrew (written in either Hebraic or Arabic letters) or, later, in Turkish. Regardless of ethnic or cultural origin, all shared and contributed to the Islamic cultural tradition. Most, though by no means all, practiced medicine at some time in their careers. A few were *ulama,* or lay persons with a special interest in medicine. Women are conspicuously absent from the biobibliographies but are known to have acquired medical expertise and to have practiced medicine in medieval times (Issa 1928; Goitein 1967).

Medical education was far less structured than in modern times. Medical students studied the medical texts independently or sometimes in mosques and madrasas (schools) along with the other sciences. Often an aspiring physician studied with one or more masters and acquired practical experience through an apprenticeship. There was no formal certification system or formal curriculum. Proof of medical expertise depended on the recommendation of a physician's teachers, demonstrated familiarity with the medical texts, as well as a reputation established through practical experience. Only much later did a system of certification come into existence, in which a head doctor (*bash hakim*), appointed by the ruler, would issue an *ijaza* (permission or license) to a prospective physician testifying to his competence.

Most of the physicians discussed earlier limited the realm of their activities to the large cities, usually at court or in the homes of the wealthy. Several were directors of major hospitals in Baghdad, Damascus, Cairo, and elsewhere.

Hospitals in Islamic regions were usually funded by waqfs (religious endowments for charitable purposes). The concept of waqf funding of hospices for the sick, which may have been adapted from Byzantine custom, remained standard practice in Islamic regions until the expansion of the modern nation-state. For example, in 1662, in Tunis, the ruler Hamuda al-Muradi established a waqf funded by revenues from designated hotels, shops, public ovens, kilns, water pipes, mills, and baths and from the rent on houses. The funds were for a doctor, nurses, servants, and food for the staff and patients. In addition, the funds were to maintain the building itself, which contained 24 rooms and was intended for the sick and wounded of the army and navy and the poor who had no family to care for them. The charter of this waqf specifically stated that there was to be no distinction among Arabs, Turks, or foreigners. In Tunis and elsewhere, those who could, however, preferred to seek medical care at home from relatives and local practitioners (Gallagher 1983).

In the sixteenth and seventeenth centuries when Muslim rulers became aware of the military and commercial expansion of the European powers, they did not hesitate to recruit European physicians to their courts. Although European physicians of the era could treat most diseases no better than their Muslim counterparts, Muslim rulers, extrapolating from European advances in other fields of science and technology, suspected that the Europeans could (Gallagher 1983). The European physicians had an advantage because, although they still relied on the medical texts of Avicenna, Averroes, and Rhazes, they were more systematically educated than their Muslim counterparts. Often both Muslim and European physicians were retained at Muslim courts and were consulted according to the dictates of the ruler. European physicians at Muslim courts also sometimes served as intermediaries, interpreters, and diplomatic representatives. They were generally well compensated and held in high esteem.

A few prominent Muslim physicians also sought the new European medical knowledge. In the seventeenth century, Ibn Sallum, an important physician at the Ottoman court, relied on the works of the sixteenth- and seventeenth-century Paracelsian scholars, whose theories of chemistry (later proved wrong) had emphatically rejected the ancient Greek medical theories. Ibn Sallum translated several treatises in Paracelsian medicine from Latin to Arabic, modifying them slightly for use in Islamic regions. He is credited with being the first Muslim physician to subscribe to the new European science and was not himself trained in Greco-Islamic medicine (Savage-Smith 1987). In the eighteenth and nineteenth centuries, Muslim physicians from North Africa to Iran occasionally used European source materials to discuss the etiology and treatment of new diseases such as syphilis and cholera. Muslim scholars did not, however, understand or adopt the new experimental methods that underlay the Scientific Revolution.

The transmission of European medical knowledge was accelerated in the early nineteenth century when Muhammad Ali, the modernizing ruler of Egypt, recruited Antoine Clot-Barthelemy to organize his medical services. Clot founded a medical school in Cairo where European medicine alone was taught. European physicians were subsequently called to Istanbul, Tunis, Tehran, and other Muslim capitals to organize modern medical schools and health services. By the early twentieth century, Islamic medicine, which bore little resemblance to medical practices of the medieval era, was held in official disrepute and the Greco-Islamic theories themselves had been overturned by the experimental methods and systematic observations of modern Western medicine.

The term *Indian medicine* usually refers to Hindu or Ayurvedic medicine. It is a medical tradition distinct from either Greek or Islamic medicine. Ayurvedic scholars trace its roots to verses from the ancient Vedic hymns, which contain medical doctrines, mostly of a magicoreligious character, and date from as early as the second millennium B.C. The medical doctrines based on treatment with extracts of plants (vegetable decoctions, oils, and ghees, usually prepared at home) featured in classic Ayurvedic medicine are, however, not found in the Vedic hymns. Perhaps they derived from the herbal medicines of Buddhist monks. The term *Ayurveda* may have served to legitimize the medical system by associating it with the Vedic religious tradition. The term *Veda* refers to an abstract idea of knowledge that is found in all branches of Hindu learning. *Ayur* means prolonging or preserving life or the science of longevity. Ayurveda is, in fact, a code of life. It deals with rebirth, renunciation, salvation, soul, the purpose of life, the maintenance of mental health, and of course the prevention and treatment of diseases.

The most important Ayurvedic medical texts are the *samhitas* (the four canonical texts of the Hindu scriptures) of the mythical savants Caraka and Susruta. Both are compilations of medical traditions and exist only in incomplete or copied form. Caraka's work was apparently compiled in about the first century A.D. and that of Susruta in the fourth or sixth century. Caraka described more than 200 diseases and 150 pathological conditions. He also mentioned older magical ideas along with the rational humoral approach based on drug therapy and diet. Susruta included a long chapter on surgery, which was apparently widely practiced in antiquity but was nearly unknown in later years.

The ideas of Ayurveda have permeated Hindu cultural ways of dealing with life and death and sickness and health. Whereas Greek medicine has four humors, Ayurvedic medicine has three humors, or *dosas,* wind, bile, and phlegm, which govern health and regulate bodily functions. These are the three microcosms of the three divine universal forces, wind, sun, and moon. Illness results from an imbalance of the three *dosas.* Although an essentially rational understanding of disease and treatment underlies Ayurvedic medical doctrine, Brahmin myths, gods, and demons are sometimes cited in the classic texts to explain the origins of diseases and the character of medicine. Epidemic diseases, for example, might be caused by drought, excessive rainfall, calamities sent by the gods in punishment for sins, poisonous miasmas, or the influence of planets. The body is considered to be a manifestation of divine energy and substance, and is a microcosm of the universe. Whereas Islamic medicine acknowledged its Greek and Indian origins, Ayurvedic medicine emerged from the Hindu religious and cultural tradition (Zimmer 1948; Jolly 1951; Basham 1976; Zyzk 1985).

Medical knowledge was generally transmitted from a master practitioner to his pupil. Often, medical knowledge was handed down from father to son for many generations. Medical students also studied at medical establishments attached to large temples or in schools and universities. In the ideal, Ayurvedic physicians (*vaidyas* or *vaids*) were to be Brahmin and thoroughly learned in the Sanskrit texts. In practice, they were usually from the top three castes (*varna*), Brahmin, Kshatriya, and Vaisya, but were sometimes considered to have compromised their status by the nature of their profession. Brahmins, for example, would often not accept food from a *vaidya* because he had entered the homes of persons of lower caste and had touched excrement

and other impure substances (Basham 1976). Most people, however, had no access to the formal or learned Ayurvedic medical tradition and relied on home remedies and consultation with local medical healers. With few exceptions, only the rulers, military leaders, and male members of elite castes had access to Ayurvedic medicine.

Yunani (Ionian or Greek) medicine should also be considered a part of the Indian medical tradition. Yunani medicine was probably introduced into India with the Turco-Afghan conquests of the thirteenth century and the expansion of Persian culture in the fifteenth century. Lahore, Agra, Delhi, and Lucknow became renowned centers of Islamic learning where the classic medical texts were copied, studied, and reformulated, usually in Arabic. From the thirteenth century, Indian physicians attempted to synthesize Islamic and Ayurvedic medicine and there was much borrowing between the two systems (Leslie 1976). Ayurvedic physicians learned to classify and interpret diseases in Yunani terms. They began to diagnose disease by feeling the pulse of the patient, a practice developed in Yunani but not in Ayurvedic medicine. They used mercury, which Muslim physicians had borrowed from Europe, and opium and practiced alchemy, a science not found in Ayurvedic texts. They studied the case histories found in Yunani but not in Ayurvedic texts. In turn, the Yunani physicians (hakims) borrowed extensively from the Ayurvedic pharmacopeia and adopted many Ayurvedic ideas concerning dietary principles. Both systems were widely used in India's Muslim and Hindu communities, and Muslim physicians are known to have practiced Ayurvedic medicine and Hindu physicians to have practiced Yunani medicine.

Ayurvedic medicine reached its highest point of development from the first to the sixth century A.D., considerably earlier than Islamic medicine, which reached its highest point from the ninth to the thirteenth century. Both traditions lent themselves to sophisticated reasoning, earnest speculation, and scholarly curiosity, but also to involuted argumentation, abstract distinctions, and increasingly obscurantist generalizations. In Indian as in Islamic medicine, there was no systematic experimental research. In the sixteenth and seventeenth centuries, Ayurvedic and Yunani physicians were even less exposed than were their counterparts in the Middle East and North Africa to the new ideas of the Scientific Revolution.

The British conquest of India, begun in the mid-eighteenth century, did not immediately disrupt

long-standing medical traditions. In 1822 the British colonial authorities established the School of Native Doctors at Calcutta, where students could study both Ayurvedic and Western medicine. The British authorities also sponsored courses for the training of hakims and recruited them for medical relief projects. Within little more than a decade, however, the British government had decided that higher education in India would follow a Western model and the schools and courses in indigenous medicine were abandoned. In 1841 a British medical surgeon in the Bengal medical service found that only four or five Ayurvedic medical practitioners could read the Sanskrit texts (Leslie 1976; Metcalf 1985).

Even after the British suspended patronage of indigenous medical systems, a few princes continued to sponsor Ayurvedic and Yunani colleges. In 1889 the family of Hakim Ajmal Khan, the famous Muslim reformer and physician, established a Yunani school in Ballimaran and later a pharmacy that provided Yunani and Ayurvedic medicines. In 1906 Ajmal Khan established the Tibb (medical) Conference. Its purpose was to reform and develop Yunani medicine and to work with Ayurvedic physicians for their shared interests. In 1907 Ayurvedic practitioners established the All-India Ayurvedic Congress, which remains the leading Ayurvedic professional association. In 1910 Ajmal Khan expanded his earlier organization into the All-India Ayurvedic and Yunani Tibb Conference. The medical associations successfully opposed the Registration Acts that fully certified only allopathic, or Western-trained, British and Indian physicians. They also called for placing the ancient indigenous medical systems on a scientific basis (Metcalf 1985). Indigenous practitioners established links between their medical concepts and those of modern Western medicine in order to sanction them. When British authorities moved the capital to Delhi, Ajmal Khan requested and received land for an indigenous medical college. With funding from princes and merchants, the foundation stone for the Ayurvedic and Yunani Tibb College was laid in 1916 and the college was formally opened in 1921. Despite much ambivalence, both the British viceroy and Mahatma Gandhi gave their support to the college because it was an important symbol of the Indian cultural revival and of Hindu–Muslim cooperation (Metcalf 1986). The Indian National Congress, founded in 1920, called for government sponsorship of Indian medicine. In the 1920s and 1930s *vaidyas* and hakims who had formed professional associations in rural areas actively campaigned for government recognition.

Well before independence in 1947, more than 60 Ayurvedic and Yunani colleges existed throughout India and there were official Boards of Indian Medicine in Bombay, Madras, and elsewhere. After independence, Ayurvedic and Yunani physicians expected to win equal status with physicians trained in the Western medical schools, but despite strikes and other organized protests they did not do so. In 1956 the government established the Central Institute of Research in Indigenous Systems of Medicine and the Post Graduate Training Centre for Ayurveda in Gujarat State and similar institutions elsewhere. Although the number of Ayurvedic and Yunani colleges and dispensaries has multiplied since independence, government funding has been minimal. Many of the colleges teach anatomy, nosology, and other Western medical subjects in addition to the basic courses in Ayurvedic and Yunani medicine, but the result is popularly regarded as inadequate training in any medical system. Ayurvedic and Yunani practitioners, for example, often prescribe antibiotics and give injections, but without the understanding of the physician educated in Western medicine. According to Paul Brass, a political scientist specializing in modern India, the students in the indigenous medical schools are popularly perceived to have failed in secondary school or to have failed to gain admission to modern medical or professional schools (Brass 1972). For the treatment of serious ailments, Western medicine is preferred by those who can obtain and afford it. Nevertheless, the struggle for "medical equality" continues.

The process of medical professionalization in the Middle East was quite different. In Egypt in the late nineteenth century, medical works by Avicenna and others were published by Cairo's Bulaq Press. This could have been a sign of a revival or of a new institutionalization of Islamic medicine. Thus, Ullmann (1978) suggests that the manuscripts were published because they were part of a living medical tradition rather than part of medical history. It is probably truer that they were part of Egypt's nationalist revival and were valued primarily as part of its cultural heritage. Egyptian medical students studied exclusively Western medicine at the Qasr al-Ayni medical school or went abroad to study in British or French medical schools. By the post–World War I era, most governments in the Middle East required practicing physicians and pharmacists to be licensed, and medical schools specializing in Western medicine alone had been established in Istanbul, Beirut, Cairo, Tunis, Tehran, and many other major

cities. In Iran, for example, the modernizing government of Reza Shah required all physicians and pharmacists to be licensed by the early 1930s. Unlicensed physicians with established practices had to take an examination that, according to Byron Good, an anthropologist specializing in Iran, covered internal medicine, pharmacology, and traditional Galenic–Islamic medicine. The license given to these (*mojaz,* or permitted) physicians was not equivalent to that given by the accredited Western medical schools but was rather comparable to the *médecin toléré* license given to indigenous practitioners in French colonies. To pass the exam, the candidates had to study European medical texts in order to familiarize themselves with the new medical theories and practices. This resulted in a modification of existing medical practices, and after the early 1930s all new physicians and pharmacists had to hold licenses from the accredited medical schools (Good 1981).

The unlicensed indigenous practitioners in Egypt, Iran, and elsewhere – health barbers, midwives, bonesetters, herbalists – continued to have clients, of course, because most people did not have access to European medicine, which was expensive and confined to the large cities. But such practitioners did not themselves organize in order to establish medical schools, pharmaceutical companies, or journals specializing in Greco-Islamic medicine.

There are several possible explanations for these very different responses to the new dominance of Western medicine. Ralph Croizier (1968), a specialist in Chinese medical systems, has suggested that Islamic medicine differed from Ayurvedic and Chinese medicine because it did not claim that it contained special knowledge unknown in the West. Indeed, unlike the Hellenic medical theories shared by both Islamic and pre-Renaissance Western medicine, the ideas of Ayurvedic medicine were nearly unknown to Western scholars until the colonial era. The unique origin of Ayurvedic medicine therefore may have distinguished it from Islamic medicine.

Another explanation may be that the Ayurvedic texts were believed to have originated in Hindu holy scripture, whereas the Greco-Islamic medical texts were clearly of non-Islamic, secular origin. Barbara Metcalf, a historian of India and Pakistan, has observed, however, that, in Muslim India, Yunani medicine was considered to be an ancillary dimension of religion and its practitioners were expected to be pious men. Yet, as she cautions, Muslim scholars were aware that Yunani medicine did not contain the truths of the religion as did the *Quran* and the

hadiths, and did not consider it part of the Islamic religious sciences (Metcalf 1982).

In the Middle East, there was no competing medical system associated with a dominant indigenous religion, and Muslim, Christian, and Jewish physicians all studied the Greco-Islamic medical theories. Although Islamic medicine was not an integral part of the Islamic sciences, most people considered it to be compatible with correct Islamic values. Because not only Ayurvedic but also Yunani physicians formed professional associations, it would seem that the "unique origin" and the "religious versus secular or foreign origin" explanations can only partially explain the different responses to modern medicine and to colonial rule. An additional explanation may lie in the fact that the Middle East was closer to the European metropoles than was India, making its exposure to European political and cultural influence more intense. The main support for Ayurvedic and Yunani professional organizations has, in fact, come not from the main cities of India but from the provinces. A further explanation may be found in British colonial administrative policies. The British authorities in India initially attempted to preserve local traditions. They even combined the indigenous and European systems in their new medical schools, where courses were taught in Sanskrit and English.

The process was quite different in the Middle East and North Africa because in the nineteenth century, when the British and French established colonial rule, indigenous ruling elites such as Muhammad Ali of Egypt and his successors had for some time been trying to strengthen their own power by learning the secrets of European power. India's rulers had not had such a long exposure to European science and technology before the onset of colonial rule. Indigenous rulers in India had not, therefore, been able to emulate Muhammad Ali of Egypt or the other modernizing rulers of the Middle East, for they had been relegated to a largely ceremonial and traditional role in the British raj. The sequential establishment of colonial rule may thus have contributed to the difference in medical professionalization. Furthermore, as the nineteenth century progressed, the discovery of quinine, smallpox vaccination, new methods of public health sanitation, anesthesia, antisepsis, and other advances made the prevention and treatment of disease more effective and the modern medical profession in general more confident. The Ayurvedic and Yunani physicians, protected by British colonial policies, managed to upgrade their skills by adopting new methods of medical intervention learned from European medicine and, rather like practitioners of home-

opathy and chiropractic in the West, were able to obtain a degree of official recognition.

Finally, because the ruling elites of the Middle East and North Africa had opted for European medicine long before the colonial era, indigenous practitioners in these regions, unlike their counterparts in India, had no support from their local (Muslim) rulers and none from their European colonial rulers. Because they had been represented at most by a head doctor appointed by the ruler, they had no organized means of protest. In contrast to the authoritarian, centralized political systems of the Middle East, the constitutional form of government established in India in the twentieth century lent itself to lobbying by special interest groups such as professional associations. The result is a dual system of officially recognized medical education, professional organization, and certification in India and a single system in the Middle East and North Africa. Nevertheless, in all these regions, as in the West, a wide variety of medical practitioners continue to flourish.

Apologists for the Islamic and Indian medical traditions argue that Western medicine cannot treat all diseases. They correctly observe that many diseases have a cultural component that a local healer familiar with the beliefs of the patient might treat more satisfactorily than a counterpart trained in European medicine. It is widely recognized that diseases partly caused by psychological stress can be more effectively treated by healers who understand the religious, cultural, and political beliefs of the patient. Recognizing this and, more important, the unavoidable fact that the majority of the world's population does not have access to modern medicine, the World Health Organization has been attempting to upgrade existing indigenous medical traditions rather than to replace them with modern medicine. In practice this has meant studying local remedies with the techniques of modern science in order to distinguish between effective and harmful practices and to train practitioners to modify these methods in accord with their findings. Success has been very limited, however.

Today, in India, as Charles Leslie, an anthropologist specializing in Indian medicine, has pointed out, one must distinguish between the Ayurvedic medicine of the Sanskrit classic texts; the Yunani medicine of the classic Arabic texts; the syncretic Ayurvedic and Yunani medicine of the traditional culture; contemporary professionalized Ayurvedic and Yunani medicine (both of which have borrowed from modern Western or allopathic medicine); folk medicine; popular culture; homeopathic medicine;

and learned magic-religious medicine (Leslie 1976). Yet all must be considered part of Indian medicine.

Similarly, in the Middle East, one must distinguish between the classical Islamic medical tradition; the everyday practices of the health barbers, herbalists, midwives, bonesetters, and religious healers; and, of course, Western medicine. Throughout the Islamic world, Muslim fundamentalists are especially active in the medical schools. But outside of India and, to a lesser extent, Pakistan, they have given no thought to developing Islamic medicine along Western institutional lines. They argue that medical sciences have no nationality, but that (modern or Western) medicine should be administered according to Islamic law. Thus, charitable clinics attached to fundamentalist mosques dispense Western medicine, and the fundamentalists call merely for the revival of the comprehensive worldview and the humanistic concern that, they contend, characterized the Islamic medical system. They advocate what would in the West be called the holistic approach to patient care, with modern medicine subsidized through the legal Islamic taxes and accessible to all.

I.4
Disease, Human Migration, and History

There is a story told among the Kiowa Indians of North America's southern Great Plains about the arrival in their midst, in a time long past, of a stranger in a black suit and a tall hat. This missionary-appearing figure is confronted by Saynday, a mystic hero of the Kiowa.

"Who are you?" asks the stranger.

"I'm Saynday. I'm the Kiowa's Old Uncle Saynday. I'm the one who's always coming along. Who are you?"

"I'm smallpox."

"Where do you come from and what do you do and why are you here?"

"I come from far away, from across the Eastern Ocean. I am one of the white men – they are my people as the Kiowa are yours. Sometimes I travel ahead of them, and sometimes I lurk behind. But I am always their companion and you will find me in their camps and in their houses."

"What do you do?"

"I bring death. My breath causes children to wither like young plants in the spring snow. I bring destruction. No matter how beautiful a woman is, once she has looked at me she becomes as ugly as death. And to men I bring not death alone but the destruction of their children and the blighting of their wives. The strongest warriors go down before me. No people who have looked at me will ever be the same." (Crosby 1986)

Stories such as this abound among indigenous peoples throughout the world. Sometimes they are simple sayings, as among the Hawaiians: "Lawe li'ili'i ka make a ka Hawai'i, lawe nui ka make a ka haole" – "Death by Hawaiians takes a few at a time; death by white poeple takes many." Among some, such as the Maori of New Zealand, they are more cryptic: White people and their diseases are *"he taru tawhiti"* – "a weed from afar." And among still others elaborate systems of disease differentiation have emerged, as among the Southwest American Indian Pima and Papago, who distinguish *ká:cim múmkidag,* or "staying sicknesses," from *'óimmeddam,* or "wandering sicknesses." Staying sicknesses are those the Indians have always had; they are noncontagious, and whom they afflict and the appropriate response to them are well understood. Wandering sicknesses, in contrast, originated among other, distant peoples, principally white peoples; they are relatively new to the Indians, are highly contagious and indiscriminate in whom

they attack, and are "wrong" because there is no way to defend against them (Bahr et al. 1974).

To some Western readers these may seem like quaint notions among simple peoples. In fact, they are clear-eyed and accurate recognitions of historical and ongoing reality. For millennia upon millennia, over most of the earth's surface, the vast majority of humankind lived in relatively isolated enclaves. Diseases, of course, existed in those enclaves, but among most peoples for most of that time, none of the diseases were so-called crowd-type ecopathogenic infections such as smallpox, yellow fever, typhoid, malaria, measles, pertussis, polio, and so on (Newman 1976). Nor for most of the history of humankind did the majority of the world's populations suffer from such afflictions as hypertension, diabetes, obesity, gallstones, renal stones, coronary heart disease, appendicitis, diverticular disease, and more, including various forms of cancer (Trowell and Burkitt 1981).

During these huge stretches of time, before humans developed the ability to move great distances into areas inhabited by other humans, population growth among these generally quite healthy people was restrained by the same phenomenon that restrained growth among other animals – limited resources. With the rise of agriculture, however, the domestication of animals, and the first appearance of urban communities in Sumeria about 5,000 years ago, the resource restraint on population growth began to loosen. But another restraint emerged – infectious disease.

Early Urban Environments

Before the domestication of various kinds of birds and mammals, hunter-gatherer societies had little everyday contact with large numbers of animals except, in some cases, dogs. As humans learned to contain, control, and breed pigs, sheep, cattle, goats, horses, and fowl, however, they were forced to share those animals' environments. Although their dietary protein intake thus increased, so too did their exposure to pox viruses, distemper, measles, influenza, and other maladies, all diseases carried by the newly domesticated creatures in their midst.

Damaging as these diseases were when first encountered, in time they became the troublesome, but relatively nonlethal childhood diseases of the evolved stockbreeding societies. The diseases, along with the animals, in effect became domesticated, but only for the specific people who had endured the lengthy immunization process. As these people moved from place to place, encountering other groups, they deposited pathogens that were disas-

trous to the newly contacted, nonimmune communities. Their travels were rarely extensive, however, at least in the early centuries of animal husbandry, agriculture, and urbanization.

A major problem at this stage of social development was founded on the concentration of humans in the new protourban centers, initially in the Middle East and later elsewhere. First, the people in such locales were dependent on those in the surrounding countryside for food supplies; any depletion of those supplies, because of drought or other natural disaster, spelled catastrophe for the urban dwellers. In addition, the concentration of a large number of people in a relatively small geographic area greatly increased the opportunity for the infectious communication of various diseases from one human host to another. On occasion, and in the short term, this resulted in epidemic outbreaks of disease. Generally, however, and in the long term, it probably meant the creation of endemic diseases that did not erupt like firestorms, but that gnawed away at the well-being of the community and in part undermined its ability to reproduce.

A larger consequence of the urbanization–disease dynamic was that urban populations were often unable to sustain themselves without external support and a steady stream of in-migration from the countryside. This was a perpetual problem from the time of the rise of urban centers until the nineteenth century; throughout this period, observes William H. McNeill (1979), "rural peasantries [were required] to produce a surplus of children as well as a surplus of food to sustain urban life and the civilized social structures cities created."

This is not to say, however, that in-migrating rural peasants were greeted as saviors of civilization. On the contrary, they were fodder to be wasted in the interests of civilization's continuance. As Lawrence Stone (1977), among others, has vividly shown, as late as the seventeenth, eighteenth, and nineteenth centuries, the centers of Western civilization were cesspools of disease, exploitation, starvation, and death. In Manchester, England, for example, for much of the nineteenth century, the mortality rate for children under 5 was around 50 percent (Forbes 1986). All during this time urban dwellers in Europe were dying of bubonic plague, smallpox, syphilis, typhus, typhoid fever, measles, bronchitis, whooping cough, tuberculosis, and other diseases (e.g., Matossian 1985), which still had not spread to what – to Europeans, at least – were the most remote portions of the globe.

Migration outward to the Caribbean, the Ameri-

cas, and the Pacific from the densely packed, disease-infested urban centers of Europe and then Asia – with an involuntary assist from Africa – probably created the greatest explosion of epidemic disease and the worst human catastrophe the world has ever seen. Before turning to that holocaust, which began in the late fifteenth century, it is worth glancing at the first great disease exchange that brought both China and Rome nearly to their knees long before the peoples of the Pacific or the Americas would experience the initial forays of bacteria and viruses.

Disease and Commerce

In his well-known study *Plagues and Peoples,* and in subsequent writings as well, the historian William H. McNeill has shown that a useful way to understand the evolution of human society is to examine the complex interactions between and among microparasites and macroparasites. Microparasites, in this context, are the microscopic organisms that live off human tissue, sometimes carrying disease and death, sometimes provoking immune reactions in their host that destroy the microparasites, and sometimes developing a reciprocal relationship that allows both host and parasite to survive in a state of relative equilibrium. In the last case, the host may become a carrier of infection, capable of spreading it to others although he or she remains symptomless.

Macroparasites, in the traditional sense, are predatory animals such as lions and wolves that feed on the flesh of other animals – but McNeill suggests that, in a more metaphorical sense, humans who seize the goods of others or who compel others to provide services are also macroparasites. Like microparasites, macroparasites of this sort sometimes kill their hosts in the immediate assault, but more often they develop a long-term exploitative relationship, again a state of relative equilibrium, albeit to the much greater advantage of the parasite than the host (McNeill 1976, 1980).

Throughout the course of human evolution there have been long stretches of time when it seems that states of equilibrium have existed among the masses of people and the microparasites and macroparasites that lived off their bodies and their labor. To be sure, during these times neither the physical nor the social conditions of the majority of humankind may have been ideal, but neither were they often in a state of crisis. This was true even in the early centuries of urban society discussed earlier: Although certainly punctuated from time to time by epidemic or political upheaval – usually in tandem, the case of

Athens in the fifth century B.C. being the classic example (Shrewsbury 1950) – those early civilizations remained sufficiently separate from one another that biological and social stability was more the rule than the exception.

This began to change at about the time of the Christian Era (to use the Western chronological guidepost) as overland caravans and open-sea ships expanded trade throughout the Middle East, Asia, and Europe. The outer extremes of that new network of commerce – China and Rome – were also the least experienced in terms of previous trade interactions and cosmopolitan disease. To use the earlier-noted Pima and Papago Indian terminology, both China and Rome were well adapted to their own "staying sicknesses," but unlike the more trade-experienced peoples in much of India and the Middle East they had little experience with the "wandering sicknesses" that existed outside their realms. As a consequence, whereas most of India and the Middle East seem to have experienced no major pathogenic demographic reactions to the new expansion of commerce, China and Rome were convulsed by it.

In the late second century A.D. both Rome and China were probably overwhelmed by pestilence. In Rome the so-called Antonine plagues of A.D. 165–80 were followed less than a century later by another round of empirewide pandemic. Although it is impossible, at this distance, to determine what diseases entered Rome and caused such havoc during these times, opinion has long centered on smallpox or something similar or ancestral to it as the primary agent (Hirsch 1883; McNeill 1976). No doubt, however, other newly introduced infections (including, probably, measles) were present as well. The result was severe and prolonged population decline and, perhaps consequently, political upheaval.

A very similar epidemiological and social pattern developed in China during the same early centuries of this era (McNeill 1976). In short, the mobility of commerce, to a degree unprecedented in previous world history, introduced new and devastating waves of microparasitism to geographic locales that previously had existed in widely separated realms; the consequent population collapses probably gave rise to upheaval in the macroparasitic equilibrium (however uneasy it may already have been), with eventual deterioration and collapse of the existing political orders – the Roman and Han empires – altogether.

The European Middle Ages and After

The thousand years following the second- and third-century Roman and Chinese pandemics witnessed

recurring bouts of disease upheaval, but generally these were confined to specific geographic areas. In particular, it seems that the Mediterranean world experienced major epidemiological assaults during the middle to later centuries of the first millennium A.D., due in large part to that locale's openness to migrations and seaborne contagions. To some extent in response to this, European civilization began a slow northward shift (Biraben and Le Goff 1969).

The early medieval period in northern Europe was one of a relatively large number of disease outbreaks, but few of major epidemic consequence (Bonser 1944). As McNeill (1976) notes, "A pattern of increasing frequency but declining virulence of infectious disease is exactly what a population learning to live with a new infection experiences as the accommodation between hosts and parasites moves toward a more stable, chronic state." In sum, a parasite–host equilibrium was emerging. To be sure, by modern standards mortality from endemic diseases was high – and the urban centers were still unable to maintain growth without significant in-migration from the countryside – but overall the population of Europe probably tripled during the half-millennium between 800 and 1300.

By any standards, however, the fourteenth-century population of Europe was far from robust. The famous agricultural revolution of the Middle Ages had greatly increased European nutritional levels, thus undergirding the relatively rapid population growth (White 1962), but it was a precarious foundation for population maintenance. England, for example, was hit by major famines between 1315 and 1317, although less disastrous times of starvation were common as agricultural yields declined by nearly 20 percent in the first half of the century (Braudel 1973). Then, in midcentury, plague struck.

For some centuries migrations from Europe to the Middle East had been growing, beginning with small pilgrimages and culminating in the Crusades. These population movements generated trade networks, which themselves gave impetus to the creation of new and larger urban centers in Europe – centers of extreme crowding and extraordinarily poor public health conditions. As one English legal statute of the fourteenth century described things, as a prelude to a futile effort at correction:

So much dung and filth of the garbage and entrails as well as of beasts killed, as of other corruption, be cast and put in ditches, rivers, and other waters, and also in many other places, within, about, and nigh unto divers cities, boroughs, and towns of the realm, and the suburbs of them, that the air there is greatly corrupt and infect, and

many maladies and other intolerable diseases do daily happen. (Robertson 1968)

The worst of those "many maladies and intolerable diseases" descended on Europe from China through the trade routes of the Mediterranean, moving through southern Russia and the Crimea between 1331 and 1346, finally exploding across the length and breadth of the Continent between 1346 and 1350. By the time this first wave of the bubonic plague pandemic, the Black Death, had passed, at least a third of the population of Europe had died. Then it returned in the 1360s and 1370s to kill again, though each new visitation brought progressively lower death rates as immunity to the disease began to develop.

The weight of evidence suggests that in the wake of the plague nothing remained the same. It is perhaps an exaggeration to label the Black Death the "cause" of events ranging from the Peasants' Revolt to the Reformation, as some have done, but there is no doubt that spiritual and political faith were profoundly shaken by it. Certainly this disequilibrium – when, as one nineteenth-century historian put it, "faith disappeared, or was transformed; men became at once skeptical and intolerant" (Jusserand 1891) – made an important contribution to the great social changes that occurred in Europe from the fifteenth to the seventeenth century.

During those later centuries epidemics continued to haunt the Continent, and population recovery was slow (Flinn 1981). As before, the cities could not sustain themselves without constant in-migration from the countryside. As one writer has flatly stated, during these centuries "immigration to the towns was vital if they were to be preserved from extinction" (Mols 1973). Until the eighteenth century, however, the geographic extent of most Europeans' internal urban migrations appears to have been quite small: Apart from the forced migrations caused by warfare, as one large study has shown, the majority of those people who moved at all during their lifetimes were unlikely to have migrated more than 10 miles from their original home (Clark 1979).

The crucial point, however, for present purposes at least, is that by the close of the fifteenth century, Europeans had accumulated and exposed one another to an enormous number of what had evolved into chronic infectious diseases – including measles, mumps, influenza, chicken pox, smallpox, scarlet fever, gonorrhea, and tuberculosis, to name but a few. Although occasionally breaking out in epidemic episodes, these diseases had principally become slow

killers, many of them preying largely on children, nearly half of whom died before reaching their tenth birthday (Flinn 1981), or the aged.

It was neither children nor the aged, however, who manned the sailing ships that, near the turn of the fifteenth century, began the most extensive explorations and migrations the world had ever witnessed and, as already mentioned, in the process created what may well have been the worst series of human disasters in history.

Africa and the Caribbean

The massive African continent, with a commerce, migration, and disease history that was at least Europe's match, loomed large in the imagination of the earliest open-sea European explorers. With all its riches, however, as Alfred Crosby (1986) has commented, "Africa was a prize well within European reach, but it seared the hand that tried to hold it." In addition to malaria, one of the most destructive diseases humans have ever faced, so extensive was the barrage of African diseases that greeted the Europeans – in Crosby's words, "blackwater fever, yellow fever, breakbone fever, bloody flux, and a whole zoo of helminthic parasites" – that Africa quickly became known as the "white man's grave." Even as late as the nineteenth century it was routine for British troops stationed on the Gold Coast to lose half their number in a single year to the ravages of African disease, and European soldiers stationed alongside black troops in West Africa died from disease at a rate 15 to 20 times higher than their African counterparts (Curtin 1968). The Europeans, of course, returned some of these favors with diseases of their own to which the Africans had little or no resistance – in particular, syphilis and tuberculosis, which took a heavy toll among their African recipients.

Whereas some explorers plied the African trade, others ventured deep into the Atlantic. There they encountered peoples living in the most salubrious of island environments, peoples with no domesticated animals and no history of almost any of the diseases Europeans had had to live with for centuries and even millennia. In their great isolation, the natives of the Caribbean had long since come to biological terms with the relatively few microparasites in their midst. In this sense, they were probably similar to the Old World populations of thousands of years earlier. Predictably, European contact was calamitous for them. The Caribbean island natives, living in fairly dense coastal settlements, were overwhelmed by the barrage of diseases that rolled over

them. Unlike even the worst epidemics the Europeans had historically had to endure, including the infamous Black Death, the biological invaders of the Caribbean came in a swarm: A variety of scourges hit them all at once. In their confined island worlds there was nowhere to hide.

The island of Hispaniola was the first to be hit. In 1492, when contacted by Columbus, its population may have been as large as 8 million; less than half a century later its people were, for all practical purposes, extinct (Cook and Borah 1971). The pattern was the same throughout the islands of the Caribbean. Diseases descended on the natives in clusters. And with no one in the community having any resistance, everyone fell sick at the same time. With no one left to haul water or feed children or provide comfort to anyone else, nutritional levels plummeted and despair swept over the populace – further reducing their resistance to infection.

As the first epidemic waves passed, longer-term illnesses like tuberculosis and gonorrhea took hold, reducing the island populations still further while undermining their reproductive potential and thus any possibility of recovery. In this condition the natives were yoked to forced labor by the Spanish invaders. With the failure of native labor to produce as desired, the Europeans turned to Africa for their work force. This spelled the end for the Caribbean's native island peoples, for the enslaved Africans brought with them the diseases that earlier had made their continent the storied "white man's grave." Whipsawed between the diseases that had been accumulating in Europe and Africa for millennia, the island natives at last ceased to be (Kiple 1984).

In the centuries that followed, down to the present, the European and African diseases did most of their damage to the populations native to the other continent – tuberculosis, smallpox, and pneumonia attacking the African immigrants, malaria and yellow fever assaulting the Europeans. Demographically, the Africans triumphed: Today the descendants of African slaves dominate the populations of the Caribbean. As Kenneth Kiple (1984) has clearly shown, however, new catastrophes now lie in wait as population pressures build in the region and the safety valve of out-migration threatens to close.

The Americas

Following their invasions of the Caribbean, the sixteenth-century European explorers headed for the American mainland. Again, they encountered peoples with no previous exposure to the diseases

the Europeans bore so easily – and again the result was a holocaust.

Whereas it now appears that influenza, carried by pigs aboard Columbus's ships, may have been the initial principal killers in Hispaniola (Guerra 1985, 1988), on the American mainland the initial major cause of death was smallpox (Crosby 1972; Dobyns 1983). Death rates were much higher in coastal than in inland areas, those in the former often approaching the extermination-level rates of the Caribbean (Borah and Cook 1969). Inland areas, however, though faring somewhat better in a comparative sense, still suffered at a level that strains comprehension. The population of central Mexico, for example, appears to have dropped by one-third, from about 25 million to less than 17 million, in a single decade following European contact. Within 75 years it had fallen by 95 percent (Cook and Borah 1960; Borah and Cook 1963).

So rapidly did the viruses and bacteria spread up and down and across the North and South American continents that historians have been unable to trace their paths with any precision. It is now clear, however, that the diseases moved across the land at a much faster pace than did the men who brought them, destroying whole populations long before their very existence could be known by the European invaders (Ramenofsky 1987).

Although the overall size of the population in the Americas at the time of European contact and its subsequent rate of collapse have long been a subject of much controversy, it is becoming increasingly apparent that both numbers represent magnitudes that earlier scholars had never imagined. It is possible, in fact, that the pre-Columbian Americas contained more than 100 million persons – more than resided in Europe, including Russia – at the time of the European arrival (Dobyns 1966).

Recent regional estimates continue to support the thesis, originally propounded by Sherburne Cook and Woodrow Borah, that massive and sudden depopulation was the rule in early native European contact situations throughout the Americas: From Peru, where a population of about 9 million dropped to 600,000 during the century following contact (a 93 percent decline rate), to Nicaragua, where it fell by more than 92 percent (Cook 1981; Newson 1987); from California, where the native population declined by 95 to 98 percent before bottoming out in the nineteenth century (Thornton 1987), to Florida, where it appears to have fallen by 75 percent in only 15 years and 95 percent within the first century of European contact (Dobyns 1983); from New England, where the

Patuxet tribe was extinguished in two years and the Massachusett tribe fell by 97 percent in two decades, to Guatemala, where the highland population alone dropped by 94 percent in little more than a century (Axtell 1985; Lovell 1985). Other examples abound.

Terrible as the epidemic invasions were in all these cases, it is now becoming evident that viral and bacterial assaults, by themselves, do not sufficiently account for such large population losses. As in the Caribbean, it appears likely that in the rest of the Americas the epidemics initiated a process of collapse, which then was exacerbated by the rapid withering away of village life and social supports, along with the pervading sense of despair and helplessness that was a natural concomitant of the epidemic firestorm (Neel 1977). In addition, comparative research now suggests that the fundamental cause of the most drastic population declines may well have been an overwhelming degree of infertility directly caused by the waves of smallpox, tuberculosis, measles, and venereal infection that attacked these epidemiologically virginal populations (Stannard 1990).

The Pacific

The Pacific – from the continent of Australia to the islands of Hawaii – was the last major region of the world affected by the great era of European exploration in the sixteenth, seventeenth, and eighteenth centuries. The same lugubrious tale of explosive epidemics and drastic population decline that we have encountered in the Americas was repeated here.

The lengthy ocean voyages required to reach the Pacific screened out the danger of smallpox during the earliest years of exploration, although in time smallpox epidemics did devastate native populations throughout the entire region (for examples from Australia, Pohnpei, and Hawaii see Greer 1965; Butlin 1983; Campbell 1985; and Hanlon 1988). Influenza may have been restrained to some extent by the same distance-screening process, although influenzalike epidemics were reported in many early records and ongoing research on the spread of influenza viruses suggests ways in which the distance restraint may have been overcome (Hope-Simpson and Golubev 1987). Of greatest importance in the first decades of Western contact, however, were tuberculosis (which can explode with epidemiclike intensity in a previously uninfected population; see, e.g., Dubos 1965) and venereal diseases.

An account of the devastation visited on the Pacific is as lamentable as is the account of what happened in the Americas. In southeastern Australia about 95 percent of the aboriginal population died

off in slightly more than 60 years (Butlin 1983). In New Zealand the native population fell by about 60 percent in 70 years and at least 75 percent in a century (Lewthwaite 1950; Pool 1977). In the Marquesas Islands the population dropped by 90 percent in 65 years and by 96 percent in just over a century (Dening 1980). In Hawaii the native population was halved within 25 years following Western contact and reduced by at least 95 percent in a little more than a century (Stannard 1988). There are many more examples.

As with the natives of the Caribbean and the Americas, a primary cause of the Pacific peoples' vulnerability to the introduced infections was their lack of immunity to the new diseases and the fact that they were assaulted by a barrage of them simultaneously. In addition, some genetic factors may have also played a part. Because initial populations were relatively small in each newly settled island, the evolved gene pool in each case was probably relatively small, making large-scale die-offs more likely than would be the case in populations with a more complex and heterogeneous composition. Like American Indians, who also grew from a comparatively small population of early immigrants and who were isolated from the world's gene pools and great disease experiences for a vast period of time, Polynesians, for example, show a remarkably narrow range of blood types, with an almost complete absence of type B (Morton et al., 1967; Mourant 1983).

In the Pacific, as in the Americas, the populations that were not extinguished by their contact with the West in time began to recover. Partly because of the development of acquired immunities, and partly because of amalgamation with the races that had brought the new diseases (among Hawaiians, for example, the worst health profile today remains that of so-called pure Hawaiians, whose numbers have dwindled to less than 1 percent of those at the time of Western contact), the Pacific's native people now have birthrates higher than most of the immigrant populations in their homelands.

Conclusion

It is easy, in light of the historical record, to believe that migration-caused health disasters are a thing of the past. There are, after all, few if any hermetically remote populations left on earth; and as we have seen, from Rome and China in the second century A.D. to the Pacific in the eighteenth and nineteenth centuries – as well as parts of South America in the twentieth century – virgin-soil conditions were the seedbeds of the great disease holocausts.

The problem, however, is much more complex. In addition to the fact that immigrants to many parts of the world suffer greatly increased incidences of coronary heart disease and various forms of cancer – as, for example, Japanese immigrants to the United States (Waterhouse et al. 1976; Robertson et al. 1977) – there is the ongoing tragedy of the acquired immune deficiency syndrome (AIDS), which should be sufficient to quell undue optimism. It is far from impossible, as Joshua Lederberg (1988) has noted, that the AIDS viruses will continue to mutate, perhaps even, in his words, "learning the tricks of airborne transmission," and, as he says, "it is hard to imagine a worse threat to humanity than an airborne variant of AIDS."

Of course, that may not – indeed, probably will not – happen. But it may. Even if it does not, the great ease of human mobility and migration, along with the ability of our worst diseases to sustain themselves, ensures that – with or without virgin-soil populations in the traditional sense – we have not seen the last mobility-caused infectious catastrophe.

PART II

Changing Concepts of Health and Disease

II.1
Concepts of Disease in the West

The semantic and logical quagmires that await anyone audacious enough to safari through the changing concepts of disease, illness, and health are portended by a cursory analysis of the definition formulated by the World Health Organization. "Health," we are informed, "is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" (Caplan, Engelhardt, and McCartney 1981). Aside from the fact that this seems more realistic for a bovine than a human state of existence, problems abound in what appears to be a fairly straightforward statement. The word "complete" immediately removes the definition from the realm of human reality. What is complete mental well-being, or physical for that matter? Worse still, the phrase "complete social well-being" is so freighted with individual interpretations that it alone renders the definition useless, if not pernicious.

This essay concentrates on ideas of physical health and disease, which is not to minimize the importance of psychiatric disease, but rather to admit that concepts of mental health and illness, although sharing most of the definitional difficulties of physical health and disease, are even more difficult to handle. In large part this is because with mental illness we lack the kinds of objective tools to measure brain function that have helped, though not resolved, questions of what constitutes health and disease in the physical realm. This is not, however, to deny the interconnectedness of the psychic and the physical, which is assumed in all of what follows.

Perhaps no one sentence captures the history of changing notions about disease better than a paraphrase of Humpty Dumpty's haughty admonition: "When I use the word *disease,* it means just what I choose it to mean – neither more nor less." Disease has always been what society chooses it to mean – neither more nor less. A number of important considerations lead to this generalization. Among these are the following: (1) The definition of disease has varied with time and place in history; (2) the names assigned to diseases are ultimately abstractions, although it is useful at times to act as though they are real; (3) what we mean by diagnostic terms, as with

words in general, can be discerned more accurately by what we do with them than what we say about them.

There have been countless attempts to define illness, disease, and health (Faber 1923; Riese 1953; Lush 1961; Meador 1965; Hudson 1966; Niebyl 1971; Boorse 1975; Burns 1975; Engel 1977; Temkin 1977; Taylor 1979; King 1982; Sundström 1987). Most share certain features, but it remains a practical certainty that no mortal could come up with short definitions of these words that would satisfy all who have an interest in them.

Although they will not be treated in what follows, even traditional definitions of death are no longer sufficient. This is due, in part, to the same developments in knowledge and technology that have forced us continually to redefine our notions of health and disease. Death, according to *Webster's Third New International Dictionary,* is the "cessation of all vital functions without capability of resuscitation." But we now have a state of existence that may last many minutes in which there are no apparent vital functions, but during which the capability of resuscitation is unknown. What do we call such a state of existence? This confounding of traditional definitions by today's knowledge and technology leads to such strange article titles as "Prevention of Recurrent Sudden Death" (Rapaport 1982).

The judicious historian, after even a dampening immersion into the literature of changing concepts of disease, will conclude that the subject is unmanageable in a brief essay. Accordingly, what follows excludes non-Western concepts of disease and focuses on the tension between those who believed diseases were real entities with an existence of their own (ontologists) and the opposing camp, which held that disease should be viewed properly as illness, as a unique process in one person over time (physiologists).

The ontology–physiology tension has persisted because physicians perceive that, at a minimum, they must have a reasonably precise definition of what they mean by disease in order to distinguish themselves as professionals. Try to imagine convincing a patient to submit to exploratory abdominal surgery without using a diagnostic term; or to study pathology without the use of disease names; or to mount fund-raising campaigns without words such as *cancer* or *muscular dystrophy.* The essential contradiction that practitioners have confronted over the centuries is that understanding disease demands thinking in abstract generalizations, but the practice of medicine deals with ailing individuals.

The question of disease vis-à-vis illness is not sim-

ply an intriguing philosophical persistency, although it has been a source of much intellectual enjoyment as well as frustration. The viewpoint adopted has definite implications for what physicians do in practice. Lord H. Cohen perceived five dangers in an inordinate ontological orientation:

It promotes a "penny-in-the slot machine" approach to diagnosis by seeking for pathognomonic signs, especially the short cuts of the laboratory; . . . it suggests that diagnosis is arrived at by comparing an unknown with a catalogue of knowns; the method of recognizing an elephant by having seen one before; . . . it reduces thought to a minimum; . . . it is of little help and may be positively misleading where the disease process varies significantly from the usual; and . . . it leads to all those dangers associated with a label which Cowper implied when he wrote of those – "who to the fascination of a name, surrender judgment, hoodwinked." (Lush 1961)

In this view, the diagnostic label attached to a patient tends to dictate the treatment that follows. If the patient is jaundiced, has pain in the right upper abdomen that radiates through to the back beneath the scapula, and the X-ray demonstrates gallstones, the diagnostic label is cholelithiasis and the treatment is removal of the stones. "Surgery does the ideal thing," wrote a health columnist around 1930 in a statement of pristine ontology, "it separates the patient from his disease. It puts the patient back to bed and the disease in a bottle" (Clendening 1931). But are such patients really separated from their diseases? They retain the genetic predisposition or eating habits or whatever produced the gallstones originally. Somehow it seems insufficient to speak of separating patients and diseases with such ready surgical facility.

A complete reliance on the opposite notion of illness has hazards of a different sort. Physicians who think largely in terms of illness aptly consider the whole patient, but if they are ignorant of the natural history of the disease, they may miss the diagnosis and, for example, operate needlessly or too late.

A number of commentators have accepted as fact that disease is ultimately defined by the words and deeds of those persons constituting a given society. They agree as well that physicians usually have had an important voice in these social definitions. What is often neglected at this point is the role that the biology of diseases has played in shaping societal conceptions of the nature of disease (Risse 1979).

Granted that cultural, social, and individual considerations contribute to the expression of diseases in society, we may not overlook the importance of the biological aspects unique to diseases. A current example is the acquired immune deficiency syndrome (AIDS). The period of time between infection with the human immunodeficiency virus (HIV) and the body's development of a testable antibody response can be as long as a year. One practical consequence of this inherent characteristic of the virus is that, during this period of time, blood that tests negative for the antibody may be transfused and infect recipients. Furthermore, the period between infection with the virus and development of the clinical disease may be 8 to 10 years or longer. This trait of the HIV greatly confounds the question of who should be tested for AIDS and what a positive test means. Thus, even as we correctly emphasize the role of cultural factors in the spread of AIDS (homosexual activity and intravenous drug use), we may not forget the central importance of the biological characteristics of the virus itself.

This critical significance of the nature of the disease appears in earlier historical examples as well. One of the most intriguing mysteries in the history of disease is that the Greeks, in the words of Karl Sudhoff, were "blind to the fact of contagion" (Adams 1886; Garrison 1929). The enigma is darkened by the fact that some of the diseases they described so well are contagious – mumps and childbed fever, for example.

Nonetheless, contagionism was never completely eliminated from medical thinking after the acceptance of the Jewish Old Testament as a holy book in the Christian religion. In large part this was because of the attention accorded leprosy, which increased with the return of the Crusaders from the Middle East. The notion of disease as contagious was even more strongly reinforced by the sweeps of bubonic plague in the fourteenth century. In a passage from his work *On Plague*, the fourteenth-century Arabic physician Ibn al-Khatîb wrote, "The existence of contagion is established by experience, study, and the evidence of the senses, by trustworthy reports on transmission by garments, earrings; by the spread of it by persons from one house, by infection of a healthy sea-port by an arrival from an infected land" (Arnold 1952). Even though the writer had no inkling of the intermediate role played by the flea and common house rat in the spread of plague, the patterns of spread convinced him that the disease was contagious.

Historical Survey
As revealed by what physicians say and do, an ontological orientation dominates our late-twentieth-

century thinking, but this was not always so. Historically, the dominance of ontological and physiological thinking shifted time and again. Concepts of disease in ancient Israel, Egypt, and Mesopotamia were too diffuse and vague to fit easily into ontological or physiological compartments. In the Golden Age of Greece, however, physiological thinking is easily identified. Plato needed no formal medical experience to see the deficiencies of compartmentalizing human illness. In *Charmides* he has Socrates say the following: "If his eyes are to be cured, his head must be treated; and then again they say that to think of curing the head alone and not the rest of the body also, is the height of the folly. And arguing in this way they apply their methods to the whole body, and try to treat and heal the whole and the part together." And a bit further on, "The great error of our day in the treatment of the human body [is] that physicians separate the soul from the body" (Jowett 1892).

The Hippocratic approach was also decidedly physiological. Not only did the Hippocratics see the patient as an integrated whole, they appreciated the need to study ailing individuals in the context of their total environment, as evidenced in *Airs, Waters, Places*. Yet Hippocratic physicians could not escape the essential dichotomy between illness and disease. In part this was because they were superb clinical observers. They described a number of cases so faithfully that we can affix modern diagnostic names to them with certainty. At times they even gave specific names to these symptom complexes, such as *pneumonia* and *pleurisy*.

If the Hippocratics were so sensitive to the differences in individual episodes of illness, how did they deal with the similarities they detected in specific syndromes to which they gave names? The answer is that they considered both, but neither to the exclusion of the other (Temkin 1977). One takes account of the symptoms, because the nature of the disease is important, but so too is the unique nature of the individual. The wise physician works not with the ontological red and physiological yellow, but with the orange that results. A return to Hippocratic holism has been advocated recently under the rubric of a "biopsychosocial" model (Engel 1977).

In asking why the balance seen as ideal to the Hippocratics did not become and remain the dominant outlook, it must be remembered that Hippocratic thought did not rule the Hellenistic period. Indeed, contemporaneously with developing Hippocratism, the nearby Cnidians, although postulating an erroneous single common pathway for disease

causation, constructed a system of definite disease entities. Neither approach was entirely sufficient. As has been said, "Hippocrates did the wrong thing well; the Cnidians did the right thing badly" (Jones 1952).

As Greek culture spread first to Alexandria and then to Rome, the Hippocratic tradition was but one of many Greek schools of thought. Hippocratism is cherished today because it is more congenial to modern medicine than the other competing systems of the time. In Alexandria the ontological approach was advocated by Erasistratus, who in the third century B.C. wrote books on gout, dropsy, and paralysis. In the second century A.D., Galen returned the emphasis to the Hippocratic theme, saying in effect that a disease is not only a change in a body, but also a change in a particular body. After the decline of Rome, the Hippocratic–Galenic tradition survived in the Greek-speaking East, where it was picked up and modified by the Arabs and returned to the Latin West beginning in the eleventh and twelfth centuries.

Characteristically, however, throughout Western history, neither the physiological nor the ontological notion disappeared completely, even as one or the other was dominant. In the ninth century, Rhazes was echoing the ontological when he distinguished between measles and smallpox. In the sixteenth century, Paracelsus not only broke with Galen's version of disease causation (i.e., the doctrine of the four humors) but refuted Galen's conception of the nature of disease itself. For Paracelsus there were as many specific diseases as there were "pears, apples, nuts, and medlars." In his strong opinion Paracelsus influenced the physician-chemist Jean Baptistie van Helmont, who believed disease was "due to a creative 'seed' which gets hold of a part of the material frame of the body and 'organises' it according to its own schedule of life" (Pagel 1972). For Paracelsus and van Helmont it was the disease, not the patient, that varied (Pagel 1972). The move of these two men toward ontology presaged the arrival of the "arch-ontologist" of the seventeenth century, Thomas Sydenham.

Although he never worked out a detailed system himself, Sydenham believed diseases could be classified in much the same way as Linnaeus would later group plants. In an oft-quoted passage Sydenham (1848) wrote the following:

Nature, in the production of disease, is uniform and consistent; so much so, that for the same disease in different persons the symptoms are for the most part the same; and the selfsame phenomena that you would observe in the

sickness of a Socrates you would observe in the sickness of a simpleton. Just so the universal characters of a plant are extended to every individual of the species; and whoever ... should accurately describe the colour, the taste, the smell, the figure, etc., of one single violet, would find that his description held good, there or thereabouts, for all the violets of that particular species upon the face of the earth.

To do this with any hope of accuracy, Sydenham realized that physicians must return to the Hippocratic seat at the bedside. Beginning in 1666 he used this method to execute detailed descriptions of smallpox, syphilis, dysentery, gout (his personal nemesis), and measles, which he differentiated from scarlatina.

Although he would later be acclaimed the "English Hippocrates," this honor is not related to his conception of disease. As noted, the Hippocratics described individual illnesses, which they perceived as unique events limited in time. Sydenham, conversely, strove to discover syndromes that, because of their general characteristics, could be recognized when encountered in another patient. As Henry Sigerist (1971) put it, "Hippocrates wrote the histories of sick persons, but Sydenham wrote the history of diseases."

The greatest attempt to accomplish the goal of classification that Sydenham espoused came in the eighteenth century at the hands of François Boissier de Sauvages when he published *Nosologia methodica,* in which diseases were divided into 10 classes, 40 orders, and so on, to 2,400 species (Sauvages 1768). For the most part he was unwittingly describing symptoms and syndromes, not disease entities. Yet the idea was widely emulated. It appealed to clinicians, who had only to classify their patients' conditions correctly: Proper treatment followed as a matter of course.

During the seventeenth century the iatromechanists came to the fore. This departure was led by François de la Boë, also known as Sylvius, who followed van Helmont's lead in the development of iatrochemistry and its cousin, the iatrophysics championed by Giorgio Baglivi. The details of their systems need not be explored here, neither do those of the eighteenth century, the "century of medical systems," featuring the theories of Friedrich Hoffmann, William Cullen, John Brown, and Benjamin Rush.

Though their systems were ephemeral, the ideas of these men retained one element of humoralism, which linked them to the nineteenth century. In general, they held that disease was due to an imbalance – too much or too little of something, whether stimuli, or spasm of the arteries, or nervous fluid. In the nineteenth century, disease would be defined as a deviation from the normal. Because physiological normality had a range, disease, in a sense, was a departure from the limits of range within which health was balanced. In different terms, Brown and his eighteenth-century kin, with their ideas of too much or too little, were using deviation from the normal as the definition of disease. Their problem was that they lacked the knowledge and technology needed to confer objectivity on the various ranges of physiological normality.

The French clinical school of the first half of the nineteenth century exploited the investigative tool called the clinical–pathological correlation. This was the system used effectively by Giovanni Battista Morgagni a half-century earlier, which had led him to conclude that diseases originated locally in the organs of the body, and not in some imbalance of the vague fluidal humors. The process remains one of the most effective teaching devices in medicine – obtaining a detailed history and physical examinations, which change following the natural course of the disease, and finally submitting to the judgment of the autopsy table.

French clinicians Jean Nicolas Corvisart and René Laennec raised this exercise to such excellence that it became known as *la méthode.* In the process, many diseases that had never existed by name or had been confused with others were sorted out in such a way that they could be detected in living patients. This naturally gave great impetus to ontological thinking.

As it turned out, however, a more forceful and effective contemporary personality belonged to the antiontologist François Broussais. For Broussais, disease occurred when certain structures were excessively stimulated. Such stimulation (irritation) produced visible inflammatory lesions, which in his scheme centered in the stomach and intestines. There were then no such specific diseases as diphtheria and typhoid; these were considered merely variations of inflammations. In part due to Broussais's influence, between 1800 and 1880 ontology was pushed into the remote reaches of medical thinking. In his turn, Broussais would yield to the laboratory data produced by such physiologists as François Magendie and Claude Bernard, and even more decisively to the apparently irrefutable proof that specific microbes caused specific diseases.

As noted, an important conceptual emphasis of the nineteenth century was the idea of disease as deviation from normal. The idea existed as early as Plato's *Timaeus* and, of course, was basic to the

enduring humoral pathology. The word *normal* has a number of meanings, only two of which are germane here. The first is the notion of conforming to a type, to an ideal or an object of desire, and thus is a value judgment. The second refers to something that is usual and that can be determined by enumeration (King 1982).

The problem of normality as it confounded medical practice was not a matter of accepting the definitions just given, but of fixing the ranges of normality and agreeing to the magnitude of departure from these ranges that should be labeled disease. The promise of a practical solution to this age-old problem expanded in the nineteenth century with rapidly developing methods of quantifying physiological functions.

As the century progressed, these methods came to include a host of chemical determinations and tools, such as the clinical thermometer, the X-ray, and a portable blood pressure apparatus. Their important common denominator was an unprecedented objectivity. As experience was added to these new technologies, clinicians increasingly held that old and new notions of what constitued disease must satisfy the new methods of quantification. The whole process was reinforced in the last quarter of the nineteenth century by the establishment of the concept of specific etiology with the final vindication of the germ theory of human disease. Not only were there specific diseases, but each apparently had a specific cause. No longer was the notion of disease as deviation from the normal burdened by such vague and unquantifiable etiologic agents as the four humors or nervous energy.

Now the agent responsible for the deviation from health in tuberculosis could be seen under the microscope. It could be recovered from human sputum grown in pure culture, injected into healthy guinea pigs, where it produced a characteristic tissue reaction and clinical picture, recovered from the tuberculous animal, grown again in pure culture, and on and on. More impressive proof that disease was real would be difficult to imagine. If not *diseased,* what was one to call a cavity-ridden lung from which identical pathogenic microbes could be recovered in every instance?

Social forces added to the swing back to ontology. The rise of hospital practice brought together many patients whose diseases were, for practical purposes, identical. Such devices as the ophthalmoscope and laryngoscope gave impetus to specialization, which in turn gave practitioners exposure to a large number of similar clinical pictures. Out of this conflu-

ence of developments, the ontological view returned at the turn of the twentieth century more powerfully than ever before (Faber 1923).

Still, as always, the concept of disease could not be reduced to black or white. New questions arose. What does one do with "Typhoid Mary" Mallon, whose gallbladder teemed with typhoid bacillus but caused Ms. Mallon no symptoms at all? The bacteriologist labeled this the "carrier state," which may have comforted science, but not society. Everywhere that Mary went typhoid was sure to follow. Was she diseased? Certainly in the eyes of public health authorities and society. But was she ill? Not to Mary herself.

To accommodate the increasing accuracy with which late-nineteenth-century scientists could define normality, practicing physicians had to reenlist an old friend, impairment, or as they called the updated concept, impediment. Impediment implied that, before a departure from the still-imprecise boundaries of normality could be labeled disease, a person must suffer physical or social impairment to a significant degree.

In the seventeenth century, Daniel Sennert had defined health and disease in terms of a person's ability to perform in a natural way. In the eighteenth century, Hermann Boerhaave used the presence or absence of impairment in a strikingly similar fashion. Boerhaave also specifically anticipated one of the major problems of disease as impediment: Suffering the same objective physical deficiency, persons differed in their subjective perception of impairment (King 1982). The quadriplegic confined to a wheelchair for years would feel little impairment from an attack of polio involving his lower limbs. Yet a previously healthy person would experience paraplegia as a catastrophic impediment.

Beyond this, there were differences between what scientists considered unacceptable departures from normality and how these variations were considered by patients. Enumerating blood pressure readings in thousands of persons led medical scientists to classify any determination above, say, 160 over 95 as the disease hypertension. The problem was that many patients with such elevations experienced no impediment whatever – indeed, felt perfectly well. What was the practitioner to do in this instance? He might argue that, even if these persons were not impaired at the time, there was a significant probability that they would be in the future. But, again, not always. Some persons carried their elevations without symptoms to the age of 80 and died of unrelated causes.

Confounding all this was the question of what constituted *significant* impairment. The cardiac neurotic may be almost totally impaired by a fear of the heart attack that claimed his father and grandfather at early ages. He may refuse to get out of his easy chair even though repeated thorough medical examination including sophisticated indicators of heart disease have all been negative. In practical terms, the hypertensive is diseased but not ill and the neurotic is ill but not diseased. Such a framework can satisfy the needs of the practitioner, but it likely leaves the philosopher unfulfilled.

Functional Disease

The word *function* has been in English usage for some 400 years. Earlier in medical terms it meant both the physiological activity of an organ and the psychological activity of the brain. This dual usage persisted into the 1830s, after which neurologists began classifying diseases as organic and functional, the latter reserved for conditions in which current technology could not demonstrate structural alterations (Trimble 1982).

Later in the century the concept of functional disease spread to medicine generally. Between 1867 and 1869 Adolf Kussmaul introduced a tube into the stomach to relieve gastric dilation. He realized that, in addition to relieving the patient's symptoms, the technique could be used to study the function of the stomach as well. The idea was picked up by Ottomar Rosenbach, who used the term *ventricular insufficiency* to indicate a disproportion between the muscular reserve of the stomach and the physiological demands on it. From this grew a vast range of tests designed to determine the functional capacity of a bodily structure in health and disease. The model forms the basis of much of clinical laboratory medicine today. But once again semantic confusion entered the scene as evidence that psychological activity as well as structural changes could produce profound disturbances in bodily function.

After the work of Sigmund Freud, the word *functional* returned largely to its psychological meaning, and today is used indiscriminately to mean disturbed function of the nervous system, or as a word for symptoms that do not fit prevailing diagnostic terms, as well as a euphemism for a variety of psychiatric disorders and the antithesis of what is meant by organic disease. When used without qualification, it can only lead to confusion. As was said of the sobriquet *psychogenic,* "it would be well . . . to give it decent burial, along with some of the fruitless controversies whose fire it has stoked" (Lewis 1972).

Conclusion

Many health professionals continue to define disease and health simply in terms of each other. This school of thought contends that the two are on a spectrum, their extremes – serious disease and excellent health – being at opposite ends. There is a heuristic value in this viewpoint, but it poses serious problems in the real world of medical practice. The problems are related in part to medicine's ability to fix points on the spectrum of disease more discretely than in the region of health. When patients tell health professionals that they are "not quite up to par" or are feeling "very sick," there are often objective means for translating these expressions into useful information. Beyond this, the concept of illness has reasonably finite points on the spectrum. At its extreme, hospitalized patients are classified as serious, critical, very critical, and, ultimately, deceased.

Even though the concept of relative health can be traced to the ancient Greeks, the spectrum of health (as opposed to illness) has no such clear points or distinctions (Kudlien 1973). Patients may state that they feel very good or are in excellent or perfect health, but even if there is a reason to objectify their assessments, there are no logical or technological tools for performing the task. If the examination and laboratory results are normal, a patient will generally be classified simply as healthy. Any qualification of a statement about health, such as "almost healthy," moves the patient to a point on the spectrum that coincides with slightly impaired or ill. A measure of the difficulties here is seen in one author's suggestion, then rejection, of the idea that health could be quantified by fixing a point on the scale and allowing health to be two standard deviations from the norm (Caplan et al. 1981).

One reason for this state of affairs is that, from the standpoint of time, health is on a generally unidirectional spectrum directed toward illness and death. Things are a bit more complicated than the old saw "We are all dying from the moment of conception," but the element of truth in looking at human existence in this way may help us understand why health and disease are not au fond a tension or balance. True, for many years we may be in the healthy range of the spectrum, but during this time, our unidirectional genetic program (as best we now understand it) is moving us inexorably toward disease. True, also, in a given illness episode, we may reverse the direction and return to the spectrum of subjective and objective health, but this turnabout is temporary. The key element, time, remains unidirec-

tional. Even as we move out of a given illness to health, we are advancing toward death, much as we are both gaining and losing ground as we walk against the direction of a moving sidewalk.

In desperation someone once defined disease as something people go to doctors for. As simplistic as this seems, and as unsatisfying as it may be to medical historians and philosophers, there is more than a germ of truth in the definition. Indeed, it reminds us of the original meaning of our elusive term – dis-ease. It covers situations in which the "patient" is simply ill at ease, without regard to the finer nuances of normality and impediment. Originally the word had no connection to pathological conditions, so that one might be said to be reluctant to dis-ease oneself by attending a lecture on changing concepts of disease (Garrison 1966).

The older definition of dis-ease applies to much of what physicians do nowadays. The young graduate student is dis-eased by a pregnancy that threatens to disrupt her academic career. The ensuing elective abortion relieves her dis-ease, but it is difficult to fit a normal pregnancy into any system of illness–disease considered so far. Some might contend that the student suffers an impediment, and in career terms, that might be true. But we would seem to be headed for even murkier depths if we translated into disease the impediment occasioned by a physiological alteration so profoundly normal that the species would die out in its absence.

Many encounters between patients and physicians result from similar social and cultural pressures. The middle-aged executive who resorts to plastic surgery to eliminate his perfectly normal, and even honorable, facial wrinkles is dis-eased, as are most who undergo cosmetic surgery. And, of course, the vast majority of persons seeking psychotherapy are dis-eased, in that it is basic to human existence to experience anxiety, insecurity, loneliness, and even depression. Certainly when physicians treat persons whose complaint is not only diagnosed as normal, but almost universal, dis-ease in the older sense must be involved rather than disease as it has been analyzed in the ontological or physiological meanings.

It is properly humbling to attempt to summarize an essay that one realizes has not succeeded completely in its aim. Under these circumstances, the temptation is to suggest that the question being asked is not a proper one in the sense that it cannot be answered by logic or experiment. Indeed, one of the more cogent summaries of our conundrum was expressed in precisely these terms by Owsei Temkin:

The question: does disease exist or are there only sick persons? is an abstract one and, in that form, does not allow a meaningful answer. Disease is not simply either the one or the other. Rather it will be thought of as the circumstances require. The circumstances are represented by the patient, the physician, the public health man, the medical scientist, the pharmaceutical industry, society at large, and last but not least the disease itself. For our thinking about disease is not only influenced by internal and external factors, it is also determined by the disease situation in which we find ourselves. (Temkin 1977)

Claude Bernard (1865) held that seeking the cause of life or the essence of disease was wasting time in "pursuing a phantom. The words life, death, health, disease, have no objective reality." Here Bernard was only partly right. It is not a waste of time to struggle with these definitions. There is much to be gained if the task does nothing more than force society, and especially medical people, to think of the consequences each time they use words to describe disease and health. The process is a waste of time only if one enters into it with the exclusive goal of arriving at universal and timeless definitions.

II.2
Concepts of Disease in East Asia

In the inscriptions that record the divinations of Shang dynasty China (eighteenth to eleventh centuries B.C.), we find a number of diagnostic queries like this: "Divining this tooth affliction. Should we hold a festival for Fuyi?" Fuyi refers to a Shang ancestor, and the concern about a propitiatory festival reflects the belief, frequently voiced in the oracles, that sickness arises from the anger and envy of ancestors toward their descendants (Hu 1944; Miyashita 1959). If the welfare of the dead depended on the rituals of the living, the resentments of the dead were something to which the living remained ceaselessly vulnerable.

Disease thus first appears in China embodied in dangerous others, as a menace from without. After the Shang dynasty, the focus of concern would broaden and shift from disgruntled ancestors to parasites and poisons, demons and witchcraft spells. But whomever or whatever the Chinese accused of inspiring sickness, the defining feature of the earliest conceptions of disease was their independence from a conception of the body. In other words, the peculiarities of an individual's somatic condition were no more relevant to understanding a fever or a toothache than they were for explaining why one's crops were destroyed in a storm. The fact that an affliction happened to attack the body was incidental. The vengeful spirits that brought sickness could just as easily have inflicted drought and famine.

This accounts in part for why a collection of cures such as the *Wushier bing fang* (Recipes for fifty-two ailments) of the late third century B.C. tells us so much, on the one hand, about noxious demons and the techniques for exorcizing them and teaches us so little, on the other hand, about the afflicted body itself (Harper 1982). For whether a shaman literally beat the disease out of the patient or appealed to benevolent divinities for assistance, whether demons were coaxed out with magical formulas or transferred sympathetically to other objects, the treatment of disease, like the diagnosis, concentrated on agents alien to the self. The body merely provided the stage for the drama of sickness; it was not an actor.

This was a remarkably influential vision of disease. For instance, a dictionary of the later Han

dynasty (25–220), the *Shiming*, glosses *yi* (epidemic disease) as *yi* (corvée), explaining that diseases were the corvée imposed on humans by demons. From the Sui (581–618) through the Yuan (1279–1368) dynasties, professors and masters of exorcistic rituals and incantations (*zhoujin*) constituted a part of the official medical bureaucracy, alongside professors of such other medical specialties as acupuncture and massage (Kano 1987). At a more popular level, the folklore of medieval Japan abounds in accounts of beguiling fox spirits that seduce or possess young men and women and cause them to waste away, go mad, or die (Veith 1965). And even today, a Korean shaman will acknowledge in his healing chant "ghosts of the drowned, ghosts who were shot . . . maiden ghosts, bachelor ghosts" (Kendall 1985).

In the evolution of East Asian disease conceptions, therefore, the imagination of menacing outsiders represents not a transient stage of superstitions, which the rise of philosophy would supersede, but a thematic pole to which reflection on sickness would repeatedly return. At the same time, by the late Zhou (770–403 B.C.) and Warring States (403–221 B.C.) periods, suspicions of supernatural mischief were already slipping from the intellectual mainstream. In the philosophical ferment of these periods, a new conception of disease was emerging – one that would seek the origins of sickness not in the whims of some dangerous other, but in the desires of the self.

In the late Zhou and Warring States periods, disease became a reflection of somatic condition, and somatic condition, a reflection of the self. For the Confucian and Taoist philosophers of this era, the body was the dynamic product of experience, a reality continually shaped and reshaped by how one was living and had lived. *Shen*, "the body," was the same *shen* emphasized by the ideals of *xiushen*, "self-cultivation," and *deshen*, "self-possession": It was the embodied self, a lifetime of decisions and indecisions made manifest.

The failings of the body, therefore, were inseparable from failures of self-mastery. Sickness in this view had little to do with ancestral ire or demonic cruelty. It arose principally from within, from immoderation and carelessness, from gluttony and overexertion, from protracted grief and explosive anger, and sometimes from the mere imagination of dangers. One man falls ill after experiencing a terrifying dream and is cured only when a clever physician suggests that the dream was one reserved for future kings. Another suffers severe cramps after

being compelled to drink a cup of wine in which he thinks he sees a snake. Only when he is made to realize that what he saw in the wine was merely the reflection of an archer's bow hanging on the wall does he recover (Li 1960). The close identification of body and self went hand in hand with a subtle awareness of the many ways in which human beings could make themselves sick.

According to the most devoted and influential students of the body, however, the real essence of disease was depletion. The experts of *yangsheng*, or "the cultivation of life," envisaged the body as the container of a precious and finite vitality. If properly conserved, this vitality could sustain one for a hundred years, free of all affliction, and free even of the ravages of age. True health found its proof in ever-youthful longevity. If most people succumbed to disabilities and senescence, and died before reaching their hundredth year, if most, in short, were sick, it was because they depleted the body by squandering this vitality.

Ghosts and malevolent spirits were not involved. Yet the body was still surrounded by enemies. Early historical and philosophical texts refer frequently to individuals struck down by wind or cold, rain or scorching heat. Wind and cold especially loomed large as noxious forces. To winds fell the blame for afflictions ranging from sneezing and headaches to paralysis and madness, and proverbial wisdom would soon have it that "the myriad ailments all arise from wind." As for cold, the study of the feverish disorders to which it gave rise would eventually become the subject of the most influential treatise of the pharmacological tradition, Zhang Ji's *Shanghan lun* (Treatise on cold afflictions), written around the end of the second century. Wind, cold, and other meteorological elements thus replaced the demons and spirits of shamanistic medicine as embodiments of the dangerous outsider. Like demons and spirits, they were objective pathogens that penetrated and roamed throughout the body; and like demons and spirits, they figured both as the cause of disease and as the disease itself.

But wind and cold differed from demons and spirits in one critical respect: Their pathogenic character was contingent on the condition of the body. They would invade only when the body was vulnerable, or more precisely, depleted. As the *Lingshu* of the Han dynasty later explained: "Unless there is depletion, wind, rain, cold and heat cannot, by themselves, injure a person. A person who suddenly encounters brisk winds or violent rains and yet does not become ill is a person without depletion" (Chen

1977). In a body brimming with vitality there was no room for noxious influences to enter.

The depletion of vitality was thus doubly noxious. It left one vulnerable to the virulence of wind, cold, and other climatic pathogens. More immediately, however, depletion was itself a form of sickness, a diminution of possibilities: It meant that even without the intrusion of alien influences the senses and limbs that should be strong and unimpaired until age 100 might already be weak or failing at age 50 or 60.

The leitmotif of *yangsheng* reflection on the body, therefore, was *bao,* "preservation" – "preserving the body" (*bao shen*), "preserving the vital essence" (*bao zhen*), "preserving life" (*bao sheng*). To maintain the body intact, to protect it against attacks from without by carefully conserving and containing vitality within – such was the heart of the "cultivation of life." But preservation was difficult. A considerable disparity separated the attentions required to preserve vitality and the ease with which it slipped away, for preservation demanded concentration whereas the outflow of vitality often accompanied the experience of pleasure. If the depletion of vitality constituted the root of disease, the roots of depletion lay in desire.

This was most apparent in sexual intercourse. Already in the sixth century B.C., we find a physician tracing the illness of the duke of Jin to his frequentation of concubines (Li 1960). Later Chinese and Japanese writings on regimen would even specify the precise number of times per month or year to which intercourse should be limited (Kaibara 1974). On few points would opinion be as unanimous: Semen was the distilled essence of life, and there could be no surer path to debility and early death than to exhaust one's supply in frequent intercourse. Although moral strictures against pleasure per se were rare, philosophers and physicians constantly warned against the physical drain of sexual indulgence. It is revealing that the response in classical China to the temptations of the flesh was not mortification, but rather the art of the bedroom (*fangzhong*) – psychophysical techniques centered around the prevention of ejaculation and the "recycling" of semen within the body (Van Gulik 1974).

The expenditure of vital essence in intercourse was, however, just one form of the intertwining of desire and depletion. Vitality could slip away from all the orifices: It flowed out of the eyes as one became absorbed in beautiful sights, and from ears as one lost oneself in rapturous harmonies. The orifices were, the *Huainan zi* explained, "the windows

of the vital spirit," and when the eyes and ears dwelled on pleasures of sight and sound, this vital spirit streamed outward, depleting the body and inviting affliction (Liu 1965). This movement of the spirit toward the desired object was the very essence of desire. Literally, as well as figuratively, desire entailed a loss of self: Physical depletion and lapses in self-possession were just different views of the unique phenomenon of sickness. Conversely, somatic integrity and emotional self-mastery coalesced in the notion of health. As the philosopher Han Fei of the early third century B.C. summarized it: "When the spirit does not flow outward, then the body is complete. When the body is complete, it is called possessed. Possessed refers to self-possessed" (Li 1960).

The secret of health thus lay in a mind devoid of desire. Such was the lesson of the "cultivation of life" in the Warring States period; and such also was the lesson of medical theory as it first crystallized in the classical treatises of the Han dynasty (206 B.C. to A.D. 220). But in the latter case the meaning of the lesson was more complex, because the meaning of disease was more complex.

Classical medicine yoked together what were in fact two conflicting images of the body and its afflictions. On the one hand, the key theoretical treatises of the Han dynasty – the *Huangdi neijing,* consisting of the *Suwen* and the *Lingshu,* and the *Nanjing* – perpetuated *yangsheng* intuitions of the vital self warding off the dangers of the world around it. Body was clearly separated from nonbody by the protective barrier of the skin, which both sealed in vitality and kept out noxious winds and cold. The two key terms of etiologic analysis, *depletion* and *repletion,* preserved in their definitions the distinction between what is healthy and proper to the body (*zheng*) and what is pathogenic and alien to it (*xie*): Depletion (*xu*) was a "deficiency in the body's vitality (*zhengqi*)," repletion (*shi*), an "excess of noxious influences (*xieqi*)."

Yet already in these definitions a new and alternative conception of disease was clearly emerging for the main distinction between depletion and repletion was not the opposition of inner and outer, but rather the complementary nature of deficiency and excess. Subtly, but surely, the earlier rhetoric of defense and attack was giving way to the new logic of balance and compensation; fears of threatening outsiders were being supplemented, and to an extent supplanted, by a conception of disease as unequal distribution.

In the schemes that articulated the emerging etiology of imbalance (the dialectic of yin and yang and the five-phase cycle [*wuxing*] of wood, fire, earth, metal, and water), the dichotomy of body and nonbody had little significance. Cosmic events and somatic events figured on the same plane: Deep grief could cause the repletion of yin and the depletion of yang, but so too could winter cold; a state of replete wood and depleted earth might involve a hyperactive liver (a wood organ), but it might also stem from easterly winds (also associated with wood). Moreover, both body and nonbody were subject to the same universal law of rhythmic change, the alternation of hot (yang) and cold (yin), the cycle of spring (wood), summer (fire), fall (metal), and winter (water). With indefinite and infinitely permeable boundaries, the body was seamlessly fused to a world ceaselessly transforming itself (Chiu 1986).

Disease in the Han dynasty became above all a seasonal phenomenon. Earlier observers had already recognized that different afflictions tended to characterize different seasons. The *Zhou li* (Rituals of the Zhou dynasty) observed, for instance, that headaches were prevalent in spring, whereas summer was characterized by the spread of scabieslike itching, autumn by malarial and other fevers, and winter by respiratory disorders (Lu and Needham 1967). Also widely noted was the fact that the same climatic pathogens of wind and cold had different effects in different seasons. Unseasonal weather, such as cold in summer, posed special dangers and often engendered epidemics.

The Han medical classics, however, went further and situated the seasonality of disease in the seasonality of the human body itself. According to the *Nanjing*, the most vigorous organ in spring should be the liver; in summer the heart should dominate; in autumn the lungs; and in winter the kidneys. In spring the pulse should begin to rise, gently, but growing like the first primaveral shoots; in summer it should be strong and overflowing; in autumn it should be slower and more constricted; and in winter it should lie deep as if in hibernation. To the discerning physician, each season exhibited its distinct physiology, and it was only with respect to this seasonal physiology that the standards separating health from sickness could be defined. The same signs, considered perfectly normal for one season, might certify disease in another.

Health, therefore, was a state of dynamic attunement in which the directions of an individual's energies paralleled the ebb and flow of the cosmos as a whole. For every season there were appropriate foods, appropriate activities, and even appropriate feelings. For example, in spring, the *Huangdi neijing* advised:

The myriad things flourish, engendered by heaven and earth together. Going to sleep at nightfall one should get up early and stride leisurely in the garden. Letting down one's hair and putting oneself at ease, one should give rise to ambitions. Engender and do not kill. Give and do not take away. Reward and do not punish. This is what is appropriate to the spirit of spring. (Chen 1977)

Failure to follow the spirit of the season, motivations and actions out of phase with cosmic transformation, resulted in deficiencies and excesses of yin and yang and the five phases, that is, in disease. The principle governing health and sickness was thus simple: Those who followed the flow (*xun*) flourished; those who opposed it, fell ill or died.

As part of the cosmos, human beings were naturally attuned to seasonal rhythms. Yet this attunement, like the intact body prized by proponents of *yangsheng*, was an ideal frequently compromised in actuality by unruly passions. The *Lushi chunqiu* explained: "What fosters life is following the flow (*xun*); but what causes life to depart from the flow (*bu xun*) is desire" (Li 1960). Desire here referred not to the depletion of vitality, but to disruptions in the smooth and balanced circulation of influences, to rigid attachments that resisted cosmic rhythms, and to impulses that deviated from the directions of seasonal change. If desire in the etiology of depletion implied a partial loss of self, desire in the etiology of imbalance entailed forgetting that the self was but one part of a much larger, ever-evolving world.

The cosmic dimensions of Han medical thought mirrored the expansive ambitions of the first great age of universal empire. In the same way that the political vision of universal empire would survive the rise and fall of subsequent dynasties, so the vision of the body as a seasonal microcosm would continue, along with *yangsheng* ideals of somatic integrity, to define medical orthodoxy for nearly two millennia. Yet the views of orthodox physicians did not by any means represent the views of all. In the chaos of the disintegrating Han empire, there emerged an alternative approach to illness that had a far greater and immediate impact on the popular imagination – an approach concerned not with the cosmic systems, but with individual morality and its consequences.

Intimations of sickness as punishment can be traced as far back as Shang fears of ancestral ire, and the

moral failings of more than one emperor in the early Han dynasty (206 B.C. to A.D. 8) would be blamed later for the epidemics that devastated their people. But especially in the late Han dynasty (25–220), with the rise of religious Taoism, and the Six Dynasties (222–589) period, with the influx of Buddhism, the equation of sickness and personal transgression came to pervade popular consciousness (Kano 1987). With the diffusion of these religions, reflection on disease assumed an introspective aspect as religious healing turned increasingly toward the scrutiny of personal memory and conscience.

Zhang Lu, leader of a Taoist rebellion in the early third century, thus required the ailing first to spend time in a "chamber of silence," where they explored their consciences for the possible transgressions underlying their afflictions. Disease was the result of past sins, and recovery required the confession of these sins (Unschuld 1985). The Buddhist concept of karmic disease (*yebing*) also traced sickness (*bing*) to an individual's past actions (Sanskrit, *karma;* Chinese, *ye*). Karmic analysis diverged somewhat from Taoist intuitions in that these actions might go back many reincarnations, beyond conscious recall and beyond confession – thus explaining such puzzling phenomena as congenital diseases and the afflictions of the virtuous. But in the popular understanding, Buddhist precepts of karmic consequence and Taoist teachings of sickness and sin tended to coalesce into the same basic lessons: Good actions are rewarded, and misbehavior eventually punished; the ailments of today have their origins in the wrongdoings of yesterday.

Folk religion frequently framed these lessons in a divine bureaucracy. Unlike the often-unpredictable ancestral spirits of the Shang, the divinities of Han and Six Dynasties religion frequently resembled government officials, keeping track of a moral ledger of good and evil deeds (Eberhard 1967). For each transgression, appropriate afflictions were imposed, and days were detracted from one's allotted lifetime; meritorious acts, conversely, earned relief from sickness, and the restoration of longevity. The bureaucratic regularity of this scheme even allowed the early fourth-century Taoist Ge Hong to specify the number of days subtracted from one's life for each level of demerit.

The idea of moral accounting also formed the core of what was perhaps the most intriguing conception of disease in medieval East Asia, namely the theory of the body's three "corpses," or *shi*. Originating in China no later than the early fourth century and attaining its mature form by the Tang dynasty (618–

907), this belief posited the existence of three small creatures (*shi*) who inhabited various regions of the body and who recorded all the individual's evil yearnings and deeds. Then, once every 60 days, on the *gengshen* night of the astrological cycle, these *shi* would leave the body while the person slept, and fly up into heaven. There they would report to the heavenly emperor (*shangdi*) on the wrongdoings that they had witnessed, and the heavenly emperor would mete out punishment in the form of disease and shortened life. It was thus imperative for all who hoped to escape illness and live long lives to somehow restrain or purge these *shi*.

This was the origin of the custom whereby entire communities gathered together on *gengshen* night and stayed up until dawn to prevent the *shi* from escaping the body. The custom had many variants: Some villages would spend the night reciting Lao Zi's *Daode jing;* others would revel in drink and merriment; and in eighth-century Japan the importation of the three-*shi* theory gave Heian aristocrats an excuse for all-night music and poetry competitions. Although some philosophers, like Liu Zongyuan, denounced the idea of the *shi* as superstition, *gengshen* practices flourished and spread throughout East Asia, surviving in rural areas well into the twentieth century (Kubo 1961).

The popularity of three-*shi* etiology derived in no small part from the fact that it united many streams of East Asian reflection on disease. Though the three *shi* were originally conceived as small humanoids, they quickly became assimilated into traditions going back to the Shang about the infestation of the body by parasites and poisonous insects, and the same drugs were used against them as were habitually used to purge parasites. The notion that they would betray one only on particular nights fed, of course, into medicoastrological associations of health and cosmic rhythm. And in their role as keepers of the moral ledger, the three *shi* internalized the accounting of merits and demerits that linked sickness to sin.

Finally, the theory of the three *shi* reaffirmed the conviction that sickness was somehow tied to desire. According to some accounts, it was the presence of these *shi* that explained the pullulation of desires in the human heart; other accounts, conversely, stressed how killing off desire was the only way the *shi* could be exterminated. But all accounts of the *shi* and their dangers underlined their intimate connection to human beings as creatures of passion. Sickness and desire, which had, with different implications, been tied together by the *yangsheng* thinkers of the Warring States period and by

the medical classics of the Han dynasty, were again united in medieval religion.

The physicians of the Song (960–1126) and Yuan (1279–1368) dynasties inherited a tradition of medicine that knew disease under two guises. On the one hand, there was the disease of theory, sickness as elucidated by the complementarity of somatic depletion and alien intrusion and by the system of yin and yang and the five phases. On the other hand, there was disease as it had been observed and experienced by physicians and patients over the course of a millennium. As evidenced by the sprawling seventh-century nosological compendium of Chao Yuanfang, the *Zhubing yuanhou lun* (On the origins and symptoms of all diseases), this tradition was protean and unwieldy, with seemingly limitless combinations of ever-diverse symptoms (Chao 1955). A great distance separated the perspicuity of theory from the dense tangle of experience. The key theme of Song and Yuan reflection on disease was the quest to reduce that distance.

The quest translated into two basic strategies. One strategy aimed at refining the classical etiology of depletion. Although recognizing that a complex variety of factors converged in the genesis of disease, many physicians from the Song and Yuan periods onward nonetheless sought to isolate a single crux of vulnerability. Li Gao, for instance, argued in the thirteenth century that "the hundred illnessess all arise from [disorders of] the spleen and stomach" (Beijing zhonqui xueyuan 1978). By contrast, his contemporary Wang Haogu sought the predisposing origins of sickness in depleted kidneys (conceived as the repository of semen), whereas Zhu Zhenheng of the fourteenth century focused on the tendency of human beings to experience "a superfluity of the yang element, and a deficiency of the yin" (Beijing zhonqui xueyuan). Later, in the Ming (1368–1662) and Qing (1662–1912) dynasties, still other physicians would blame the depletion of a variously defined organ known as the "gate of life" (*mingmen*) (Beijing zhongyi xueyuan 1978).

The other strategy sought to extend the classical etiology of imbalance, to articulate exhaustively the paradigms of yin and yang and the five phases so that they might provide a more adequate language for describing the rich variability of symptoms and syndromes. This produced a highly abstract perspective, which translated the concrete pathogens of wind, cold, and heat into the transparent logic of dialectical balance and seasonal rhythms; but it also produced a more unified approach to disease.

Whereas in Han medicine the marriage of the etiology of imbalance with the etiology of depletion had been at best an uneasy alliance, their strategic extensions in Song and Yuan medicine often blended smoothly together. Thus, desire, without entirely losing its long-standing associations with the depleting outflow of vitality, was recast as yang fire. Zhu Zhenheng's identification of the crux of vulnerability in excess yang and deficient yin referred, among other things, to the propensity of emotional agitation (yang) to predominate over rest and collected self-possession (yin). For him it was especially the inner feverishness (fire) generated by the tumult of passions that dispersed and dried up the moist vital essence (water) and gave rise to depletion. Similarly, Li Gao, who insisted on sound digestion as the pivot of sickness and health, analyzed the critical impact of emotional unrest in terms of the effect of fire (passions) on the earth-associated organs of the spleen and stomach. By translating in this way the analysis of depletion into the schemes of yin and yang and the five phases, these physicians framed the understanding of disease in a single comprehensive and integrated system.

The new technology of printing ensured the broad dissemination of Song and Yuan medical treatises, and these were assiduously studied not only by Chinese physicians in the Ming and Qing dynasties, but also by their counterparts in Yi dynasty Korea (1392–1910) and Tokugawa Japan (1600–1868) (Fujikawa 1980). No small part of the persisting myth of Chinese medicine as based on a timeless, monolithic theory is due to the resultant identification, throughout East Asia, of medicine with the systematizing tradition established by Song and Yuan physicians.

In reality, of course, Song and Yuan medicine itself comprised many diverging viewpoints, and subsequent periods witnessed a widening spectrum of ideas. Zhang Congzheng at the turn of the thirteenth century, for instance, rejected the prevailing focus on inner depletion and attunement and urged that intrusive attack was the primary fact of disease. His nosology, accordingly, recognized six basic kinds of disease, corresponding to the six climatic pathogens of wind, cold, fire, humidity, dryness, and heat. Later, in extensive investigations into epidemics in the Qing dynasty, Wu Youxing, born just before the middle of the seventh century, and Wu Tang, born a century later, probed even deeper into extrinsic causation. They distinguished between commonplace infiltrations of cold and other climatic agents, which occurred through the pores, and epidemic fi-

ery afflictions (*wenbing*), which entered through the mouth and nose (Beijing zhongyi xueyan 1978).

Beyond China's borders, there were outright critics as well as devoted followers of this systemizing tradition. In the late seventeenth and eighteenth centuries, the Ancient Practice school (*kohoha*) of Japanese medicine rallied specifically around the overthrow of the Song–Yuan spirit of system. It inspired some radical conceptions of disease, such as Yoshimasu Todo's eighteenth-century theory that all disease arises from one poison and Goto Konzan's earlier notion that all disease results from stagnation in the flow of vital energy (Fujikawa 1980). Although these theories themselves did not have a lasting impact, the critical ferment they represented inspired physicians and scholars in late-eighteenth-century Japan to undertake the first serious studies of Western medicine in East Asia.

Students of medicine and health care in contemporary East Asia have stressed the persisting plurality of disease conceptions (Kleinman et at. 1975; Leslie 1976). As in the past, the advent of new approaches to disease, and in particular the introduction of ideas from the West, has led not to the abandonment of traditional assumptions, but simply to a more complex skein of beliefs and practices.

Some aspects of medical pluralism are obvious. A Korean healer who specializes in exorcizing noxious spirits may also refer patients to acupuncturists and hospitals (Kendall 1985). Acupuncture texts published in Taiwan today habitually refer to both the nosology of cosmopolitan medicine and the language of yin and yang.

There are also subtler forms of syncretism. The ostracism of tuberculosis patients and their families in early-twentieth-century Japan, for example, combined a vague understanding of modern theories of infection and heredity with traditional notions of contagious pollution and sickness as sin (Namihira 1984; Johnston 1987). But perhaps the most intriguing manifestations of the ever-present past have to do with the actual experience of illness.

Medical anthropologists have observed that patients in East Asia tend to experience all illness as illnesses of the body. That is, whereas a North American patient might complain principally of anxiety or depression, a Chinese patient will complain rather of palpitations, digestive disorders, or suffocating sensations in the chest (*men*), focusing on physical rather than emotional symptoms. Moreover, rather than seeking psychological explanations such as stress or frustration, Chinese and Japanese patients manifest a distinct preference for understanding diseases in terms of climatic and somatic etiologies – chilling wind, change of seasons, sagging stomach, acidic blood, imbalance in the autonomic nervous system, or simply weak nerves (Kleinman 1980; Ohnuki-Tierney 1984).

Such concepts as the autonomic nervous system and blood pH derive, of course, from modern science, but the general attachment to somatic symptoms and analyses surely goes back thousands of years. Desires and emotions figured centrally in traditional East Asian conceptions of disease, but they were never based in some disembodied psyche. They were invariably intertwined with somatic experience. Thus anger, for Han physicians, entailed the rise of the vital spirit, fear the sinking of the spirit, joy its relaxation, and grief its dissipation. The *yangsheng* thinkers before them saw self-possessed freedom from desire and the physical containment of vitality as one and the same reality. If, as anthropologists report, patients in East Asia manifest an unusual sensitivity to and interest in the body, this sensitivity and interest are perhaps related to a long cultural tradition that conceived of the body as the dynamic product of lived life, that is, as the embodied self.

II.3
Concepts of Mental Illness in the West

We are not ourselves when nature, being oppressed, commands the mind to suffer with the body.
                                                    Shakespeare, *King Lear*

Mental disease refers, at present, to disorders of perception, cognition, emotion, and behavior. The disorder may be mild or severe, acute or chronic, and may be attributed to a defect of mind or body or of some unknown combination of the two. A diagnosis of mental illness is the judgment that an individual is impaired in his or her capacity to think, feel, or relate to others. In mild cases, the impairment may intrude on a person's ability to gain satisfaction from meeting the challenges of everyday life. In severe instances, an individual may be thought so dangerous or incompetent that sequestration within a psychiatric facility is necessary, with a resulting loss of rights normally granted to citizens.

The Problem of Mental Illness

The simple title of this section belies the extraordinary scope, complexity, and controversial state of contemporary psychiatric thought. Some have argued that if the myriad types of disorders bedeviling humankind were ranked by the net misery and incapacitation they caused, we would discover that psychiatry captures a larger share of human morbidity than does any other medical specialty. It seems ironic – if not tragic – that a clinical field of such magnitude is at the same time distinguished among its peers by a conspicuous lack of therapeutic and philosophical consensus. That the discipline lacks a set of internal standards by which to differentiate unequivocally the correct theory from the false, or the efficacious therapy from the useless, is an open secret. In a sense, if the disputing psychiatric camps are all equally able to claim truth, then none is entitled to it. Consequently, there exists not one psychiatry, but many psychiatries, a simple fact that alone has had enormous ramifications for the field's comparatively low medical status and conceptual disarray. Everywhere recognized and yet nowhere fully understood, insanity continues to challenge us as a problem that demands attention and yet defies control.

Situated so uneasily within the medical domain, the subject of mental illness poses a challenge of singular difficulty for the geographer and historian of human disease. One typically locates disease in place and time by first asking an array of standard questions: What are its immediate and predisposing causes? How does it normally progress? Upon whom is it most likely to befall? For example, in this volume any of a number of essays on infectious diseases (cholera, smallpox, plague) may begin with a tightly drawn narrative of how the disease unfolds in an untreated victim, knowable to the patient or casual observer by conspicuous signs and symptoms and to the medical investigator by the additional involvement of organ or systemic changes. We learn about the life course of the offending infectious agent and about the mechanisms by which it wreaks physiological havoc.

Once a clinical portrait and a chain of causation have been well established, it is possible to position a disease on the social as well as geographic landscape; its prevalence by age, sex, social class, and nation may be determined with some justification. At the same time, the work of the medical historian comes into focus. Paradoxically, as the present becomes clearer, so does the past. Using our clinicobiological model as a guide, we can search the historical record for answers to additional questions: When did the disease first appear and how did it migrate? Over the centuries, how wide has been its trail of

morbidity? We can also reconstruct the story of when and how medicine, in fits and starts, first isolated the entity as a specific disease and then unraveled its pathogenic mechanisms. Indeed, endeavors such as this volume are indicative of the high confidence we have that our current nosology (fashioned by such triumphs as bacteriology and molecular biology) does, in fact, mirror the contours of biological reality. We are certain that typhus and cancer are not the same disease, and thus tell their stories separately.

Contemporary psychiatry, however, provides us with no map of comparable stability or clarity. When the standard array of aforementioned questions are applied to a mental disorder, satisfactory answers fail to emerge. Indeed, for a given mental illness psychiatrists would be hard-pressed to point to any unambiguous anatomic markers, to describe its pathophysiological process, or to explain its cause with a model that is intuitive, testable, and conforms to prevailing biological wisdom. Lacking in these familiar desiderata of scientific medicine, a mental disorder such as paranoia simply is not granted the same level of ontological certainty that is ascribed to an "organic" disease like leukemia. Until such time as we solve the age-old conundrum of the relations between mind and body, discovering a formula that converts states of consciousness to properties of matter (or vice versa), it is likely that such barriers will persist.

Visibly unmoored to fixed biological truths, classifications of mental disease thus seem capable of infinite drift. In consequence, the task of writing a history or geography of any given psychiatric illness might be regarded as a pointless, premature exercise. What exactly are we trying to map? If we follow the development of the word *neurosis,* we find that in one century it refers to exclusively nonorganic conditions, and in a century earlier, it includes organic disorders. If we disregard this problem as one of mere wordplay and try to identify the actual conditions that were labeled to such mischievous effect, another quandary develops. It is difficult enough to establish whether a given mental disease appears in another country, let alone in a distant time. That different eras produce variant mental diseases is more than plausible. Unfortunately, there exists no assay of human experience that can bridge the past. Though the bones of a mummy may reveal to X-rays whether a pharaoh suffered from arthritis, they remain silent as to his having suffered a major depression. Finally, each of the many psychiatries has its own guide to understanding mental disease; which

filter, then, do we apply to the past? Do we look for anxiety disorders as interpreted by the behaviorist, neuropharmacologist, or psychoanalyst?

Current philosophical critics of psychiatry, such as Thomas Szasz, advise us to abandon the effort. Szasz contends that, strictly speaking, mental illnesses are not valid medical entities and thus their stories have no place in any compendium on human disease. Madness exists, to be sure, but it is a quality of personhood, not of body or disease. Problems of living are manifold and serious, but without positive evidence that an individual's condition is due to a physiological cause, the physician has no business intervening. Unless psychiatrists can meet the best standards of scientific medicine, they should be thought of as modern quacks, laughable if not for their countless victims. According to Szasz, labeling someone a schizophrenic in the late twentieth century is no different from calling someone a witch in 1680 or a communist in 1950. It means that you disapprove of them, wish them ill, and have conspired with the community to punish them.

Any critique that brings to light real and potential abuses of psychiatry is laudable. As a general historical framework, however, Szasz's approach is limited, in that it conflates a philosophical ideal of what medicine should be with what the historical record shows it in fact is. A significant portion of current – and virtually all of past – medicine fails to meet similar tests of scientific purity. Are there only a few "real" physicians? It is easy to forget that the criteria of what constitutes "good" medical science are not fixed, but evolve. For example, controlled clinical trials became the ideal only after World War II. We may be chagrined to learn, just a few decades from now, that our remaining "real" physicians were quacks, too.

A better approach is to revisit categories of mental disorder in their original historical context, to see how they fit within prevailing conceptions of disease – not to define an illness according to an abstract standard, but to derive its meaning from the actual interpretations of patients and physicians. Otherwise, we are left with the absurdity that only those doctors who employ correct therapeutics, and conceptualize in terms of true disease categories (as judged by today's knowledge), have the right to be called physicians. Rather, we might follow the lead of Donald Goodwin and Samuel Guze and simply consider as diseases those conditions linked to suffering, disability, and death, which the lay and medical community regard as the responsibility of medicine. As much recent writing in the history of

medicine argues, the "existence" of a disease can be as much a matter of social convention as a question of its biological reality.

This alternative approach to the history of mental disease will also sidestep the pitfalls associated with following the story of any particular psychiatric disorder through the centuries. The goal of this essay is to reconstruct the stages and processes by which insanity came to be seen first as a medical problem and then as a matter for specialized expertise. Particular attention will be given to the interactions between lay and medical conceptions of mental illness, in which physicians become drawn to issues of social concern and, in turn, their theories are incorporated into social thought; to the fit between the specific professional agenda of physicians and the medical conceptions they espoused; and to the challenges as well as opportunities that advances in general medicine posed for psychiatric practitioners. In so doing, we might arrive at a better appreciation of what is embedded within our current categories of mental illness and a clearer perception of what is the social function of psychiatry as a medical discipline.

Early Modern Europe to the Seventeenth Century

In this period, no single approach to the problem of insanity dominated. Although categories of insanity in the Renaissance derived mainly from the classical system of mania, melancholy, and dementia, which were based on the broad medical doctrine of bodily humors, the implications were diverse in practice. Physicians and lay people alike typically depicted mad persons as wild beasts, devoid of reason. Brutal handling of the insane was commonplace. Yet a pattern of hospital care for the insane had been emerging since the late Middle Ages. The famous English hospital of St. Mary of Bethlehem, later known as "Bedlam," was founded in 1450 as an institution to care for those who had "fallen out of their wit and their health." Moreover, in that age a belief prevailed that melancholics and some mad persons held powers similar to those of saints, such as talking in tongues and prophesying. Erasmus himself wrote that Christianity is a form of madness. This tradition stemmed from the rediscovery of Plato's teachings, that human beings are compound beings, part heaven and part earth. When the organic part is disturbed, as in madness, the soul becomes partially liberated. Poets, seers, and lovers might all exhibit true mania. And because this was a time when religion infused everyday life, visions were not rejected as deformed thoughts of diseased minds. Rather,

they were embraced as tangible manifestations of a divine universe that was otherwise liminal.

More to the point, religion, magic, and medicine in this eclectic age were viewed as overlapping – not incommensurate – domains. Loss of reason was attributed to any combination of natural illnesses, grievous misfortunes, evil spirits, and deeds so sinful as to incur God's direct wrath. Insanity thus became the proper business of astrologers as well as physicians, and of clergymen as well as lay adepts. Moreover, these roles often merged. A healer of sick souls might offer counseling to assuage a spiritual affliction in combination with a therapeutic regimen to restore a humoral balance. A course of physic might be accompanied by a magic spell and implemented according to the patient's horoscope. For the Renaissance doctor, an individual instance of madness was a thorny interpretative challenge, for its meaning might be located in bodily corruption, in devilry, or even in the signs of sainthood.

These entangled threads, however, pull apart in the seventeenth century as a consequence of intellectual and social revolutions. A foundation was being constructed for a naturalistic interpretation of insanity that would eventually overshadow supernatural and religious frameworks. First, the scientific revolution that culminated in the work of Francis Bacon and Isaac Newton placed science and the experimental method at the forefront of human achievement. The universe was beheld as a clockwork whose structure and mechanism could be understood – and eventually manipulated – by rational human investigation. As the macrocosm could be found in the microcosm, such investigations explored the physiology of the human body; the most notable was William Harvey's demonstration of the function of the heart and circulatory system.

Attention was also drawn to the mechanisms by which the soul commanded the body – the search was on for the *sensorium commune*, the organ that might mediate between passions, sensations, and body humors. The pineal gland, the organ suggested by René Descartes during the first half of the seventeenth century, was one of many candidates proposed at the time. Descartes's philosophical tour de force of dualism, although known for its splitting the analysis of mind from the analysis of body, nonetheless spurred research into the somatic mechanisms that commute a volition into an action. The seventeenth-century work of Thomas Willis, who is often considered the father of neuroanatomy, stands out for its pioneering efforts to place the brain at the

center of human action – and disease. For example, Willis's studies on women with hysteria led him to conclude that the disease originated in the brain, not in the uterus, as maintained in classical doctrine. His teachings, later expanded by such students as John Locke, directed investigators to uncover the role of the nervous system as the basis of human experience and knowledge. Paralleling the interest in the somatic mechanisms of self was a focus on the range and force of the passions. Of special interest were the late-sixteenth- and early-seventeenth-century physicians Thomas Wright, who discussed how patients' mental states could be critical to their recovery from illnesses, and Robert Burton, whose *Anatomy of Melancholy* (1621) stressed the psychological causes and cures of insanity.

Major social upheavals were also underway. Following the midcentury English Revolution, in which religious enthusiasts temporarily gained power, respectable people repudiated religious fanaticism in all its forms. Embracing the rationalist worldview of scientists and natural philosophers, the educated classes ridiculed astrologers and empirics, in the process abandoning therapies based on religious and magical means. The way was clear for the nascent scientific communities to construct new interpretations of health and illness. In turn, the consolidation of the naturalist model had important consequences for the cultural boundaries of insanity. During the Reformation, Puritan ministers often demonstrated the powers of their practical divinity by healing sick souls. Considering themselves "physicians of the soul," they led afflicted individuals through intense rituals of community prayer and healing fasts. Such potentially helpful ties between learned religion and popular culture were lost, however, in the rush to remove demons from psychopathology.

In addition, the naturalist model allowed for a novel form of ideological warfare. Where Anglican pamphleteers might be labeled heretics by their religious enemies, the favor was returned when they denounced these foes as sufferers of a mental disease. Madness thus emerged as a form of "counterreality," an appellation that marginalized the religious fanatics who so recently had destabilized the nation. Before the Restoration, a time when talking directly to God was still thought possible, hallucinations and delusions were not especially important signs of insanity. Afterward, however, such experiences were considered the very essence of madness. In the hierarchical world order before the Revolution, it was one's willingness to obey that determined one's insanity. In the new political order, which was constructed around innovative theories of social contract and willful association, it was the inner choices behind assent that were open to dispute and control. Not yet sorted out, however, was the exact role that physicians would play in constructing, and responding to, this new "counterreality."

The Enlightenment

The eighteenth-century period of the Enlightenment has been characterized as the Age of Reason, when the powers of mind reached out to command both nature and human affairs. The goal was the perfectibility of "man" and of "man's lot" on earth, and the means to this end was rationality tempered by direct observation. Within this context, all that held back or confounded the development of civilization – whether particular individuals or society as a whole – came under heightened scrutiny, a problem to be solved by the reasoned application of science and medicine. Madness, or, as some might put it, "unreason," stood out as a dark challenge to the light of progress. Indeed, this was the era in which physicians discovered that the insane presented a significant and distinct institutional population, one amenable to medical intervention; that society was wracked by distressing conditions composed of psychic as well as physical ailments; and that the source of most diseases was traceable to the newly dissected nervous system. Because of the numerous ties forged between medicine and the problem of insanity, many consider the modern concept of mental *illness* to have been itself an Enlightenment product.

In traditional histories, modern psychiatry dawns with the legendary moment in 1795 when Philippe Pinel, chief physician of the Salpêtrière asylum for women, struck the chains from the inmates. The mad were no longer to be considered mere brutes deprived of reason, amusing grotesqueries, but as afflicted persons in need of pity, humane care, and enlightened physic.

Applying the principle of direct clinical observation, Pinel reorganized categories of mania, melancholia, dementia, and idiocy to reflect specific, identifiable symptom clusters derived from his cases. For example, he distinguished between mania with delirium and mania without delirium – a disturbance of will without intellectual deficit. (Later, Pinel's nosological stance would revolutionize general medicine.) Mental illness resulted when persons of unfortunate hereditary stock were overwhelmed by their social environment, poor living habits, a disruption in routine, or unruly passions. Physical factors, such

as brain lesions, fever, and alcoholism, were thought possible but not as common as "moral" or psychogenic factors. Asylum statistics revealed that mental illness was, surprisingly, an intermittent or temporary condition, curable if treated before it had a chance to become somatically ingrained. The physician's best weapon was discovered to be the hospital itself, for its strict regimens were the very tools by which the superintendent might instill into his charges an inner discipline, emotional harmony, and the habits of productive citizenship. In linking, in one stroke, progressive reform to medical advance and, in another stroke, the stability of a patient's inner psychic milieu to the proper management of the external hospital environment, Pinel set in motion the optimistic expansion of institutionally based psychiatry.

Recent critics, such as Michel Foucault, view Pinel's accomplishment less favorably. Physical chains were indeed removed, but only to be replaced by internal ones, more insidious for their invisibility – shame and guilt can be just as constraining as iron. Through the guise of humane treatment, patients were coerced into conforming to putative "normal," "healthy" standards of conduct. Moreover, critics like Foucault hold, it was no accident that insanity was placed under the purview of the large centralized institutions of Paris, since Pinel's model fit well with the demands of the emerging political order. The growing asylum populations were themselves only a part of a larger phenomenon. Those who, for whatever circumstances, failed to fulfill their duties as citizens within the new state became managed increasingly through civic institutions, be they almshouses, jails, workhouses, hospitals, or asylums. Physicians, in reaching out to asylum inmates through an expanded medical view of insanity, were at the same time complicit in cementing the new political realities. Pinel may indeed have rescued asylum inmates from base neglect, but the benevolent paternalism of the "clinical gaze" has had its toll. Henceforth, "modern man" is enslaved within a medicalized universe, for there can be no form of protest that cannot be interpreted, and thus dismissed, as pathological in origin.

Foucault's approach has since been shown to be not wholly satisfactory. True, it was in this period that the institutional face of insanity was dramatically revealed. The pattern is not uniform, however. The model works best in such contexts as France and Germany, where larger asylums for the poor evolved within a spirit of centralized authority and medical police. By contrast, in England, such growth oc-

curred mostly in the small private asylums patronized by the higher classes, which were directed by lay as well as medical superintendents. The formation of relations between nascent psychiatry and its clientele remains a complicated, poorly understood story. Clearly, though, the growing institutional populations sharply focused both social and medical attention on severe madness as a problem requiring solution.

An exclusive concentration on the institutional history of psychiatry may also obscure the broader social currents that already were greatly expanding the concept of mental illness. Milder forms of insanity, such as hypochondriasis and hysteria, had by Pinel's day gained a status as the period's quintessential medical complaint. These conditions, also known as the vapors, spleen, melancholy, or later "nerves," referred to an irksome cluster of psychological and somatic (especially gastric) complaints, ranging from ennui to flatulence. Through such works as Richard Blackmore's *Treatise of the Spleen and Vapours* (1725) and George Cheyne's *The English Malady* (1733), the valetudinarian "hypochondriack," known by oppressive moodiness, oversensitive skin, and bad digestion, became enshrined as a stock Enlightenment figure.

The arrival of the "nervous" disorders coincided with the emergence of new social functions for the concept of mental illness. Woven out of the perceived interactions between psyche and soma, temperament and life-style, such conceptions offered a facile interpretative matrix for connecting to issues that stretched beyond personal health. In particular, members of polite society found in the "hypochondriack" disorders a rich social resource. Such complaints enabled one to mull endlessly over the minor discomforts of life and were also a self-replenishing well for claims on others' sympathy. But they served a more subtle function as a conspicuous indicator of social location, for those believed at risk for the ailments were only those of a truly refined and exquisite temperament. In the words of the *Encyclopedia Brittanica* (1771), hypochondriasis was a "peculiar disease of the learned." Indeed, James Boswell wrote that the suffering hypochondriacks – himself included – might console themselves with the knowledge that their very sufferings also marked their superiority.

When "furious distraction" or severe mania was the hallmark of the psychically afflicted, the designation of insanity was tantamount to banishment from normal society. In contrast, hypochondriasis was a form of social promotion. There was a collective func-

tion, too. Contemporaries explained the dramatic outcropping of the malady as a direct consequence of the unnatural circumstances imposed by the new urban, "civilized" life-style. Sedentary living, rich food, populous towns – all were thought to exact a toll, the price of progress. In short, through the innumerable discourses on hypochondriasis, the anxieties and ambivalences of a rising class found a favorite means of expression.

The new power of the disease categories did not remain for long the exclusive property of the higher classes. By the end of the eighteenth century, physicians were chagrined to find that tradesmen and domestic servants were equally likely to exhibit hypochondriack or hysteric complaints. As it happened, when elite physicians looked to the hospital infirmary for new sources of medical advance, they were confronted with the realities of the sick poor. Institutional portraits of disease thus clashed with those derived from private practice – the democratization of hysteria and hypochondriasis was but one consequence. The poor, for their part, had discovered that the nervous disorders served as entry tickets to one of the few sources of medical charity then available.

The popular appeal of the new concepts of mental illness must also be attributed to developments in medical research and theory that stressed the importance of the nervous system to all pathology and that presumed a psychosomatic model of interaction between mind and body. The trend stems from Willis, who looked to the brain as the fundamental organ; his model, though, remained humoral, based on poisonous "nervous liquors." As the extensions of the nervous system became further elaborated in the eighteenth century through the work of Giovanni Morgagni, Albrecht von Haller, and Robert Whytt, a new medical system appeared that was based on the "irritability" and "sympathy" of the muscles and nerves. The renowned Scottish physician William Cullen went so far as to declare that the majority of all diseases were caused by either too much or too little nervous "tone," a pathological condition that he termed a *neurosis*. Neuroses, as defined by Cullen, were afflictions of sense and motion that lacked fever or localized defect – a "functional" as opposed to structural condition. Subsumed within this new category were such afflictions as hysteria, epilepsy, tetanus, asthma, and colic. (Cullen's model of neuroses persisted well into the late nineteenth century.) Through Cullen and his followers, the nervous system was elevated to central importance within physiology, pathology, and nosology, laying the conceptual

groundwork by which general medicine was to break away from the neohumoral systems that had dominated since the Renaissance.

Cullen's nosology, in which diseases were classified on the basis of the patient's presenting symptoms, be they physical or mental, was essentially psychosomatic in orientation. Medical interest in the inner contents of self also followed in the wake of Lockean theorists who were building a new psychology of mental associations, and of William Battie and others of the eighteenth century who were exploring the role of the passions in determining mental and physical harmony. Perhaps the best example of the strength of the psychosomatic model can be seen in the heroic treatments of the insane, which included the notorious dunking chair. This intervention was not simply an expression of random cruelty or cultural atavism. Rather, it was a logical product of the belief that mental shocks were akin to physiological action, with effects as powerful as those induced by bleeding or purging. Terrifying the mind was a medical recourse used for a broad range of pathological conditions.

To explain the proliferation of the psychosomatic model in this period, sociologists and historians look to the nature of the patient–physician relationship. Because medical practice consisted of private consultations, where physicians were dependent on satisfying the whims as well as the needs of their wealthy patrons, medicine was patient-oriented. Treatment was formulated to satisfy the client, a tailored reading of life-style, circumstances, and habits, with heroic treatments applied in response to demands for dramatic action. Similarly, Cullen's symptom-based nosology was based not on direct physical examination – the physician's own domain – but on patients' descriptions of their complaints. Given these circumstances, it was the totality of the sick-person's experience that gave unity to the day's medical theories, a phenomenological orientation in which psychic complaints were on a level ontological footing with somatic disturbances. Medical priorities – and hence realities – were thus set by what patients considered bothersome. We must remember that physicians as professionals were only then developing an institutional base, such as the hospital, wherein they might control their patients and establish internally derived standards of research and treatment.

Finally, the ties forged between the problem of mental illness and medicine must be placed in the context of the new social meaning of health and the expansive role of physicians in the Enlightenment.

Historians have described how in this period health itself become a goal, if not an obligation, for individuals and society to pursue, a secular gauge of progress that could be accomplished in the here and now. In response to a thirst for practical knowledge, medicine was "laid open," translated from Latin texts, and popularized in an explosion of pamphlets and health guides. Health as a commodity generated a tremendous market for physicians' services and, in the age of Franz Anton Mesmer and electricity, for any treatment remotely fashionable. Psychic disorder was a particularly fertile niche for physicians to exploit. This was especially true after it was linked by the neurosis model to a broad range of everyday conditions and once its curability in even severe forms was demonstrated. (The work of Pinel and the dramatic turnabout in behavior of mad King George III was particularly effective in this regard.)

Medicine, defined as keeper of the welfare of the human race, extended far beyond matters of individual treatment and grew into an Enlightenment metaphor for broad political reforms. Guiding thinkers such as the philosophes saw themselves as nothing less than medical missionaries who cured the ills of society itself. Since the individual was a product of society and nature, the science of physiology came to signify the proper functioning of the social as well as individual body. Moral philosophy and biology joined in the new science of man; theories of the perfectibility of human society were interlaced with secular theories of health. Thus, Pinel's striking of the chains was understood to be as much an act of civic benevolence as the first step of a new "medical" approach. Medical progress and benevolent reform commingled, a shared task. Furthermore, the problem of mental illness and the proper development of mind were of special fascination in an age obsessed with how reason was self-consciously mastering nature and reconstituting society. Through a cause célébre like the case of the Wild Boy of Aveyron, the original feral youth, and the contention of Pierre Cabanis that the brain excreted thought like the liver excreted bile, the belief was growing that the forward movement of civilization might depend on scientific forays into the darkness of human pathology.

In sum, madness during the Enlightenment became a central cultural concern. Mental afflictions were newly visible in the asylums, in the rise of hypochondriasis and related disorders, and in the investigations into the functions of the nervous system. With the expansion of the concept of mental illness to include conditions that were not drastically removed from everyday experience and that

were considered amenable to medical intervention, mental afflictions became important social resources for the expression of individual and collective anxieties. Physicians discovered in the growing popularity of these conditions not only a fresh source of patients and an institutional base, but new service roles for themselves as social critics and experts – madness became the very measure of civilization. Thomas Trotter, enlarging on the work of Cheyne, claimed that the nervous diseases resulted when citizens' life-styles and occupations did not fit their constitutions and temperament. He warned that England, owing to a combination of its peculiar climate, free government, and wealth, was the most threatened country. The survival of civilization, with its complex social differentiation of labor, depended on the decreasingly likely event of persons working within their proper stations in life – lest the nation degenerate into one of idiots and slaves. Physicians bore the responsibility for "diagnosing" the need for adjustments in the biological – and social – hierarchy.

We must not, however, overstate the extent of insanity's "medicalization." Persons were transported to asylums not so much because medical treatment was considered necessary as because these people were perceived to be dangerous or incompetent. The insanity defense had become an increasingly popular resort in criminal trials, yet the examination of a defendant's mental status was as likely to be performed by a lay authority as by a medical one. And there existed as yet no professional grouping of psychiatrists, let alone regular physicians, who had specialized knowledge of the insane. The concept thus remained a product mostly of general culture, transparent for all to read and make judgments upon.

1800 to 1850

In the first half of the nineteenth century the treatment of mental illness was marked by two trends: a wave of asylum building and the differentiation of a small band of medical professionals who claimed mental disorders as their special domain. These two developments were linked through a materialist model of mental physiology that had reformist connotations and the arrival of new categories of mental illness that advanced the value of psychiatric expertise.

Written as only a modest, local report of the way Quakers cared for their small number of lunatics, Samuel Tuke's *Description of the [York] Retreat* (1813) nevertheless launched a worldwide movement of asylum construction. In this system of care later known as "moral treatment," the asylum was envi-

sioned as a functional microcosm of society at large where troubled persons might reconform to proper social behavior through a vigorous program of occupational therapy and moral suasion. Chains were to be replaced by admonitions, bars by comfortable furnishings, and the inmates' mania quelled by distracting amusements. In the words of John Connolly, an asylum pioneer known for his popularization of the "nonrestraint" method, the combined psychological effect of enlightened architecture and behavioral management had rendered the asylum a "special apparatus for the cure of lunacy." Originally designed for fewer than 30 patients, the new asylums were artificial family environments, heavily dependent on the talents and personality of the superintendent. His burdens included intimate contact with patients and their families; the judicious meting out of an array of mild rewards and punishments; and immediate attention to the smallest administrative problem. A commanding presence, diplomacy, boundless sympathy, worldly wisdom, moral probity, and frugality were all characteristics essential to the task. A medical background was not a necessary qualification – and by no means was it a sufficient one.

The Tuke model of moral treatment was particularly fruitful in developing asylums in the United States, a success attributed to several factors. As civic responsibilities shifted from town to county and later to state government, officials looked to the centralized asylum as the rational (albeit more expensive) site of humane care not available in local jails, almshouses, or homes. Also, it has been argued that in the troubled times of Jacksonian America the well-ordered asylum gained favor as an innovative symbol of social control. Moreover, families increasingly looked to the asylum as a solution to their terrible burdens. It is not clear whether this was due to social changes that rendered them either unwilling or unable to provide home care, or whether they had become convinced by the vaunted success of asylum cures. In either case, the unquestioned ease with which patients were shipped to asylums had prompted even Connolly to warn that the proof of an individual's sanity was quickly collapsing into the simple question of whether he or she had ever been institutionalized.

Although when first constructed the asylums were as likely to be managed by lay authorities as by medical ones, their growth nevertheless provided a base for a new breed of physicians whose practice was limited to mental problems. Such posts were often quite attractive, and an esprit de corps developed among the elite who occupied them. The origin of psychiatry as a profession is typically traced to the 1840s, when these medical superintendents, or "mental alienists," banded together to form specialized organizations and medical journals. (For example, the forerunner of today's American Psychiatric Association began in 1844 as the Association of Medical Superintendents of American Institutions for the Insane; this predated by four years the American Medical Association.)

The challenge for the first psychiatrists was to expand both their institutional base and their claim to specialized knowledge. The former goal was advanced by championing the idea that insanity was curable if its victims were removed at once from their homes to asylums, where they might receive the full advantages of moral treatment – in combination with a regular medical regimen. Moral treatment as a nonmedical practice was thus neatly coopted. In turn, the growing empire of asylums crystallized the young profession around a privileged therapy. Patients were locked in, but just as significantly, medical competitors were locked out. The alienists also made progress in advertising their expertise. In France, when the Napoleonic code made provision for a legal defense of not guilty by reason of insanity, alienists attracted national attention by their involvement in celebrated homicide trials. In advocating social if not legal justice for insanity's unfortunate victims, the alienists were advancing a political cause of liberal philanthropy (in the heat of Restoration politics) and also a professional one, the elevation of their status to that of experts.

The alienists seized on the concept of *monomania*, a term coined by Jean Etienne Esquirol around 1810, to argue that a person could be driven by delusions to perform acts for which he or she was not responsible. Descended from Pinel's *manie sans délire*, monomania referred to a nosological region intermediate between mania and melancholia. Unlike those with nervous or hypochondriack disorders, which comprised the gray zones between everyday preoccupations and total loss of mind, monomaniacs were indeed quite insane, but only in one part of their mind, and perhaps intermittently so. A morbid perversion of the emotions did not necessitate a corresponding loss of intellect. The defining characteristic of the disorder was that, save for a single delusion or disturbance of mind, an afflicted individual might appear entirely normal. Here, then, was a semiotic wall that could not be breached by lay or even nonspecialized medical knowledge. Significantly, at the trials the alienists employed neither arcane technique nor extensive jargon. Their claim to expertise

was the discerning eye of a seasoned clinician, a skill that was honed on asylum populations where insanity was visible in all of its protean and elusive forms. Knowledge does not have to be exceedingly learned to be restrictive. It was a sufficient argument that only those with extensive asylum experience could reliably distinguish the true monomaniac from the false.

The term *monomania* seems to have fallen into fast decline in France after 1838, immediately following the passage of legislation that provided greatly expanded roles for alienists in France. In success, the term lost its ideological edge. Elsewhere, similar concepts of *partial insanity* and *moral insanity* (coined by J. C. Prichard in 1835) took root, which played equally vital roles in demonstrating that questions of lunacy were matters best left to experts.

Expansion of the profession depended on communities that held potentially antagonistic viewpoints, a situation that presented the alienists with a difficult balancing act. On one hand, ties were maintained to the nonmedical constituencies who were driving forward institutional reform. On the other hand, general medicine was making great strides in the Paris clinics, where the anatomopathological approach to the localization of disease was launching modern medicine. A new medical standard had to be met. These separate goals found mutual expression in the doctrine of phrenology, a powerful movement in Europe and the United States that was based on the late-eighteenth- and early-nineteenth-century work of Franz Joseph Gall and Johann Spurzheim. Holding to the twin assumptions that psychological faculties were localized in specific regions of the brain and that cranial morphology was a guide to brain structure, the doctrine popularized "reading bumps on a head" as a means of revealing an individual's innermost talents and deficits. Although later generations heaped abuse on it, phrenology has since been credited with disseminating into general culture a materialist philosophy in which the brain was the organ of the mind and with motivating researchers in several fields to explore mental physiology as a serious pursuit. For the alienists, phrenology provided a framework for considering disordered personality, one that incorporated society, the asylum, and general medicine. Through this model, alienists participated in the movement to better society through useful knowledge, explained the effectiveness of moral treatment as a program that strengthened specific mental faculties, and followed the organicists' lead in insisting that insanity could be attributed to brain lesions. Moreover, the psychological

and physiological models merged: The well-ordered asylum restored the patient by keeping the brain in a tranquil condition.

1850 to 1900

The late nineteenth century witnessed an explosion of interest in the problems of mind and mental problems, one that extended across the cultural landscape into art, literature, science, and politics. A new frontier had been opened: the human interior. Thus commenced a wave of ambitious explorations into the conscious – and later unconscious – mind, with the aim of understanding what qualities of the self within were necessary to sustain civilization without. With the formal appearance of the human sciences, fragmented into the disciplines of anthropology, sociology, psychology, economics, and history, and a similar specialization in medicine that generated the modern professions of neurology, neurophysiology, neuroanatomy, and even psychiatry, a dizzying growth occurred in the number and variety of schools of thought on the structure and function of the human mind. From this point forward, any attempt to systematize the development of psychiatric conceptions is vastly more complex and unwieldy. Indeed, any disease category that even remotely touches on human behavior would henceforth have multiple, and perhaps contradictory, meanings – depending on who employed it, and where. Hysteria meant different things to the novelist than to the alienist or general practitioner, to the French psychologist than to the German investigator, to the neurologist in Paris than to his or her colleague in Nancy.

In addition to the interest spawned by these intellectual currents, the subject of mental disorders drew impetus from "below," from powerful social concerns. On several fronts, much more now appeared to be at stake, for the individual and for society, in the realm of the troubled self.

The Asylum and Society

The once-small asylum had swelled in size and population far beyond what its creators had initially hoped – or had farsightedly dreaded. A typical public mental institution in the United States now housed hundreds of inmates, resembling more a small town than an intimate extension of a household. Simply put, the superintendents had oversold their product; patients streamed into the institutions faster than they could be cured. And through accretion, or what contemporaries referred to as "silting up," the small but significant percentage of patients who would prove untreatable now occupied

a majority of the beds. The public costs of indefinitely maintaining tens of thousands of such unproductive members of society (as well as of building additional beds to treat the incoming curables) were indeed staggering.

In subtle ways, the institutions' success in attracting patients had the unintended effect of heightening fears that the problem of mental illness was somehow worsening. What was only newly visible to the public was considered but newly existent. Moreover, the simple bureaucratic act of generating institutional records itself distorted clinical perceptions. As hospital tallies began to reveal that the same patient might be released only to be readmitted years later, and that new admittees were often related to past inmates – graphic illumination of insanity's fearsome generational grip – mental disorders of the day were concluded to be far more virulent and insidious than when the institutions originally opened. Such fears were compounded by the consequences of slow but profound demographic shifts that reinforced racial stereotypes. Where asylums based on the Quaker model of moral treatment assumed a homogeneous population, in that physician, patient, and community shared similar religious and social values, the public institutions had become cultural mixing pots filled with diverse immigrant and working-class populations. Alienists, now mostly salaried employees of the state and no longer beholden to families for private fees, became even further removed from the cultural milieu of their charges. Severe mental illness thus loomed as a social problem of paramount importance, one that had become even more grave.

"Nervous" Disorders

At the same time, the public had become obsessed with ailments of a less serious but more commonplace nature, especially those conditions in which mental and physical attributes blurred together. Rapid industrialization and urbanization brought forth dramatic transformations in the family, workplace, and society. In turn, the anxieties and inner conflicts that arose from survival in the fast-changing modern world found expression in a slew of somatic complaints, ranging from dyspepsia and skin disorders to hysteria and hypochondriasis. Cullen's and Trotter's neuroses had been resuscitated – but with a twist.

Owing to the rise of the middle class, a higher level of literacy, and the formation of a consumer culture oriented to such things as the creation of markets for health remedies, such "fashionable" diseases penetrated faster and deeper into society. Moreover, the unifying metaphor – the nervous system – had metamorphosed well beyond mere "irritation." Since even Trotter's time, neurological investigators scored major accomplishments in understanding how the brain mediates between sense impressions and motive action. In the age of the telegraph and the dynamo, of centralized bureaucracy and the division of labor, the new model of the nervous system – one part wiring diagram and one part administrative flowchart – offered an intuitive, adaptable framework for explaining how human thought or action was guided, executed, and powered. Any number of confusing conditions or troubles could now be plausibly explained by the lay public and medical personnel alike as simply a case of "nerves" – which at once said everything, and nothing. Indeed, so popular was the new framework that some have referred to the late nineteenth century as the "nervous" era.

Secondary Gains

A diagnosis is never socially neutral because the "sick role" associated with an illness has practical consequences for the patient that are as real as any physical manifestations of pathology. In the Victorian world of moralism and industry, where individuals were tightly bound by standards of duty and economic performance, the role of the nervous invalid was promoted to central stage. Legitimated by the growing prestige of scientific medicine, this and other categories of disease provided one of the few socially acceptable opportunities for many persons to step away from, at least temporarily, their everyday obligations. Because of their protean nature, nervous disorders were particularly well suited for exploitation as a social resource. While virtually any mysterious symptom or combination of symptoms might indicate an underlying nervous condition, physicians had precious few criteria by which to rule out such a disorder. The presence – and departure – of a nervous ailment was decided more by the patient than by the physician, to the immense frustration of the latter. Nervous diseases, often with simple and well-known components, were thus available to all.

This is not to say that these conditions were without drawbacks. On the contrary, the distress and limitations on existence associated with a sick role are often quite drastic. For example, historians have explained the outbreak of hysteria in this period as emanating from the conflicting and impossible demands placed on women. Although such a "flight into illness" offered some measure of reprieve, even allowing the exactment of a small manner of domestic tribute, it exposed these women to painful treatments, left the underlying conflicts unresolved, and

reinforced their dependency. Benefits were gained at a definite cost, but for many, such a flight nonetheless remained a viable option.

The example of hysteria is only one illustration of a pervasive trend, the appearance of medical disorders as significant resources for the indirect negotiation of social conflicts. In addition to the battleground of household or gender-related politics, a person's health status might figure heavily in such polarized issues as the responsibility of corporations to protect the public, fitness for employment or military service, and criminal trials. Thus, victims of train wrecks (a notorious hazard of the industrial world) might be awarded some compensation on the basis of their suffering from the vague syndrome of "railway spine"; mothers accused of infanticide might be judged temporarily insane rather than be sent to prison; and battle-weary soldiers might be diagnosed as suffering from irritable heart syndrome rather than face execution as deserters.

In answering the call to pronounce judgment on matters with such public consequences, physicians were expanding their authority over everyday affairs. As indicated in the examples just given, some of the more volatile health debates touched on neuropsychiatric conditions, an area of medicine in which diagnostic and explanatory models were insufficiently powerful to enable a designated "expert" to deliver a verdict that would remain uncontested. Many opportunities for professional growth were opened, but the path was uncertain.

Thus, in the second half of the nineteenth century, mental disorders gained a commanding social presence due to the perceived threat of the asylum population, the profusion of nervous disorders, and their linkage to a range of polarized issues. This social interest was mirrored by the attention of diverse groups of learned scientists and physicians who competed for the privilege of claiming the field of mental disorders as their own. Such groups varied greatly in their institutional location, professional service role, scientific orientation, and political aims. Their disparate agendas led to a jumble of theories regarding insanity; in turn, these theories both strengthened and limited the professional opportunities of their proponents. Let us visit, in turn, the asylum alienists, three types of neurologist (the researcher, the private practice consultant, and the urban clinician), and university psychiatrists.

Asylums and Their Keepers

French Alienists and Degeneration Theory. In France, the manifold problems of asylum psychiatry surfaced by midcentury, enshrouding the young profession of *alienisme* in an unexpected fatalism. Worse yet were the political circumstances of the Second Empire (1852–71), in which the materialist basis of mental physiology was linked to the suspect ideas of Republicanism and atheism. Although their institutional posts afforded some degree of protection, alienists nevertheless were under siege. In the decade of the 1860s, for example, their public lectures were suppressed by government decree. The pessimism of the profession found expression in the theory of degeneration, or morbid heredity, which derived from the publication of B. A. Morel's *Treatise on the Physical, Intellectual, and Moral Degeneracy of the Human Race* (1857) and J. J. Moreau de Tours's *Morbid Psychology and Its Relationship to the Philosophy of History* (1859). Drawing together currents in biology, medicine, and social thought, degeneration theory was perhaps the most significant influence on late-nineteenth-century psychiatry.

The degeneration model asserted that hereditary factors were the primary cause of insanity, pathology occurring when a weak disposition was overwhelmed by intoxicants (alcohol, malaria, opium, cretinous soil), social milieu, or moral sickness. Combined effects of physical and moral injuries were especially treacherous. The distinguishing feature of the degenerationist model was its *developmental* (or "genetic," in its original meaning) orientation.

Even as enthusiasm for lesion-based systems of psychiatry waned, a new intellectual foundation was emerging from the biological theories of Jean Baptists Lamarck, Herbert Spencer, and later Charles Darwin. With evolution supplanting pathological anatomy as the core biology, questions of process overshadowed those of structure. Static taxonomies of disease thus gave way to dynamic systems, in which most mental disorders were stages of a unitary disease, stratified not by anatomic location but by a defined temporal order. Simple ailments were linked to severe ones, as the seed is to the tree. Mental illness now had a plot.

For the French alienists, the degeneration model provided a way to navigate past the Scylla and Charybdis then facing the profession, the dual hazards posed by either holding to materialist positions that invited political attack or abandoning these in favor of psychological models that were insufficiently "scientific" to silence medical critics. Morel's solution was to argue that a specific case of mental illness was the expression of a "functional" lesion of the nervous system, one based on its performance as an integrated whole. Although an organic mechanism was presumed (satisfying demands for scien-

tific rigor), its elaboration was considered unnecessary for understanding the clinical significance of mental illness. Moreover, the integrationist stance remained agnostic on the precise interaction between mind and body. Religious conservatives need not be enthusiastic supporters of the degenerationist model, but at minimum it was palatable; although the soul no longer held a perpetual lease on the body, neither was it in immediate danger of eviction. Morel himself was deeply religious, finding in the degenerationist model a biological statement of original sin.

The theory states that the development of the individual is a reenactment of that of the species as a whole, a viewpoint later encapsulated in Ernst Heinrich Haeckel's famous phrase "Ontogeny recapitulates phylogeny." Civilization's forward progress had depended on the triumph of government and order over barbarism and base desires. Individual survival depended on no less. If anarchy and mob rule were evidence of a breakdown in the social order, a reversion to an earlier – and hence evolutionarily lower – state, then madness was its equivalent in the individual, an atavism from a time when emotions ruled the intellect. Because we are biological as well as spiritual entities, the animal beneath the skin can only be controlled, never exorcised. Mental composure depended on an interminable conquest of desire by discipline.

Although heuristically powerful, the degenerationist framework offered no immediate therapeutic advantage for institutional practice. Rather, its strength lay in its expansion of psychiatric authority beyond the walls of the asylum. With overfilled institutions belying the curability of severe mental illness, alienists faced the prospect of becoming an alliance of mere custodians, should no dramatic treatment appear. Instead, alienists looked outward, recasting their medical responsibility to include prophylaxis – society would be served best by staunching the flow of inmates at its source. The new explanations of madness provided alienists with a blueprint for such extramural intervention, one that augmented and did not undermine their institutional base.

Asylums provided alienists with a unique vantage from which to observe directly countless broken lives. Every new admission was an object lesson in the fragility of normal life, of how a single path wrongly taken – perhaps a pint of gin, an act of masturbation, or a flirtation with prostitution – might set a once vigorous individual on a course of dissolution that would end in a locked asylum ward.

Such stories provided alienists a rich harvest from which to manufacture their most valued product: advice. Moreover, given the Lamarckian assumption of the day, that a person's habits over time were eventually transmitted to future generations as heritable traits, it was not just an individual's life, but the life of the nation, that was at risk. With dissolution as the key to insanity, mental illness acquired a definite moral as well as biological structure. Unless the alienists' warnings were heeded, a generation of dissolute citizens would flood the country with nervous children, and insane grandchildren in even greater numbers. Madness was the very destiny of a people unfolded.

Alienists thus trumpeted themselves as advisers on matters of social policy, alone competent to pilot civilization past hidden reefs. Their message was especially poignant in France in the 1870s, when the country was recovering from the devastating military loss to the Prussians and from the turmoil of the Paris Commune. It seemed that one had to look no further than the specter of working-class mobs to see the link between social revolution and morbid degeneracy. The model gained popular credence through the work of Cesare Lombroso, an Italian author who devised popular categories of criminal insanity. As we shall see, aspects of the degenerationist model penetrated virtually all major conceptual systems of mental illness espoused in the late nineteenth century. Indeed, the model resurfaces even today, whenever life-style is evoked as a basis for understanding disease.

Neurology

The latter half of the nineteenth century was neurology's "golden age," in research, private practice, and the urban teaching clinic. Each of these three neurological domains had significant repercussions in the medical conceptualization and treatment of madness.

British Experimental Neurology and Epilepsy. Through the efforts of mostly British, German, and Russian investigators, the reflex became the building block of neurophysiology. In the 1830s Marshall Hall demonstrated the importance of the reflex system in maintaining all vital bodily activities. Following the British philosophical tradition of volitionalism, however, purposive acts and thought processes were left inviolate. Such dualism of mind and body came under assault by Thomas Laycock. Drawing on German science, in which a *natur-philosophie* orientation presumed a unity of man in nature and a continuous evolution from animal to man, Laycock argued for a

gradual blending of automatic acts, reflexes, instincts, emotions, and thought. Laycock's student, John Hughlings Jackson, is often described as the true originator of modern neurology. Incorporating Hall's and Laycock's ideas, Jackson went furthest in constructing a neurological basis for human action. In his classic research on the localization of epilepsy (the major epileptic syndrome long bore his name), Jackson focused on the pattern by which nervous functions disappear in the course of a fit; here was an indirect means of peering into the functional organization of the brain.

Combining Spencer's evolutionary cosmology with the degenerationist outlook, Jackson constructed a topology of self in which the nervous system was hierarchically layered according to the evolutionary scale. At the lowest or most "primitive" level was the spinal system, which was controlled by the "middle" level, the motor system; this in turn was mastered by the "highest" level, the frontal lobes – the organ of the mind and the acme of evolution. Epilepsy could now be understood as nothing less than a body caught in the visible throes of dissolution. This answered Jackson's clinical puzzle concerning why aberrations of conscious thought were the first epileptic symptoms to appear; nervous functions were lost in precisely the reverse order of their evolution.

Much of the appeal of the degenerationist model resulted from its resonance with fundamental changes then occurring in the social fabric. Issues of social differentiation and hierarchy surfaced in the wake of nationalism which pitted one country's heritage and international standing against another's; industrialism, which produced a vast laboring underclass; and imperialism, which placed whole countries of "primitives" under European stewardship. With religious authority in decline, models of scientific naturalism were expected to provide a rational social order in step with the times. Jackson's model, which dovetailed a neurological "localization of superiority" with Spencer's dictum that "separateness of duty is universally accompanied by separateness of structure," exemplifies the fact that in the Victorian era visions of the external world could be disaggregated from those applied to the internal one. Jackson's accomplishment was a paradigm that continues to influence us today, one that all too neatly converged neurological, evolutionary, and social stratifications into a spatial metaphor of unusual power.

With Jackson's model, the degenerationist model of insanity now has a firm neurological basis. As Jackson himself argued, mental illness resulted from the dissolution of the higher centers, compli-cated by overactivity in the lower centers. Empirical proof of the connection could be found in the asylums, all of which housed a significant number of epileptics. For some time to follow, the ignominy associated with the biological corruption of the epileptic would spill over into categories of mental illness. Not clearly inferable from Jackson's work, however, was the actual involvement the neurologist was to have with the problem of mental illness, for although a solution to grave mental illness might come from a cure for epilepsy, this awaited much further neurophysiological research. The divide between neurology and mental illness was a matter of professional location as well as knowledge, in that few neurologists had access to asylum patients. As for the noninstitutional population, Jackson's preference for disease models based on clear organic mechanisms led him to declare that "functional" disorders were best left to other aspiring specialties such as gynecology and obstetrics.

Neurology and Neurasthenia in the United States.
Neurology as a viable profession in the United States dates from the Civil War, which produced a larger number of soldiers with nerve injuries and severe emotional disorders requiring specialized care. After the war, neurology rode the wave of specialism that was transforming urban medicine. Physicians with graduate training in European medical science hoped to build alternative medical careers by limiting their practice to areas that might benefit from specialized knowledge. Cities provided both the requisite critical mass of varied clinical material and the pool of motivated, affluent citizens to support these ventures.

In 1869 New York neurologist George M. Beard diagnosed Americans as especially prone to nervous exhaustion. His conception of *neurasthenia* – literally weak nerves – achieved international usage as a major trope of the Victorian era. The condition referred to a cluster of distressing, often vague symptoms that ranged from simple stress to severe problems just short of certifiable insanity. Bodily complaints such as headaches and hot flashes appeared alongside psychological ones such as lack of interest in work or sex and morbid fears about trivial issues. Thus burdened, neurasthenics retreated from the fulfillment of obligations to their families, employers, or social groups. The physiological link common to all these cases, Beard suggested, was the depletion of the vital nervous forces.

Neurasthenia's prevalence in the modern era was

no mystery, Beard argued. The telegraph, railroad, daily press, crowded quarters, and financial market had rendered life simultaneously more hectic, intense, and stressful. Civilization placed demands on our nervous systems that nature had never anticipated. Reminiscent of earlier interpretations of hypochondriasis, the eighteenth-century "English malady," the presence of neurasthenia served as a marker of advanced society. Once again, mental illness was a conspicuous price of progress. Americans, world leaders in industrialization, paid dearly. Here, too, patterns of incidence were interpreted as clues to social hierarchy. Men thought most likely to succumb were those at the vanguard of social advance, such as inventors and entrepreneurs. Women, whose smaller brains were dominated by their reproductive systems, might be overcome by the daunting task of running a Victorian household or by excessive intellectual effort. The ranks of the lower classes, to be sure, did yield a significant number of neurasthenics. But since their hardier constitutions would bear up under all but the worst shocks, such as alcoholism or inveterate depravity, the condition in them was more a badge of shame than one of honor.

For practicing neurologists, the concept of neurasthenia brought order to chaos and provided a defensible base for the profession's enlargement. The bewildering array of ailments that fell under the category of "functional" disorders (all those without gross anatomic damage or known organic cause, such a hysteria and hypochondriasis) were unified into a single clinical picture that was comprehensible to both neurologist and patient. Briefly stated, nervous energy was a precious quantity that must neither be squandered nor misdirected; temporary habits eventually became fixed pathways in the brain and might even be transmited to the next generation.

The reality of the functional diseases had been an open question for the public, which was often far more skeptical than many medical experts. The neurasthenic model, although lacking a precise organic mechanism, was able to relegitimate these disorders by imparting the cachet of a state-of-the-art scientific theory. Furthermore, the emphasis on brain physiology was consistent with the growing emphasis in biology and medicine on the central nervous system as the dominant bodily system. This displaced the open-ended physiological models of the eighteenth and early nineteenth centuries in which pathogenic processes might arise from the influence of any of a number of interconnected systems that included the liver, stomach, circulation, or nerves. Previously, any knowledgeable physician might have been able to understand the development of a mental pathology, based on a reading of the balance of the organism as a whole. Now, however, only a nerve specialist was qualified. And as an untreated cold might lead to pneumonia, so a nervous complaint not handled by a neurologist might be the portal to an asylum. In short, by establishing the principle that troubling but otherwise unremarkable mental states might produce morbid bodily changes as dramatic as any physical insult, Beard and his followers were constructing a neuropathology of everyday life.

The strength of Beard's model lay not in its originality but in its artful extension of medical and social trends. Indeed, by this time, nervous conditions represented to family physicians a significant portion of their practice and were also responsible in large measure for the booming market in health products and services. At first, neurologists followed uninventive therapeutic programs, endorsing the standard use of mild tonics and sedatives, dietary restrictions and supplements, massages, low-current electrical stimulation, and visits to water spas and other health resorts. The goal was to help patients restore their "strength" and to maintain a healthy "nervous tone." Morbid thoughts and other dangers of introspection were to be derailed through outdoor exercise and cheerful admonitions by the doctor and family.

The neurasthenic model also gained impetus as an articulation of a Victorian conception of self, one that incorporated health's new moral meaning. Character was indeed a matter of destiny, but neither heredity nor rational intent solely determined one's fortunes. Rather, it was one's *will* that mediated between what one could be and what one should be. Not all persons were created equal, nor were they forced to meet stresses and tests of comparable severity. Nevertheless, what individuals made of their lots was inescapably their responsibility. In this worldview, health became a secular measure of moral character. Although illness in general was no longer interpreted as a direct manifestation of God's wrath, conditions that resulted from a damaged constitution were read as the certain consequences of immoral or unnatural habits – a failure of will. Observers noted that unlike malaria or the pox, which might attack the weak and the strong indifferently, mental diseases fell only on those who lacked self-control. The concept of neurasthenia, which focused on activities that damaged the will itself, thus provided an adaptable matrix for the consideration of human character.

The special business of neurologists, in addition to providing the usual treatments for nervousness, was to offer individuals the expert guidance necessary to avoid permanent or worsened injury to the constitution, advice based on their putative knowledge of brain function and human affairs. Thus construed, the role of neurologists combined both intimacy and scientific objectivity. On one hand, neurologists were to be consulted by patients on an expanding variety of personal issues, ranging from major life decisions, such as the advisability of marriage, to minor points of life-style, such as the amount of fat to be included in one's diet. The role of adviser merged with that of confessor: Critical to the success of the treatment was the patient's full disclosure of all behavior, no matter how disreputable. Indeed, it was precisely on questions of damage caused by vices that medical treatment so often appeared to hinge. Medical penance, as outlined by neurologists, became the new absolution. On the other hand, in the interest of invading clinical territory already inhabited by either alienists or family physicians, neurologists were obliged to base their expertise on the emerging laboratory and clinical science of the brain. This dual obligation of scientist and counselor proved difficult to reconcile.

Neurologists learned soon enough what alienists had discovered already: Mental disorders are more managed than cured. Furthermore, such close intervention in patients' lives yielded a clinical paradox. A nervous complaint, successfully treated, might disappear only to be replaced by another; or a wide range of treatments might prove equally effective – for a time. Even as they were constructing elaborate scientific justifications for their clinical intervention, neurologists were discovering that it was not so much the specific medical treatment that mattered as it was the discipline that patients exhibited in adhering to the treatment plan. With this in mind, S. Weir Mitchell perfected his famous "rest cure," in which patients were isolated from their families and placed in the full care of a neurologist and nurse. Stripped of all power to make decisions, and consigned to a state of ultradependency (which included such things as spoon-feedings), patients were supposed to rebuild their willpower completely. Focus thus shifted away from external signs and symptoms to the dynamics of the patient–physician relationship. The resistance of the patient to being cured became a new index of pathology. Ostensibly following a somatic program, New York neurologists uneasily awakened to the reality of psychological aspects of nervous disorders.

Charcot's Parisian Teaching Clinic and Hysteroepilepsy. Although Esquirol, in the 1840s, ignored hysteria as an uncertain diagnosis of little significance, by the 1880s the condition had risen to a newfound prominence. This turnabout was directly attributable to the efforts of Jean Martin Charcot, an internationally renowned neurologist whose teaching clinic at the Salpêtrière Hospital greatly influenced a generation of students who were destined to become leaders in medicine. At the height of his clinical and pedagogic career, Charcot committed his full resources to the vexing problem of hysteria. If successful, one more trophy would be added to his collection that boasted classic descriptions of amyotrophic lateral sclerosis, multiple sclerosis, tabes, and locomotor ataxia.

Charcot insisted that hysteria was like any other neurological disorder, with a definite, even predictable, clinical course. The truth of hysteria would surely be revealed once exhaustive clinical observation was combined with the experimental method recently outlined by Claude Bernard. The Salpêtrière provided Charcot with the resources necessary for just this kind of medical campaign: a concentration of scientific equipment and trained personnel to perform exacting measurements and a reliable supply of clinical material. The clinic's social structure was an equally important factor. The rigorous program of experimental study that Charcot envisioned necessitated privileged access to human bodies, access that was of a scale and manner inconsistent with the realities of private practice, where permission would have to be negotiated case by case, if it was obtainable at all. Indeed, Charcot's experimental protocols called for the incessant monitoring of every conceivable physiological index, including hourly urinary output and vaginal secretions; these humiliations might be followed by the application of painful ovarian compresses. At the Salpêtrière, a public charity hospital, Charcot could ignore rebuffs to such requests, for its wards were filled with lower-class women over whose bodies the physician in chief held full dominion.

After some effort, Charcot announced his discovery that hysteria indeed had a definite clinical form. A true hysteric attack passed through four complex stages, beginning with hysteroepileptic spasm of tonic rigidity and ending with a resolution in grand theatrical movements. Hysteria's elusive "code" had been broken. At his celebrated clinics, which the elite of Paris attended, Charcot was able to demonstrate the disease in its full glory through hypnotic induction on patients known for their spectacular

fits. Because the code was essentially visual, an iconographic reading of the outward manifestations of the body, Charcot devised the technique of making extensive drawings and photographic recordings so that clinicians not present might "see" the disease in its natural progressions.

Charcot's model of hysteria tapped into several currents that aided neurologists in the extension of their social and professional base. With hysteria mastered by science, they now had a justification for reaching outside the walls of the clinic to treat the masses afflicted with its milder forms. Since Charcot's hysteria was constructed in a degenerationist mold, neurologists would have a new basis for commenting on such worrisome social problems as crime, adultery, and mob unrest. Furthermore, in the reversal of political fortunes that followed the installation of the Third Republic, secular models of behaviors became useful in anticlerical vendettas. Charcot, for example, went so far as to identify one type of fit as "religious possession" and to denigrate past examples of stigmata and other miraculous displays as forms of hysteria. Finally, the model provided the first wave of a promised series of incursions by neurologists into a clinical domain that was still dominated by alienists. Charcot, first holder of a French chair on *nervous* diseases, was establishing the institutional precedent for such an expansion.

Academic Psychiatry

German University Psychiatry and the New Nosology. Through the creation of university chairs of psychiatry, a pattern that began in Berlin (1864) and Göttingen (1866), Germany soon took the lead in establishing the academic study of mental illness. Unique to the German approach was a psychosomatic orientation that held to a fundamental parity between mental, somatic, and even environmental forces and insisted that this parity also be reflected in the relations among academic disciplines. Thus, both psychology and neuropathology might be joined in a common medical investigation. Legitimated as an integral part of mainstream medicine, psychiatry also shared in the developments that propelled Germany to the position of world leader in medicine by the end of the nineteenth century. Led by Wilhelm Griesinger and then Emil Kraepelin, the German school of psychiatry created a lasting framework for classifying mental disorders.

Griesinger was an accomplished internist who also lectured on medical psychology at Tübingen. Believing that further medical progress in mental disease would not come from asylum managers, who lacked training in recent medical advances, or from academic psychologists, who had no direct contact with patients, Griesinger decided to bring psychiatric patients into his own general clinic. Although he was known for his promotion of the doctrine that all mental disease was in fact brain dysfunction, Griesinger's major focus was on the process by which a person's *ego,* the integrated self, disintegrated. Rejecting nosological systems based on faculty psychology, which led to a diverse array of symptom-based disease categories, Griesinger maintained that insanity was a single morbid process, differentiated by stages of degeneration. This point was reinforced by his acknowledgment of the inherent closeness between sanity and insanity and of the existence of borderline conditions.

In Griesinger's approach, a mentally ill person was someone who no longer had the same desires, habits, and opinions and thus was estranged from him- or herself (alienated). This judgment could be made only by reference to a patient's premorbid life, a history that must include family background, mode of living, emotional state, and even the nature of the patient's thoughts on world affairs. Once a full portrait of the individual was constructed (from in-depth interviews with family and friends), symptoms that at first seemed bizarre were now understandable – perhaps even predictable. Moreover, the importance of any specific contributing cause, such as alcoholism or prostitution, could not be ascertained without reference to the individual's case history. Mental illness originated as a confluence of multiple factors, psychological as well as somatic, that interacted early in life, when character was being formed. Developmental knowledge of mental illness thus was joined to a contextual reading of the patient's past.

With Kraepelin, the German clinical school of psychiatry reached its zenith. Trained as a neuroanatomist, an experimental psychologist under Wilhelm Wundt, and a mental hospital physician, Kraepelin brought a diverse background to the problem of mental illness. Insisting on a combination of neurological, neuroanatomic, psychological, and even anthropological studies, Kraepelin held that the case study was the sine qua non of psychiatric investigation. Combining Griesinger's clinical conception of a unified personality with Rudolph Virchow's new principle of diseases as separate entities, Kraepelin closed the century with a classificatory system that has been recognized as the foundation of modern psychiatry.

Where Griesinger blended one mental disorder into another, just as hues subtly progress in a single color spectrum, Kraepelin differentiated conditions on the basis of essential clinical syndromes, as revealed by their signs, course, and outcome. Drawing from published case reports as well as his own clinical work, Kraepelin grouped Morel's *dementia précoce,* Ewald Hecker's hebephrenia (1871), and Karl Kahlbaum's catatonia (1874) into a single category of mental disease termed *dementia praecox,* which began at puberty and progressed inevitably toward early senility and death. Manic-depression, which was known by its favorable prognosis, and paranoia were identified as the second and third types of major psychosis. Into separate divisions Kraepelin placed the neuroses (hysteria and epilepsy), psychopathic states (compulsive neuroses and homosexuality), and states of idiocy. Confusion as to which disease was afflicting a mental patient would not last forever, for it was only a matter of time before the disease would resolve into an endpoint that identified the underlying syndrome. For example, true neurasthenia was rare, since most diagnosed cases were simply early instances of a major psychosis or a complication of a cardiac or bowel irritation.

Clinicians worldwide celebrated the immediate applicability of Kraepelin's nosology to their practices, for cases of his major syndromes were easily recognized in any asylum. Moreover, here was a system of mental disease that was based on the highest standards of clinical medicine, one that incorporated a program for continued empirical revision. Contemporaries did recognize that Kraepelin's work, at heart a descriptive system, offered little explanation of mental illness, suggested few novel treatments, and indicated mostly fatalistic prognoses. It was a sufficient triumph, however, for Kraepelin to have liberated the study of insanity from its ancient classifications of melancholia and mania, as well as from the more recent and confusing additions of partial insanities, which continued to multiply, and of neurasthenia, which threatened to dissolve all distinctions. (In addition, by incorporating a measure of despair into the clinical diagnosis, Kraepelin to some extent relieved asylum psychiatrists of their obligation to cure, allowing attention to be concentrated on description and study.) Accurate diagnosis was to be the avatar of the new scientific psychiatry.

The Problem of the New Science.   We have thus seen how, in the second half of the nineteenth century, the great social interest in the problem of mental afflic-

tions, mild as well as severe, was met by an equally strong response from a broad array of learned disciplines. Both inside the asylums and outside, a vast terrain of clinical problems was opened for cultivation by practitioners and researchers representing diverse specialties. Since the late Victorian era was the period in which science and medicine forged their modern image as engines of power, faith grew that even problems as elusive and intractable as mental illness might be mastered by empirical investigation. Moreover, positioned at the nexus of major social and scientific concerns, the mystery of insanity gained a special poignancy. As human beings were increasingly revealed to be products of nature, and a nation's destiny a matter of its biological as well as cultural heritage, the unnatural in humans became a counterpoint to the advance of civilization. Merged together were issues of brain and behavior, willpower and productive vitality, and even national harmony and international struggle. In this context, the derangement of an individual was a sign of a larger social decay, which required immediate solution by the new hero of civilization, the scientist.

The joining of the new medical science to the problem of mental illness was extremely problematic, however, for several reasons. First, there was no one specialty that controlled the field. The profession of psychiatry is a creation of the twentieth, not the nineteenth, century. As we have seen, alienists and the various types of neurologists each brought to the subject their distinct professional agendas, resulting in the proliferation of widely varying conceptual orientations. In practice, no single model proved able to bridge the gulf between the disorders that appeared in the asylums and those that surfaced in everyday life.

Second, scientific models of brain and behavior were in transition, proving to be fickle sources of legitimation. Although a new form of scientific knowledge can confer respectability on a particular specialty, the benefit is not permanent. The alienists of the early nineteenth century, who had predicated their expertise on the presumption that lesions of the brain affected specific mental functions, found their prestige fading as neuroanatomic findings failed to confirm their theory. The introduction of the degenerationist model extended the reach of alienists outside of the asylum, but did little to allow the new medical science to peer within it.

Private-practice neurologists were all too happy to point out, soon enough, that alienists in their splendid isolation had let the latest science pass by. To bolster their own status as experts, they pointed to

new theories of an integrated nervous system that supported their reading of the constitutional hazards of particular life-styles. Beard's model of neurasthenia drew strength from its equal mixing of nature and nurture, whereby a single disease category contained an expansive matrix of moral and biological elements, a framework that empowered the clinician to intervene as both counselor and scientist. In due course, however, this approach was undermined by the further elaboration of the brain's fine structure and a new emphasis on specific disease entities. Further knowledge of nature had constrained nurture's sphere of influence.

Third, science often creates or distorts the very objects it putatively observes. This simple fact led to subtle, unintended consequences in the arena of mental disorders. For example, Charcot discovered this paradox, to his misfortune, yielding one of the grand ironies in the development of the human sciences. In the rigorously controlled order of the neurological ward, Charcot's patients were indirectly cued to produce symptoms in the exact sequence and form predicted by his theory. When it became clear that only patients in the Salpetrière manifested "pure" hysteria, contemporaries soon ridiculed Charcot for perpetrating theatrical creations as true clinical syndromes. In his original act of constructing hysteria as a regular neurological syndrome, Charcot had already set in motion his own undoing.

Another example is provided by the difficulties of private-practice neurologists in confronting neurasthenia. Beard and his followers, unlike Charcot, did not create their patients' symptoms outright, but they did fall into a different kind of trap. Patients termed neurasthenics had come to these physicians with an array of mysterious, but nonetheless truly bothersome ailments. Neurologists were thus in the position of having to construct a new reality out of the material presented to them, a role that was becoming increasingly common in the nineteenth century as science-based professions were expected not only to manipulate nature, but to construct a new map of reality itself. However, the very act of legitimating the patients' complaints as a new disease transformed the delicate social balance of what was at stake in the symptoms. Indeed, as Mitchell realized, the dynamics of the patient–physician relationship was itself somehow related to the expression of the disorder. Since the organic models of disease provided no means of recognizing these secondary effects, neurologists were forced to belabor a theory whose very dissemination had changed the clinical reality under observation. How to integrate the psychological dimension of mental disorders within a scientific framework remained a confounding problem.

1900 to 1950

The first half of the twentieth century is marked by two somewhat opposing currents in the conception of mental illness: the entrance of the Freudian model of psychodynamics and a rash of somatically oriented theories and treatments. Furthermore, when medical schools began to offer systematic instruction in the medical treatment of insanity, they united "nervous and mental disorders" in a single curriculum as dictated by the new nosology, thus bridging the historical gap between the asylum and private practice. The modern profession of *psychiatry* was born.

Freud and the Unconscious

The realm of human activity and experience that lies outside normal consciousness was attracting considerable literary and scholarly attention in the late nineteenth and early twentieth centuries. Psychological novels shared the theme that the rational intellect had only a limited ability to shape our lives. Neurological investigators, constructing ever more complex systems of reflex integration, described as unconscious those bodily activities that did not require continuous volitional monitoring. Nonconscious mentation was also investigated by academic psychologists, although the concept was often rejected as oxymoronic. Some psychologically oriented neurologists, such as Charcot's rival Hippolyte Bernheim, became interested in the powers of the mind over body – *ideodynamism* – through the dramatic effects of hypnosis and suggestion. The work of Morton Prince, Boris Sidis, and Pierre Janet focused attention on the clinical significance of minds that have disintegrated, or even divided. Janet developed an extensive theory of *psychasthenia,* paralleling neurasthenia, that referred to the inability of a weakened mind to maintain a unified integrity. Neurotic symptoms resulted from traumatic memories, such as unfortunate sexual episodes, that had been "split off" from the main consciousness. Cathartic treatment was the cure.

Perhaps the strongest exponent of the unconscious before Freud was Frederic W. H. Myers, a nineteenth-century British psychologist known mostly for his advancement of psychicalist (paranormal) research. Myers popularized the theory of the *subliminal* self as a hidden domain that was vast and profound, providing the basis for all psychic life. Incorporating such phenomena as genius, hypnosis, and even telepathy,

Myers cast the unconscious world in a highly spiritual, positive light, establishing a rationale for the use of psychotherapy as a tool for unleashing the inner creative forces. In the United States, religious healing cults like Christian Science and the Emmanuel movement made psychotherapy synonymous with a practical means of tapping into the subconscious, the reservoir in human beings of God's spirit and power.

Sigmund Freud was a Viennese neurologist trained in neuroanatomy, neurophysiology, and neuropsychiatry, who also boasted a deep knowledge of literature and anthropology. Freud's own journey into the hidden self, an exploration that commenced with *The Interpretation of Dreams* (1900), has been generally recognized as one of the monumental intellectual achievements of our time. Only a sketch of his work can be attempted here. Although the therapeutic merit of psychoanalysis remains a controversial issue, there can be little doubt that the Freudian model of human action has had a tremendous and pervasive influence in many areas of culture. In his early publications, Freud argued for the importance of the *unconscious* in directing most of our waking activities and all of our nocturnal ones. Consciousness represented only a fraction of our true selves. In contrast to the ideas of Myers and other supporters of psychotherapy, Freud's conception of the unconscious referred to a realm of primitive, even carnal, desires that followed its own irrational inner logic of wish fulfillment. Indeed, our entire mental apparatus, even our conscious selves, depended on the energy, or libido, that derived from the unconscious. Our path to normal adulthood consisted of successfully negotiating certain developmental challenges, which included the oral, anal, and genital stages, and resolution of the notorious Oedipal conflict. Developmental aberrations could be traced to the after-effects of sexual conflicts in childhood.

In his later work, Freud developed a tripartite metapsychology of self, comprised of the *id,* the pool of unconscious desires and memories; the *ego,* the core adaptive mechanism, which was built on territory reclaimed from the unconscious as the infantile pleasure principle was superseded by the mature reality principle; and the *superego,* the ego's censor, a mostly unconscious system of rules and mores internalized from parental and societal instruction. The ego, the component of self we most identify with, is a partly conscious and partly unconscious structure that must continually mediate between the desires of the id and the restrictions of the superego. Toward the end of his career, in such publications as *Civilization and Its Discontents* (1929), Freud turned his attention to the interaction between individuals' desires and society's demands, highlighting the relation between repression and culture.

From in-depth clinical studies, Freud assembled a model of the mind as a dynamic battleground where libidinous energies surge from the unconscious through a preconscious stage and then to consciousness, but only after intensive censorship that misdirects the energy to less threatening endpoints. Internal harmony is maintained at the price of continual suppression of unwanted thoughts and memories; anxiety is the internal warning that the dynamic equilibrium is becoming unstable. Psychopathology results from the desperate attempts by the ego – weakened by childhood trauma and saddled by insecurity and guilt – to maintain control in the face of intrapsychic conflict. At low levels of stress, the ego copes through simple defense mechanisms, such as displacement, projection, and denial. Higher levels may yield full psychoneurotic symptoms such as phobias, hysteria, and compulsions. For example, a hysterical paralysis of the legs might afflict a young actor who, although feeling otherwise normal stage fright, is unable to confront his fears because of long-internalized parental demands that he not admit failure (associated with some childhood trauma). The paralysis allows the actor to sidestep the conflict and even the very fact that that is what he is doing. Such symptoms may allow psychic survival, but they exact a heavy price in inflicting a diminished level of existence. At the highest level of stress, the unconscious demands overwhelm the ego's defenses, resulting in psychotic disintegration.

A distinguishing characteristic of Freud's system was the insistence that mental disorders had meanings. Being neither random nonsense nor mere neurological defects, such symptoms were in fact creative responses to specific problems that confronted a troubled individual. (Freud thus departed from Janet's model of neurosis as a product of a weakened mind, seeing it instead as resulting from a mind that was all too vigorous.) A psychopathological symptom was like a key to an unidentified lock; the clinical challenge was to make the shape of the lock visible. Psychoanalysis was to provide the clinician with the knowledge and tools necessary for recognizing what the immediate conflict was and then tracing backward to the distant trauma that had engendered this particular symptom formation. Until the underlying conflict was disinterred, neurotics were condemned to react inappropriately to current challenges, unwittingly seeing in them replays of a past battle that

could no longer be won. Therapy consisted of analyzing unconscious material, as revealed in dreams, slips of the tongue, and free associations, and a careful manipulation of the patient–physician relationship, in which patients made visible their neurotic structures by transferring onto the therapist their unresolved emotions. The couch was to become a dissecting table for the dispassionate analysis of psychic morbidity. In time, patients, liberated from externalized demands and guilt, would be free to reintegrate their desires into more authentic, stronger selves. Deprived of their function, the symptoms would simply cease to exist.

After Freud, the analysis of human behavior would never again be simple. Henceforth, the surface or manifest meaning of any action might belie multiple hidden or latent desires that would have to be decoded. The nineteenth-century hierarchical model of reason mastering desire was humbled by the realization that there existed no pure rational part of self that acted without the distorting influence of the unconscious; and every noble accomplishment of civilization was now sullied as a by-product of excess libido. The lines between sanity and insanity, and between normality and abnormality, were forever blurred, for each individual existed in a dynamic equilibrium in which unconscious forces held sway every night and at times during the day. Furthermore, in making a distinction between our instinctual aims and their objects (the aim of the sex drive was reproduction; the object was one's lover), Freud severed the connection whereby mental disease was equated with behavior contrary to instinct. Normal desires could lead to perverse acts, and vice versa. Judgments of mental illness were no longer simply statements of what was "unnatural."

Freud's immediate effect within psychiatry was to achieve for the neuroses what Kraepelin had accomplished for the psychoses. In Kraepelin's system, neuroses were an unsettled mixture of somatic and functional disorders. Freud directed psychoanalysis at the latter group, heightening the distinction by the use of the term *psychoneurosis*. Thus, certain disparate conditions, such as hysteria, obsessions, compulsions, and phobias, were united in a single category, yet each retained its own integrity as a clinical syndrome, recognizable in case histories. So successful was Freud's approach that soon the original somatic connotation of *neuroses* was entirely lost and the term *psychoneurosis* was dropped as redundant. Freud went even further than Kraepelin, however, in providing a model that was causal as well as descriptive. Although psycho-

analysis for some time remained targeted mainly on neuroses, his psychodynamic model was of sufficient heuristic strength to encompass psychotic disorders as well. The combination of Freud and Kraepelin was a nosological framework that integrated private practice and institutional systems of mental disorder – the beginning of modern psychiatry.

Psychoanalysis provided a fresh solution to the vexing problems facing neurologists who had built their practices on theories of neurasthenia, already in decline. Where psychological interactions of patient and physician were devilish problems for practitioners following organically justified systems, Freud's psychogenically based models turned a liability into a virtue. As a high technique of the mind, created by a distinguished Viennese physician, psychoanalysis co-opted religiously suspect psychotherapy, transforming it into a medically legitimate tool that office practitioners could adopt. Even better, for those physicians who relied on uncertain methods of suggestion, hypnosis, or enforced discipline, psychoanalysis provided a direct means of handling those nervous patients who undermined the doctors' competence by refusing to get better. The fault was thrown back into the patient as "resistance."

In the United States, which would become the largest supporter of Freud's theories (rejected as "Jewish psychology" in his homeland), not only psychologically oriented neurologists but many psychiatrists as well welcomed the new model. Even though psychoanalysis was irrelevant in the institutional context, which represented the majority of psychiatric care, the advent of a system that brought with it the trappings of learned study and European prestige was welcomed by many as a means of raising the status of what was widely regarded as the most backward of medical specialties. This interest was particularly strong in research institutes, which many states had created in this period to serve as catalysts for scientific advance.

The precise manner in which the Freudian doctrine rose to prominence in general culture is still not well understood. As one example, recent historical work suggests that World War I played a precipitating role in Britain when a large number of soldiers broke down in battle. That anyone might act insane, given sufficient stress, was forceful testimony of sanity's fragility. Neurologists diagnosed these soldiers as suffering from "shell shock," originally interpreted in terms of a somatic injury. Neither reflex hammer nor rest cure proved useful, however. The best success was obtained by physicians who applied a form of Freudian psychotherapy to

relieve the trauma. Overnight, psychoneuroses gained national currency. Those neurologists involved in the war effort were precisely the ones who would later gain for Freudianism a solid professional footing in Britain.

Biology

In the 1920s and 1930s, virtually every branch of biomedical science sought to apply the tools of experimental medicine to the problem of psychiatry. Indeed, given the isolation of the asylum from centers of medical advance, it was an even bet whether the next scientific breakthrough would emerge from within psychiatry or from an outside field. The paradigm was syphilis, whose tertiary state, general peresis, had been responsible for up to 20 percent of mental hospital admissions. In 1897 Richard von Krafft-Ebing demonstrated the long-suspected connection between syphilis and paresis, a link soon confirmed by the Wasserman test. The culpable spirochete was identified in paretic brains by Hideyo Noguchi in 1913. Finally, in 1917 the Austrian physician Julius von Wagner-Juaregg developed a method of fever therapy to halt further paretic deterioration; in 1927 he was awarded the Nobel Prize. The success of a purely organic solution to a major psychiatric disorder suggested that other such achievements were sure to follow.

Leading researchers thus pursued metabolic, endocrine, neurophysiological, and even toxicological models for psychopathology. Constitutional theories were advanced by the German Ernst Kretschmer, who correlated body types to predispositions for specific mental illnesses. Franz Kallman investigated the genetics of mental illness by studying schizophrenic twins. I. V. Pavlov launched a model of experimental neurosis in which animals frustrated in conditioned learning tests developed forms of mental breakdowns. The introduction of a wave of somatic treatments for mental illness in the middle 1930s transformed psychiatric practice. Insulin shock, metrazole shock, electric shock, and psychosurgery had dramatic effects on patient behavior, raising hopes that the fatalism associated with severe mental illness might prove untrue. Psychosurgery in particular was believed to restore chronic schizophrenics to productive citizenship. Its inventor, Portuguese neurologist Antonio Caetano de Egas Moniz, was awarded the 1949 Nobel Prize in medicine.

Classification at Midcentury

After World War II, professional organizations such as the American Psychiatric Association became active in the creation of standardized systems of nomenclature. Military experience and the growth of centralized reporting bureaus highlighted the need for diagnostic uniformity. The first *Diagnostic and Statistical Manual, Mental Disorders* (DSM), created in 1950, reflected the extension of the Kraepelin and Freudian systems, augmented by new theories of personality. Earlier, dementia praecox had been reconceptualized by Swiss psychiatrist Eugen Bleuler into the *schizophrenias* (hebephrenia, catatonia, paranoia), a term that referred to the splitting of thoughts from affects. Incorporating some aspects of psychoanalysis, Bleuler emphasized the development of the psychotic mental process.

In contrast to Kraepelin, Bleuler argued that favorable outcomes were possible in many cases. The DSM followed Bleuler in its description of the category of major psychoses, referring to personality disintegration and a failure to relate effectively to people or work. Included within this group were the schizophrenias, as well as paranoia, manic-depression, and involutional psychosis (depression of old age). The second major category consisted of psychoneuroses, described in Freudian terms as disorders caused by the unconscious control of anxiety through the use of defense mechanisms. These included anxiety reactions, dissociation, conversion reaction, obsessive-compulsion, and depression. The third category, comprising personality disorders, was differentiated by its stress on behavioral as opposed to emotional disturbances. Described in this category were such popular terms as *sociopath, antisocial behavior,* and *sexual deviate.*

As a shift from earlier attempts at standard psychiatric nosology, which were directed toward inpatient populations, the DSM reflected the new reality of psychiatry's burgeoning private-practice base, as well as the experiences of military psychiatrists, whose observations on broad populations revealed that the vast majority of psychopathologies did not fit the earlier classifications. Published statements of nosology do not necessarily reflect full clinical reality, however. The DSM was by no means universally adopted. It reflected more the penetration of Freudian psychiatrists into the power structure of the profession than it did any dramatic shift in the state hospitals, where niceties of diagnosis were considered superfluous to the daily choice of treatment plan.

After 1950

In the decades following World War II, psychiatry as a medical profession experienced tremendous expan-

sion. In the United States the advent of community mental health centers and third-party payments swelled the ranks of noninstitutional practitioners. The shift away from the state hospital, the historical center of the profession, redirected momentum toward mild disorders and their treatment through counseling. Psychodynamically oriented psychiatrists found their authority further magnified as a new army of clinically trained psychologists, social workers, and guidance counselors looked to them for professional training and supervision. Psychotherapy, though not necessarily Freudian psychoanalysis, became viewed by the middle class as both useful and affordable. Psychiatrists and their proxies in the allied professions offered a colorful array of different forms of counseling, which included behavior therapy, group therapy, client-centered therapy, existential therapy, and even primal scream therapy.

At the same time, dramatic developments occurred in somatically oriented treatment and research. The introduction in the mid-1950s of the major tranquilizers, such as chlorpromazine, revolutionized hospital care. By dampening hallucinations and other florid psychotic symptoms, the new drugs quieted ward life and encouraged new "open-door" hospital policies. Also, they accelerated the process of deinstitutionalization, helping many patients to achieve a level of functioning consistent with some form of extramural existence. Tranquilizers were soon followed by other classes of psychoactive drugs, such as antidepressants and the use of lithium in the treatment of manic-depression. The growing importance of psychopharmacology spurred neurophysiological research, leading to suggestive models of neurotransmitter deficiencies as the mediating cause of severe mental disorders. Other biological research has pursued genetic interpretations of the tendency of severe mental disorders to run in families. In recent years, there has been a clear shift within psychiatry to the somatic orientation.

One of the striking developments of the postwar years in the conceptualization of mental disorders has been the influence of the social sciences, especially sociology and anthropology. Once behavior is understood to reflect the matrix of psychological, social, and cultural forces that mold an individual, it is a natural progression to assume that abnormal or impaired behavior is likewise shaped and should be investigated with these additional tools. Again, the literature is much too large to provide other than a bare outline. Sociologists have reported on such influences as social class, role conflicts, social control, life stress, social integration, family interactions,

institutional milieu, and even the very act of psychiatric labeling in determining patterns of mental disorder. Anthropologists have brought the power of cross-cultural study to the problem of mental illness, showing that what was assumed to be biologically fixed often was in fact "culture bound," a local product, specific to place and time. Within any major U.S. city are subpopulations who conceptualize – and experience – disease in incommensurate ways. Moreover, if a diagnosis of mental illness reflects a judgment as to adaptive functioning, mental disorders can no longer be held to be natural, universally true categories of illness, for what is adaptive in one local culture is maladaptive in another. These studies of health and healing have also brought to light the manifold ways in which concepts of disease and therapeutic rituals enter into the complex web of power relations we call society.

Psychiatric conditions, which touch on our most intimate concerns and relationships, are especially rich cultural resources and have embedded meanings and structures not easily seen – and often denied by the professional culture of scientific medicine. Mental illness is a fundamentally messy construct, an irreducible mixture of personal, social, cultural, and scientific beliefs.

Classification in the 1980s

In 1980, the third version of the DSM was released, signaling a new departure in psychiatric nomenclature. Responding to calls for a diagnostic system that might elevate psychiatry's status as a scientific discipline, the DSM task force pared down medical classification to its most basic elements, the description of known phenomena, usefully arranged. Without question, the most stable and powerful nosologies are those based on proven etiology. For example, identification of the culpable spirochete made it possible to distinguish paresis from senility. Because debate still surrounds the true cause of any mental disorder, the DSM argues that it is premature for psychiatry to construct etiologically based systems. At present, we find that phobic disorders can have Pavlovian, Freudian, or somatic explanations. In disagreeing about theory and treatment, however, clinicians nevertheless can reach a consensus on the identification of a disorder.

The stated goal of the DSM-III is simply to provide a set of criteria and procedures by which all camps of psychiatrists might speak a common diagnostic language. In the interest of ensuring interrater reliability, disorders were to be defined unambiguously and based on checklists of easily verified data. The diag-

nostic categories were themselves to be constructed in the form of statistically significant clusters of symptoms, derived from extensive field trials and empirical reports. Without etiology, psychiatric ailments can be referred to only as *syndromes* or *disorders,* not specific diseases. Indeed, it is expected that elements from several different disorders might appear in any one individual. The authors of DSM-III argue that the quest for scientific purity has not, however, negated all clinical utility. Tightly defined and empirically tested descriptions of syndromes do allow practitioners to predict a patient's course and outcome, and they provide some guidance in treatment choice. For example, the identification of a major depressive syndrome alerts the clinician to the likelihood of the patient's having a future hypochondriacal reaction.

As of 1980 the DSM outlined the following categories: disorders of childhood or infancy (hyperactivity, anorexia, retardation, autism); known organic cause (diseases of old age, drug-induced); disorders of schizophrenia (disorganized, catatonia, paranoid, undifferentiated); paranoid disorders (without schizophrenic signs); affective disorders (bipolar, major depressive); anxiety disorders (phobias, obsessive-compulsive); somatoform (conversion disorder, hypochondriasis); dissociative (fugue states, amnesia, multiple personality); and personality disorders. Perhaps the most controversial change in the new approach was the elimination of the category of psychoneuroses. In the "atheoretical" approach, disorders were grouped according to symptoms, not underlying psychic mechanism. Neurotic disorders thus resolve into various forms of anxiety states. Also removed was the heading of *psychosis,* which had included the major affective disorders; experience showed that many patients labeled psychotic did not have psychotic features. Involutional melancholia was collapsed into ordinary depression, because no evidence surfaced to show that it was unique.

It is, of course, far too early to make informed judgments about the consequences of the new DSM. However, some trends can be discerned. First, DSM-III clearly marks a loss of professional authority by psychoanalysis, one that will worsen. Much of the need for teaching Freudian theory to the mass of workers within the allied mental health professions – most of whom would never practice true psychoanalysis – was based on the need to explain the psychiatric diagnostic system.

Second, a more subtle and unpredictable effect of DSM-III concerns its diminution of the value of clinical judgment. On one hand, its "atheoretical" empha-

sis shifts power into the hands of the statistical researcher and away from the clinician. DSM-III sets in place procedures for the continued revision of diagnostic categories, whose organization may soon reflect more of what seems "statistically significant" than the realities of clinical practice. On the other hand, the symptom-based nosology also harkens back to the eighteenth century, when patients' subjective assessments of their problems set the pace of medical practice. In DSM-III homosexuality was eliminated from the rolls of mental disorders – except when it is considered bothersome by the patient. Squeezed between deference to patients' self-rating scales and statistical priorities, the clinician has less room to form independent diagnoses.

Mental Illness and Psychiatry: Retrospect and Prospect

From our historical survey, several themes emerge concerning the linked development of psychiatry and conceptions of mental illness. Psychiatry as a learned discipline contains no one school of thought that is sufficiently dominant to control the medical meaning of insanity. Given the administrative realities within which mental health professionals currently labor, the move to a standardized diagnostic system may nonetheless win out. It is important for the various factions to share a common language, but this is not the same as reaching a consensus on why someone is disturbed and what should be done about it – two components of illness as a cultural reality.

This difficulty reflects in part psychiatry's unique evolution as a medical specialty. Common sociological wisdom holds that the livelihood of a scientific specialty depends on its capacity to defend the perimeter of its knowledge base. This task has always been problematic for psychiatrists, for the borders between lay and learned conceptions of madness remain indistinct, a situation that also pertains to the relations between psychiatry and other disciplines, medical as well as nonmedical. To begin with, mental disorders are not restricted to the controlled environs of the analyst's couch or laboratory bench, but are manifested in the home, school, or office, as disruption in love, work, or play. When the very stuff of madness is reduced to its basic elements, we find nothing more than a tangled heap of curious speech acts and defiant gestures, odd mannerisms and perplexing countenances – surely nothing as removed from everyday experience as is the retrovirus, the quark, or the black hole. Available for all to see and

interpret, psychiatric phenomena thus form an epistemological terrain that is not easily defended by a band of professionals who look to stake claims on the basis of privileged, expert knowledge.

Psychiatry's turf is also vulnerable at its flank, from adventurers in other learned disciplines who find that their own research endeavors, logically extended, encompass some aspect of mental illness. Thus, as a performance of the body, insanity has routinely been investigated by all the tools available to biomedical scientists and clinicians. Commentators have often noted that, as soon as a valid biological model is found to exist for a specific mental disorder (as in the case of syphilis and general paresis), that condition is moved out of the purview of psychiatry and is claimed by some other field – perhaps neurology or endocrinology. Over time, the condition even ceases to be considered psychiatric. And now that madness is known to have a cultural reality as well as a biological one, psychopathology has become a proper focus of most social sciences as well.

Unable to police its own borders, it is no wonder that psychiatry remains a confusing, polyglot world, one that reflects the input of myriad disciplines and sources. The surfeit of conceptual approaches to the problem of mental illness has often been cited as evidence that psychiatrists are a singularly contentious or poor-thinking lot. A popular professional response has been to invoke a "biopsychosocial" model of disease (expressed, e.g., by the multiaxial system of DSM-III), one that is interdisciplinary and multidimensional. The root of the problem is deeper, however. As mental disorders reflect the entirety of a person, so the study of insanity comes to reflect the present contradictions inherent in our universe of scholarly disciplines. Our various knowledge systems are unified more in rhetoric than in reality. The status of psychiatry and of the concept of mental illness suffers for making this situation visible.

Our historical survey provides us with another approach to the problem of mental illness, one that focuses not so much on the intellectual boundaries of knowledge as on the professional and social function of psychiatry. First, we have seen how modern psychiatry emerged not in isolation, but in relation to other areas of medicine: Psychiatry's peculiar domain is precisely those problems that baffle regular medicine. (The rise of the "nervous" disorders provides an excellent example of this phenomenon.) In the late nineteenth century, as medicine gained status as a scientific discipline, this role attained a special significance. Before, when virtually all of medicine was based on uncertain knowledge, there was no clinical problem that could be said to lie outside the physician's grasp. But as the physiological and bacteriological terrain came into sharper focus, so too did those areas in which medicine was admittedly ignorant. Paradoxically, as our scientific knowledge becomes increasingly sure, leading to ever higher expectations, those problems that cannot be solved develop an increased capacity to threaten our faith in science. "Functional" or "nonorganic" disorders, whose explanation as well as cure remain outside the boundaries of regular medicine, thus become disturbances not only within an individual but within the system of medicine as well. It is psychiatry's intraprofessional obligation to deal with these problems, shoring up the faith that, although no precise medical answers yet exist, they are still medical problems – and not yet the business of the astrologer or faith healer. Ironically, psychiatry is despised by the rest of medicine for this lowly, but vital role.

A more fundamental service role has been that of responding to personal crisis. As a specific construct, the term *schizophrenia* may one day find its way into the dustbin that holds *neurasthenia, chlorosis,* and other long-abandoned medical concepts. But the suffering and torment felt by persons so afflicted are not as easily dismissed, nor is the distress of their families. Patients and their families look to the psychiatrist to intervene in a situation where there is often little hope, to "do everything possible" to make the person whole again.

Put simply, psychiatry is the management of despair. This is the heart of the psychiatrist's social function, to care for those whose problems have no certain cure or satisfactory explanation, problems that often place a serious burden on society. To a large extent, this function stems from psychiatry's historical ties to the asylum, an institution into which poured a new class of social dependents. But psychiatry is more than custodial care that can be supervised by hospital administrators. Apparently, we find a measure of emotional security in entrusting these special woes to a group of trained professionals who have dealt with similar matters, believing that practical wisdom comes with experience; to those who can link our seemingly unique problems with past cases and thus somehow lessen the alienation and shame. The additional value of a medical degree is the promise that with it comes a trained intellect, a calm authority in response to crisis, and access to all available medical tools that might yield even a remote possibility of benefit, even if they are not yet understood.

In sum, psychiatry is a field defined not by reference to a specific part of the human body, like podiatry, or a specific class of people, like gerontology, or even a specific disease process, like oncology. Rather, it is a field demarcated by our collective helplessness in the face of human problems that by all appearances should be solvable and understandable through medical science, but as yet are not. Hence, what comprises mental illness is fundamentally a moving target, a hazy area that is redrawn by every generation and local culture as new problems and dilemmas arise. Specific categories of mental disorder are formed at the interface of social concern and professional interests, much in the way that the pressures of tectonic plates produce new features of the physical landscape. Thus, shifts in either cultural anxieties or professional priorities can shape the clinical geography. We have also seen that this border is a dynamic one, as professionals both respond to and in turn shape these areas of concern. That a given disease, once understood, is no longer considered psychiatric is thus not so much a loss for psychiatry as it is an indication of what has been psychiatry's true function. Once a disorder is well understood, psychiatry's proper business with it has in fact come to an end.

Now we have a perspective from which to view, in retrospect and prospect, the peculiar geography of mental illness. Looking backward at the history of the conditions associated with mental illness, at such things as hypochondriasis and monomania, we see an archaeological record not to be dismissed as mere professional folly, but a record of life's tragedies, large and small. No matter how successful science will be in the future in providing additional tools to alter the mind or brain, some of us nevertheless will be overwhelmed by life's new challenges, finding our own internal resources insufficient. For some, whether because of faults of biology, environment, or will, the collapse will be complete. That is the reality of mental disorders, which is surely not soon to disappear.

What the future holds for the organization of psychiatry as a medical specialty is not easily predicted. The special task of psychiatrists, in managing the unmanageable, is increasingly difficult to perform as it becomes harder to maintain the dual role of counselor and medical scientist. As medicine in general relies on ever stricter laboratory standards of what is real or valid, the definition of what constitutes a good doctor becomes that much narrower. The decline of the status of psychoanalysis, for example, may reflect the shrinkage that already has oc-

curred. In the past, part of a physician's medical authority stemmed from the assumption that he or she was learned in the ways of people and society, a knowledge that was seen as legitimating his or her right to intervene in intimate human affairs. Psychoanalysts, among the most scholarly of physicians, were thus looked upon as effective doctors. Now, however, such broad cultural learning is no longer considered an appropriate route to a career that demands the absorption and analysis of a tremendous volume of scientific facts. Whether psychiatry will dissolve into two separate professions, one of lay counseling and the other of purely biological treatment, remains to be seen. Yet there is also a possibility that general medicine will reintegrate the special function of the healing relationship into its list of medical priorities. Perhaps in this psychiatry might lead the way.

II.4
Sexual Deviance as a Disease

Sexual "deviance" is technically any deviation from the sexual norm. Sexual disease, a new diagnostic category in the eighteenth century, was classed as a syndrome and seems in retrospect to have been an iatrogenic one based more on philosophical and moral grounds than on any medical ones. The disease entity, however, was fitted into some of the medical theories of the time, and as these theories were challenged and undermined, modifications were made in order to justify maintaining certain forms of sex behavior in the category of disease.

In recent decades much of the sexual behavior previously classed as disease has been removed from that category. This redefinition has been based on a better understanding of sexual behavior. It has also been a result of the protests of some groups who reject being classed as ill or sick and having their behavior categorized as pathological, emphasizing the iatrogenic component of the disease. Nonetheless, efforts are being made to maintain other kinds of sexual activity under the rubric of disease. Generally, these are activities that are regarded as unacceptable by society or viewed as compulsive behavior by behavioral psychologists. Perhaps both groups maintain the classification as a way of justifying their intervention or of promising a cure.

Medical Background
Though physicians throughout recorded history have been interested in diseases and infirmities that affect sexual performance, the concept that certain forms of sexual behavior constitute a disease in and of themselves is a modern phenomenon. It also seems to be restricted to western Europe and people and cultures descended from or influenced by western European culture.

One reason for the development of the concept of sexual "deviation" as a disease can be found in some of the early modern challenges to the humoral theory of medicine. Early in the eighteenth century, the great clinician Hermann Boerhaave, a dominant figure in medical thought, had written in his *Institutiones Medicae* (1728) that the rash expenditure of semen brought on lassitude, feebleness, a weakening of motion, fits, wasting, dryness, fevers, aching of the cerebral membranes, obscuring of the senses, particularly that of sight, decay of the spinal cord, fatuity, and similar evils. Though Boerhaave's idea undoubtedly was based on observations of the general lassitude usually afflicting men and women after orgasm, it was also an encroachment of traditional Christian teaching about sex into the medical field.

Boerhaave's observations of sex as a causal factor in some forms of illness also fit into a new medical theory known as "vitalism," based on the work of Georg Ernst Stahl as well as others. Stahl (1768) had taught that there was a unity of soul and body, a unity symbolized by the anima, which protected the body from deterioration. When the tonic movements of normal life were altered by the body or its organs, disease supervened. Disease was thus little more than the tendency of the anima (or of nature) to reestablish the normal order of these movements as quickly and efficiently as possible.

A contemporary (and rival) of Stahl, Frederich Hoffmann, equated life with movement, whereas death corresponded to the cessation of movement. The living organism was composed of fibers having a characteristic neurogenic tonus (the capacity to contract and dilate being regulated by the nervous system) centered in the brain. When tonus was normal, the body was healthy, but every modification of tonus brought a disturbance of health. Thus, a man who indulged in masturbation gradually damaged

his memory because of the strain on the nervous system.

Building on this foundation were other physicians, including John Brown and Théophile de Bordeu. Brown's medical philosophy, summarized in his *Elements of Medicine* (1803), is based at least in part on his own experience with gout. In theorizing about his gout, he concluded that "debility" was the cause of his disorders and that the remedy was to be sought in "strengthening measures." To overcome his gout he had to strengthen himself, avoid debilitating foods, and treat himself with wine and opium.

Whether his gout was cured remains debatable, but from his experience he erected a medical philosophy known as "brunonianism." Basic to his belief system was the notion of excitability, defined as the essential distinction between the living and the dead. The seat of excitability was the nervous system, and all bodily states were explained by the relationship between excitability and excitement. Too little stimulation was bad, whereas excessive stimulation had the potential of being worse because it could lead to debility by exhausting the excitability. Excitability was compared to fire. If there was not enought air (insufficient excitement), the fire would smolder and die out, but under a forced draft (too much excitement), the fire would burn excessively, become exhausted, and go out.

This led Brown to conclude that there were two kinds of diseases, those arising from excessive excitement (sthenia) and those from deficient excitement (asthenia). Too much stimulation carried an asthenic ailment into a sthenic one. Contact between the sexes, through kissing and being in each other's presence, gave an impetuosity to the nerves, and intercourse itself, though it gave temporary relief, could release too much turbulent energy if carried to excess and could thus cause difficulty. Taking a somewhat different approach but ending up with a similar conclusion was de Bordeu, who maintained that the lymphatic glands as well as the muscular nervous system had vital activity. Secretions, including seminal secretion, drained the vital essences residing in every part of the body.

Onanism

At the same time these medical authors were developing new theories of medicine, concern over onanism was increasing. The concept of onanism is based on the story in Genesis 38:7–10 of Onan, who, following the Levirate custom, was supposed to take over the wife of his deceased brother Er, who had been killed by Jehovah. In addition, Onan was sup-posed to impregnate his sister-in-law, which he was ordered to do by his father Judah:

And Onan knew that the seed should not be his;
and it came to pass, when he went in unto his brother's wife,
that he spilled it on the ground,
lest that he should give seed to his brother.
And the thing which he did displeased the Lord;
wherefore He slew him also.

Though the story has often been interpreted as a prohibition against masturbation, the act described is coitus interruptus; the punishment seems to have been meted out not so much for Onan's having spilled the seed as for his having refused to obey the Levirate requirement that he take his brother's wife as his own.

Around 1700 an anonymous writer, perhaps in London, wrote a work in English dealing with onania. This had a wide circulation and was translated into several languages. The first U.S. edition was published in Boston in 1724 under the title of *Onania; or, the Heinous Sin of Self-Pollution, and all its Frightful Consequences, in both Sexes, Considered. With Spiritual and Physical Advice to those, who have already injur'd themselves by this Abominable Practice. And Seasonable Admonition to the Youth (of both SEXES) and those whose Tuition they are under, whether Parents, Guardians, Masters, or Mistresses. To which is Added, A Letter from a Lady (very curious) Concerning the Use and Abuse of the Marriage-Bed. With the Author's Answer thereto.* The author attributed a number of "corruptions of the body" to "self-pollution," including palsies, distempers, consumptions, gleets, fluxes, ulcers, fits, madness, childlessness, and even death itself. Some of these ideas were derived from Boerhaave, but the author went so far as to imply that onanism could affect offspring, who were likely to be born sickly and ailing.

A copy of the book eventually passed into the hands of the distinguished Swiss physician Simon André Tissot, doctor to a pope, a correspondent of François Voltaire and Jean Jacques Rousseau, and a researcher very much interested in the prevention of disease. In Lausanne, Tissot (1758) had printed his own *Tentamen de Morbis ex Manusturpatione*, which went through many editions and translations. Later editions, including Tissot's own French version, were entitled *Onanism*. The English translation by A. Hume was published in 1776. There were many printings and editions in most Western languages.

Although he considered the earlier treatise on

onania truly chaotic and the author's reflections nothing but theological and moral trivialities, Tissot did adopt some of the concepts it contained (including the association of sexual activity with insanity). More important, he put onanism into the theoretical medical framework of the day. Tissot believed that the physical body suffered from continual wastage, and unless this was periodically restored, death would result. Much could naturally be restored through nutrition, but even with an adequate diet the body could waste away through diarrhea, loss of blood, and, more important for the purposes of this chapter, seminal emission. The importance of semen to the male, Tissot observed, was documented by the effect it had on physiognomy, because semen was what caused the beard to grow and the muscles to thicken. Proof of this influence came from the fact that these physiognomic effects could be eliminated by amputation of the testicles. Though Tissot recognized that semen was lost in the process of "replenishing" the human race, he held that too great a loss (from too great a frequency) was dangerous and hence sexual intercourse had to be limited if health was to be preserved. Tissot asserted that involuntary emissions such as "wet dreams" were also weakening. Most dangerous, however, was the "unnatural loss" of semen through masturbation.

Masturbation (or onanism) comprised a broad category of sexual activities. For men, it included all seminal emissions not intended for procreation, and thus in effect every sexual activity not leading to procreation was not only a cause of illness but an illness in itself. Tissot defined the sequelae of masturbation as the following: (1) cloudiness of ideas and sometimes even madness; (2) decay of bodily powers, resulting in coughs, fevers, and consumption; (3) acute pains in the head, rheumatic pains, and an aching numbness; (4) pimples on the face, suppurating blisters on the nose, breast, and thighs, and painful itching; (5) eventual weakness of the power of generation, as indicated by impotence, premature ejaculation, gonorrhea, priapism, and tumors in the bladder; and (6) disordering of the intestines resulting in constipation, hemorrhoids, and so forth. Though Tissot recognized that not everyone addicted to onanism was so cruelly punished, he felt that most were, and that everyone was afflicted to some degree or another.

Onanism affected women even more than men because in addition to most of the male sequelae, onanism left women subject to hysterical fits, incurable jaundice, violent stomach cramps, pains in the nose, ulceration of the matrix, and uterine tremors that deprived them of decency and reason by lowering them to the level of the most lascivious and vicious brutes. Even worse than simple masturbation in women was mutual clitoral manipulation that caused them to love one another with as much fondness and jealousy as they did men. Onanism was far more pernicious than excesses in simple fornication, although both were dangerous. Onanism was particularly debilitating to those who had not yet attained puberty, because it tended to destroy the mental faculties by putting a great strain on the nervous system.

Tissot's explanation gained a number of followers not only because it fit into some of the general medical theories, but because it was consistent with general superficial observations. It also tied into the general anxiety about sexual activity that was so much a part of the Western Christian tradition.

Many of the sequelae that Tissot associated with onanism we now know derive from sexually transmitted diseases such as syphilis, gonorrhea, genital herpes, and others, all of which at that time were often explained by the concept of onanism. Moreover, it was observed that individuals in some mental institutions frequently masturbated, as did those who were developmentally disabled, and rather than being regarded as a consequence of institutionalization, it was believed to be a cause. The decline in male potency and sexual activities with age were indicative, according to Tissot's theory, of the dangers of having lost semen or vital fluids earlier in life. The neatness of Tissot's explanation was that it not only squared with current medical theory but explained so many previously unexplained illnesses and diseases.

In sum, if a syndrome can be defined as the concurrence or running together of signs and symptoms into a recognizable pattern, then onanism furnished such a pattern. As Tristam Engelhardt (1974) put it, onanism was more than a simple pattern, because a cause was attributed to the syndrome, providing an etiologic framework for a disease entity. If the development of the concept of disease is seen as a progression from a collection of signs and symptoms to their interrelation in a recognized causal mechanism, then the disease of onanism was fairly well evolved.

Once established as a disease entity, onanism had a long and varied life, adapting to new developments in medicine and in society. One of the leading exponents of Tissot's ideas was Benjamin Rush (1794–8), the dominant medical figure in the United States of the late eighteenth and early nineteenth centuries. Rush, after studying in Edinburgh, returned to

the United States to introduce a variation of John Brown's medical beliefs whereby all disease was considered to be the result of either a diminution or an increase of nervous energy. Because sexual intercourse was a major cause of excitement, careless indulgence in sex inevitably led to a number of problems, including seminal weakness, impotence, dysuria, tabes dorsalis, pulmonary consumption, dyspepsia, dimness of sight, vertigo, epilepsy, hypochondriasis, loss of memory, manalgia, fatuity, and death. Rush, however, also cautioned against abnormal restraint in sexual matters because it too could produce dangers.

The syndrome of onanism was seized on by a wide variety of popularizers as well, some physicians and some not. In the United States, Sylvester Graham (1838) concluded that excessive sexual desire led to insanity, and insanity itself incited excessive sexual desire. In fact, the influence of sexual desire was so pervasive that it could disturb all the functions of the system, causing a general debility. Claude-François Lallemand, a French surgeon, was concerned with the involuntary loss of male semen, spermatorrhea, which he felt would lead to insanity. This caused his U.S. translator (1839) to report that 55 of the 407 patients in the Massachusetts State Lunatic Hospital at Worcester had become insane from the effects of masturbation.

William Acton (1871), an English physician, had a somewhat different view of the dangers of sexual activity, arguing that God had made women indifferent to sex in order to prevent men's vital energy from being totally depleted. John Harvey Kellogg (1882), another popularizer in the United States, held that the nervous shock accompanying use of the sexual organs was the most profound to which the nervous system was subject, and even those who engaged in procreation would have to place rigid limitations on themselves or else insanity would result.

Because the dangers of sexual activity were so great, one problem with the new syndrome was to explain why the human race had not died out earlier. George M. Beard (1884) believed that it had not been necessary for earlier generations to be so concerned about excessive sexual activity because their lives had been simpler. It was the growing complexity of modern civilization and evolutionary development that put so much stress on men and women. Consequently, a larger and larger number of them were suffering from nervous exhaustion. This exhaustion, he held, was particularly serious among the educated and intelligent workers in society, who represented a higher stage on the evolutionary scale than the lower social classes. In other words, as humanity advanced, it became more and more necessary to save nervous energy.

Those who were unable to control their sexuality not only would suffer physical debilities but would become homosexuals, which was a consequence of youthful masturbation according to such nineteenth-century writers as John Ware (1879), Joseph Howe (1889), James Foster Scott (1899), and Xavier Bourgeois (1873). The alleged correlation of sexual activity with nervous energy, which in turn was associated with intellectual development, led some writers such as Edward Clarke (1874) to argue that, because menstruation was a result of nerve stimulation, women should not engage in mental activity at all. Some even argued that menstruation itself was pathological.

Challenges to the Diagnosis and New Classifications

The idea of sexuality as a disease entity was undermined, in part, by a better understanding of sexually transmitted diseases and their sequelae, which came about during the last part of the nineteenth century. The discovery and acceptance of the germ theory also undermined the belief that sexual activity caused ailments such as tuberculosis. Medicine, however, did not abandon its emphasis on the disease potential of nonprocreative sex. It was simply placed in another category.

The latter is usually associated with the efforts of Carl Westphal, professor of psychiatry at the University of Berlin, who was influenced by the German homosexual movement. Led by such individuals as Karl Heinrich Ulrichs (1881) and Karoly Kertbeny (1905), that movement sought to establish that homosexuality was inborn. In 1869 Carl Westphal had published the case histories of a young woman who from her earliest years liked to dress as a boy and of a young man who liked to dress as a woman. From these cases he argued that sexual abnormality was congenital, not acquired. He called the phenomenon "contrary sexual feeling" and insisted that, although neurotic elements were present in such individuals, they were not insane (Bullough 1989).

If the "contrary sexual feeling" was inborn, was it also incurable? Jean Martin Charcot, the director of the Salpêtrière Hospital, and a colleague had attempted to cure several cases of "contrary sexual instinct" or "sexual inversion" with only modest success and concluded in an 1882 publication that inversion was a constitutional nervous weakness due to hereditary degeneration.

This concept was further developed by Paul Moreau (1887), who theorized that in addition to the usual senses of sight, hearing, touch, taste, and feeling, humans had a sixth sense, a genital sense that, like the others, could suffer physical or psychic injury without damage to the other senses. This propensity to injury stemmed from either a hereditary taint or a predisposition to perversion provoked by certain other factors such as age, proverty, constitution, temperament, and seasons of the year. The result could be sexual inversion, nymphomania, satyriasis, bestiality, rape, or profanation of corpses. The only way to deal with these individuals so afflicted was to turn them over to asylums, where they could be cared for. Not everyone agreed with this, however.

One of the early researchers who was most important in influencing public opinion was Richard von Krafft-Ebing, whose *Psychopathia Sexualis,* first published in 1886, remained in print until the 1980s. He combined several prevailing nineteenth-century theories to explain sexual "perversion": (1) the idea that disease was caused by the physical nervous system, (2) the notion that there were often hereditary defects in this system, and (3) the concept of degeneracy. Civilization, he claimed, was possible only because lust had been tempered by altruism and restraint, based on the knowledge that sexual excess weakened the body. The purpose of sex was reproduction, and sexual activities not undertaken with this ultimate purpose in mind were "unnatural practices" and a perversion of the sexual instinct. Though Krafft-Ebing distinguished between innate and acquired perversion, even acquired perversion existed only when there was hereditary weakness in the nervous system, and onanism was a causal factor in this.

Differing from Krafft-Ebing somewhat was Sigmund Freud (1913, 1922a, 1922b, 1924–50, 1938), his younger and even more influential contemporary. Freud agreed that variant sexual behavior came from misdirected sexual drives, but he held that the cause of the misdirection lay in the nervous system and the mind through which the instinctual drive operated. Though Freud himself paid comparatively little attention to most forms of variant sexual behavior, his followers seized on his concepts to emphasize environmental and accidental causes of variant sexual impulses.

Later behaviorists carried this kind of thinking to an extreme, so that the practical result of both Freudianism and the learning psychologies was to suggest that everyone had the ability to channel his or her drives. Although they differed about specific factors, followers of Freud usually agreed that deviant sexu-

ality was caused by environmental rather than constitutional factors and was, by implication, curable. Some groups, however, still looked upon it as inborn, though treatable if not curable. In any case, variations in sexual behavior were now regarded as coming under the jurisdiction of psychiatrists, and there they have remained.

Certain forms of variant sexuality, such as homosexuality, are no longer regarded as an illness, and masturbation is considered as normal behavior. Much of this latest change in attitude grew out of challenges to the research methodologies and theories that had originally classified much of human sexual behavior as an illness.

One challenge was made by Alfred Kinsey and his colleagues (1948), whose data on what actually constituted sexual behavior resulted in a redefinition of some of the norms. A second kind of challenge was aimed at the research of earlier physicians and psychiatrists. Most of the theorizing of Tissot and his successors had been rejected as germ theory gained credence and the endocrinological forces involved in sexuality came to be understood. This left psychiatrists as the only major group to maintain the contention that deviant sexual behavior could be illness. Prominent among them were psychoanalysts, who were attacked by a number of researchers in the 1960s and 1970s for working with small samples, not using control groups, and not taking into account cultural differences.

Attitudes toward nonprocreative sex also changed with the widespread adoption of contraceptives and the acknowledgement that sex was an enjoyable activity for both men and women. The recognition that people engaged in sex for pleasure as well as for procreation also weakened hostility to forms of sexual activity other than conventional heterosexual intercourse and raised questions about medical categorization. The knowledge that other cultures and peoples had attitudes toward sex that were radically different from those of Westerners was also important in challenging the western European and U.S. notion of sexual deviation as disease. Finally, in 1974 homosexuality was eliminated from the *Diagnostic and Statistical Manual* (DSM) of the American Psychiatric Association as a category of illness.

Not all forms of "deviant" sexual behavior, however, have been removed from the DSM, and in fact there remains a strong tendency to categorize as ill individuals who are pedophiles, exhibitionists, or necrophiliacs and those who engage in numerous other more or less forbidden sexual activities. There is also a countermovement as of this writing to estab-

lish a new category – that of sexually compulsive people – perhaps to get them into the offices of behavioral psychologists to be treated through behavior modification. Thus, although theories have changed and challenges to previous categorizations have been mounted, there remains a strong belief in the helping professions that socially unacceptable sexual behavior is an illness or at least a behavior problem of one sort or another. Since the time of Tissot these professions have essentially replaced religion in determining what sexual activity is permissible and what should continue to be stigmatized.

II.5 Concepts of Heart-Related Diseases

In 1628 William Harvey, physician to St. Bartholomew's Hospital, London, used quantitative, experimental methods to show that the blood must move in a circle, rather than being continuously regenerated as earlier theories had proposed. In addition, Harvey showed that the heart supplies the power to send the blood on its circuit around the body. Harvey's revolutionary ideas reflected ancient thought about the perfectibility of circular motion as much as they did new ideas about the value of experimental evidence. Nonetheless, in many ways and by most accounts, the year 1628 marks the beginning of current Western ways of looking at the heart and its diseases. However, although Harvey's demonstration of cardiac physiology in animals seemed logically applicable to human beings, it failed to lead immediately to any dramatic changes in the diagnosis or treatment of human heart disease. Over the next few centuries many people tried to discover what was going on within the thoraxes of patients who showed the debilitating signs of cardiac disease. Their notions about heart disease were reflected in the diagnostic techniques they thought appropriate.

Diagnosing Heart Disease

Physical Diagnosis

During the mid-eighteenth century, Leopold Auenbrugger, working in Vienna, described a new diagnostic technique. By percussing the chest – that is, by striking the chest and both listening to and feeling the reverberation – he was able to tell, to some extent, what lay within. His method enabled him to ascertain the size of the heart and to determine the presence of fluid in the chest, a common manifestation of heart failure. However, because prevailing disease theories placed little importance on the localization of lesions in the body, Auenbrugger's technique attracted little attention. His work was to gain greater attention as a result of a political upheaval in a nearby country.

The French Revolution not only reshaped the political structure of France, but also radically changed the institutions that controlled hospitals and medical schools. Physicians practicing in these institutions changed the perception of disease. Their emphasis on the importance of specific lesions in the body stimulated a desire to correlate clinical physical findings with anatomic lesions found at autopsy. Every day, Parisian physicians in the early nineteenth century went from bedside to bedside, examining patients with all manner of diseases, and all too often they had the opportunity to correlate their physical findings with those found at autopsy. In this milieu, René Laennec invented the stethoscope for listening to sounds in the chest. Auenbrugger's technique of percussion became widely used when it was discovered that lesions could be localized in the chest with Laennec's stethoscope. Although both of these techniques were used primarily to diagnose diseases of the lung, they were also used to diagnose heart problems.

Auscultation with the stethoscope was not immediately accepted. It was a skill that took time and practical experience to learn, and one that could yield misleading results. Furthermore, it was of no help in diagnosing many cardiac diseases that did not produce physical signs and could be diagnosed only by the patient's own sensations. One of these diseases was manifested by chest pain and is now understood to be caused by occlusion of the coronary arteries of the heart.

Diagnosis by History: Coronary Heart Disease

In addition to anatomic studies, eighteenth-century practitioners published descriptions of coronary heart disease based on patients' reports of characteristic symptoms. (*Coronary heart disease,* as we now use the term, encompasses such entities as angina pectoris and myocardial infarction, or "heart attack.") In 1768 William Heberden of London gave a lecture at the College of Physicians of London, published in 1772, in which he coined the term *angina pectoris* and differentiated it from other pains in the chest:

They who are afflicted with it, are seized while they are walking, (more especially if it be up hill, and soon after

eating) with a painful and most disagreeable sensation in the breast, which seems as if it would extinguish life, if it were to increase or to continue; but the moment they stand still, all this uneasiness vanishes. . . . In all other respects, patients are, at the beginning of this disorder, perfectly well. . . . Males are most liable to this disease, especially such as have past their fiftieth year.

Heberden focused on the clinical manifestations of the disease, not on its cause. However, others had earlier described disease of the coronary arteries. The English surgeon John Hunter, after finding this condition during an autopsy on a person who had died in a fit of anger, declared: "My life is in the hands of any rascal who chooses to annoy me." Hunter's words proved true. He collapsed and died in 1793, presumably of a myocardial infarction, soon after leaving an acrimonious meeting.

Many different manifestations of coronary heart disease were noted over the next century. Although the first diagnosis before death was probably made in 1878, recognition of coronary heart disease did not become widespread until its diagnosis by technological means became common early in the twentieth century. That new technology was derived in some ways from one of the oldest forms of diagnosis – feeling the pulse.

Mechanical Diagnosis: The Pulse and the Electrocardiogram

People have felt the pulse to diagnose disease since antiquity. Attempts to analyze the pulse have included timing its rate and noting its pattern, particularly any abnormalities in its rhythm. John Floyer, who in 1709 constructed a portable clock with which to time the pulse, noted that the natural pulse rate varied according to a person's place of residence, age, and sex.

A very slow pulse, one of the most striking abnormalities, was often associated with intermittent loss of consciousness, or syncope. This condition has come to be known as Stokes–Adams (or occasionally Adams–Stokes) disease, after two Dublin physicians, Robert Adams and William Stokes, each of whom described characteristics of the disease in the first half of the nineteenth century. Today this condition is treated with pacemakers (described later). Early attempts to understand the cause of a slow beat led to the development of mechanical devices for analyzing heartbeat.

In 1859 the French physiologist Etienne-Jules Marey drew on the earlier work of German physiologists such as Carl Ludwig, inventor of the kymograph, to devise an instrument that could produce a permanent record of the cardiac pulsations on a drum of smoked paper. Marey used this instrument to record the pressure within the heart of a horse. He also recorded pressure tracings from the arteries that could be felt on the surface of the human body. In the 1890s the English physician James Mackenzie developed the polygraph, an instrument that recorded the pulsations of the arteries and veins directly onto a continuous strip of paper. With this device he was able to describe many abnormalities of the pulse and to identify the cardiac causes of several of these. His work was advanced by the London physician Thomas Lewis, who analyzed abnormal cardiac rhythms with the electrocardiogram (EKG), a new instrument that could record the electrical signals generated by the heart. Invented in 1902 by Willem Einthoven, the EKG earned its inventor the 1924 Nobel Prize in medicine or physiology.

Because Lewis and Mackenzie were working within a social system that placed a high value on the clinical skills of the physician and a low value on the use of technology, neither thought of the EKG machine as an instrument that could replace the senses of the skilled bedside observer. However, working in a climate in which the role of the physician was not so socially important, James Herrick of Chicago saw the value of the EKG for diagnosing diseases that could not be diagnosed with the unaided senses. Coronary artery disease was one such disease. Herrick's clinicopathological description of it in 1912 received little attention; however, after his collaboration in 1918 and 1919 with Fred Smith to describe the characteristic EKG changes, Herrick's definition of the disease entity became widely recognized. This was an early example of a pattern to be repeated throughout the twentieth century – a disease first described clinically would become more widely accepted once it was defined in terms of a laboratory technique.

Hemodynamic Diagnosis: Diagnosis by Measuring Physiology

In a sense, the development of hemodynamic diagnosis was returning full circle to the issues of pressures and volumes in the heart that Harvey was working with in 1628. Harvey had been unable to measure these parameters in human hearts. Physicians' daily use of these measurements today is in large part the result of a self-experiment performed in 1929.

During the spring of 1929, while working in the relatively unsophisticated setting of a small German country hospital, Werner Forssmann became fascinated by the work of nineteenth-century French

physiologists such as Marey, and particularly by a diagram showing Marey's recorded pressures from a horse's heart. Forssmann decided to perform the procedure Marey had used on himself by passing a urethral catheter from the main vein in his arm up into his heart, hoping to provide a new, more effective means of delivering medication. Despite his supervisor's refusal to grant him permission, Forssmann was determined to perform the experiment. However, he needed the cooperation of the surgical nurse who controlled access to the necessary instruments.

Forssmann was eventually so successful in convincing her of the safety and importance of the experiment that she insisted he perform the experiment on her. Forssmann, however, persuaded the nurse to lie down on a cart, where he strapped her down, claiming the action to be a "precaution against falling off." With the nurse thus immobilized, Forssmann inserted the catheter into his own arm, pushed it through the veins into his heart, and then released the nurse. She helped him walk down the stairs into the basement, where an X-ray image confirmed that the catheter was indeed within his heart. The experiment earned Forssmann some praise, but much more hostility, and as a result, he left academic medicine and did no more work on cardiac catheterization.

But others went forward with Forssmann's method. In 1932 Dickinson Richards, Jr., and André Cournand began collaborating on studies of the heart and circulation at New York Hospital. They started with the assumption that the heart, lungs, and circulatory system form a single system for the exchange of gases between the environment and the organism. In order to calculate the cardiac output, they needed to obtain blood samples from the right atrium, the cardiac chamber that collects blood from the body before pumping it to the lungs to receive more oxygen. After practicing Forssmann's technique on laboratory animals for four years, Cournand, Richards, and their colleagues determined that the passage of catheters into animals' hearts did not significantly interfere with cardiac functioning.

Although their first attempt to perform the procedure on a patient, in 1940, was unsuccessful, they were encouraged to continue their efforts by senior investigators studying cardiac output determined by the ballistocardiogram, an instrument that recorded the motion of the body caused by the heartbeat. Cournand was eventually able to insert a catheter into a human heart and to compare the directly measured cardiac output with that determined by the ballistocardiogram. He showed that cardiac output as measured by the ballistocardiogram was too low. More important, he showed that it was practical and safe to insert a catheter routinely into the right side of the human heart.

During the next few years, Richards, Cournand, and their colleagues designed a new catheter that was easier to maneuver and constructed a measuring device that enabled them to record simultaneously four different pressure tracings along with the EKG. In 1942 they advanced the catheter into the right ventricle, and in 1944 into the pulmonary artery, thus making it possible to measure the hemodynamic pressure and the amount of oxygen present in the blood at each stage of passage through the right side of the heart. Funded by the federal government through the Committee on Medical Research, from 1942 to 1944 this group studied more than 100 critically ill patients suffering from traumatic shock, hemorrhagic shock, burn shock, and shock caused by rupture of an internal organ. They outlined the profound effects of reduced circulating blood volume on cardiac output, particularly on the flow of blood to peripheral organs and the kidneys, and described how the condition could be reversed by replacement of the appropriate volume of blood. Later, they used the same catheterization technique to diagnose congenital cardiac defects: An abnormal opening between the cardiac chambers was detected by means of pressure and oxygen measurements made with the catheter. Similarly measuring the pressure in the cardiac chambers was found to be valuable for diagnosing acquired cardiac defects, particularly diseases of the heart valves.

Richards and Cournand shared the 1956 Nobel Prize in medicine or physiology with Forssmann. Not long after the discovery that right-sided pressures could be measured, others extended the technique to measure pressures on the left side of the heart. The procedure has greatly aided our understanding of the pathophysiology underlying various forms of congestive heart failure. The invention of electronic devices for measuring pressures has enabled physicians to analyze the pulsatile pressure tracings in various disease states. Other investigators have shown how injecting dye into the heart can aid in diagnosis. Today, the passing of diagnostic catheters into the heart is such a routine procedure that patients may not even spend a night in the hospital.

These techniques for hemodynamic monitoring have come to define and dominate places in hospitals set aside for the care of critically ill patients. Some intensive care units are designed specifically for the care of patients suffering from coronary artery dis-

ease. Physicians and nurses working in coronary care units, which first became widespread in the United States in the 1960s and 1970s, utilize both hemodynamic monitoring and EKG monitoring of the pulse, the latter to detect and correct life-threatening cardiac dysrhythmias. In other intensive care units, cardiac catheters are used to monitor the cardiac function of patients suffering from a wide variety of noncardiac disorders. Although they are useful for some groups of patients, whether coronary care units are necessary for all patients with myocardial infarction remains unclear.

Western ideas about what constitutes heart disease are based increasingly in technological diagnosis and on the ability to invade the thorax in order to make diagnoses and also to intervene. Along with the increased use of technology has come the unstated but generally pervasive assumption that diagnosis has finally become objective, transcultural, and reflective of some natural, inevitable underlying diagnostic system. The validity of this assumption is doubtful. Historical analysis shows that the definition of heart disease, as well as of the specific diseases and their appropriate diagnostic tests, is a product of both biology and culture.

Changing Concepts: What Constitutes Heart Disease?

Concepts about what constitutes heart disease have changed a great deal in the past century. For example, the corresponding section of a predecessor to this work, August Hirsch's *Handbook of Geographical and Historical Pathology* (1883–6) is entitled "Diseases of the Heart and Vessels," not diseases of the heart, and one of the main topics is hemorrhoids. Anatomic linkage of the heart and vessels into a single unit was common in the nineteenth century, as is shown by such titles as *Diseases of the Heart and Aorta* and *Diseases of the Heart and Great Vessels*. Around the end of the nineteenth century, however, the conceptualization of heart disease changed fundamentally. As Christopher Lawrence has pointed out, British physicians started to think about the heart in terms of its functional capacity rather than in terms of its anatomy. This led them to regard cardiac murmurs, such as would be detected by a stethoscope, as less important than physiological measurements of function.

This conceptual change was particularly apparent in discussions of a soldier's disease described at one time as "DaCosta's syndrome" and later, at the start of the First World War, as "soldier's heart." Afflicted by breathlessness, fatigue, and a feeling of impend-

ing doom, soldiers with this syndrome were initially treated by the British military with extended hospital bedrest. The presence of a cardiac murmur was taken as ipso facto evidence of heart disease. However, as the war continued, lasting far longer than originally anticipated, heart disease became a serious military, economic, and political problem. It was, in fact, the third most common reason for military discharge. Yet heart disease held out far more hope of treatment and return to service than did the most common cause of discharge, "wounds and injuries." Nonetheless, the long convalescence strained both the military hospitals and the political fortunes of England's leaders, who were forced to institute a military draft in 1916. Given these political exigencies, physicians working for the Medical Research Council reconceptualized the disease as the "effort syndrome." They decided that heart murmurs were important only insofar as they impaired the ability of the soldier to work, and then prescribed a series of graded exercises rather than hospitalization and bedrest. The result was that many soldiers previously declared "unfit for service" were reclassified as "fit." All of this demonstrates that some notions about what constitutes heart disease are informed by social needs.

Physicians' ideas have continued to be shaped by social context. Studies of the incidence of heart disease in black Americans early in the twentieth century were influenced by the cultural context in which they were written. Many investigators concluded that coronary artery disease was rare in black people, largely because black people were considered less likely to experience stress, owing to their assumed disinclination to hurry or worry about their lot in life, and because they were presumed to be less intellectually alert than the "refined, intellectual" classes.

In the late twentieth century, culture has continued to have an impact on our definitions of heart disease. For example, Lynn Payer has pointed out that failure to appreciate that the West German concept of heart disease differs from the U.S. concept could lead to the erroneous conclusion that death rates from ischemic heart disease are lower in West Germany than in the United States. In fact, the rates are approximately the same, but that type of heart disease is more likely to be called "ischemic heart disease" in the United States and "cardiac insufficiency" in West Germany.

The Rise of Cardiac Diseases
Changes in disease classification reflect both social and biological events. Even after accounting for

changes in definitions, it seems clear that there has been a significant change in the types of disease from which people die. During the twentieth century, our methods of classification have helped to make heart disease an increasingly important cause of death and disability. The predominant causes of sickness and death were once infectious diseases. In the mid-nineteenth century, for example, tuberculosis accounted for an estimated one-seventh of all deaths in western Europe. Yet the impact of infectious diseases has subsequently decreased in many parts of the world, partly because of improved living conditions and partly because of improved treatment with antibiotics.

Two major forms of heart disease related to infectious agents have undergone a dramatic shift in pattern. Rheumatic fever, a disease related to infection with a specific streptococcus that can cause heart disease, was once a major cause of heart disease in Western countries. In industrialized countries, it has now become a relatively minor cause of heart disease, with a prevalence as low as 0.6 per 1,000 school-aged children in the United States and 0.7 per 1,000 in Japan. In other parts of the world, however, rheumatic heart disease remains a serious problem; the prevalence per 1,000 school-aged children has been reported to be in the range of 15 to 20 for Algeria, Bolivia, and Thailand.

Endocarditis, an infection of the heart valves, carried an almost certain death sentence before the advent of antibiotics. At one time, endocarditis in the United States primarily afflicted people with valvular disease caused by rheumatic heart disease. The changing pattern of this illness reflects changes not only in treatment but also in life-style. Now endocarditis is far more often a disease of intravenous drug abusers.

Another result of the decline of infectious diseases has been an increase in the average life expectancy. People now live long enough to succumb to diseases that take time to develop, which is the case with many cardiac diseases, particularly coronary heart disease. And again life-styles have changed. A lack of physical activity and a change in diet may contribute to the increased incidence of coronary heart disease.

Finally, the development of cardiology as a major field of specialization in the United States is indebted in large part to the earlier campaign against tuberculosis, which prompted the development of the voluntary health movement. The first U.S. cardiology organization, the American Heart Association, drew substantial intellectual, organizational, and financial support from the antituberculosis movement, primarily the National Tuberculosis Association.

Coronary Disease

Coronary disease has become the major form of heart disease in industrialized countries. As such, it has become a major object of attention for health care workers. Much of that attention has been focused on explaining the geographic and historical changes in the pattern of disease.

Heart disease caused 979,000 deaths in the United States in 1986. Accounting for 47 percent of all deaths, it is by far the leading cause of death, with myocardial infarction the most common diagnosis. Many more people suffer from heart disease than die from it. In the United States, there were an estimated 57,700,000 people with cardiovascular disease in 1983, 21,500,000 of whom had heart disease and 7,200,000 of whom had coronary heart disease. Of those with heart disease, 12,600,000 were under age 65, as were 3,200,000 of those with coronary heart disease. The physical activity of one-quarter of those with heart disease was limited, making the condition an important cause of disability as well as death.

Declining Coronary Death Rate in the United States

At the turn of the nineteenth century, heart disease was the fourth leading cause of death in the United States, behind pneumonia and influenza (combined), tuberculosis, diarrhea, enteritis, and ulceration of the intestines. All of these produced death rates in excess of 100 per 100,000 population. A sharp upward trend in coronary disease became apparent around 1920, and coronary disease was recognized with increasing frequency throughout most of the first 50 years of the twentieth century. By 1940 only two disease categories with death rates of more than 100 per 100,000 remained: cancer and diseases of the heart. The death rate from heart diseases then began a dramatic series of changes.

As Figure II.5.1 shows, the death rate reached a peak in 1963 and has declined continuously since then. There was some initial concern about whether the decline was real or only a product of a 1968 change in disease classification. But now there is little doubt that the death rate for coronary heart disease in the United States has fallen dramatically since the 1960s. However, that decline has not been evenly distributed. The mortality rate for heart diseases in California, for example, peaked relatively early, around 1955, and the subsequent decline there
Figure II.5.1. Rate of coronary heart disease per 100,000 people in the United States (age-adjusted to 1940 age distribution). (Data from Vital Statistics of the United States, as prepared by the National Heart, Lung, and Blood Institute; data for 1987 provisional.)

Figure II.5.2. Annual change in mortality from ischemic cardiac disease, 1968–77 (men aged 40 to 69). (Data from WHO MONICA 1988.)

was repeated in other parts of the United States throughout the 1960s and 1970s. By 1986 the death rate for coronary heart disease was 55 percent of the 1966 rate, and the decline in the death rate for all cerebrovascular diseases was proceeding three times faster than the decline for all other causes of death combined.

Worldwide Variation in Coronary Diseases

Such countries as Australia, New Zealand, and Canada have experienced similar declines in the death rate from coronary disease among men. Other countries, however, have experienced significant increases in death rates, as revealed in Figure II.5.2. These have included countries, such as Scotland and Northern Ireland, with death rates initially comparable to that of the United States, as well as countries, such as Poland and Switzerland, initially having death rates much lower than that of the United States.

Some of the increase may be due to the impact of industrialization. In China, for example, infectious diseases such as tuberculosis and nutritional deficiencies were the major causes of morbidity and mortality, with cardiovascular disease of little concern until the late 1950s. Even among industrialized countries, the rate of death from cardiovascular diseases has varied widely, from 913 per 100,000 in Finland (for men aged 40 to 69 in 1975) to 379 in Japan.

Attempts have been made to explain these differences in disease rate. The World Health Organiza-

tion's Multinational Trends and Determinants in Cardiovascular Disease (MONICA) has made one such attempt. With 41 projects in 21 countries, MONICA is helping to make cardiovascular disease a focus of international and cross-cultural comparisons. Only AIDS has received similar worldwide attention.

Studies of changing patterns of cardiac disease have contributed to the invention of risk factor, a concept that is receiving widespread attention as a way of conceptualizing the cause of many diseases. Unlike infectious diseases, which are defined in terms of a single, specific agent, risk factor is conceptualized on an epidemiological and probabilistic basis.

Risk Factors for Coronary Heart Disease

Much of our current explanation for the historical and geographic differences in death rates from coronary heart disease derives from the concept of risk factor. A number of long-term prospective studies have enhanced the utility of this concept. The most widely known study is the Framingham Heart Study, in which 5,209 men and women have been carefully examined every two years since the investigation began in 1948 in Framingham, Massachusetts. Studies such as this have identified a number of factors that contribute to the likelihood of developing coronary heart disease. Some of these cannot be modified. For example, men are more likely to suffer from heart disease than women; older people are more likely to develop the disease than younger ones; and those having a family history of early

cardiac disease are at greater risk than those without such a history.

However, other factors can be modified. Cigarette smoking dramatically increases the likelihood of a coronary event and represents the greatest and most preventable cause of heart disease. Once a person stops smoking, the risk rapidly declines to a level approximately the same as it would be if the person had never smoked. High blood pressure and diabetes are also important risk factors.

A positive relationship between blood cholesterol level and the development of heart disease has been clearly demonstrated. Almost no Japanese men have serum cholesterol levels above 200 mg/dl, whereas almost no Finnish men have concentrations below that level. Consistent with the hypothesis that cholesterol is associated with death from coronary heart disease, the death rate from coronary heart disease in Finland is more than 10 times that in Japan. Historical analysis has shown that the death rate from heart disease in Europe fell during the Second World War, presumably as a result of a lack of foods that elevate serum cholesterol level. Most population-based studies have shown a consistently positive relationship between increased serum cholesterol level in the form of low-density lipoprotein and the rate of heart disease. At high levels the association is particularly strong; the risk of death for persons having cholesterol values in the top 10 percent is four times the risk of persons in the bottom 10 percent. There is now good evidence that lowering cholesterol level with drug therapy will lower the death rate from coronary disease. This effect of reducing cholesterol level is most beneficial for those having the highest levels, but the value of reducing cholesterol level for those without elevated cholesterol remains unclear.

Exercise has a beneficial effect on the types of lipids circulating in the bloodstream. Although obesity is associated with hypertension, whether obesity is an independent risk factor for coronary heart disease is as yet unclear.

In the 1950s some U.S. investigators argued that people who were hard-driving, competitive, overcommitted, impatient perfectionists and who found it difficult to relax – these with the so-called type A personality – were at increased risk for coronary heart disease. These findings have been a subject of intense debate. Some studies of workers in Great Britain have identified civil service manual workers, not those with the hard-driving behavior indicated in the original research, as those at greatest risk from their behavior type. Although the exact role of type A behavior as an independent risk factor

in the development of coronary heart disease remains unclear, recent studies suggest that the type A personality may actually improve longevity after a myocardial infarction.

Alcohol intake in small quantities – two or fewer drinks per day – may diminish the risk of developing coronary disease. However, alcohol in greater amounts is clearly associated with greater morbidity and mortality from both cardiac and noncardiac disease.

Explaining Change

Many investigators have attempted to use the concept of risk factor to explain geographic and historical changes in the rate of death from coronary heart disease. The decline in the U.S. death rate may have been due partly to improved medical interventions, including the widespread establishment of coronary care units, improvements in prehospital resuscitation and care, better surgical and medical treatment of those with known heart disease, and more extensive treatment of the large proportion of the population with hypertension. The decline may also have been due in part to changes in life-style. Cholesterol consumption peaked in 1959, and the percentage of North Americans who smoke has declined steadily over the past few decades. However, a significant part of the change cannot be fully explained.

Although coronary heart disease appears to be an increasing cause of death in developing countries, accounting for 15 to 25 percent of all deaths as the mean life expectancy reaches 50 to 60 years, more is required to explain the rates of death from coronary heart disease than merely to blame increasing industrialization. People moving from one industrialized country to another tend to develop the susceptibility to heart disease prevalent in the host country, suggesting that other environmental factors play an important role in determining the incidence of heart disease. Striking confirmation of this comes from a study of 11,900 people of Japanese ancestry living in Japan, Hawaii, and California. Those living in Japan had the lowest incidence of heart disease, those living in Hawaii had an intermediate incidence, and those living in California the highest. The best predictor of the incidence of heart disease among those living in California was not the presence of known risk factors, but the extent to which those Japanese who had moved from Japan to California continued to adhere to traditional Japanese values: those who retained more of these values had a lower rate of heart disease.

Geographic Variation in Types of Heart Disease

In many parts of the world, other types of heart disease are more common than coronary heart disease. Endomyocardial fibrosis, for example, is common in the tropical rain forest belt of Africa and South America. The disease has a characteristic pathological process and leads to heart failure, accounting for up to 20 percent of patients with heart failure in Uganda, the Sudan, and northern Nigeria. It can affect people who live in the area as well as those who visit from other parts of the world. Although its precise cause is unknown, and in some instances it may be due to a parasitic infection, the underlying cause may be an increase in the number of eosinophils. In many parts of South America, the parasite *Schistosoma mansoni* is a common cause of heart disease. Also common in South America is Chagas' disease. Other heart diseases having characteristic geographic patterns include some forms of congenital heart disease that are more significant for people who live at high altitudes, where the concentration of oxygen in the inspired air is reduced.

Peripartum cardiac failure is developed by up to 1 percent of women in northern Nigeria during the postpartum period. Occurring most often in July, it seems to be caused by a combination of extreme heat, exhaustion exacerbated by the traditional custom of lying on a bed over a fire, and eating food rich in lake salt. Thus, peripartum cardiac failure appears to be largely a result of cultural patterns. In this respect it resembles coronary heart disease, which is linked to Western culture in ways that we identify as risk factors and in ways that we do not fully understand, as exemplified by the impact of Japanese cultural values on coronary disease just described.

Recent Changes

Perhaps because of the prevalence of cardiac disease as well as the symbolic significance of the heart, concern for heart-related diseases has been central to much of what we have come to identify as late-twentieth-century medicine. That includes both "high-tech" innovations and preventive medicine strategies, such as risk-factor intervention and lifestyle modifications.

The echocardiogram is a "high-tech" approach to cardiac diagnosis based on the reflection of sound waves in the body. The technique was first demonstrated in the 1950s, and recent advances have greatly increased the quality of the images, such that it is possible to diagnose heart disease even in a fetus. By bouncing sound waves off the interior of the heart, a picture can be generated that reflects the heart's anatomy, and by the use of small air bubbles to provide contrast, the passage of blood can also be traced. The echocardiogram's greatest advantages lie in its complete safety (so far as is now known) and freedom from pain.

Other imaging techniques applied to cardiac disease include tagging blood constituents with radioactive substances (which can be used to measure both function and blood flow) and both computerized axial tomography and magnetic resonance imaging. The latter two techniques make use of digital processing and imaging to provide cross-sectional images based on a computerized reconstruction of the information provided by scanning from many different directions. In addition, computerized axial tomography and positron emission tomography are now being used to measure the metabolic state of the heart muscle.

Treatment of patients with acute myocardial infarction has evolved from observing and supporting the patient to attempting to intervene in the disease process itself. Typically, patients with myocardial infarction suffer from an obstruction of one of the coronary arteries that supply blood to the heart. Two methods for relieving that obstruction are now being used, one mechanical and one in which medication dissolves the blockage. The mechanical intervention is percutaneous transluminal coronary angioplasty (PCTA), during which a catheter is directed into the coronary artery and expanded in order to clear the lumen. Since its introduction in 1977, PCTA has become widely used for the treatment of coronary disease. The number of procedures performed in the United States rose from 32,206 in 1983 to 175,680 in 1987. The procedure has also become popular in other countries, with approximately 12,000 procedures being done in the Federal Republic of Germany and 10,048 in Japan during 1987. The initial success rate approaches 95 percent at some institutions, but a significant percentage of patients experience later failure. PCTA continues to be used for people who suffer from symptoms caused by an obstruction of the coronary arteries, but who have not yet suffered death of the heart muscle. The technique has been attempted as well with patients who have recently suffered death of the heart muscle, causing myocardial infarction, but recent studies suggest that it is not as useful for urgent therapy.

Tissue-dissolving agents include products of recombinant DNA technology. These agents should be administered soon after a person suffers a heart at-

tack in order to dissolve the clot before irreversible damage has been done to the heart muscle. Although PCTA requires rapid transportation of a heart attack patient to the hospital, often via helicopter, treatment with clot-dissolving agents can be initiated before the patient reaches the hospital. This therapy must be closely monitored, however, making hospitalization necessary for optimal treatment. This may negate studies from the 1970s that showed that hospitalization made no difference in the prognosis of patients suffering from an uncomplicated myocardial infarction. The optimum therapy for patients with myocardial infarction is being evaluated.

The first successful transplantation of a human heart into another human being was performed in South Africa by Christian Barnard in 1967. Transplantation was at first reserved for critically ill patients not likely to survive for long. However, a series of advances, primarily in the posttransplant management of patients, has led to a dramatic increase in survival after transplantation and to a tendency to carry out the procedure on patients with severe heart failure much earlier in the course of the disease. As a result, the number of transplantations performed worldwide increased from 3,000 in 1986 to more than 6,800 by January 1988. The five-year actuarial survival worldwide exceeded 70 percent and was more than 80 percent for some subgroups. Moreover, more than 80 percent of survivors were able to return to their previous occupations or comparable levels of activity. The success of cardiac transplantation prompted Medicare, the primary federal means of payment for elderly U.S. citizens receiving health care, to fund heart transplantations. It did so, however, at only a few locations, selected on the basis of results and experience, thus linking reimbursement with some measure of quality. Although not all heart transplantations are covered by Medicare, many insurance plans have indicated an intent to employ Medicare criteria in deciding which institutions will be paid for the procedure.

That some patients suffer from an abnormally slow heartbeat has been known for some time. Current treatment for many of them (perhaps too many) is provided by an artificial pacemaker. The first pacemaker was implanted in 1959, and now more than 200,000 pacemakers are implanted each year worldwide, approximately half of these in the United States. The pacemaker, which usually weighs about 40 grams, is connected to the heart by wires and is powered by lithium batteries that commonly last 7 to 10 years. At first pacemakers produced electrical pacing signals at a constant rate in order to treat

Stokes–Adams disease; more recent models can be programmed to respond to changing conditions in a variety of ways. A new device can electrically shock the heart out of an uncoordinated rhythm called ventricular fibrillation. This automatic implantable defibrillator, first used in 1982, appears to be helpful for patients who suffer from arrhythmias that are difficult to control.

Unlike the stomach or the limbs, for example, a person's heart cannot stop functioning for long or the person will die. This fact made operations on the heart difficult to contemplate during the nineteenth century, when great advances were being made in surgery on other organs. Some leading surgeons of the day flatly asserted that surgery on the heart would always be impossible. Nonetheless, early in the twentieth century, surgical treatment of valvular heart disease was attempted. From 1902 to 1928, 10 attempts were made to cure mitral stenosis (a narrowing of the valve leading to the main pumping chamber of the heart); 8 of the patients died. Because of the dismal outcomes, no one attempted another such operation until the mid-1940s. Starting in the 1950s, the availability of cardiac bypass in the form of an effective pump and oxygenator enabled surgeons to work on a still, "open" heart rather than on a beating organ. Valve replacements became relatively easy. Coronary artery bypass grafting (surgery to bypass blocked coronary arteries) is now a common means of treating coronary artery disease. Whereas at first surgeons bypassed only one or two obstructed vessels, now many more are commonly bypassed during a procedure.

Our ability to replace diseased valves has also greatly increased. Some patients suffering from abnormal heart rhythms can be helped by heart surgery designed to interrupt abnormal conduction pathways within the heart. Some centers are investigating a heterotopic prosthetic ventricle, a mechanical device designed to support a failing heart until a suitable transplant can be procured. Others have attempted to use an artificial heart for long-term support. Such a device would not be subject to the immunologic phenomena associated with transplantation and would obviate the need to locate a donor heart. However, problems with clots and hemolysis have thus far severely limited the attractiveness of this option.

Coda

The heart continues to have a central place in Western medicine. Heart diseases are common, and many of the most prominent new approaches to disease in

the past few decades have been directed at heart disease. Cardiologists have become the most powerful subspecialists in internal medicine.

But the heart has long been central to the broader Western culture as well. The heart is seen as the seat of the emotions – as in the expressions a "broken heart," "crimes of the heart," a "bleeding heart," and a "change of heart." The heart is also the source of strength: "Take heart!" or "You've gotta have heart." The heart is metaphorically the site of a central issue or concern, as in the "heart of the country" or the "heart of the issue." Finally, the heart is often seen, both metaphorically and literally, as the source of life, and its failure is considered both a cause and a marker of death. Concepts of heart disease are drawn from general cultural concepts of what it means to be human, and studies of how and when they change will increase our understanding not only of the history of medicine but of history in general.

II.6
Concepts of Cancer

In past centuries people feared epidemic diseases with their sudden onset, ghastly symptoms, agonizing death for many, and sometimes disfigurement or physical impairment for survivors. Today, especially in the developed world (with a few notable exceptions), the dread of epidemic contagion seems almost as anachronistic as the burning of witches. It has been replaced by the dread of cancer. As with the epidemics of yesterday, the basic causes of cancer remain shrouded in mystery, while its effects in terms of human suffering are all too well known.

Cancer is a process whereby a loss of control of normal cell division and multiplication produces a tumor that can invade adjacent tissues and metastasize, that is, implant cancerous cells at a site that is noncontiguous to their origin, where abnormal multiplication continues. When cancer originates in connective tissues (mainly bone or muscle), it is called *sarcoma;* when it originates in epithelial tissues (lining tissues and organs such as the breast, lungs, or stomach), it is called *carcinoma.* The latter is by far more common. Invasive tumors occur in all complex species and probably antedate the advent of vertebrates. The oldest paleopathological evidence is limited to lesions that affected bones, such as those found in dinosaurs. Tumors have been found in Egyptian mummies dating from 2000 to 3000 B.C., and physicians of that ancient land knew of and treated patients for cancers of several sites.

Certainly the ancient Greeks were familiar with this disease, or perhaps better, this group of diseases. The condition is discussed in the Hippocratic corpus, and in fact its nomenclature is dominated by Greek words. Hippocrates himself is credited with having named the disease cancer from *karcinos,* the Greek word for crab, perhaps because some cancers of the breast have a crablike appearance or perhaps because the pain that cancer can produce resembles the pinching of a crab. Similarly, *neoplasm,* meaning "new formation," and *oncology,* literally the "study of masses," are derived from the Greek, as is the word *tumor.*

Hippocratic medicine attributed tumors – which included all sorts of swellings – to an abnormal accretion of humors. Although some remedies are mentioned, aphorism VI.38 advocates conservatism: "It is better not to apply any treatment in cases of occult cancer; for, if treated, the patients die quickly; but if not treated they hold out for a long time." Galen sought to differentiate more clearly cancers from inflammatory lesions and gangrene. Cancer was held to be caused by black bile; if the cancer ulcerated, the black bile was undiluted; if there was only a tumor, the pathogenic humor had been diluted.

Carcinoma of the breast was probably the earliest actual neoplasm for which surgical eradication was attempted. Leonides of Alexandria, who slightly preceded Galen, is known to have progressively incised and cauterized, both to prevent bleeding and to destroy the neoplasm. Galen, conversely, recommended that bleeding be permitted, presumably for the pathogenic humor to be drained. Some surgeons performed a total mastectomy. Little was written about the healing of these terrible procedures, but Rhazes warned in the ninth century that those who performed surgery on a cancer generally only caused it to worsen unless it was completely removed and the incision cauterized.

Although barber-surgeons probably incised and excised boils and warts in the belief that they were curing cancer, it seems likely that few cancers were treated surgically until relatively modern times. Ambroise Paré wrote toward the end of the sixteenth century that those who pretended to cure cancer surgically only transformed a nonulcerous cancer into an ulcerated one. "I have never seen a cancer cured by incision, nor known anyone who has." Nevertheless, in the seventeenth century, Wilhelm Fabricius of Hilden described the removal of axillary nodes in a breast cancer operation and provided adequate descriptions of operations for other cancers.

The discovery of the lymphatic system by Gasparro Aselli in 1622 directed medical attention away from the black bile theory, which no one had demonstrated, toward abnormalities of the lymphatic structures in the causation of cancer. Basically, the idea was that cancer was an inflammatory reaction to extravasated lymph, the type of lesion depending on its qualities. About 150 years later John Hunter

modified the lymph theory by defining "coagulating lymph" (i.e., blood serum), as opposed to true lymph, as that component of blood that clotted spontaneously when it was extravasated. It was this "lymph," when it was contaminated by a "cancerous poison" and oozed into tissues, that Hunter viewed as the cause of cancer. Quite presciently, he described metastases as "consequent cancers" that reached distant parts via lymphatic channels.

A more transitory hypothesis advocated particularly by the German Daniel Sennert and the Portuguese Zacutus Lusitanus early in the seventeenth century was that cancers, at least when ulcerated, were, like leprosy, contagious. Popular fear of the contagiousness of cancer persisted into the twentieth century. The first accurate etiologic observation about any cancer can be attributed to the London surgeon Percival Pott, who reported in 1775 that many men who had worked as chimney sweeps since boyhood and were routinely lowered into narrow chimneys suffered scrotal cancer. He linked this observation to the irritating effect of chronic contact with soot and thereby identified the first occupational cancer.

The impact of microscopy on cancer research came very slowly. Robert Hooke, the pioneering seventeenth-century microscopist who coined the term *cell,* thought that tissues were composed of fibers – a hypothesis that persisted into the nineteenth century. Not until after 1830, when Joseph J. Lister designed the first achromatic microscope lenses, did progress in histology begin, made mostly by German investigators. The first new concept, advanced by Theodor Schwann and supported by Johannes Mueller, was that all tissues were composed of microscopic cells, not fibrils. Yet the lymphatic theory was not easily abandoned, and cells were thought to derive from "blastema," which was organized from intercellular fluids. In 1854, however, Rudolph Virchow questioned the existence of the unidentified blastema, and in the following year he stated the principle that all cells originated from cells and postulated that neoplasms developed from immature cells. But even then the spread of cancer was considered to result from some sort of a humor rather than the dissemination of cells. In 1867 Edwin Klebs advanced the opinion that most cancers originated in epithelial tissues (carcinomas in modern terminology), and coincidentally, Wilhelm Waldeyer applied the old, previously unspecific term *sarcoma* to neoplasms that arose in connective tissues.

Despite these scientific developments, cancer research is usually viewed as a twentieth-century undertaking and, despite its antiquity, the disease itself is viewed as largely a twentieth-century phenomenon. As infectious ailments have receded, cancer, along with cardiovascular diseases, has been perceived to be the greatest single health problem facing the developed world. Actually, cancer presents a set of problems, because the term should be considered a collective noun. The World Health Organization has classified some 100 kinds of cancer depending on their sites of origin, a figure that may be too conservative.

It is generally estimated that some form of cancer will develop in one-third of the inhabitants of the industrialized world. Moreover, the probability is increasing. Less than two decades ago it was calculated that one in four would develop cancer – with even those odds prompting the charge that cancer represents the "failure of medicine" (Braun 1977). Certainly this seems to be the case when a comparison is made with medicine's triumphs against epidemic illnesses, which came one on top of the other after the advent of the germ theory. Although we are well into the second century since the beginnings of cell theory, cures for cancer have thus far largely eluded scientific medicine. Nor has Virchow's observation that irritants could summon forth cancerous cells proved very helpful in cancer prevention – although irritants are among the foci of cancer research today.

The concept of *autonomy* suggests that once a cell has become truly cancerous it is beyond bodily control. The concept was established around the turn of the century by Arthur Hanau, Leo Loeb, and Carl O. Jensen, who transplanted cancer cells into healthy animals and plants of the same species and observed the unrestrained growth of new cancers in the previously healthy hosts. Yet the fact that cancers, once established, can enter a stage of remission – sometimes permanently – argues that the body can rally to retard or even reverse previously uncontrolled cell proliferation.

Following these transplantations, the next advances in research were made when cancer was produced experimentally in plants and animals by the administration of various chemical, physical, and biological agents. These experiments revealed, for example, that some 150 different viruses cause tumors in living organisms, that ultraviolet light and X-rays as well as radioactive substances such as radium and uranium induce cancer, and that coal tars, dyes derived from them, and other substances can also induce the disease. Moreover, even natu-

Table II.6.1. *Ten most common invasive neoplasms and estimated new cases as percentage of all new cases in the United States, 1990*

Neoplasm	Percentage	Cases
Male		
Prostate	21.1	30,000
Lung	19.6	92,000
Colon	10.0	26,000
Bladder	6.9	6,500

Colon	11.1	27,300
Lung	10.6	50,000
Uterus	6.3	4,000
Rectum	4.0	3,600
Ovary	3.9	12,400
Non-Hodgkin's lymphomas	3.3	8,700
Pancreas	2.8	12,900
Cervix	2.6	6,000
Bladder	2.5	3,200
Total	75.9	172,100

Table II.6.2. *Deaths due to cancer as percentage of all deaths according to sex and age group, United States, 1986*

Age	Male (%)	Female (%)
1–14	10.0	11.6
15–34	5.9	14.0
35–54	21.4	41.0
55–74	30.2	34.6
75+	19.2	13.8
Total	22.7	21.8

Table II.6.3. *Most common cancers as causes of death from cancer, according to sex and age group, United States, 1986*

	Male		Female	
Age	Cancer	Percentage	Cancer	Percentage
1–14	Leukemia	37.0	Leukemia	35.6
15–34	Leukemia	18.5	Breast	18.8
35–54	Lung	34.4	Breast	30.8
55–74	Lung	39.2	Lung	23.3
75+	Lung	26.9	Colon and rectum	17.9

rally occurring substances in the body, such as the sex hormone estrogen, have been shown to cause cancer when given to experimental animals.

The extent to which the incidence of cancer is increasing is a complicated issue. It is predominantly an illness of middle age and, with the exception of a few forms, such as certain leukemias, it is relatively rare in children. Thus, people in the developed world, having escaped famine and epidemic disease, have had their life expectancy extended beyond 50 years of age into that age in which the frequency of cancers becomes increasingly high. Although a shift in the age distribution of a population affects the actual incidence of cancer, the statistics have also shown artifactual increases. These are due to vast improvements in the diagnostic techniques of endoscopy, imaging, and biochemistry that can now be used to detect many asymptomatic cancers and pathological techniques that facilitate the differentiation of neoplastic from inflammatory lesions, primary from secondary neoplasms, and so forth.

The following interpretation of the most recent

U.S. cancer statistics offers some quantification of the impact of the disease in relation to age, sex, and race (see Tables II.6.1 through II.6.4). The three most common cancers of men, those arising in the prostate, lung, and colon, comprise about 50 percent of new cases and 55 percent of deaths due to cancer. The three most frequently occurring cancers of women, breast, colon, and lung, also comprise about 50 percent of new cases and account for 50 percent of deaths. As a proportion of all deaths, those from cancer do not increase linearly with age. This is mainly because of the accidental deaths of children and young adults, on the one hand, and cardiovascular diseases in the elderly, on the other. Of deaths from cancer in women, the peak, 41.0 percent, occurs in the 35 to 54 age group. In contrast, men have a somewhat older average age of death with 30.2 percent in the 55 to 74 age group. Most of this difference is attributable to the difference in the age distribution of women with carcinoma of the breast and men with carcinoma of the prostate. Survival has improved variably from the 1960s to the 1980s. The

Table II.6.4. *Five-year survival rates by race in two time periods from principal malignant neoplasms in the United States*

Neoplasm	1960–5		1980–5	
	White	Black	White	Black
Lung	8	5	13	12
Breast (F)	63	46	76	64
Prostate	50	35	73	63
Colon	43	34	55	48
Bladder	53	24	78	56
Uterus	73	31	83	52
Ovary	32	32	38	38
Cervix	58	47	67	59
Rectum	38	27	53	39
Non-Hodgkin's lymphomas	31	?	51	44
Kidney	37	38	52	55
Leukemias	14	?	34	27
Stomach	11	8	16	19
Pancreas	1	1	3	5

Note: Data are percentages.

greatest improvements have occurred in the treatment of stomach cancer in both sexes and in uterine cancer. Of the more common neoplasms, only lung cancer has increased in incidence in both sexes, as has carcinoma of the prostate in men. Survival was below 20 percent for four of the more common neoplasms in the 1960s (leukemias, stomach, lung, pancreas), and save for the leukemias, it remains below 20 percent. The explanation for the decrease in death from stomach cancer lies in a decline in its occurrence, not by a great improvement in therapeutic success. Survival generally has been and remains poorer for black than for white patients. In 1960 white patients had a 42 percent better chance than their black counterparts of survival following treatment of carcinoma of the uterus, a 29 percent better chance with carcinoma of the bladder, and a 17 percent better chance with carcinoma of the breast. In 1980 the greatest race-related survival differences were such that whites had the following better chances than blacks: carcinoma of the bladder, 22 percent; carcinoma of the uterus, 21 percent; and carcinoma of the rectum, 14 percent. These differences have often been attributed to the black population's poorer access to medical care. However, this is obscured by the fact that there do not seem to be race-related differences in survival of other relatively common carcinomas such as those of the lung, kidney, and stomach.

For the incidence of a disease to be considered meaningfully, it must be presented in age-specific terms. As the average age of a population increases and the proportion of an age group in which various cancers most commonly occur becomes larger, an increase in the number of cases is to be expected. This increase, however, can tend to blur the more important question of whether the incidence of that disease is increasing in a specific age group. The statistical analyst must also be cognizant of the impact of technological improvements on the finding of potential cases and the establishment of a diagnosis, as well as changes in interest in the disease in question and changes in access to medical care.

Moreover, the addition to or removal from the environment of a carcinogen is a convenient explanation for the waxing or waning of the occurrence of a cancer. In this regard the long latent period of most clinical cancers is often overlooked. For example, an argument used in the 1940s against the hypothesis that cigarette smoking was a major cause of lung cancer was that many more women were smoking than had previously been the case, yet no increase in lung cancer among women had occurred. Consequently, the relationship between smoking and lung cancer in men was viewed by some to be coincidental rather than causal. But of course, in retrospect we can see that most of the women in question had not yet smoked for a sufficient length of time for the result to become evident in cancer statistics. Perhaps future analysis will clarify in a similar fashion why gastric cancer is decreasing in the United States or why prostate cancer is increasing. Certainly one of the most difficult problems in identifying causes of cancer is that of cocarcinogenesis. The most flagrant example is the additive effect of the inhalation of both cigarette smoke and asbestos particles on the occurrence of lung cancer. Both of these agents are independently carcinogenic, and their combined effect greatly increases the incidence of the disease.

With regard to public health, the greatest problem of exogenous carcinogenesis today is not exposure to industrial pollutants, as many believe, but rather the use of tobacco products. Whereas cigarette smoke appears to exert the most potent carcinogenic effect, cigar smoke and chewing tobacco are also implicated. Historically, the possibility that an increase in lung cancer was related to an increase in cigarette smoking was first raised in Germany in

the 1920s. In the United States interest in this question was stimulated in 1950 with the publication of three epidemiological studies, each of which showed that lung cancer patients were likely to be heavy smokers.

Although an epidemiological association cannot prove a causal relationship, the satisfaction of five criteria make such a connection highly probable: (1) The association between the suspected pathogen and the disease is observed consistently. (2) In comparison with suitable control groups, the association is strong. (3) The association is relatively specific with the disease in question. (4) The temporal relationship between exposure to the pathogen and the onset of the clinical disease is appropriate and consistent. (5) The association is consistent with a known or plausible explanation of the natural history of the disease.

Resistance to the acceptance of a causal relationship between smoking and the development of lung cancer was based initially on doubt that the incidence of lung cancer was actually increasing and then on a failure to appreciate the long preclinical phase of the disease. A massive prospective study of the effects of smoking on health published by E. C. Hammond and D. Horn in 1958 purported to show that smoking was not uniquely associated with lung cancer.

Similarly, the observation that cigarette smoking was associated with neoplasms of organs, such as the bladder, which did not come into contact with smoke, and with cardiovascular diseases was used by proponents of tobacco interests and some biostatisticians to cast doubt on a causal relationship between the inhalation of cigarette smoke and the development of lung cancer. This argument ignored the multiplicity of components of tobacco smoke, which could easily act differently on different tissues, and the clearly quantitative relationship between smoking and the increased probability of lung cancer developing. Nevertheless, lung cancer occurs in a small minority of even heavy smokers. This has been taken to indicate an intrinsic predisposition that, if identified, could be used to warn persons at risk. But investigations have thus far failed to yield useful results. Finally, there have been no reproducible experiments in which tobacco smoke has caused lung cancer in experimental animals. Although positive results would be convincing, negative results are attributable to species differences and, perhaps, insufficient duration of exposure.

Eight prospective studies of male cigarette smokers have shown an excess mortality from lung cancer in comparison with nonsmokers ranging from 3.8 to 14.2 percent (mode 11 percent). In four studies of women the excess was smaller, ranging from 2.0 to 5.0 percent. Despite the fact that no specific sufficiently potent pulmonary carcinogens have as yet been identified in tobacco smoke, a 1970s finding appears to clinch the causal relationship between smoking and the development of lung cancer. R. Doll and R. Peto (1976), in a 20-year investigation of the mortality of British physicians in relation to smoking, showed that the risk diminishes increasingly after smoking has been discontinued for several years. This obviously cannot be ascribed to genetic or psychological factors. However, even 15 years after cessation the risk among former smokers remained twice that of men of similar age who had never smoked.

Smoking has now been common among women long enough to be reflected in an alarming increase in the incidence of lung cancer. This began in the mid-1960s, and the incidence now is half that of men in the United States. As of 1986 the rate of death from lung cancer for U.S. women equaled that for breast cancer, which has remained stable. In the case of the latter disease it appears that, of the half-million women worldwide in whom breast cancer develops annually, half reside in North America and western Europe, which contain less than 20 percent of the world's population. However, it is hazardous to compare prevalence or even mortality statistics without knowing critical local circumstances. For example, why would the age-adjusted rate of death from breast cancer in Finland and Denmark be more than triple the rate in Sweden, and why would the rate in Scotland be quintuple that of England?

A daughter or sister of a woman with breast cancer has a nearly three times greater risk of developing this disease than a woman without such an association. The risk is greater if the relative's cancer was found at an early age, and a great deal more if both mother and sister have been affected. This suggests a genetically mediated predisposition, as does the increased risk of a secondary primary breast cancer as compared with the risk of a first occurrence. However, other observations indicate that environmental factors must also enter in. For example, the prevalence of breast cancer in Japan is about one-fourth that in northern Europe or North America. Nevertheless, among women of Japanese ancestry living in North America, the incidence of breast cancer by the second generation matches that of white North American women. Whether dietary or other potential cofactors are implicated remains unresolved.

Unfortunately, cancer statistics often reveal the complexities of the disease under investigation rather than causal explanations. Carcinoma of the prostate is the second most frequently occurring cancer among U.S. men; it is the fifth worldwide. This disease is more prevalent among U.S. blacks, despite their heterogeneity, than any other population that has been studied. It is about 80 percent more common in black than in white men in the United States. It is also common in black Caribbean populations, whereas sketchy information from Africa indicates much lower prevalences. Carcinoma of the prostate is 28 times as common among blacks in Atlanta as among Japanese in Osaka. Although the incidence appears to be low throughout the Orient, it is much higher among men of Chinese and Japanese extraction living in Hawaii.

The incidence of clinically evident prostate cancer is more highly correlated with increasing age above 50 than is any other neoplasm. It is six to seven times more prevalent in the 75 to 84 than the 55 to 64 age group, and the black–white difference in prevalence diminishes with increasing age. There is no convincing evidence of the pathogenicity of any industrial exposure for this neoplasm. However, an increased risk is associated with chronic cigarette smoking, and there appears to be a correlation between an above-average sexual drive and susceptibility to prostatic carcinoma. This could mean that a subtle alteration in the metabolism of sexual hormones has a predisposing role, but studies have yielded inconsistent results. Alternatively, men with a high sexual drive, particularly in a permissive culture, have an increased likelihood of exposure to multiple sexual partners. A correlation between promiscuity and prostatic carcinoma, if substantiated, would suggest an analogy to the better-documented correlation between promiscuity and carcinoma of the cervix in women and the possibility that a sexually transmitted virus is a pathogenetic agent. None of these hypotheses, however, explains the increase in the occurrence of this disease in the late 1900s.

With regard to possible roles of diet in carcinogenesis there has been particular interest in whether the presence or deficiency of certain components of food influences the development of colorectal cancer. Both diets low in fiber and high in fat have been proposed to be pathogenetic. Investigations have yielded conflicting results, but the best evidence now points to a carcinogenic effect of increased fat consumption, particularly in women. Colorectal cancer has been reported to be up to 10 times as common in central European countries as in tropical countries such as Peru, Ecuador, or Panama, but data from other countries conflict with these extreme examples.

Certainly the Westernizing of the Japanese diet has provided persuasive evidence of the carcinogenic role of fat. Nutrition surveys of 1955 and 1984 indicate that the fat intake of Japanese women increased by about 180 percent during these years and the mortality from colorectal cancer increased by about 130 percent. There was a lag of about 15 years between the beginning of the widespread dietary change and the beginning of the increase in death from this neoplasm. A recent U.S. study has also demonstrated an association between a high level of animal fat consumption and the occurrence of this neoplasm. The predominant hypothesis for this association is that, since a higher fat consumption increases the excretion of bile acids and the growth of colonic bacteria, the opportunity to convert bile acids into carcinogenic substances by bacterial metabolism is facilitated. In the United States the incidence of colorectal cancer has remained stable in white men and has decreased moderately in white women, but has increased in the black population. In addition to changes in incidence, an unexplained pathological change has been occurring: In U.S. patients the lesion is less commonly located in the rectum and more commonly found in the colon. It would be satisfying to conclude that this is a reflection of the increasingly frequent removal of premalignant lesions from the rectum, but medical intervention is an unlikely explanation.

One well-recognized environmental carcinogen is the ultraviolet component of sunlight, which is a major cause of skin cancers. Susceptibility is related to paleness and a poor ability to tan, as well as to chronic exposure to sunlight. The overall incidence of nonmelanoma skin cancers in the white U.S. population is about 165 per 100,000. However, the prevalence in Texas is about three times that in Iowa. The incidence of melanoma is only about 4 per 100,000, but 65 percent of the deaths attributed to skin cancers are caused by this disease. The lesion occurs twice as often on the legs of white women as on those of white men. It occurs nearly twice as frequently on the male trunk than the female trunk. This may reflect relative exposure to sunlight due to differences in clothing. Not only is melanoma uncommon in blacks, but its location tends to be different: It is more commonly found on palms or soles and within the mouth – less heavily pigmented areas. The incidence of melanoma has been found to be increasing wherever statistics have been kept. The highest inci-

dence has been found in Arizona (16 per 100,000), where the disease has more than quadrupled in the brief period from 1969 to 1978. It also quadrupled in Connecticut from 1939 to 1972. The smallest increase has been observed in Sweden: 80 percent from 1957 to 1971. Consistent with the increased incidence, mortality has nearly doubled. Whether the increase of this lethal disease is attributable to changes in ultraviolet intensity due to atmospheric pollution is as yet unknown.

Turning to human cancers definitely attributable to "civilization," X-rays and related ionizing radiation are estimated to be the cause of no more than 3 percent of cancers. Exposure to radon gas has been clearly shown to be a cause of lung cancer in uranium miners. Although this is a small group at risk, if it were confirmed that the concentration of radon in some homes was sufficient to be carcinogenic, presumably the proportion of cases of cancer known to be due to radiation exposure would increase substantially. Thyroid cancer results from a small to moderate radiation exposure to the neck with a latency period of about a decade. A dose that is large enough to destroy the gland leaves no tissue to undergo neoplastic transformation. Bone marrow is another radiosensitive organ. The increased risk of developing leukemia, depending on dosage of radiation, begins as early as 2 years after exposure, reaches a peak probability after 6 to 8 years, and then diminishes. Fetuses and infants are particularly sensitive.

Suspicion of potential carcinogenesis has also fallen on synthetic food additives, such as dyes and flavoring agents, and contaminants, such as pesticides and fertilizers, either from direct spraying or from absorption of affected groundwater. Because of this suspicion, the Delaney amendment to the U.S. Food, Drug and Cosmetic Act was passed in 1958. The amendment requires the banning of food additives if they cause cancer in any species of experimental animal in any dosage. One result has been the forced withdrawal of some products based on quite dubious and unrealistic experiments. In view of the huge number of compounds, both synthetic and natural, to which people are exposed, usually in combinations having unknown interactions, deciding which ones to test and what tests are both relevant and practical is an insoluble problem.

Worldwide, stomach cancer, which has become relatively uncommon in the United States, is the most prevalent visceral cancer (second for men, fourth for women). Nevertheless, death rates have been declining since the 1930s to become only about 35 percent of what they were at that time. The de-

crease has been worldwide and for unexplained reasons. It remains the most prevalent carcinoma in East Asia, with the rate in Japan being more than seven times that in the United States, accounting for one-third of all cancer deaths on those islands. The repetitive ingestion of high concentrations of salt irritates the stomach lining, and this has been proposed as a potential cause of gastric cancer. In fact, the decline in the incidence of this disease has been correlated with the decline in the salt preservation of foods. In regions in which stomach cancer remains common, such as Japan, salted seafood has remained a dietary staple. The incidence of gastric cancer among first-generation immigrants from Japan to the West is similar to that in their communities of origin, but it declines to the incidence of the Western community in which the next generation resides. This suggests that the neoplastic process begins irreversibly during childhood, regardless of relocation or dietary changes after a certain age. Because this is not a genetically determined disease, a generation that has not been exposed to the inducing irritant of salt at a critical age presumably will not suffer inordinately from this neoplasm.

Carcinoma of the cervix appears not to be related to geography, but primarily to the sexual practices in a given region or subculture. The commencement of sexual intercourse during adolescence, multiple partners, or partners who have had numerous partners are all factors associated with an increased risk of developing the disease, as is a large number of pregnancies. Thus, carcinoma of the cervix is rare among nuns and common among prostitutes. A sexually transmitted virus is suspected to be a causative factor or cofactor. As with prostatic cancer, chronic cigarette smoking appears to increase the risk of occurrence of this neoplasm. Another peculiar difference, at least in the United States, is that carcinoma of the cervix occurs about twice as frequently among black as among white women, whereas carcinoma of the uterus occurs two to four times as often in white women.

Cancer of the liver is much more prevalent in many of the developing countries than in the industrialized world. Its incidence is highest in sub-Saharan Africa, China, southern Asia, and Japan (the exception among industrialized countries). China alone accounts for about 45 percent of the world's cases. The liver is subject to two principal types of cancer. One originates in liver cells, and a history of infection with the hepatitis B virus predisposes to this. The other originates in cells of the bile ducts. A predisposition to develop this form of cancer

is caused by infestation with the liver fluke *Clonorchis sinensis* and related parasites. The geographic distribution of these parasites is reflected in the prevalence of this disease. Alcoholism has not been shown to be a major predisposing factor.

Other cancers in the developing world are associated with indigenous infectious agents and with cultural practices. Betel nut chewing, for example, is linked with high rates of oral cancer in central and southeast Asia and Kashmir; Bantu natives, who hold warming pans of charcoal against their bodies, are subject to cancers of the abdominal wall. The frequent occurrence of esophageal cancer has been related to the consumption of very hot beverages in some cultures. Burkitt's lymphoma, which occurs almost exclusively in central Africa and New Guinea, is probably caused by the Epstein–Barr virus in genetically predisposed individuals. Bladder cancer is a common problem in North Africa, and especially Egypt, because infestation with the parasite *Schistosoma haematobium* induces the disease.

In summary, the concept of cancer has evolved through the ages from that of a single disease to one of many diseases with many causes. Most prevalent are carcinomas of the stomach, lungs, breast, cervix, colon and rectum, prostate, and liver. Chief among carcinogens are irritants such as fumes of tobacco and certain metals, ionizing and ultraviolet radiation, specific chemical compounds, some helminthic parasites, and possibly viruses. Everyone is constantly bombarded by carcinogens of various potencies, but cancer develops in a minority of people. A few uncommon neoplasms clearly are genetically determined, but the degree of resistance to carcinogens also appears to have a genetic basis.

Yet even if cancer is viewed as multiple diseases with multiple causes, each disease involves the same phenomenon: an inadequately controlled division and multiplication of cells that can infiltrate adjacent tissues and, in many types, form distant secondary lesions. The factors that permit metastatic tumor cells to survive and implant remain just as mysterious as the factors that initiate the loss of control of cell division.

The available treatments are generally drastic and poorly selective of the foci of disease and, in many circumstances, not curative. Earlier diagnosis improves the cure rate of many but not all cancers. Therefore, public education about the signs of cancer and further improvements in the sensitivity of diagnostic methods should be sought. However, until our understanding of the fundamental biology of cancer improves, preventive measures, such as minimizing exposure to known carcinogens, will exert by far the greatest benefit to public health.

PART III

Medical Specialties and Disease Prevention

III.1
Genetic Disease

The idea that a particular physical feature, either normal or abnormal, is hereditary is probably as old as our species itself. However, as has been noted by many other writers, tracing the origins of an idea is a formidable, if not impossible, task. Clearly, the concept of "like begets like" found a practical expression in the early domestication of animals; breeding stock was chosen on the basis of favorable traits. The first tangible evidence that human beings had at least a glimmer of the notion of heredity can be found in the domestication of the dog some 10,000 years ago. Yet it is only in the past 100 years that we have begun to understand the workings of heredity.

This essay traces the development of the concept of heredity and, in particular, shows how that development has shed light on the host of hereditary and genetic diseases we have come to recognize in humans. It begins with a brief discussion of some basic concepts and terms, which is followed by an outline of the heuristic model of genetic transmission that has come to be the standard of modern medical genetics. Once this groundwork is in place, the history of the study of human genetic disease is developed from the earliest records, through the birth of medical genetics, to the molecular era. Naturally, a detailed narrative of this history would require several volumes. Therefore, some events and ideas have been omitted or treated only cursorily.

The most recent development in the study of human genetic diseases is traced through three specific examples. Each of these represents a microcosm of the development of medical genetics. Our understanding of the first of them, sickle cell anemia, represents a triumph of the molecular model of human disease. The discovery of the second, Down syndrome, reveals the role in medical genetics of the cytogeneticist, who studies chromosomes. The third, kuru, exemplifies a case in which the expectations of modern medical genetics led initially to an erroneous conclusion, although that failure led eventually to spectacular new knowledge. This essay closes with a brief assessment of the future development of medical genetics in the molecular era.

Some Operational Definitions

More often than not, when the term *hereditary* is applied to a particular trait, the natural inclination is to equate it with the term *genetic*. However, *hereditary* refers only to the sustained passage of a trait from generation to generation. Surnames, property, and titles may be hereditary by law or custom, but they are not genetic. We may regard a hereditary trait as genetic only when the passage of that trait from generation to generation is determined, at least in part, by one or more *genes*. In much the same way, the term *congenital* has often been equated with *genetic* when, in fact, this term signifies only that a trait is present at birth. A congenital trait is not necessarily genetic or even hereditary. Thus, the purview of medical genetics may be said to include those traits, both congenital and of delayed onset, whose origins lie in defects in single genes, in groups of genes, or in the size or number of the chromosomes.

A useful checklist for assessing whether a trait is genetically determined was provided by J. V. Neel and W. J. Schull (1954). A trait is genetically determined by the following:

1. It occurs *in definite proportions* among persons related by descent, when environmental causes have been ruled out.
2. It fails to appear in unrelated lines such as those of in-laws.
3. It displays a characteristic age of onset and course of development, in the absence of other known causes.
4. It shows greater concordance in monozygous (identical) twins than in dizygous (fraternal) twins.

When the role of chromosomal anomalies became fully appreciated in the 1960s, a fifth item was added to the checklist:

5. It consists of a characteristic suite of features (syndrome) coupled with a clearly demonstrated chromosomal abnormality (Thompson and Thompson 1980).

In the present era of molecular biology and recombinant DNA technology we must add yet another item to the list:

6. It is linked to a specific DNA sequence (probe) that has been mapped to a particular region of a chromosome.

Throughout the following discussions, traits that are regarded as genetic but not chromosomal, having met criteria 1 through 4 and 6 but not 5, are accompanied by a reference number. This number is

the entry number of a given disorder in the catalog complied by V. A. McKusick (1986) of more than 3,000 Mendelian phenotypes in human beings. For example, the entry number for sickle cell anemia is 14190. An excellent reference for chromosomal conditions is E. Thurman (1986).

Models of Genetic Transmission

In recent years, medical geneticists have been supplied with a battery of sophisticated analytic tools to be used in conjunction with advanced laboratory techniques for determining the transmission of various traits. These analytic methods have been derived from what is now called the multifactorial (or mixed) model (see Morton 1982). According to this model the observed variation in a trait, such as the clinical presentation of a genetic disease or the liability to develop a complex disorder like heart disease, is determined by the joint effects of major gene loci and a background composed of multiple minor loci (a polygenic effect) and a nongenetic component (an environmental effect). A graphic representation of the multifactorial model is shown in Figure III.1.1. The most important difference between this model and earlier ones is that the nongenetic component is regarded as transmissible, as are genetic effects.

The impact of this model has been twofold. First, it has provided a theoretical underpinning for the field of genetic epidemiology (Morton and Chung 1978;
Figure III.1.1. Mixed model of liability for complex human disease. The abscissa reflects an arbitrary liability scale in which the left-most point is low risk and the right-most is high risk. Z is a threshold beyond which (shaded area) individuals will develop the disease in question. The effects of a single major locus are indicated by the frequency distributions of the alleles: $AA = (1 - q^2)$, $Aa = 2q (1 - q)$, and $aa = q^2$, where a is taken to be the disease gene. The presence of AA and Aa individuals beyond Z indicates the further effects of the multifactorial background, including nongenetic effects. The value u is the mean population liability, t the deviation in mean genotype-specific liability, and d the degree of dominance at the locus. (From Comings et al. 1984, with permission from the *American Journal of Human Genetics*.)

Morton 1982). Second, it has become a heuristic device through which clinical variation in the presentation of a disease can be assessed. After spending more than half a century studying the inheritance of complex traits, Sewall Wright (1968) concluded that there is a network of effects leading from the gene to the final outward manifestation, the *phenotype,* and that a number of basic generalizations can be made:

1. The variations of most characters are affected by a great many loci (the multiple-factor hypothesis).
2. In general, each gene replacement has effects on many characters (the principle of universal pleiotropy).
3. Each of the innumerable alleles at any locus has a unique array of differential effects in taking account of pleiotropy (uniqueness of alleles).
4. The dominance relation of two alleles is not an attribute of the alleles but of the whole genome and the environment. Dominance may differ for each pleiotropic effect and is in general easily modified (relativity of dominance).
5. The effects of multiple loci on a character in general involve much nonadditive interaction (universality of interaction effects).
6. Both ontogenetic homology and phylogenetic homology depend on calling into play similar chains of gene-controlled reactions under similar developmental conditions (homology).
7. The contributions of measurable characters to overall selective value usually involve interaction effects of the most extreme sort because of the usually intermediate position of the optimum grade, a situation that implies the existence of innumerable selective peaks (multiple selective peaks).

From this perspective one must say that no gene responsible for a human genetic disease exists in a developmental vacuum. It exists in a milieu composed of its own locus, its chromosomal position and close neighbors, the various effects of other genes elsewhere in the genome, the inter- and intracellular environment, and the external environment, both intra- and extrauterine, in which it ultimately finds expression. However, the mechanisms by which this multitude of effects operates are only just being discovered. This phase of the history of genetic disease has yet to be written.

History of the Study of Genetic Disease: From the Greeks to Garrod

As already stated, the idea that the features of parents could be transmitted to their offspring was ap-

plied very early in human history in the domestication of animals. Some of the knowledge of "good inheritance," the transmission of favorable features, undoubtedly came from observations of "bad inheritance." Thus, for some 10,000 years we have been aware to a greater or lesser degree that certain malformations and diseases are hereditary, if not genetic. However, only from the written records of ancestors can we reliably assess the state of their awareness regarding heredity.

Early History

By the time of the Greeks, ample evidence already existed that people were cognizant of heredity, both good and bad. Moreover, many Greek scholars speculated as to the mechanism of heredity. Nearly all of them had a theory of vertical transmission, but the theory promoted by Hippocrates survived until the Renaissance. Writing in the fourth century B.C., Hippocrates put forth the idea that each organ and tissue produced, in its turn, a specific component of semen. This composite semen was then transmitted to the woman through coitus, whereupon it incubated to become a human baby. This, of course, included the good *and* the bad:

... of the semen, however, I assert that it is secreted by the whole body – by the solid as well as by the smooth parts, and by the entire humid matters of the body. . . . The semen is produced by the whole body, healthy by healthy parts, sick by sick parts. Hence when as a rule, baldheaded beget baldheaded, blue-eyed beget blue-eyed, and squinting, squinting; and when for other maladies, the same law prevails, what should hinder that longheaded are begotten by longheaded. (Hippocrates in Vogel and Motulsky 1979)

Note that in this single passage Hippocrates accounts for the inheritance not only of desirable traits but of the abnormal and undesirable as well, and by the same mechanism. So powerful was the idea of heredity among the Greeks that many scholars felt the need to warn against unfavorable unions. Thus did the sixth-century B.C. scholar Theognis lament:

We seek well bred rams and sheep and horses and one wishes to breed from these. Yet a good man is willing to marry an evil wife, if she bring him wealth: nor does a woman refuse to marry an evil husband who is rich. For men reverence money, and the good marry the evil, and the evil the good. Wealth has confounded the race. (Theognis in Roper 1913)

Clearly, Theognis believed that marriage for the sake of money would cause the race to sink into mediocrity and greed.

The traits commented on by the Greeks when dis-cussing heredity were usually abstract qualities such as good and evil or desirable normal characteristics such as eye color, strength, speed, and beauty. Of course, they also took notice of the shocking and fantastic, gross malformations, or severe illness. Empedocles suggested in the fifth century B.C. that the cause of *monsters,* as grossly malformed infants came to be called, was an excess or deficit of semen. Many other writers held similar views, which presumably became part of the hereditary theory of Hippocrates. The treatment of infants with abnormalities was roughly the same everywhere in the ancient world. They either were left to die or were killed outright. Often, the mother suffered the same fate as her offspring. The practice of destroying abnormal infants was advocated by Hippocrates, Plato, Aristotle, and virtually all others whose works on the subject have survived. Yet the practice was not universal, as evidenced by the mummy of an anencephalic (20650) infant at Hermopolis. The archaeological evidence suggests that this baby, who would have been stillborn or died shortly after birth, was an object of worship (Glenister 1964).

The physical, mechanistic interpretation of the causes of birth defects was modified by the somewhat more mystical Roman frame of mind. In the first century A.D., Pliny the Elder wrote that mental impressions resulting from gazing on likenesses of the gods during pregnancy were sufficient to produce monsters. Indeed, the root of the word *monster* is the Latin word *monere,* "to warn." Thus, such children were regarded as warnings from the gods transmitted to pregnant women. J. W. Ballantyne (1902) related the circumstances of a black queen of ancient Ethiopia who presented her husband, the black king, with a white child. It was concluded that the queen had gazed on a white statue of the goddess Andromeda during the early stages of her pregnancy. The description of the white infant, however, leads one to suspect that it was an albino (20310), particularly given the propensity for royalty to marry close relatives.

The decline of reason that marked the Middle Ages was reflected in interpretations of the birth of malformed infants. T. W. Glenister (1964) notes that such children were called "Devil's brats" and were generally believed to have been conceived in a union with Satan. As was the case with any perceived deviation from piety, the fate of both infant and mother was quickly and ruthlessly determined. Late in the Middle Ages, however, the rise of astrology sometimes made for surprising outcomes. For example, when in the beginning of the thirteenth century

a deformed calf said to be half human in its appearance was born, the cowherd was immediately accused of having committed an unnatural act, the punishment for which was burning at the stake (Glenister 1964). Fortunately for the cowherd it was pointed out that a particular conjunction of the planets had recently occurred, a conjunction that was often the cause of oddities of nature. The cowherd's life was spared.

As the Renaissance dawned, reason returned to the writing of discourses on heredity and failed heredity. Scholarly works of the classical era were rediscovered, and the development of a science of heredity was once again underway. A curious episode occurred a few years after the death of Leonardo da Vinci in 1519. A half-brother of Leonardo conducted an experiment in an attempt to produce a second Leonardo. The half-brother, Bartolommeo, who was 45 years younger than the great artist and scholar, tried to recreate the exact circumstances of Leonardo's birth. Leonardo was the illegitimate son of Fiero, a notary of Vinci, and a peasant girl of the same city named Caterina. Bartolommeo, a notary by trade, moved to Vinci, whereupon he sought out a peasant girl much like Caterina. He found one and married her, and she bore him a son, whom they named Piero. One author notes the following:

Bartolommeo had scarcely known his brother whose spiritual heir he had wanted thus to produce and, by all accounts, he almost did. The boy looked liked Leonardo, and was brought up with all the encouragement to follow his footsteps. Pierino da Vinci, this experiment in heredity, became an artist and, especially, a sculptor of some talent. He died young. (Ritchie-Calder in Plomin et al. 1980)

As the foregoing passage indicates, the Rennaisance saw a revival of the principles of heredity. The writings of Hippocrates and Aristotle were translated and amplified by medical scholars such as Fabricius ab Aquapendente and his pupil William Harvey. In addition, there was a growing interest in rare and unusual medical cases. Weeks before his death in 1657, William Harvey wrote a letter of reply to a Dutch physician's inquiry about an unusual case in which he counseled, "Nature is nowhere accustomed more openly to display her secret mysteries than in cases where she shows traces of her workings apart from the beaten path" (in Garrod 1928).

For Harvey and others, rare pathology was not a source of revulsion or the workings of Satan but, rather, a subject demanding study and understanding. In 1882, Sir James Paget made a similar appeal on behalf of the study of rare disorders: "We ought not to set them aside with ideal thoughts and idle words about 'curiosities' or 'chances.' Not one of them is without meaning; not one that might not become the beginning of excellent knowledge." He went on to speak of new diseases that "are due mainly to morbid conditions changing and combining in transmission from parents to offspring."

The debt owed to scholars such as Harvey was acknowledged in the twentieth century, when medical genetics was coming into full bloom. Archibald Garrod, the father of human biochemical genetics, of whom we will hear more, paid homage to his intellectual ancestor: "It is rather, as Harvey saw so clearly, because we find in rare diseases the keys to note a few dark places of physiology and pathology, that I recommend them to you as objects of study" (Garrod 1928).

The Forgotten Origins of Medical Genetics

With the Enlightenment the floodgates to inquiry were opened for medical scientists and progress was made on nearly all fronts in understanding pathology. However, in spite of eloquent writings on heredity in general and on rare cases in particular, few references to specific genetic diseases were made before the twentieth century. Yet among those few instances are to be found brilliant insights.

Between 1745 and 1757 the French natural philosopher Pierre Louis Moreau de Maupertuis conducted studies on the heredity of polydactyly (the condition of having more than the normal number of fingers and/or toes; 26345). Maupertuis published a four-generation pedigree of polydactyly and commented, "That peculiarity of the supernumerary digits is found in the human species, extends to the entire breeds [races]; and there one sees that it is equally transmitted by the fathers and by the mothers" (Glass 1947).

He based his theory of heredity on these studies and suggested that *particles* of inheritance were *paired* in the "semens" of the father and the mother and that "there could be ... arrangements so tenacious that from the first generation they dominate" (Glass 1947). This led him to suggest that hereditary pathologies were accidental products of the semen. In other words, he correctly predicted genes, dominance, and mutation. In addition, he estimated the probability of polydactyly at 1 per 20,000 by his own survey and noted that the chance of a joint occurrence of an affected parent and an affected offspring was 1 per 400,000,000 and that of an affected grandparent, parent, and offspring in sequence was 1 per

8,000,000,000,000 if the disorder was not hereditary. This made the probability of his four-generation family being chance so small as to be immediately dismissed. Here, then, was also the first use of statistics in a study of heredity.

Various sex-linked, or X-linked, disorders such as color blindness (30370) and hemophilia (30670) were accurately described in the late eighteenth and early nineteenth centuries. A German physician and professor of medicine, Christian F. Nasse, presented in 1820 a detailed pedigree of X-linked, recessive hemophilia and noted:

All reports on families, in which a hereditary tendency toward bleeding was found, are in agreement that bleeders are persons of male sex only in every case. . . . The women from those families transmit this tendency from their fathers to their children, even when they are married to husbands from other families who are not afflicted with this tendency. This tendency never manifests itself in women. (Vogel and Motulsky 1979)

Perhaps the most remarkable instance before the work of Gregor Johann Mendel (which although published in 1866 had to await rediscovery until the beginning of the twentieth century) was an 1814 publication by British physician Joseph Adams (Motulsky 1959). In this study, the author drew a distinction between familial diseases, which he considered to be confined to a single generation, and hereditary diseases, which he noted were passed on from generation to generation. Moreover, Adams defined congenital disorders as ones appearing at birth and regarded them to be more likely familial than hereditary. He observed that familial inherited diseases were often very severe, so much so that subsequent transmission from the affected individual was ruled out by early death. These conditions increased among the offspring because of mating between close relatives and were often to be seen in isolated districts where inbreeding was common. Clearly, from a modern perspective, Adams's familial diseases were what we term recessive and his hereditary diseases were what we term dominant.

Adams also concluded that hereditary diseases (in the modern sense) were not always to be found at birth but might have later ages of onset, that correlations existed among family members with regard to the clinical features of a hereditary disease, and that hereditary diseases might be treatable. Adams hinted at the phenomenon of mutation when he remarked that a severe disease would last only a single generation were it not for the fact that normal parents occasionally produced offspring in whom the disease originated. Finally, he called for the establishment of hereditary disease registers that could be used for the study of these diseases: "That to lessen anxiety, as well as from a regard to the moral principle, family peculiarities, instead of being carefully concealed, should be accurately traced and faithfully recorded" (Adams 1814, in Motulsky 1959).

The Impact of Mendelism

The story of the discovery of the basic hereditary laws of segregation and independent assortment by the Austrian monk Mendel and of their subsequent independent rediscovery by Carl Correns, Hugo de Vries, and Erich von Tschermak some 35 years later has been told many times (e.g., Olby 1966; Stern and Sherwood 1966). Mendel, conducting experiments in hybridization with the common garden pea, *Pisum sativum*, in his garden at the Augustinian monastery in Brno, Czechoslovakia, demonstrated that alternative hereditary "characters" for a single trait segregated from one another each generation and that the characters for multiple traits assorted independently in each generation. Moreover, the observed distribution of characters for multiple traits followed a precise mathematical formulation – a binomial series. Mendel reported his results to the Natural Science Association of Brno in 1865. His written report was published the following year, but almost no attention was paid to it until 1899.

By that time, however, numerous investigators were pursuing experiments in heredity, and many of them had chosen simple plants as their experimental systems. Professor Hugo de Vries, a Dutch botanist, studying hybridization, came upon a reprint of Mendel's report, where he found the solution to the problems he had been working on. Thus, while he had independently derived his own formulation of the law of segregation, he reported the Mendelian results as well and stressed their importance in a 1900 publication (Olby 1966). At the same time, both the German botanist Correns and the Austrian botanist von Tschermak independently discovered the Mendelian laws and recognized their significance. All three published translations of Mendel's paper and commented on the laws therein. That these papers opened the new field of genetics and put it on a sound analytic footing from the outset is undeniable. However, as we will see, the translation by de Vries had an almost immediate impact on the study of human genetic disease.

The English biologist William Bateson was also interested in plant hybridization. However, his inter-

est stemmed from the fact that, as an ardent advocate of evolution, he was unable to reconcile his belief that hereditary variation was discontinuous with the Darwinian model of evolution through selection on continuous variation. Bateson thus had spent years searching for a mechanism for discontinuous traits (Carlson 1966). Then in 1900 he read de Vries's account of Mendel's experiments. As E. A. Carlson (1966) notes, Bateson called the moment when he recognized the importance of Mendel's work "one of the half dozen most emotional moments of his life." In Mendel's work, Bateson believed he had found the mechanism for discontinuous variation for which he had searched. Shortly after this time, Bateson mistakenly championed Mendelism as an alternative to Darwinism, a position that haunted him the rest of his life (Sturtevant 1966). In 1901, however, Bateson, as we shall see, made an almost offhand comment that turned out to be a fundamental contribution to the study of human genetic diseases.

In 1897 Sir Archibald E. Garrod, a member of the staff of London's St. Bartholemew's Hospital, came upon and was intrigued by a case of alkaptonuria (20350). Alkaptonuria is a nonfatal disorder, present at birth, that is characterized by the excretion of homogentisic acid in the urine, which turns the urine dark upon standing. The disorder is often accompanied in later years by arthritis and a black pigmentation of cartilage and collagenous tissues. At the time that Garrod was diagnosing his first case of alkaptonuria it was believed that the condition was infectious and that the excretion of homogentisic acid was the result of bacterial action in the intestine. Garrod, however, refused to accept this view, believing instead that the condition was a form of abnormal metabolism (Harris 1963). He published this theory in 1899 along with the contention that the error of metabolism was congenital (Garrod 1899).

Less than a year later Garrod made what would prove to be his crucial observation. He noted that, among four families in which all alkaptonuric offspring had two unaffected parents, three of the parental pairs were first cousins. In 1901 he wrote in the *Lancet:*

The children of first cousins form so small a section of the community, and the number of alkaptonuric persons is so very small, that the association in no less than three out of four families can hardly be ascribed to chance, and further evidence bearing upon this point would be of great interest.

This circumstance would hardly have surprised Garrod's fellow countryman and physician Joseph

Adams, who, it should be remembered, had made a similar observation about inbreeding nearly 90 years earlier. William Bateson read the paper and discussed its conclusions with Garrod. Bateson recognized that the pathology was discontinuous, all or none, affected or normal. Moreover, the high incidence of consanguinity and the characteristic familial pattern of normal, consanguineous parents having affected offspring were precisely what would be expected were the abnormality determined by a rare, recessive Mendelian character. Bateson commented on the case in a footnote in a 1902 report to the Evolution Committee of the Royal Society with E. R. Saunders:

Now there may be other accounts possible, but we note that the mating of first cousins gives exactly the conditions most likely to enable a rare and usually unseen recessive character to show itself... first cousins will frequently be bearers of *similar* gametes, which may in such unions meet each other, and thus lead to the manifestation of the peculiar recessive characters in the zygote.

In Bateson's interpretation of the situation, Garrod saw the solution to the problem of alkaptonuria. Garrod published the landmark paper "The Incidence of Alkaptonuria: A Study in Chemical Individuality" in 1902, adding further clinical data and incorporating the hereditary mechanism proposed by Bateson. Therein he reported on nine families of alkaptonuries and noted:

It will be noticed that among the families of parents who do not themselves exhibit the anomaly a proportion corresponding to 60 per cent are the offspring of marriages of first cousins.

However, he continued:

There is no reason to suppose that mere consanguinity of parents can originate such a condition as alkaptonuria in their offspring, and we must, rather seek an explanation in some peculiarity of the parents, which may remain latent for generations, but which has the best chance of asserting itself in the offspring of the union of two members of a family in which it is transmitted.

Garrod (1902) suggested that the laws of heredity discovered by Mendel and relayed to him by Bateson offered an explanation of the disorder as an example of a Mendelian recessive character and, thus,

there seems to be little room for doubt that the peculiarities of the incidence of alkaptonuria and of conditions which appear in a similar way are best explained by supposing that... a peculiarity of the gametes of both parents is necessary.

Here Garrod had already gone beyond alkaptonuria to include the possibility of other disorders sharing the same hereditary mechanism. Indeed, Garrod did go on to study cystinuria (22010), albinism (20310), and pentosuria (26080) and to put them all in the same class with alkaptonuria.

In 1908 Garrod delivered the Croonian Lectures to the Royal College of Physicians. To these lectures, and to the four disorders on which they were based, Garrod gave the name "Inborn Errors of Metabolism." The impact of Mendelism was fully felt by then, and there were few who doubted that these and other diseases were due to Mendelian characters. Garrod then went on to the next stage of the study of inborn errors, by noting in the case of alkaptonuria that

we may further conceive that the splitting of the benzene ring in normal metabolism is the work of a special enzyme, that in congenital alkaptonuria this enzyme is wanting, whilst in disease its working may be partially or even completely inhibited.

He was suggesting that the pathology of inborn errors of metabolism consisted of a blockade at some point in the normal pathway and that this blockade was caused by the congenital deficiency or absence of a specific enzyme (Harris 1963). The truth of his insight is evidenced by the metabolic pathways shown in Figure III.1.2. Clearly, Garrod believed that these deficiencies were transmitted as Mendelian characters, or determinants, and that the study of the families, particularly those in which inbreeding was known or suspected, was crucial to obtaining new insights into old disease entities.

The principal tenet of inborn errors of metabolism, that transmitted enzymic defects cause disease, eventually led to the "one gene–one enzyme" hypothesis (Beadle 1945) and to the theory of gene action. In 1950 G. W. Beadle called Garrod the "father of chemical genetics" (Harris 1963).

Figure III.1.2. A representation of metabolic pathways involving the amino acid tyrosine. These pathways are linked to no fewer than six genetic diseases of the type envisioned by Garrod. (A) A defect in the gene coding for phenylalanine-4-hydroxylase results in the recessive disorder phenylketonuria (26160). (B) A defect in the gene coding for tyrosine transaminase results in the rare disease tyrosinosis (27680), whereas a defect at the next step involving 4-hydroxyphenylpyruvic acid hydroxylase leads to the much more serious disorder tyrosinemia (27660). (C) The metabolic lesion suggested by Garrod for alkaptonuria is in fact a defect in the gene coding for homogentisic acid oxygenase. (D) A form of goitrous cretinism (27470) is caused when there is a lesion involving the enzyme tyrosine peroxidase. (E) Another of Garrod's original defects, albinism, arises when the gene for tyrosine-3-hydroxylase is defective. To date, more than 500 such disorders are known to exist in humans. Some are vanishingly rare, but others, such as phenylketonuria, are quite common (From McKusick 1986).

The Modern Era of Medical Genetics: Three Examples of "Excellent Knowledge"

From our contemporary perspective, the work and insights of Garrod are landmarks. There can be no doubt that the incorporation of the Mendelian laws of heredity into the study of human diseases was the turning point in the history of medical genetics. Surprisingly, however, Garrod's theories and suggestions went largely unnoticed for several decades. One reason for this slow recognition, according to H. Harris (1963), was that it was quite impossible at

the time Garrod was writing for most geneticists to reduce Mendel's laws to purely chemical phenomena. Indeed, in the earliest days of the rediscovery of Mendel much of the effort being expended in formal genetics was devoted to coming to terms with a growing list of exceptions to those laws (Carlson 1966).

This is not to say that medical genetics had been put on hold until the middle of the twentieth century. In fact, progress in understanding the hereditary nature of numerous human diseases was being made, but it did not truly come together until the

middle of this century. Two disorders that contributed greatly to this progress were sickle-cell anemia and Down syndrome.

The Triumph of the Molecular Model: Sickle-Cell Anemia

G. J. Brewer (1985) has commented that sickle cell anemia (14190) is one of the most fascinating diseases in medicine. And this one disease may be credited with having ushered in the era of molecular medicine.

The first case of sickle-cell anemia was reported in 1910 by a Chicago physician, J. B. Herrick. Upon his examination of a young black man from Grenada, West Indies, he found, among other features, "a secondary anemia not remarkable for the great reduction in red corpuscles or hemoglobin, but strikingly atypical in the large number of nucleated red corpuscles of the normoblastic type and in the tendency of the erythrocytes to assume a slender sickle-like shape" (Herrick 1910). Herrick had never before encountered a similar abnormality and reported:

Whether the blood picture represents merely a freakish poikilocytosis or is dependent on some peculiar physical or chemical condition of the blood, or is characteristic of some particular disease, I cannot at present answer. I report some details that may seem non-essential, thinking that if a similar blood condition is found in some other case a comparison of clinical conditions may help in solving the problem. (Herrick 1910)

Soon after, a similar case was reported, and within a very few years, the first fully scientific investigation of the sickling phenomenon was described. That study, published in 1917 by V. E. Emmel, was based on the case of a young black woman in St. Louis. The patient had an ulceration on her leg and severe anemia, and "instead of the typical rounded disk form, about one-third of the corpuscles are greatly elongated in shape. A large percentage of the latter have a rounded, rod-like shape with more or less tapered ends, and as a rule present a curved or crescentic form" (Emmel 1917). Emmel was the first to show that the sickling of the red cells was developmental, with seemingly normal, enucleate red cells undergoing the sickling change as they matured. He further showed that none of the red cells from controls or from any other type of anemia or leukemia could be induced to sickle. However, Emmel did find that a small proportion of the red cells from the patient's father, who was not anemic, did undergo sickling in cell culture conditions.

Curiously, even though the father of the patient

showed traces of the sickling trait and three of the patient's siblings had died at an early age of severe anemia, Emmel made no reference to a possible hereditary component in the disorder. The first such suggestion was offered six years later by J. G. Huck (1923). In addition to reporting the first large clinical sample, 17 patients, Huck displayed the pedigrees of two sickle-cell families. In one of these families, *both* parents were affected but had produced one normal offspring in addition to two affected offspring. The significance of these families was noted: "Apparently the 'sickle cell' condition in man is inherited according to the Mendelian law for the inheritance of a single factor." Moreover, "one interesting feature of this inheritance is the fact that the sickle cell condition is dominant over the normal condition" (Huck 1923). Over the course of 13 years, reports of a unique pathological finding had led to the recognition of a hereditary disease – sickle-cell anemia.

After this good start, the study of sickle-cell anemia slowed dramatically – partly because most investigators failed to recognize a fundamental difference between sickle-cell anemia and the nonanemic sickle-cell trait. Most believed that the latter was merely the dormant stage of the former. In 1933 L. W. Diggs and his colleagues suggested that this interpretation was incorrect. They showed that the percentages of hemoglobin determinations among black schoolchildren with the sickle-cell trait were not different from those of controls. In addition, no significant pathology appeared to be associated with the sickle-cell trait. Clearly this meant that "the importance of the sickle cell trait appears to be limited to the relatively small grooup who in addition to the trait have sickle cell anemia" (Diggs et al. 1933).

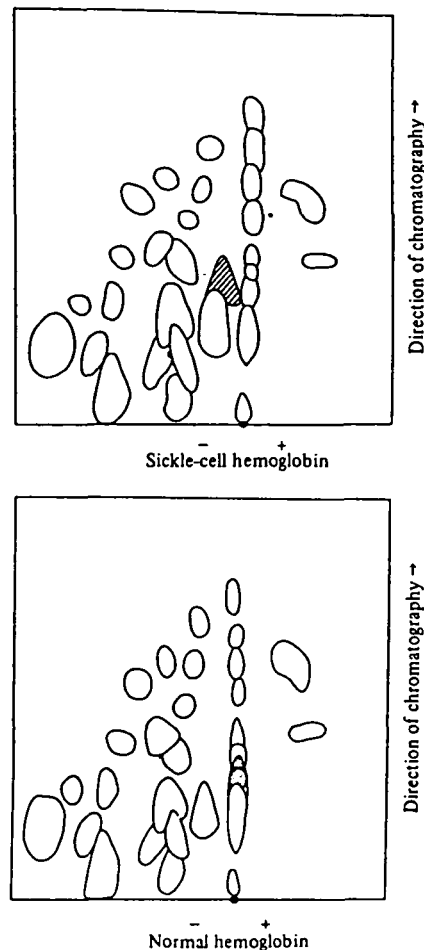
As the distinction between the trait and the anemia became fully accepted, the pace of research on sickle-cell anemia quickened, and in 1949 two milestones were reached almost simultaneously. First, two investigators independently discovered the correct mechanism of inheritance of the trait and the anemia. One of these, a medical officer serving in what was then Rhodesia, compiled several large Bantu pedigrees of the sickle-cell trait. In one he observed two affected parents having a child with sickle-cell anemia. From his studies he concluded that the sickle-cell trait appears as a heterozygote with the normal allele, whereas sickle-cell anemia is the homozygous state of the sickle-cell gene, meaning that it must be inherited from both parents (Beet 1949).

Second, J. V. Neel (1949) reported precisely the same conclusion based on a more statistical analy-

sis. These findings led to the recognition that the vast majority of dominant genetic diseases are heterozygous. The first report on the implications of an altered molecule in the pathogenesis of a human disease should probably be credited to M. Hoerlin and G. Weber, a German physician and a medical student, respectively, who wrote in 1947 that the condition known as methemoglobinemia (14170) was due to a "variant of the globin component of the hemoglobin molecule" (Heller 1969). However, the report that is celebrated is that of L. Pauling and colleagues (1949). Through a set of meticulous experiments they were able to show that the hemoglobin molecules in individuals with sickle-cell anemia and those in normal controls were fundamentally different but, "having found that the electrophoretic mobilities of sickle-cell hemoglobin and normal hemoglobin differ, we are left with the considerable problem of locating the cause of the difference" (Pauling et al. 1949).

They predicted that the abnormality would be found in the globin part of the molecule and not in the heme groups, that the sickling process involved abnormal interactions of altered molecules, and that the alteration resulted in two to four more net positive charges per molecule. Their predictions, we know, were all correct, as was shown by V. M. Ingram in 1956. Denatured sickle-cell hemoglobin (HbS), digested with trypsin, was compared with normal hemoglobin (HbA) after sequential electrophoresis and partition chromatography (Figure III.1.3). The abnormal HbS differed in only one "spot" on the filter, which had a net positive charge. Within three years it was demonstrated that the charge was caused by the alteration of a single amino acid through a mutation (Ingram 1959).

Since the moment the puzzle of sickle-cell anemia was solved, the study of mutant globins and their associated disorders has signaled nearly every major advance in molecular biology. In 1978 R. M. Lawn and colleagues and Y. W. Kan and A. M. Dozy independently demonstrated the first human restriction fragment length polymorphisms (RFLPs) in the region of the beta-chain of the hemoglobin molecule. This led to the explosion of recombinant-DNA-based studies on human genetic diseases as well as human gene mapping (Willard et al. 1985). The discovery of highly repetitive DNA sequences in globin genes has resulted in the development of the hypervariable "minisatellite" and VNTR (variable number of tandem repeat) DNA probes (Jeffreys et al. 1985, 1986; Nakamura et al. 1987). In addition, the use of other recombinant DNA techniques in the molecular

Sickle-cell hemoglobin


Normal hemoglobin

Figure III.1.3. The original two-dimensional chromatographic spreads of normal and sickle-cell hemoglobins. The different "spot" having a net positive charge is seen to have moved further left in the electrophoretic field, toward the negative pole. The alteration in the pattern represents the substitution of the amino acid valine for glutamic acid. (From Ingram 1956, with permission; copyright 1956 by Macmillan Journals Limited.)

diagnosis of genetic diseases was pioneered with HbS by Kan and Dozy (1978) and is now being applied to a wide range of disorders, including cancer and acquired infectious diseases (Caskey 1987).

The Arrival of Cytogenetics: Down Syndrome
The chromosome theory of heredity, that the Mendelian characters were contained in the chromosomes, developed soon after the rediscovery of Mendel's laws and was in large measure a direct result of the precision of Mendel's own experimental observations. W. S. Sutton had observed a very high degree of organization of the chromosomes of the orthopteran genus *Brachystola*. He concluded that the parallels between the organization and behavior of the

chromosomes and the laws of segregation and independent assortment could not be due to chance: "We have reason to believe that there is a definite relation between chromosomes and allelomorphs or unit characters" (Peters 1959). Sutton proposed that multiple characters would be found on a single chromosome and made a direct reference to genetic linkage: "If then, the chromosomes permanently retain their individuality, it follows that all allelomorphs represented by any one chromosome must be inherited together" (Peters 1959).

Spurred by the work of Sutton and others interested in chromosomes, T. H. Morgan and a group of his students at Columbia University began to study the inheritance of unit characters, the individual factors of Mendelian transmission (Allen 1978; Carlson 1981). Using the fruit fly *Drosophila* as their experimental model, Morgan and his students made a series of fundamental discoveries that led, by 1914, to their conclusion that the Mendelian factors, or genes, were physical entities present in the chromosomes in a *linear* manner (Sturtevant 1913; Morgan 1914).

In 1923 T. S. Painter suggested that the number of human chromosomes was 48, and this became the accepted number for the next 23 years. Improved cytological techniques eventually led to better resolution of the chromosomes, with the result that J. H. Tjio and A. Levan (1956) established that the correct number of human diploid chromosomes was $2n = 46$. So strong had been the belief in Painter's estimate that, as Tjio and Levan themselves noted, a previous study by another group had been abandoned because "the workers were unable to find all the 48 human chromosomes in their material; as a matter of fact, the number 46 was repeatedly counted in their slides" (Tjio and Levan 1956). (Clearly, an open mind is as important as good technique.)

It was not long after the number of human chromosomes was established that the solution to an old and curious medical puzzle became apparent. A condition called *furfuraceous idiocy* had been described in 1846 by the French physician E. Séguin. The traits marking the syndrome included characteristic facial features, slow and incomplete growth, and mental retardation. J. Langdon Down ascribed these traits to the Mongol type in 1867: "A very large number of congenital idiots are typical Mongols. So marked is this, that when placed side by side, it is difficult to believe that the specimens are not children of the same parents" (Down 1867).

From this publication the term *Mongolian idiot* replaced the previous name for the condition, and later the term *Down syndrome* became interchange-

able with it. For the next 92 years repeated studies of Down syndrome failed to produce a viable etiologic hypothesis. L. S. Penrose (1939) summarized the state of knowledge by noting that the disorder had failed to meet Mendelian expectations, though some had favored "irregular dominance" as an explanation, and that the only clear and stable correlate was late maternal age. Penrose (1939) ended his paper by suggesting that "Mongolism and some other malformations may have their origin in chromosome anomalies." Two decades later the improvements in cytological techniques that allowed the correct number of human diploid chromosomes to be determined also provided the solution to Down syndrome. In 1959 three French cytologists, led by J. Lejeune (1959), announced that patients with Down syndrome had an extra chromosome, which was one of the small telocentric chromosomes later designated as chromosome 21 (Figure III.1.4).

This first example of a human disorder caused by a specific chromosome anomaly in which there existed at least one triploid chromosome in an otherwise diploid set (now called trisomy) led to a spate of similar findings. These included Turner's syndrome (caused by the lack of one X-chromosome-XO), Kleinfelter's syndrome (XXY), trisomy 13, and trisomy 18 (Thurman 1986). In 1960 the first international congress was called, in Denver, Colorado, to establish a standardized cytogenetic nomenclature. Much of the impetus came from the discovery of chromosome banding techniques by which each chromosome could be identified individually. Over time these techniques have been refined to the point where subbands and regions within them can be identified (Thurman 1986). However, even with these refinements it has only recently been possible to study directly what specific regions of chromosome 21 are responsible for the Down syndrome phenotype.

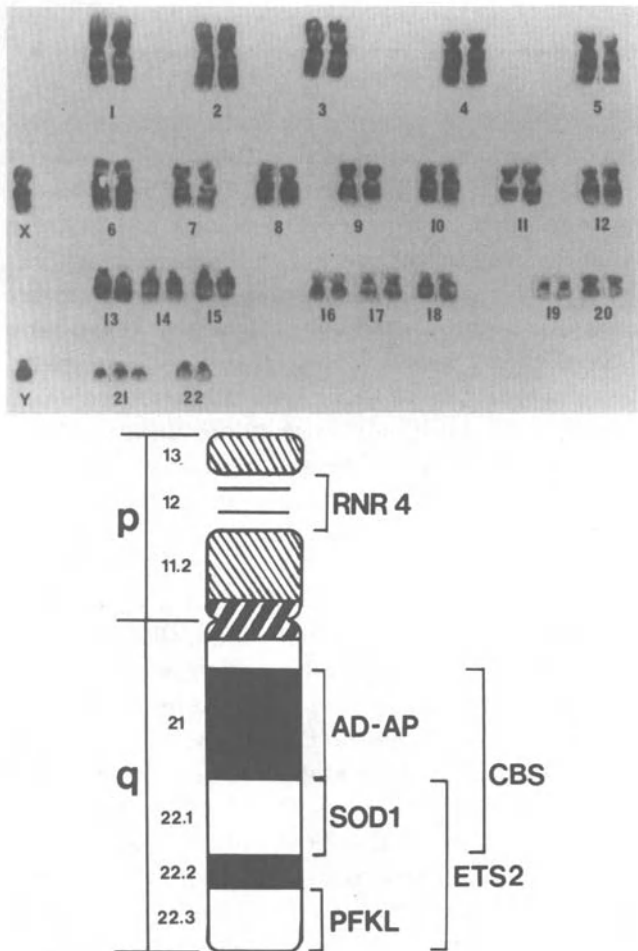
As has been the case with sickle-cell anemia and many other human diseases, recombinant DNA technology has enabled researchers to study Down syndrome with greater detail and precision. Chromosome 21 contains less than 2 percent of the DNA in the human genome, yet with an estimated 50,000 genes in the genome (Shows, Sakaguchi, and Naylor 1982), it probably houses 1,000 genes. By means of recombinant DNA and related techniques, more than 20 of those genes, along with nearly 50 anonymous sequences, have been mapped (see Figure III.1.4). Among the mapped genes is one that codes for a ribosomal RNA (RNR-4, 18045). In addition, several genes of medical interest are known. These include the gene for the enzyme cystathionine beta-


Figure III.1.4. Top: G-banded chromosome spread of a man with Down syndrome (47, XY, +21). The individual chromosome numbers are designated by convention. Bottom: ideogram of human chromosome 21 indicating the subregional localization of several genes of interest (see text). (From J. A. Fraser-Roberts and Marcus E. Pembrey 1978, with permission.)

synthase (CBS), which is implicated in the recessive metabolic disorder homocysteinuria (23620); the gene for liver-type phosphofructokinase (PFKL), which, in deficiency, leads to a type of hemolytic anemia (17186); and two oncogenes, ETS-2 (16474) and ERG (16508). The precise localization of ETS-2 to band 21q22 was a major indication that this region of chromosome 21 is the one responsible for many of the medical features of Down syndrome.

Individuals with Down syndrome have, in addition to classical facial features and mental retardation, a greatly increased risk of developing myeloid leukemia, a high incidence of cataract, and, in older patients, a neurological degeneration resembling Alzheimer's disease. The oncogene ETS-2 at 21q22 is known to be rearranged in acute myeloid leukemia

(McKusick 1986), and linked to this locus at 21q22 is the locus for the enzyme superoxide dismutase (SOD-1). Y. Groner and colleagues (1986) have reviewed molecular evidence that SOD-1 enhances lipid peroxidation, which leads to toxic neurological effects and to cataracts.

The Alzheimer's disease–like dementia of older Down syndrome patients suggested that the q22 region of chromosome 21 might be the location of the amyloid protein found in the senile plaques of Alzheimer's patients. D. Goldgaber and colleagues (1987) and R. E. Tanzi and colleagues (1987) independently reported that the amyloid-B protein gene mapped nearby at 21q21. The effect resulting from the extra copy of the amyloid-B protein gene in Down syndrome is an overproduction of amyloid and presenile plaque formation.

Finally, the advent of recombinant DNA techniques and sophisticated analytic tools for estimating genetic linkage relationships have enabled one group to focus on the cause of the trisomy. Using several well-mapped anonymous DNA sequences from chromosome 21 as well as a probe for SOD-1, A. C. Warren and colleagues (1987) have demonstrated that recombination among DNA markers on chromosomes 21 that have undergone nondisjunction, the event leading to a trisomy, occurs to a significantly lesser extent than it does in controls. Reduced recombination is indicative of *asynapsis,* or a failure of normal chromosome pairing. This result will very likely lead to the discovery of the molecular mechanism of chromosome pairing.

A Failure of Expectations: Kuru

In August 1953, an officer in an Australian government patrol working in the South Fore region of the highlands of Papua New Guinea noted a peculiar condition:

Nearing one of the dwellings [at Amusi], I observed a small girl sitting down beside a fire. She was shivering violently and her head was jerking spasmodically from side to side. I was told that she was a victim of sorcery and would continue thus, shivering and unable to eat, until death claimed her within a few weeks. (J. McArthur 1953, in Lindenbaum 1979)

The condition from which she was suffering was locally called *kuru* (trembling or fear), a progressive neurological disorder peculiar to that region of Papua New Guinea.

Because the South Fore region was relatively isolated and the villages interrelated through extensive kinship ties, it was thought that kuru was a

genetic disease occurring in an isolated district where inbreeding was elevated. However, kuru required that the gene be dominant in women and recessive in men for the epidemiology of the illness to be accounted for by a genetic factor (Bennett, Rhodes, and Robson 1959). Thus, even as early as 1963 the genetic etiology that seemed plausible was being discarded (Lindenbaum 1979).

The case of kuru is mentioned here briefly because it is a good example of the sophistication achieved in medical genetics and the study of human diseases. In the early part of the twentieth century, the power of the Mendelian model was so great that the abandonment of an unwieldy genetic hypothesis, which for kuru took only a couple of years, might have required decades. The true cause of kuru was a bizarre infectious agent that S. B. Prusiner (1982) termed a *prion,* or proteinaceous infectious particle. In an odd twist, the infectious component in prions, a relatively small protein called the prion protein, PrP 27–30 (Prusiner et al. 1984), was found to have a normal homolog in mammalian genomes, including human ones. PrP produced its effect by forming rodlike structures resembling amyloid, and it was thought that not only was the PrP gene to be found on chromosome 21 but that Alzheimer's disease and even Down syndrome might be associated with prion infection (Prusiner 1982). However, Y.-C. J. Liao and colleagues (1986) and R. S. Sparkes and colleagues (1986) independently reported cloning the human PrP gene and mapping it to chromosome 20. The story of the prion and of the PrP gene is still unfolding, and although it is not technically a genetic disease, kuru and neurological disorders like it fit well within the multifactorial heuristic model that moved the study of genetic diseases from one of recording oddities to a complex, interdisciplinary enterprise making use of a full range of techniques and technologies.

Summary and Prospects

The history of the study of human genetic diseases is not unlike that of any other area of medical science. It has been marked by periods of superstition and pseudoscience as well as by flashes of brilliant insight such as those of Maupertius, Adams, and Garrod. It has also been characterized by an exponential increase in fundamental understanding coupled with technological and methodological breakthroughs, as was clearly exemplified by sickle-cell anemia and Down syndrome. The recent development of recombinant DNA technology has ushered in a revolution in the study of human genetic disease, a quickening of

the pace of discovery matched only by that seen when Mendel's laws of heredity were revealed in 1900.

The future of medical genetics is very bright indeed. Systematic screening of the human genome has revealed hundreds of inherited DNA sequence variants, or RFLPs (Willard et al. 1985; O'Brien 1987). Exploitation of these markers has made it possible to establish genetic linkage and chromosome map locations for a large number of hereditary human illnesses including Duchenne muscular dystrophy (Davies et al. 1983; 31020), Huntington's disease (Gusella et al. 1983; 14310), cystic fibrosis (Tsui et al. 1985; 21970), adult polycystic kidney disease (Reeders et al. 1985; 17390), retinoblastoma (Cavenee et al. 1985; 18020), familial polyposis (Bodmer et al. 1987; 17510), manic-depressive or bipolar illness (Egeland et al. 1987; 30920), and neurofibromatosis (Barker et al. 1987; 16220). Moreover, the genes themselves have been cloned for retinoblastoma (Friend et al. 1986) and Duchenne muscular dystrophy (Monaco et al. 1986), as well as for chronic granulomatosus disease (Royer-Pokora et al. 1986; 30640). These successes have made the production of a genetic map of the entire human genome, first suggested by D. Botstein and colleagues (1980), not just a desirable goal but a feasible imperative. Much of this work has already been accomplished (see Donis-Keller et al. 1987; White 1987), but much more must be done. Clearly, the day of an exact science of molecular medical genetics has dawned and with it has come, after 10,000 years, the potential for treating and even curing genetic diseases (Anderson 1984).

III.2
Immunology

The knowledge of acquired resistance to disease and the practices connected with it are very old. Ancient medical systems of both East and West offered explanations of why no one got smallpox twice and how one might be protected from getting it at all. But the history of immunology as a science began only 100 years ago with the experiments of Louis Pasteur.

This history falls into two distinct periods, roughly before and after World War II. It begins with a fanfare, with the production of protective vaccines and antisera, probably the earliest example of truly effective medical treatment. The great theoreticians of the period were biochemists, investigating the chemistry of antigen and antibody and the nature of the antigen–antibody reaction. The part played by blood cells in the body's defenses had been in the foreground of discussions before the turn of the century,

but it was pushed into the shade by the discovery of the striking therapeutic effects of immune sera.

After World War II, when it became clear that antibiotics could control infections for which there was no serological treatment, interest in immunological methods of treatment waned and focused instead on the cellular biology of the immune process as a part of general biology. A single theory came to unite all of immunology, making possible the striking expansion of the field that took place in the 1970s.

Cells and Serum

The idea of cells defending the body against invaders was proposed by the Russian zoologist I. I. Mechnikov. He saw that a yeast infecting a transparent water flea was surrounded by white blood cells that stuck to the yeast and killed it. Mechnikov called the cells phagocytes (Mechnikov 1884; Besredka 1921). As Arthur Silverstein has pointed out, phagocytosis at this time was associated with the pathology of inflammation rather than immunity. The first experimental work on immunity, Pasteur's early experiments on chicken cholera, was only four years old in 1884 when Mechnikov's work appeared, and the germ theory of disease itself was hardly any older (Silverstein 1979). Mechnikov's idea attracted Pasteur's interest, and Mechnikov was invited to Paris in 1888.

In Germany, especially among the Berlin bacteriologists around Robert Koch, the chief role in defense appeared more and more clearly to belong to the blood serum rather than the cells. This group of workers had earlier mounted an all-out attack on Pasteur and the French workers, including Mechnikov. This was a transposition into scientific terms of the old nationalistic hatred between France and Germany that had resulted in the Franco-Prussian War of 1870 (Foster 1970). In this case, the Germans had some very telling ammunition. In 1890, Emil von Behring and his Japanese colleague Shibasaburo Kitasato, working at Koch's institute, diverted attention from cellular to so-called humoral immunity when they showed that animals could be made immune to the effects of the toxins produced by both the tetanus and diphtheria bacilli. Immunity could be transferred by an injection of immune serum, a finding that was quickly applied outside the laboratory. Within a year, on Christmas Eve of 1891, the serum was tried out on a child acutely ill with diphtheria. The results were sensational (Behring 1895). The production of sheep and goat serum began in 1892, and in 1894 it was introduced into the Berlin hospitals. There was an immediate fall in diphtheria mor-

tality (Behring 1895). Meanwhile in Paris, Emile Roux and Alexandre Yersin made the large-scale production of the serum possible by using horses as a source of antitoxin. In their first 300 cases, mortality fell from 50 to 25 percent. In 1894 the Pasteur serum was taken to England by Joseph Lister, and it was equally successful there (Parish 1965).

In England, cells and serum came together in the work of the clinical bacteriologist Almroth Wright. Wright demonstrated that phagocytes could not engulf their victims without the help of a serum factor that he called an opsonin. The level of opsonic activity showed the state of his patients' defenses against bacterial infection and their response to the vaccines he prepared for them. Local infections, such as boils, acne, appendicitis, and tuberculosis, were treated with autovaccines made from the patient's own organisms and calculated, in Bernard Shaw's phrase, to stimulate the phagocytes. At the Department for Therapeutic Immunization at St. Mary's Hospital in London, he and a devoted group worked night and day at stimulating the phagocytes and determining opsonic indices. Autovaccination and injections were the treatment of the moment, especially, it seems, in the English-speaking world. From about 1945 onward, however, autovaccines were superseded by antibiotics. Among the young bacteriologists who were Wright's colleagues was Alexander Fleming, who later discovered penicillin. The department Wright founded is now the Wright–Fleming Institute.

The Age of International Serology, 1900–50

In spite of the popular appeal of the struggle of phagocytes, it was not cells but serum that set the style. The key event of this period is the discovery of the striking clinical effectiveness of diphtheria antitoxin. The production and control of this serum and others like it pointed the direction for research in theory and in practice.

Although it was the diphtheria serum and its problems that lent them much of their significance, the first of the national serum institutes was established just before the appearance of the serum. The Institut Pasteur was set up in 1888, following the national enthusiasm in France created by Pasteur's success with rabies immunization (Delaunay 1962). The institute was not, strictly speaking, a state concern, because it was independently funded, but it had national status. Its opening marked the end of Pasteur's active life; he had had a stroke the previous year, and the new institute was to be run not by Pasteur himself, but by his successors, the Pastoriens.

From its beginning, the institute offered courses on

bacteriological technique. Among the students were young bacteriologists from all over the world; many were medical officers of the French colonies, which led to the establishment of the Instituts Pasteur d'Outre-Mer. The first four of these, in Saigon, Nhatrang, Algeria, and Tunis, were founded between 1891 and 1894. Among them may also be mentioned the Haffkine Institute in Bombay, founded in 1899 and led by a Pastorien, Waldemar Haffkine. As Noël Bernard points out, the vulnerability of the whites in these new areas of colonization stimulated interest in the diseases endemic in them; the Instituts Pasteur d'Outre-Mer concentrated on plague, cholera, and malaria – and snake bite (Bernard 1960). In Europe, needs were different: Centers that had begun by working on vaccines turned their attention to the large-scale production of diphtheria antiserum. Thus, Institut Pasteur set up a special center for making horse serum at Garches, outside Paris.

A similar evolution took place in London, leading to the foundation of the British Institute of Preventive Medicine, renamed the Lister Institute in 1891 (Chick, Hume, and Macfarlane 1971). Rabies at that time was an uncommon, but fatal result of animal bites in England, as on the Continent; no one could predict which bite might be fatal. Pasteur himself suggested a Pastorien, Marc-Armand Ruffer, who had connections in England and Germany, as well as Paris, to head it. In 1893 Ruffer reported on the astonishing effectiveness of Behring's diphtheria serum, and in 1894 a serum department was created at the Lister. Soon after, the Wellcome Laboratories were founded to make the serum commercially.

In the same year Carl Salomonsen, director of the University Bacteriology Laboratory in Copenhagen, went to Paris to learn the techniques. On Salomonsen's return, he applied to his government for funding for a laboratory for serotherapeutic experiments and undertook at the same time to produce diphtheria serum in quantity for free distribution. The Statens Serum Institutet under Thorwald Madsen became independent of the University in 1901 (Salomonsen 1902). Elsewhere too, rabies vaccination led the way to the manufacture of diphtheria serum, which was not only a tremendous therapeutic success, but a commercial success as well (Defries 1968).

The most important of the problems raised by the clinical use of the serum was that of standardization. The first attempt at a biological assay was made by Behring. His method was to standardize the antiserum against the toxin. The minimum fatal dose of toxin was first established, and one unit of antitoxin was defined as the amount necessary to protect a guinea pig against 100 fatal doses of toxin. The method seemed logical, but in practice the results were unreliable.

The problem was taken up by Paul Ehrlich, head of the newly established Institut für Serumprüfung und Serumforschung in Berlin. Ehrlich's assay procedure followed Behring's quite closely, but he defined his units using a standard toxin and a standard antiserum, and new batches of either were assayed by comparison with these. The Lo dose of a new toxin was the number of lethal doses (L.D.'s) neutralized by one unit of the original antiserum, and the $L+$ dose was the number of lethal doses just not neutralized. Theoretically, as Behring had expected, $L+ - Lo = 1$ L.D. But in practice, as the toxin aged, the difference increased. The toxin's capacity to neutralize antitoxin remained constant, but the toxicity of the solution gradually declined.

Ehrlich interpreted this in terms of his side-chain theory as meaning that there were two different side chains on the toxin molecule, which he called the toxophore and the haptophore groups, responsible for the toxic property and the property of neutralizing antitoxin, respectively. The toxophore group, he thought, was labile, so that toxicity declined over time. A further difficulty lay in the fact that successive additions of antiserum had unequal effects on the toxicity: The first few additions might not diminish the toxicity at all, though antibody was being absorbed. Ehrlich thought this meant that the toxin consisted of a mixture of different components, each giving a different ratio of antigen to antibody.

The most "avid" components took up the highest proportion of antibody and took it first; the less avid, later. He illustrated this by a stepped diagram, the profile of which represented the relationship between toxicity and avidity for antiserum at each stage of neutralization. Each step represented a separate, named component, which he called toxin, toxone, and toxoid, each with named subdivisions (Ehrlich 1887–8). The development of a clearly visualized, but quite speculative chemistry, along with a new vocabulary to describe the visualized substances, was very typical of Ehrlich's thinking (Mazumdar 1976). It was the first statement of his side-chain theory, the theory of immunity around which argument raged for the next 20 years and which has never quite disappeared from immunology.

The feature of Ehrlich's assay procedure that made it so successful was his insistence on measuring all new serum samples against a standard serum. The standard was preserved desiccated, frozen, and under vacuum, at Ehrlich's own new specialized

laboratory in Frankfurt, which continued to provide for international standardization up to World War I. During the war, communications with Frankfurt were cut off, and standards began to drift.

The decision to take over the regulation of serum standards was made by the League of Nations Health Committee in 1921. A series of International Conferences on the Standardization of Sera and Serological Tests was held; it was decided to keep the Ehrlich unit as the international standard, but since Germany was excluded from the League of Nations, the standard serum was to be in Copenhagen. Madsen suggested that similar agreements could be reached for other biologicals, such as hormone preparations and plant extracts. In 1924, the Permanent Commission on Biological Standardization was set up with Madsen as its chairman (Hartley 1945). Copenhagen became the center of coordination for all work on serum standards, with individual samples of diphtheria antitoxin and other antibacterial sera kept at Cophenhagen, Frankfurt, Hampstead, and Toronto, and at Paris at the Institut Pasteur (Jensen 1936).

The Nature of Specificity, 1900–50

In the nineteenth century, the startling success of the serum treatment of diphtheria had given rise not only to the practical problems of standardization and their solution, and to the international organization to coordinate the work, but also to a theoretical interest in the antigen–antibody reaction and the nature of specificity. The earliest formulation of these problems came with Ehrlich's side-chain theory. According to the theory, the antibody had a unique chemical affinity for the haptophore on the toxin. Ehrlich suggested that the union of antitoxin with its toxin tore the antibody molecule free of the cell that carried it on its surface. This trauma caused an overproduction of identical replacement molecules, rather as healing of an injury caused overproduction of new tissue (Ehrlich 1887–8; Mazumdar 1976; Silverstein 1982).

The side-chain theory had two implications that drew criticism. First, the side chains were supposed to bind to their receptors firmly and irreversibly according to the law of definite proportions, by the type of linkage now called covalent. Second, the theory required that the body be provided with preexisting antibodies to match every conceivable antigen, even those artificial molecules that could have had no possible role in the evolution of the species.

Madsen, who had learned the technique of diphtheria serum assay from Ehrlich himself, but who had

also been in contact with Jules Bordet at the Institut Pasteur, was the first to develop an alternative interpretation of Ehrlich's stepped diagram. Working with the physical chemist Svante Arrhenius, he suggested that the antigen–antibody reaction was a reversible equilibrium like the neutralization of acid by base, a type of reaction that gave a smooth exponential curve rather than a series of steps. There was no need to postulate a whole series of different substances (Arrhenius and Madsen 1902; Rubin 1980). The theory had an indifferent reception, but Ehrlich's enemies, led by Max von Gruber in Vienna, hoped that what they saw as a splendid refutation meant the end of Ehrlich's ascendancy.

For Bordet, however, the outstanding fact was that an agglutinable substance absorbed different amounts of its agglutinin according to the relative proportions of the reacting substances: The reaction was not chemical at all, but physical. He compared the phenomenon to that of dyeing: If one dipped a series of pieces of paper in a dye solution, the first few would be strongly colored, and the later ones paler and paler as the dye was exhausted. As early as 1896, he had suggested that "serum acts on bacteria by changing the relations of molecular attraction between bacteria and the surrounding fluid" (Bordet 1896).

Bordet's physical point of view was taken up by Karl Landsteiner in Vienna, who had been trained in both medicine and structural organic chemistry. He had joined Gruber's serological laboratory in 1896 and, like other Gruber students, followed the Gruber line of anti-Ehrlich argument. Landsteiner proposed a physicochemical model for the antigen–antibody reaction: the precipitation of inorganic colloids. The model was particularly apt because the form of antigen–antibody reaction that Landsteiner usually worked with was a precipitin reaction, in which a soluble antigen was precipitated out of solution by an antibody.

Colloid chemistry dealt with the behavior of materials that formed very large particles, so large that their reactions depended on the physical properties of their surfaces rather than on their chemical nature. In the early part of the twentieth century, the physical chemistry of colloids seemed to hold great promise for explaining the reactions of living tissue and its major constituent, protein. It seemed particularly appropriate for the antigen–antibody reaction, because it was thought that only proteins were antigenic. Working with the Viennese colloid chemist Wolfgang Pauli, who was one of the most enthusiastic proponents of the "chemistry of life," Landsteiner pointed

out that it was colloids with opposite charges that precipitated each other. The antigen–antibody reaction might be an electrochemical surface adsorption: Subtle surface charge effects might account for antibody specificity (Landsteiner 1909). He and Pauli developed an apparatus for comparing the charge on proteins by following their movements in an electric field. Their apparatus was adopted by Leonor Michaelis and his group in Berlin, who thought the same features might account for the activities of enzymes. Landsteiner then entered into a long program of research, aiming to define the antigenic specificity of proteins carrying known substituent groups, a project that made use of his skill in structural chemistry. The final proof of his position came in 1918, when he demonstrated that antigenic specificity was determined mainly by the charge outline of the antigen (Landsteiner and Lampl 1918). This conclusion united the colloid or physical concept of charge with the structural concept of the chemical nature of the molecule (Mazumdar 1976; Silverstein 1982).

Landsteiner's demonstration of the importance of charge outline had several implications. The first was that specificity need not be absolute, as Ehrlich's theory would have it. Cross-reactions could take place between similarly charged groups similarly placed on the antigens. A huge number of different specific antibodies was not, therefore, necessary. The second was that the antigen–antibody reaction was not a firm chemical binding; the two were linked not by valency bonds, but by the so-called short-range forces that surrounded a molecule, as in the model of a crystal lattice (Marrack 1934). The third implication, that of the generation of antibody diversity, was not made until 1930, by the Prague biochemist Felix Haurowitz.

Haurowitz's training, like that of Landsteiner, had included both colloid chemistry and structural chemistry. He spent some time with Michaelis working on the physical chemistry of charge in relation to enzyme activity. But after the war Prague had lost its links with Vienna; Haurowitz heard nothing about the work of Landsteiner until 1929, when the serologist Fritz Breinl told him about it. Breinl and Haurowitz, then working together, suggested that antibody might be assembled on the charge outline of its antigen, appropriately charged amino acids lining up by adsorption onto the antigen to form a specific antibody globulin. There was no need for Ehrlich's innumerable preformed specificities. The organism made its antibody as required. It was a simple and economical solution to the problem of antibody diversity; it made use of the most advanced thinking in both immunology and chemistry (Mazumdar 1989). In English, it became known as the template theory, and in one form or another, it was generally accepted for the next 20 years or more.

Landsteiner had been a rather isolated theoretical thinker at a time when theory was of little interest to the practical serologist. In addition, criticism of Ehrlich was not popular in Vienna. Thus, after the political and economic collapse of Austria at the end of World War I, Landsteiner was eager to leave, and in 1922 was invited to joining the Rockefeller Institute in New York. There, in a sympathetic environment, he was able to continue his work on artificial antigens. He also turned again to the blood groups, which he had not worked on since 1901–9, when he discovered them (Landsteiner 1901). It was for this discovery, and not the work on artificial antigens, that he was given the Nobel Prize in 1932.

Landsteiner's interest in the blood groups began in 1900, when he and many others tried to explain the presence of antibodies in human blood that agglutinated the red cells of other human bloods. Most proposals linked them to some common disease, such as tuberculosis and malaria. It was Landsteiner's suggestion that these were "natural antibodies" whose presence was independent of infection. Landsteiner himself showed curiously little interest in this pregnant finding, perhaps because the "natural antibodies" and the sharply defined specificity of the different groups seemed to support Ehrlich's theory. Although Landsteiner had suggested in 1901 that a knowledge of blood groups would be useful in blood transfusion, transfusion was used very little for many years afterward. It was reported on occasionally during World War I, and although a large literature accumulated, it did not become a routine hospital procedure until the establishment of blood banks shortly before World War II. In Britain, fear of civilian casualties on a large scale stimulated the organization of a blood collection and distribution system.

Landsteiner and his colleagues at the Rockefeller Institute discovered several more sets of inherited antigens on red cells, the MN and P systems, and in 1940 the rhesus, or Rh, system. These workers found rhesus incompatibility between mother and fetus to be the cause of hemolytic disease of the newborn, a discovery that led in the 1960s to an immunologic method of specifically suppressing antibody formation in the mother and so preventing the disease.

In an era when human genetics was represented by the eugenics movement, blood groups were the only normal human trait that was clearly inherited according to Mendelian laws. They seemed to be

direct products of the genes, untouched by any environmental effect. They could be analyzed mathematically as the Göttingen statistician Felix Bernstein had shown (Bernstein 1924; Mazumdar 1992), and as a model genetic system, they might come to do for human genetics what the fruit fly *Drosophila* had done for genetic theory in the 1920s. To critics of the eugenist's social biases, such as the left-wing scientists of the 1930s, blood groups represented a means of making human genetics the genuinely "value-free science" that it had so far grotesquely failed to be (Hogben 1931). In practice, the complex genetics of blood group antigens was to provide a model for the genetics of tissue types, essential in the choice of organs for grafting and for the genetics of proteins (Grubb 1989).

The Chemistry of Antibody Globulins, 1930–60

The history of protein chemistry is the history of a sequence of innovations in instrumentation and technique, each of them pointing to a new vein of knowledge to be worked. Most of these were fractionation methods; proteins could be separated in terms of charge or particle size, and biological activity correlated with the resulting serum fractions or protein fragments. For most of the period, efforts in this area were more or less independent of the work on immune specificity, but they too had their roots in colloid chemistry. Not until after World War II did protein chemists begin to feel that the high aspirations of colloid chemistry were an absurdity better forgotten.

The earliest and simplest preparative separation method for serum proteins was "salting-out," achieved by adding neutral salts to the protein solution, a technique introduced in the mid-nineteenth century. By 1930 there were still some chemists who were not convinced that the serum antibodies were actually globulins, and not some other material (Spiegel-Adolf 1930).

With their sophisticated techniques and mathematical approach, the physical chemists working at Uppsala in Sweden transformed colloid chemistry. The vitalistic enthusiasm of Pauli faded into a hard-line physical science. However, both The Svedberg and Arne Tiselius thought of themselves as colloid chemists.

Svedberg's work on protein separation began to appear in 1925. Using a high-speed centrifuge, he found that proteins were forced to the bottom of a tube in order of their size. He assigned to each a sedimentation coefficient S that indicated molecular weight. The serum globulin mainly had a sedimentation coefficient of 7 S, corresponding to a molecular weight of about 15,000, but there was a small amount of heavier 18 S globulin. As in the salting-out technique, antibody activity went along with the globulin fraction. Svedberg saw ultracentrifugal analysis as a contribution to classical colloid chemistry: Particle size and dispersal of proteins in solution were central to the colloid tradition.

In 1930 Svedberg's younger colleague Tiselius developed an apparatus for the separation of protein molecules in terms of their charge, based on the work of Landsteiner and Pauli. Tiselius, too, felt that the study of electrokinetic phenomena was among the most important of the tasks of colloid chemistry (Tiselius 1938).

Svedberg's and Tiselius's earlier methods had been useful for the analysis of protein mixtures, whereas the new techniques of the 1940s made it possible to prepare the products on a large scale. The name *chromatography* was coined by the Russian botanist M. Tswett in 1910 to describe his method of separating colored plant materials. The first good chromatographic method for proteins was introduced in 1944 by A. J. P. Martin and his colleagues at St. George's Hospital in London. Martin's method was to use a filter-paper sheet as the adsorbent, with the solvent containing the test material flowing slowly up a vertical sheet by capillary action. It also incorporated the novel idea of two-dimensional separation. When separation with one solvent was complete, the paper was turned 90 degrees and another separation with another solvent, or with an electric current, was performed. This method, called "fingerprinting," was good for identifying differently charged amino acids in a mixture of peptide fragments of proteins, and it became a favorite with protein geneticists.

After the war ended, a new group of methods for the separation of charged molecules appeared. Ion exchangers are essentially insoluble acids or bases in the form of a highly cross-linked matrix, usually a resin, through which a solvent carrying the material to be analyzed can percolate. Molecules with the same charge as the solid are repelled by it to various degrees and pass more or less quickly through, whereas those with the opposite charge are entangled and delayed. In 1951 an ion-exchange resin was brilliantly applied to the separation of amino acids by Stanford Moore and William H. Stein at the Rockefeller Institute in New York (Moore and Stein 1951). They not only obtained a quantitative separation of mixtures containing an astonishing number of different substances, up to 50 in some cases, but also automated the procedure so that it could be run

unattended overnight. In the morning, the researchers would find a series of tubes filled by an automatic fraction collector, ready for them to analyze. This type of method with its greatly increased productivity made possible the rapid accumulation of information on amino acids and their sequence in many different proteins.

Protein molecules, however, easily lost their biological activity with the rough handling that resins gave them. Investigators might succeed in isolating a protein peak by a preparative method, only to find that all the antibody activity had disappeared, "lost on the column." It was not long before a better way was found. Cellulose-based ion exchangers were introduced by Herbert A. Sober and Elbert A. Peterson and by Jerker Porath at Uppsala (Sober et al. 1956). The anion exchanger was diethylaminoethyl cellulose, or DEAE, and the cation, carboxymethyl (or CM) cellulose. These materials turned out to be far less destructive to the protein molecule. A second type of material developed by Porath was a dextran gel called Sephadex by its manufacturer. It was not an ion exchanger; it acted, to use Porath's (1960) expression, as a kind of molecular sieve. Large molecules, such as the 18 S globulin, passed almost unhindered through it, excluded from the finer pores of the gel; smaller ones, such as albumin and 7 S globulin, wandered more slowly, exploring the labyrinth within. All these materials were soon available commercially, many from firms centered in Uppsala. As the techniques and the rather expensive equipment for column chromatography and automatic fraction collecting spread through laboratories, protein chemistry, particularly the chemistry of antibody globulins, moved very rapidly (Morris and Morris 1964).

The range of separation methods now available made possible an attack on the structure of the immunoglobulin molecule. Rodney Porter, working at St. Mary's Hospital Medical School in London, separated out a rabbit immunoglobulin by chromatography on DEAE, and then digested it with the proteolytic enzyme papain to break it into sections small enough to be understood. The digest was first put into the ultracentrifuge. There was only one peak, at 3.5 S, showing that the 7 S globulin had broken into smaller fragments of roughly equal size. On CM cellulose, there were three peaks. Amino acid analysis by the Moore and Stein method on an ion-exchange resin showed that peaks I and II were almost identical, and III, very different from them; antibody activity was present in peaks I and II. Porter's first interpretation of his results was that the molecule was a long single chain with three sections,

supporting Linus Pauling's suggestion in 1940 of a long antibody molecule with a rigid centerpiece and two flexible ends, which folded, or molded, themselves on the antigen as a template to effect a specific match (Porter 1959). For Porter in 1959, a template theory of the generation of antibody diversity was still the most likely possibility.

In 1962 Porter tried a different dissection of the antibody globulin by opening its disulfide bonds. Separation of the result on a Sephadex column produced two peaks, one heavy and one light. He thought that these must be two chains of the globulin molecule, normally joined together by disulfide bonds. Amino acid analysis showed that there must be two of each chain. The relation of the chains to the papain pieces was determined immunologically, using goat antisera to the rabbit fragments. Porter then proposed a second model of the 7 S globulin molecule, with a pair of heavy chains joined by disulfide bonds and a light chain attached to each one, with the antibody site in fraction I, probably on the heavy chain. This model stood up satisfactorily to additional evidence, to the discovery of different types of heavy chain in different classes of immunoglobulin, and to the discovery of individual genetically determined polymorphisms of both chains (Porter 1973).

Using the fingerprinting technique, several laboratories in Britain and the United States, and Michael Sela and his group in Israel, found that the peptide maps of I and II from different antisera were very slightly different from each other. The chemists were getting nearer to finding out the amino acid sequence of an individual antibody; there was, however, still too much heterogeneity in normal antibody to make such detail possible.

The problem was solved by an accident of nature. To everyone's surprise, the fingerprints of normal light chains and the so-called Bence-Jones protein turned out to be almost identical. This material, named for its nineteenth-century discoverer, is found in the urine of patients with myeloma, a lymphoid tumor of the bone marrow. The only difference seemed to be that normal light chains were a mixture of two types, whereas the Bence-Jones chains were homogeneous, and therefore an ideal material available in large quantities for sequence studies on the amino acid analyzer. It appeared that each patient produced a different chain; each chain consisted of two sections, a variable region and a constant region. Of the 105 amino acids of the variable region, about 30 varied from case to case. In this variation lay the essence of antibody specificity.

Parallel with the detailed information that built up throughout the 1950s on amino acid sequences, evidence began to accumulate that these sequences were under genetic control. Information that specified each amino acid was found to be encoded in deoxynucleic acid, or DNA, transferred to a messenger ribonucleic acid, or RNA, and transcribed as an amino acid to be added to the growing peptide chain. The system appeared to be strictly directional. Francis Crick of Cambridge University stated what he called the "central dogma" of protein synthesis: Once genetic information has passed into protein, it cannot get out again. No protein could be formed by copying another protein (Crick 1957).

If this were so, it would make the template theory of antibody formation impossible. But the template theory had deep roots, and distinguished supporters, such as the U.S. immunochemists Pauling and Michael Heidelberger. Haurowitz, now at Indiana University, continued to hold that antigen could interfere, if not with the primary amino acid sequence of the protein, at least with its folding. In 1963 he was arguing that antibodies were normal globulins and that their amino acid sequences were shown by fingerprinting to be almost identical with one another, leaving only the folding to account for antibody specificity. By then, he knew that his theory was becoming less and less likely to be validated, and he often appeared to accept that its time had passed. But Haurowitz never laid down his arms. As he had said in 1960, he could not imagine the formation of a mold without a cast, or antibody without antigen.

Cellular Immunology and the Selection Theories

It was not, however, the argument from the central dogma that turned immunologists away from the template theory. In spite of the growth of molecular biology in the postwar period, it was the complex phenomena of immune cells and immunized animals that provided the impetus for building the new theory. The theoreticians, especially Frank Macfarlane Burnet, considered themselves biologists and drew their ideas from contemporary thinking in biology.

During the 1940s, a number of pieces of evidence accumulated that were to throw doubt on the template theory. One was the phenomenon of tolerance: Ray Owen in California had found that cattle twins that shared intrauterine circulation before birth each contained some of the other's blood cells and made no antibody to them as adults. In 1949 Burnet of the Walter and Eliza Hall Institute in Melbourne,

Australia, together with Frank Fenner of the Australian National University, suggested that an animal body had some mechanism for distinguishing "self" from "not-self." Antigens that were present before birth were accepted as "self," and an animal made no antibody to them (Burnet and Fenner 1949). Burnet's experiment failed, but a similar one that produced a tolerance to foreign skin grafts succeeded at the hands of a British group led by Peter Medawar. During the war, Medawar had served in a London hospital, treating the wounded and burned of the London blitz. He had tried to use grafts of donor skin in the same way he had used donor blood, which was then saving so many lives. But donor skin did not "take." It was Medawar's idea that graft rejection was an immunogenetic phenomenon, as it was Burnet's idea that self-tolerance was established in fetal life. In 1960 Burnet and Medawar shared a Nobel Prize.

From the early 1950s, attention focused on tolerance. Burnet, speaking at a conference at the Royal Society of London in 1956, saw the interest in this "vital" phenomenon as one of the ways in which immunology was becoming more and more biologically oriented (Burnet 1957). There was also the discovery by the U.S. investigators William Taliaferro and David Talmage that a very few cells, containing no detectable antigen, could transfer the full antibody-forming capacity of an immune animal to a new host. These findings could not be explained by the template theory. Alternative explanations began to appear.

Among the most important alternatives was the *natural selection theory* of the Danish immunologist Niels Kaj Jerne, which appeared in 1955. It was a theory that would have appealed to Paul Ehrlich: It proposed that "natural" antibodies were continuously being formed, before any antigen was presented. A given antigen would select its match from among this population of miscellaneous antibodies and would form an antigen–antibody complex. The complex would then be taken up by a phagocyte, which would trigger further production of the same antibody specificity (Jerne 1955). The theory fitted Burnet's concept of self-tolerance: There should be no antiself antibodies. Ehrlich had called this the *horror autotoxicus*.

Both Talmage and Burnet offered improvements on Jerne's idea. Talmage suggested that attention should focus on antibody-producing cells rather than on serum antibody: Certain cells might be selected for multiplication when their produce reacted with the antigen. Talmage's suggestion, however, was overshadowed by that of Burnet, which was similar

in many ways but much more fully worked out. Burnet called his version the *clonal selection theory,* and it was this version that eventually obtained general acceptance.

Burnet was born and educated in Australia, where he took his medical degree in 1922. His postgraduate tour, however, took him to London's Lister Institute, where he worked on bacteriophage viruses and their serological classification. After getting his doctorate, Burnet joined the National Institute for Medical Research. Here he learned the practical techniques of limit dilution and cloning used to grow a virus in pure culture. According to his colleague Gordon Ada (1989), this work at the bench may have provided him with models for his later immunologic theories.

Burnet was always careful to give Jerne full credit as the "onlie begetter" of the selection theory (Burnet 1967). But he did not like the idea that phagocytosing an antigen–antibody complex caused a cell to produce antibody. He suggested instead that the natural antibody was not free in the serum but attached to the cell surface as a receptor, rather as Ehrlich had supposed 50 years before. Antigen then selected the cell that carried a suitable antibody, and that was the stimulus for the cell to start proliferating. Somatic cells do not mate; apart from mutations, their progeny are identical, a clone of genetically identical cells, all producing identical antibodies. Burnet suggested that each cell probably produced only one or two antibodies, because that gave a reasonable number of cell types to deal with the number of different possible antigens (Burnet and Fenner 1962).

This theory explained two biological phenomena of immunity that had not gone well with the template theory. It explained tolerance of self as the absence of "forbidden clones" of cells that would have made antiself antibody. And it matched the kinetics of antibody production: the delay following inoculation of the antigen while the first few generations of cells were produced and then the exponential rise in titer as the doubling numbers of each new generation came into being. It explained why a second exposure to antigen had a more immediate and more marked effect: A substantial number of cells of the right clones already existed, ready to begin their proliferation.

Burnet did not waste much time on the central dogma, but it supported his position, and as a biologist, he very soon accepted it as a matter of course. It had become a kind of Lamarckian heresy, he said, to believe that the environment could produce heritable changes in protein structure (Burnet and Fenner 1962).

The clonal selection theory appeared in 1957. Almost at once, evidence strongly supporting the theory was produced by Gustav Nossal and Joshua Lederberg. Using the most direct means of testing clonal selection, they isolated single lymphocytes from rabbits immunized with two antigens and found that each cell produced only one specificity of antibody. It was technically a difficult feat and not easy to reproduce (Nossal and Lederberg 1959).

Although Burnet himself had not insisted on the capacity of each cell to make only one antibody, it seems to have been this finding that provided the strongest support for his theory. *One cell, one antibody:* By 1967 Jerne could call that slogan "Burnet's dogma in its uncompromising form" (Jerne 1967), thus giving it equal status with Crick's "central dogma," mentioned earlier. At the Cold Spring Harbor Symposium that year, it began to seem as if the clonal selection theory had been accepted by the leaders in the field. In the 10 years since it had been proposed, a plethora of experiments on lymphocytes had demonstrated that antigen turned a small subpopulation on to clonal expansion and that antigen was not present in all the antibody-producing cells. As Burnet had said, the way the theory was stated made it easy to think of ways to test it.

Immune System

The growing power of the clonal selection theory during the late 1960s created a magnetic storm in the minds of immunologists. The disturbance was worldwide, but the epicenter was at the Hall Institute in Melbourne, where Burnet and his students Ada, Nossal, and Jacques Miller, all biologists, disentangled the life and work of lymphocytes. The Soviet immunologist R. V. Petrov (1987) has called this the period of the dictatorship of the lymphocyte. The consequence of the acceptance and pervasiveness of the clonal selection theory was a general reorientation of the field toward the study of cells.

The thymus was an organ whose histology was described in great detail in all the elementary textbooks, but it had never been found to have any function. Thymectomy seemed to have no effect on a normal adult. In 1961 Burnet suggested to Miller that he try to discover the effect of thymectomy not on adults, but on newborns in whom, according to his theory, self-tolerance was still being established. Experiments on mice produced a striking effect: The thymectomized mice looked ill; they had constant diarrhea and infections; foreign skin grafts, even skin grafts from rats, flourished on them, and they could hardly produce any antibody (Miller 1962).

In 1963 Australian and U.S. investigators met for a conference on the thymus. It was arranged by the U.S. pediatrician Robert Good, who had been treating children with immune deficiencies, most of whom had congenital absence of the thymus. Like Miller's mice, they suffered from endless infections, and they neither rejected grafts nor produced antibodies. In some of them, the thymus looked normal and graft rejection was normal, but no antibodies were produced. The only known experimental model of this type of deficiency was the chick from which the bursa of Fabricius, an organ rather like the mammalian appendix, had been removed. The bursa seemed to be responsible for producing the cells that made antibody, suggesting that there were two different types of lymphocyte, one mediating graft rejection and the other making antibody. During the 1960s, details accumulated on the powers of different types of cell cultured in isolation. It was left to Miller and Graham Mitchell at the Hall Institute in 1968 to add one more parameter, the behavior of thymus and bone marrow cells mixed together. The mixed culture generated 20 times more antibody-producing cells than either cell type alone: The antibody response must depend on cellular cooperation. Their next paper made the roles clear. The bone marrow, or B, cells produced antibody, but the thymus, or T, cells were needed as "helpers" (Petrov 1987). It was soon found that T cells were composed of helpers, suppressors, and cytotoxic cells.

Back in 1890, Robert Koch announced that he had found a cure for tuberculosis. He was injecting a secret substance, later admitted to be an extract of tubercle bacilli, which he called tuberculin. It produced a striking flare-up of skin lesions in an infected patient. But disappointingly, it was not a cure (Koch 1891). The Viennese pediatrician Clemens von Pirquet, working on the "serum sickness" that often followed the injection of diphtheria serum, recognized that the tuberculin reaction had some relation to his concept of "allergy," or altered reactivity, but it was independent of antibody and could not be transferred by serum. Others saw the same kind of lesion in chronic bacterial infections, and it came to be called "infectious allergy" (Schadewaldt 1979). The lesions were very characteristic: a hard red lump that often had a black, necrotic center, which developed slowly over a few days and took weeks to heal. The reaction was thought perhaps to be responsible for the tissue destruction in tuberculous lungs, and as "delayed hypersensitivity," to be quite separate from protective immunity.

In an era that concentrated on serology and protection against infection, something that had nothing to do with serum and seemed to be destructive rather than protective did not attract much interest. It was not until 1939 that Landsteiner and his colleague Merrill Chase at the Rockefeller Institute made the connection between delayed hypersensitivity and contact hypersensitivity to such things as poison ivy and to the artificial antigens that Landsteiner had been working on for the past half-century (Landsteiner and Chase 1939). In the following year, Landsteiner and Chase managed to transfer contact sensitivity by means of live cells. In addition, Jules Freund (1956), working at the New York Public Health Research Institute, found that lesions could be made much bigger by injecting antigen in an oily mixture that contained a trace of tuberculin. Because there were now techniques that could be used, research could begin.

It soon became clear that delayed hypersensitivity could take the form of autoimmune disease, and that this kind of disease could often be reproduced by injecting material from the target organ in Freund's adjuvant. During the 1950s, laboratories in Britain and the United States worked on the problem using experimental allergic encephalitis as a model. Under the microscope, all the lesions looked very much the same: There was always a cuff of cells surrounding the small blood vessels. Most of the cells were lymphocytes, with some phagocytic cells, the macrophages. The New York immunologist Sherwood Lawrence insisted that he was able to transfer specific sensitization with a cell-free extract from sensitized cells; he called his putative agent "transfer factor." Other immunologists thought that there was something wrong with his experiments. There were no known soluble factors, other than antibody, or perhaps antigen – Burnet thought it must be antigen – that could transfer a specific sensitivity.

Throughout the 1960s, under the influence of the clonal selection theory, more and more attention came to be focused on lymphocytes. Byron Waksman and his group at Yale University found that they could wipe out delayed hypersensitivity with anti-lymphocyte serum, an experimental finding that could be used clinically to prolong the life of transplants as well as to dampen autoimmune disease (Waksman, Arbouys, and Arnason 1961). Tissue culture techniques improved, so that immune lymphocytes could be watched as they responded to antigen by beginning to proliferate. The relation of the two types of cell in the lesions could be disentangled; antigen stopped the migration of macrophages away from a site, but it worked through the lymphocyte,

which produced a soluble "migration inhibition factor," the first of many such factors to be described. A different group of T cells could be seen to kill the cells of foreign grafts or tumor cells. Activated macrophages, too, could kill normal cells, especially if the cells were coated with antibody. It was Wright's opsonic effect brought back to life. Attempts were made to apply this new knowledge to human pathology. Patients' lymphocytes were tested for their behavior with suspected antigens in some diseases thought to be autoimmune.

As Anne-Marie Moulin (1989) has pointed out, the Cold Spring Harbor Symposium of 1967 marked the moment at which immunologists seem to have agreed to accept the clonal selection theory. During the 1960s, different domains of immunology had evolved under the guidance of its heuristic influence. The theory suggested new questions and demanded new techniques, particularly techniques for growing and manipulating cell cultures on the microscopic scale. These new techniques in turn laid bare dozens of new phenomena and relationships. An early indicator of the crossing over between the separate areas of immunology was the change of name around 1970 of delayed hypersensitivity, first to delayed (cellular) hypersensitivity, then to cell-mediated immunity, as the barriers disappeared between the work on antibody-producing clones of lymphocytes and the work on the lymphocytes of delayed hypersensitivity.

Cell-mediated immunity in the 1970s was, as Waksman has noted, completely redefined. More than 100 descriptions of new cellular phenomena were published over the 10 years (Waksman 1989). Many experiments showed that relationships between cells were mediated by soluble factors. Some of these turned out to be capable of performing in more than one experimental scenario. The first of them was the lymphocyte-stimulating factor released by T cells that turned the B cells on to clonal proliferation. There was also a suppressor factor and a macrophage inhibitory factor, which kept the macrophage close to the active focus, and there were lymphotoxins, which were released by the "killer T cells," or "K cells," that worked directly on a foreign target cell. It became possible to define the complicated relationships that could exist among the target cell, the immunoglobulin, and the macrophage or K cell, or between antigen–antibody complexes and effector cells. Transfer factor was now in good company. As Sherwood Lawrence (1970) wrote, the spell was broken, and the ambiguity that had so long surrounded this branch of immunology was being cleared up. The diffusion of this knowledge into practical medicine was marked by the appearance of more than one textbook of clinical immunology.

Waksman has called the decade beginning in 1980 the "holocene era," the era when everything is connected to everything else. That era had already begun in the 1970s, with the work on cell–cell interactions. The end of the decade saw interaction beginning between cell biologists with their culture techniques and immunochemists and their sequence studies. The common meeting ground was now to involve not only cells and serum, but also genetics and molecular biology. The raw material was provided by the myeloma proteins, each representing a different immunoglobulin that could be studied in isolation. By 1970 it was fully accepted that antibody diversity was genetically determined. The question was still, as it had been for half a century, how such tremendous diversity could be genetically controlled.

Sequence studies had shown that the variable region on the globulin was confined to one end of each chain and that these sites were separately coded in the genome. The number of genes for the variable regions was estimated to be perhaps no more than a thousand. Were all these genes to be found in the germ line of every cell? Some immunologists, such as Jerne, argued that a small number of them were but that this number was expanded by somatic mutation in the individual after conception (Jerne 1971). The argument against this view was that the sequences within variable regions fell into distinct groups, identical in all members of a species, and these appeared to be inherited in the regular Mendelian fashion, making somatic mutation unlikely.

Yet many workers had found that the 18 S globulin formed just after immunization seemed to show less variety of variable regions than the 7 S that came later, suggesting that somatic mutation could have occurred during clonal expansion. Evidence for somatic mutation came in 1981 from Lou Hood and his group at the California Institute of Technology. They used the hybridoma technique, developed in the mid-1970s, to make a myeloma that produced antibody of a predetermined specificity. Cells from a mouse myeloma were hybridized with spleen cells from 19 different immunized mice. The variable-region sequences of the antibody globulins were compared with the germ-line sequence of mouse DNA related to the antibody binding site. Not all of the antibody sequences were identical: Half of them reflected the exact sequence as coded for in the germ line, but the others differed from one another by one to eight amino acids. The germ-line sequence

was found in the 18 S globulin and the variants in the 7 S (Crews et al. 1981; Clark 1983). It appears that the variable region is encoded by the germ-line genes but that further variants can arise after birth and perhaps after stimulation by antigen. Clonal expansion seems to generate new mutants, some of which respond to the antigenic stimulus by producing a shower of new clones. Some of these clones may produce an ever closer antigen–antibody match, rather as an animal species evolves to fill an ecological niche by natural selection.

The Clonal Selection Theory and the Field

As already mentioned, the Cold Spring Harbor Symposium of 1967 was a marker for the point at which immunologists accepted the clonal selection theory. It also marked the point at which the volume of immunology research began to expand enormously. As Moulin has pointed out, the conception of the immune apparatus as a system began to appear soon after 1967. A system implied a unified body of knowledge as well as a complex mechanism with interacting parts. Significantly, it also provided a means of formulating problems in a way that attracted grants to solve them. It provided a framework for experiment, if not a guarantee of experimental success (Moulin 1989). With the acceptance of the clonal selection theory as a basis for research programs, the sudden expansion of immunology as a research field gave birth to a large number of specialist research journals. Between 1970 and the date of writing in 1988, 47 new immunological journals came into being.

As part of the same surge of growth, immunologists began to create a formal international organization for themselves. Conferences on particular problems, such as the one on tolerance in London in 1957, the Antibody Workshop, which met irregularly between 1958 and 1965, and the Cold Spring Harbor Symposium of 1967, had always been of great importance to the workers in this very international field (Porter 1986). But from 1968, with the formation of the International Union of Immunological Societies, the connections became structured and permanent. The First International Congress of Immunology was held in Washington, D.C., in 1971. One of the goals of the International Union was to demonstrate the range and power of the new immunology, as well as its applicability in medicine and industry, so as to promote the creation of independent departments of immunology in universities and medical schools (as opposed to research institutes) and to encourage the expansion and funding of teaching programs (Cinader 1975). The first congress in 1971 attracted about 4,000 participants, the sixth, held in Toronto in 1986, about 12,000. An expansion was clearly taking place.

Conclusion

A historian of science brought up on Thomas Kuhn's concepts of paradigm change and discontinuity in science would probably want to ask whether the clonal selection theory and the massive expansion of the field that followed its acceptance could qualify as the kind of gestalt shift that Kuhn had in mind. Was there a profound discontinuity between the thinking of prewar serologists and that of cellular immunologists after 1957? In the author's opinion, there was not. The new theory had the effect of enormously enlarging the field, uniting its domains, and linking immunology to the broader biological sciences. But a large part of the practice and theory of the prewar years was carried over, intact, to the synthesis of the 1960s and 1970s.

The work on vaccines lost nothing in the transition, although some of it has been less generally useful since the coming of antibiotics. In some cases, it was the very success of the vaccination program that made its continuation unnecessary. In others, such as that of diphtheria, the rarity of the disease in the West has made the serum treatment a thing of the past, though diphtheria is still an important concern of the Haffkine Institute in India. Serological tests for disease are as important as they ever were.

One of the most significant continuities has been in blood grouping. As well as being directly utilized in hospital blood banking, the thinking about and techniques of blood group serology laid the conceptual foundation for human genetics in general. Blood group genetics with its complex antigens and its mathematical Mendelism provided a model on which human genetics, and the genetics of proteins and cells, could be patterned.

On the theoretical side, Landsteiner's work on the nature of specificity is probably more significant now than it was to most of his contemporaries, who were more interested in the control of infectious disease. The new findings extended rather than reinterpreted his work, and immunologists continue to use his techniques. Of the ideas based on Landsteiner's template theory, only Haurowitz's was totally discarded by clonal selectionists. Its destruction, in fact, had been essential to their program. Even if it had not been, it would have been run aground sooner or later on the changes in protein

genetics and the central dogma. It was embedded in the chemistry of the 1920s and 1930s, and there it had to stay. Colloid chemistry itself evolved away from the vitalism of its original exponents, but it was the source of the physical chemistry that developed in Uppsala and of the work on the antigen–antibody reaction.

The elevated position of Ehrlich's theory in contemporary immunology is rather paradoxical. On the one hand, its basic premises of perfect one-to-one specificity of antigen and antibody and firm chemical union of the covalent type had already been outgrown by his contemporaries. His diagrams, like his terminology, seemed to pretend to a concrete knowledge that he did not really possess. In addition, the side-chain theory needed a huge diversity of preformed antibody specificities. It was this weakness that Haurowitz's instruction theory of antibody formation was meant to correct. But to our contemporaries, that was just the feature that gave Ehrlich's theory its lasting value: It was a selection theory, like the theories of the 1950s. Finally, Ehrlich's drawings of the side-chain theory are a visual metaphor; they can represent a modern receptor as well as they did the receptor of 1900. Thus, Ehrlich has been given the role of an inspired precursor by historically conscious immunologists of the 1980s (Ada and Nossal 1987).

Finally, as Burnet himself saw, the conception of the clone originates in bacteriology, and that of selection, in a Darwinistic population genetics. The theory was not a new one. Instead, it was an old one transposed to a new and fertile setting, where it developed a truly explosive heuristic power. Rather than being revolutionary, it placed immunology among the biological sciences of the twentieth century, sharing with them their most fundamental assumptions.

The history of immunology, in spite of its seeming discontinuities, is one of the evolution of a single species: There are few extinctions in the fossil record of this science. But then, it is only 100 years old.

III.3
Nutritional Chemistry

The idea that diet is an important factor in health is a very old one and, if anything, had greater prominence in the time of Hippocrates than it does now. However, the development of a workable system or science of nutrition had to await the development of modern chemistry with its significant advances at the end of the eighteenth century.

Before that time, the purpose of nutrition in adults was assumed to be the replacement of abraded (or worn-out) tissues. Meat, the tissues of other animals, seemed an effective food for this purpose, because it provided essentially like-for-like, but vegetable foods seemed to be made of quite different "stuff." Animal tissues allowed to decompose became putrid and alkaline, whereas most vegetables became acid and did not become putrid. When heated and dried, animal tissues became hornlike, whereas vegetables became powdery. However, Iacopo Bartolomeo Beccari of the University of Bologna pointed out in 1728 that, when sieved (i.e., debranned) wheat flour was wetted and pummeled into a dough and then kept under running water

until the floury starch had been washed out, the residual gluten had all the properties of animal tissues. Similar fractions were found in other plant foods. It was thought that these were the essential nutrients, and it was the job of the digestive system to winnow away the unwanted starch, fiber, and so forth and leave the glutenlike material to be circulated in the blood, for patching and filling.

Protein

With the discovery of nitrogen as an element toward the end of the eighteenth century, and the development in France of methods for analyzing the amount of nitrogen in different materials, came the discovery that both animal tissues and the "animal-like" fractions in vegetables contained nitrogen, whereas starch, sugar, fats, and vegetable fibers contained only carbon, hydrogen, and oxygen.

After more work, mostly in Germany, it was concluded that these nitrogenous compounds were really all of one class, the *proteins,* and that they could be converted one to another by animals, but that as a class they had to come from the vegetable kingdom. Because they were considered the true nutrients, the value of a food or animal feedstuff could be judged by its nitrogen content. It was also thought that the force exerted in the contraction of muscles came from the "explosion" and destruction of some of their protein, with the subsequent breakdown of the residue to urea, a simple nitrogen compound that the kidneys diverted into the urine. It was therefore particularly important for those engaged in hard physical work to have a high-protein diet, and on a dry matter basis, the foods highest in protein were meat, cheese, and eggs.

As a corollary to this idea, carbohydrates (i.e., starch and sugars) and fats were considered "respiratory" foods. These were combusted in the body (i.e., they reacted with oxygen) and this produced heat; this reaction, by "mopping up" oxygen in the tissues, was thought to protect the valuable protein from oxidation.

Because people in affluent countries tended to eat more animal foods, and therefore more protein, it was concluded that the extra protein gave them extra energy, which, in turn, made them prosperous. The diet chosen by healthy, hard workers in the United States was found to contain, typically, some 120 grams of protein per day, and this was adopted generally as a recommended standard at the end of the nineteenth century.

Once set, however, the whole pyramid of ideas collapsed with the discovery that physical labor did

not cause a significant breakdown of muscle protein. Fats and carbohydrates were the main energy sources for all forms of activity. Tests showed that 60 grams of protein per day could support health and vigor in an active man. However, in the early years of the twentieth century, it was also discovered that all proteins were *not* nutritionally equal. Whereas protein molecules themselves were very large, typically containing more than 10,000 atoms, boiling them in a solution of strong acid resulted in the production of 20 or so fairly simple crystalline compounds, all of the same chemical class – the amino acids. Later work showed that proteins had to be broken down to these constituent units in the digestive tract before absorption could take place. The body proteins were then built up anew from these units, or building blocks, with each protein having a fixed composition.

The practical significance of this is that humans, and other members of the animal kingdom, have the ability to convert some amino acids to others, but about half of the amino acids must be provided by the diet. These are called the *essential amino acids*. In general, the mix of individual proteins contained in foods, even those of plants, includes all the amino acids, but the proportions differ. It was demonstrated in 1915 that growth stopped in young rats when the only protein they received was zein, a particular protein fraction from maize containing none of the amino acids lysine and tryptophan. Ordinary growth was restored by supplementing the diet with both of these chemicals, proving that they were dietary essentials. In later experiments with bean proteins, methionine (present in beans at a low level in relation to the requirements of animals) was determined to be the limiting factor for growth.

For productive farm animals, with their high rates of growth and reproduction, it has proved economic in some circumstances to supplement commercial diets with synthetic lysine or methionine. However, in practical human diets based on mixtures of foods, there is little evidence of a single amino acid being limiting. An exception are the amino acid–deficient diets of infants given some all-vegetable-protein formulas as substitutes for milk.

Energy

We return now to the role of carbohydrates and fats. After the realization that carbon, hydrogen, oxygen, and nitrogen together make up the great bulk of food materials, and the development of reasonably good analytic methods for their determination by about 1830, attempts were made in England to assess what quantities of carbon and nitrogen were required for an adequate diet. (Hydrogen and oxygen could be supplied in the form of water.) There was a demand at this time for objective, scientific answers to the problem of providing food for prisoners and inmates of poorhouses that would support health without being superior to what was within reach of honest, working laborers. The first estimate was that the average man required at least 300 grams of carbon and 15 grams of nitrogen per day.

It had been demonstrated as early as the 1780s, by Antoine Laurent Lavoisier and others, that respiration and combustion were similar processes, with carbon dioxide being an end product of each. By 1870 it had been shown that the heat produced by the metabolism of food in the body was the same as that produced by the combustion of food in the laboratory. This made it possible to transfer the physicists' new thinking about the conservation of energy and the mechanical equivalent of heat to nutrition. The contribution of carbohydrates and fats to the diet was then expressed not as so many grams of carbon, but as so many kilocalories of energy that would be released if they were metabolized to carbon dioxide and water in the body. (The amount of heat required to raise the temperature of 1 kilogram of water by 1°C is 1 kilocalorie. This is the unit used in nutritional literature, but commonly written as Kcal, the K indicating that the unit is the kilogram rather than the gram unit.)

It was possible to estimate the energy value of foods by burning them in an atmosphere of pure oxygen (to make complete combustion more rapid), using a submerged metal casket (usually called a "bomb"), and measuring the heat released from the increase in temperature of the surrounding water. This "gross" figure needed correction for the proportion of the food that was indigestible. With ordinary human foods, this was only a small correction, and for practical purposes values of 4 Kcal per gram for carbohydrates and 9 Kcal per gram for fats have been found adequate. Protein not needed for new tissue synthesis and broken down also yields approximately 4 Kcal per gram. Energy requirements were found to vary from as few as 2,000 Kcal per day in sedentary men to as many as 4,000 Kcal in someone doing long hours of physical work. Women, in general, had lower requirements in proportion to their smaller muscular frame. In practice, more than 90 percent of the food we eat is needed as fuel, that is, as a source of energy, rather than for the replacement of worn-out tissue.

Vitamins

Although the scientific evaluation of diets at the end of the nineteenth century focused on protein and energy, some realized that there were other requirements for a healthy diet. In particular, it was known that sailors on long voyages developed scurvy unless they periodically ate fresh green vegetables or fruit. Citrus fruit juice was particularly valued. James Lind, a British naval surgeon, carried out a famous controlled trial on a group of scorbutic sailors in 1747. He found that a combination of oranges and lemons produced a rapid cure, whereas neither sulfuric acid nor vinegar had any value.

Lind believed that scurvy resulted from the debilitating effect of the moist air in ships at sea and that the antiscorbutic factor in citrus fruits was not normally needed by people living on land. Nineteenth-century experience showed that this was not so. Scurvy was a serious disease among those rushing to the California gold fields in 1849, both when they were en route by ox wagon and after they had arrived. It caused thousands of deaths in the Allied armies during the Crimean War, and even broke out during the relatively short siege of Paris in 1870–1.

A lecturer at a London medical school had said in 1830: "Scurvy is a purely *chemical* disease . . . each part of the body is ready to perform all its functions, but one of the external things necessary for its doing so is taken away." He compared the condition to the suffocation of someone deprived of fresh air. The "necessary thing" for preventing scurvy, he said, was contained in fresh animal and vegetable food. By contrast, the diet of sailors and soldiers on active duty was normally restricted to dried and preserved foods. His views were finally to be proved correct 100 years later. After a series of erroneous guesses as to the nature of the antiscorbutic factor, real progress was made when a report from Norway in 1907 indicated that the disease could be reproduced in guinea pigs. This made it practicable to test different fractions of lemon juice and other foods, to concentrate the active factor, and finally to isolate it. This work was completed in 1932, and the chemical, called ascorbic acid (or vitamin C), was synthesized in 1933. Ascorbic acid proved similar to a sugar in its structure, and a daily intake of only 10 milligrams per day was sufficient to prevent scurvy. (This corresponds to approximately one-eighth of an ounce over an entire year.)

Since the discovery of vitamin C, there has been some controversy as to how much is required for optimal health. The official recommendation in most countries is from 30 to 75 milligrams per day, levels that can be provided by an ordinary mixed diet. Others, however, have recommended megadoses of up to 1,000 milligrams per day, or even more, on the principle that "if a little is good, more must be better," especially in resisting disease. In practice, such quantities can be obtained only by consuming the synthetic chemical.

A continuing role of nutritional chemistry is that of determining whether new kinds of food processing result in the destruction of vitamin C. For example, potatoes have been important in protecting northern Europeans from scurvy since their adoption as a major food staple in the eighteenth century. However, the process whereby they are converted to "instant" mashed potato powder destroys most of their vitamin C. Manufacturers therefore add synthetic ascorbic acid, so that the consumer receives the same benefit as that obtained from traditionally cooked potatoes.

Another disease that was associated with faulty diet by the end of the nineteenth century was beriberi, a potentially fatal condition first encountered by Europeans in the Dutch East Indies and Malaysia. Statistics from prisons and elsewhere indicated that it was associated with the use of white (i.e., highly milled) rice, rather than the cruder brown rice. The initial explanation was that, with the outer protective layers removed, white rice grains became contaminated by the penetration of toxic microorganisms through their porous surface. In a period when microorganisms were found to be responsible for so many diseases, the explanation seemed plausible. However, when it was discovered that chickens that had developed the same disease when fed white rice could be cured by the addition of the "branny layer" or "rice millings" to the white rice diet, the explanation seemed less satisfactory. Next it was realized that, if other starchy foods were substituted for white rice, the disease could still occur. Finally, it was accepted that this disease, and presumably others, could be explained by a *lack* of something, rather by positive toxicity. This became a central concept in the development of nutritional views.

The first attempts to isolate and identify the antiberiberi factor, using animals to test the activity of different materials, actually came before the corresponding work on the antiscorbutic factor. In 1912 Casimir Funk suggested that the factor in rice bran was a "vital amine," or "vitamine," and that a number of diseases were caused by a dietary lack of minute amounts of this or similar organic compounds. This proved to be true except that the compounds

were not all of the chemical group called *amines,* and the term was reduced to *vitamin.* At least until the chemical structures of the factors became known, they were listed as vitamins A, B, C, and so forth. And when vitamin B, the water-soluble factor in yeast, was realized to be itself a complex of factors, these factors were called B_1, B_2, B_6, and so on. These code names have now been largely replaced by the corresponding chemical names, which in this case are thiamine, riboflavin, and pyridoxine for B_1, B_2, and B_6. Altogether 13 vitamins have been discovered.

Some species need other organic compounds in addition to the vitamins required by humans; others can synthesize vitamins. Dogs, pigs, and many other animals, for example, make their own vitamin C and thus thrive on a diet that would be scorbutic for human beings.

Because the animal kingdom, as a whole, lives on the vegetable kingdom, one would expect that all of the vitamins we in the animal kingdom require would be synthesized by plants. However, there were some puzzling exceptions for investigators to unravel. The first was vitamin A (or retinol), the fat-soluble factor, the lack of which resulted first in an inability to see in dim light and then in ulceration of the cornea of the eye and permanent blindness. The richest sources of the factor were fish liver oils; it was colorless and had characteristic chemical properties. Yet green leafy foods also prevented the deficiency, but apparently did not contain the same chemical. Finally it was discovered that green leafy foods contained a group of chemicals, the carotenoids, yellow, orange or red in color, which acted as provitamins – and were converted to the actual vitamin in the body.

Another disease to be associated with the lack of a fat-soluble vitamin was rickets, and again workers engaged in studying the cause of the disease obtained apparently contradictory results. Some reported that they could cure rachitic puppies by giving them exercise, that is, taking them for walks, without changing their diet. Others reported that they could cure the condition not by giving the puppies exercise but by supplementing their diet with fish liver oil – even if the oil had been oxidized so that it had lost its vitamin A activity. This paradox was resolved by a long series of studies showing that an active factor (to be named vitamin D) was produced by the action of the sun's ultraviolet rays on sterols, such as cholesterol, which animals synthesized for themselves. Vitamin D is synthesized in animal or human skin exposed to sunlight, after which it is stored in the liver.

The function of vitamin D was next related to the absorption of calcium and its deposition in bones. Rickets, which characteristically results in bent legs, occurs when bones are soft and undermineralized. The condition so prevalent in young children in Victorian cities was caused by inadequate irradiation of the skin, because of the pall of smoke from coal-burning homes and industries *and* the use of starch-based weaning formulas that lacked the vitamin. For a given amount of irradiation, less vitamin D is synthesized in people with pigmented skins than in people with less pigmentation. At the beginning of the twentieth century, a mild case of rickets was considered almost normal in the young children of black families who had migrated to northern industrial cities in the United States. It is still a problem among children of Asian immigrants in the United Kingdom.

Cobalamin (or vitamin B_{12}), the last vitamin to date to be discovered (in 1948), is synthesized only by microorganisms. Ruminant animals obtain it from the bacteria living in their rumen (i.e., fore-stomach), and others from food with adhering soil bacteria. Omnivores, humans among them, obtain the vitamin from meat, fish, eggs, and milk.

As with ascorbic acid, the development of chemical analytic methods for determining the levels of each vitamin in foods and the inexpensive production of vitamins have enabled food manufacturers to fortify processed foods with them – without unduly raising their prices. Thus, margarine has vitamins A and D added at levels at least as high as those in butter, for which it is a substitute. White rice is fortified with thiamine, milk with vitamin D, and so on. In addition, many people in the more affluent countries take vitamin pills, or capsules, to ensure that they are receiving a sufficient dosage or in the hope of "superhealth," although there is no conclusive evidence that there is such a thing.

Minerals

The last class of long-recognized nutrients comprises minerals. Dried bones were known to consist mainly of calcium phosphate, and when other tissues were brought to red heat in a furnace, there was always a small residue of incombustible ash, or mineral salts. Up to about 1850 it was apparently assumed that a practical diet would always supply a sufficient quantity of these minerals in humans, and even in fast-growing farm animals. Yet deficiencies can and do occur, as can be seen from a discussion of three elements.

The fact that iron salts were an effective treat-

ment for chlorosis ("green sickness") in young women was not at first regarded as the correction of a nutritional deficiency. Thomas Sydenham, for example, wrote in 1670 that a medicine made from steeping iron filings in wine and boiling the liquid down to a syrup had the effect in cases of chlorosis of "returning the pale and death-like face to a ruddy color and giving the pulse strength." But there was no more suggestion of this being a nutritional use of iron than there was of mercury being a nutritional factor in the treatment of syphilis.

By 1800, however, it was understood that blood contained iron, and then that the level of iron was reduced in the paler blood of chlorotics. From 1830 pills containing ferrous sulfate were in standard use for the treatment of chlorosis, or anemia as it came to be known, and were considered to be generally effective.

German workers, however, who were in the lead from 1850 in carrying out quantitative balance studies in model animals, became skeptical as to whether these pills actually contributed iron to the blood. When large doses of ferrous sulfate were given orally to dogs, the iron was recovered almost completely in their feces, with little or none appearing in the urine. This result contrasted with the results of the Germans' previous work on protein nutrition in dogs. Proteins were absorbed almost entirely from the gut, and those not immediately required were broken down, with the surplus nitrogen appearing in the form of urea in the urine. The scientists' first conclusion, therefore, was that inorganic iron salts were indigestible and therefore useless in the treatment of anemia. But realizing that this was contrary to the clinical evidence, they hypothesized that the iron in some way neutralized the harmful effects of bacteria in the gut, leading to better absorption of the natural components of the food.

Further work showed that even iron salts injected into a dog's tissues failed to appear in the urine. In fact, it appears that animals and humans have essentially no means of excreting surplus iron from tissues. The balance is maintained by carefully controlled absorption mechanisms that normally admit only as much iron through the gut wall as is required by the tissues. However, even under conditions of acute deficiency, no more than 20 percent of iron in foodstuffs can be absorbed, and normally it may be only 1 to 2 percent. Mild anemia remains a problem in many parts of the world, particularly for women on mainly vegetarian diets. They generally eat less than men but have a greater need for iron because of their loss of menstrual blood.

Animals grazing in fields where the soil is low in particular elements are unproductive because the plants they eat are also low in such elements as copper, cobalt, and phosphorus. This problem is virtually unknown in human nutrition because of the greater variety of our diets. However, iodine is one exception. This element was discovered in 1811, and by 1820 its salts were already being used in the treatment of goiter. This is a condition of gross swelling of the thyroid gland at the front of the neck. It had always been common in particular areas of the world, usually those well away from the ocean. Traditional treatments with seaweed and the ash of sponges were explained by their high content of iodine, and by the 1830s it was proposed that goiter, and the associated condition of cretinism in children, was due to a deficient iodine intake. This was followed by the widespread use of iodine compounds, often with bad effects, so that the theory became discredited. August Hirsch, in the English edition of his *Handbook of Geographical and Historical Pathology,* published in the 1880s, referred to the "short-lived opinion" that iodine deficiency explained the problem and said that the evidence compelled one to conclude that goiter and cretinism should be classed among the infective diseases.

Gradually, however, it came to be understood that relatively small excesses of iodine could be toxic, but that a minimal average intake of 50 millionths of a gram per day was needed to avoid goiter. Indeed, the swelling of the thyroid produced by iodine deficiency is apparently a feedback reaction whereby the body attempts to capture more of the element in order to use it for the synthesis of hormones. The prevention of goiter is the only known role of iodine in animal organisms, but the stimulatory effect of hormones extends to all tissues. Children born as cretins, because of a lack of iodine, have irreversible brain damage.

Extensive chemical analysis of foods and water supplies have failed to explain the existence of goiter in a few areas of the world, and it is believed that other factors may reduce either the bioavailability of the iodine consumed or the effectiveness of the thyroid hormone produced from it. Some such factors, in cabbage family plants, for example, are already known. However, even in these areas an increase in the iodine supply has greatly reduced the incidence of goiter and also of cretinism.

In most countries where the production of domestic salt is organized in fairly large-scale units, it has been found practicable to fortify it with up to 1 part in 10,000 of potassium iodide or iodate. This has

proved an effective public means of preventing the disease. In areas where salt is not refined, those at risk are sometimes given an injection of iodized oil, which can remain effective for as long as two years. In many affluent countries, chemists must ascertain whether the consumption of iodine is excessive because of the increasing use of iodine-containing chemicals for the disinfection of food-processing equipment.

Another chemical element discovered in the same decade as iodine is selenium. In the 1930s it was found to be present at toxic levels in plants grown on soils rich in selenium in Wyoming and the Dakotas, and responsible for disease among grazing sheep. But not until 1957 was it recognized as an essential nutrient. Farm animals have been found to be deficient in places as far apart as Sweden and New Zealand; these animals have characteristic lesions in their muscles, including heart muscle. The major cause of keshan disease in parts of China, in which children die with characteristic changes in their heart muscle, is now suspected to be selenium deficiency.

Reassessments

By the 1960s the status of nutrition could be summarized as follows:

1. Apparently all of the chemical nutrients had been identified, so that it was possible to define an adequate diet in completely chemical terms.
2. There was still a great deal of malnutrition among the poorest people on the earth, mainly because of a lack of *quantity* of food. And the coarsest foods were too bulky for the small stomach capacities of newly weaned infants. The main problem was therefore one of economic distribution of purchasing power and of the organization of food production rather than programs aimed at supplying specific nutrients.
3. The main exceptions to this were the deficiency of vitamin A in children in developing countries and the large pockets of goiter and cretinism, also mainly in developing countries. Again, there were scientifically tested procedures for dealing with these deficiencies, and their execution was a matter for government programs of education and public health, with technical support.
4. The populations of the most affluent countries had diets that in general provided most of the recommended levels of nutrients. Yet life expectancy at age 5 in a country such as Cuba or Panama was greater than that for corresponding children in a country like the United States or Sweden, with a

much greater average income per head and far more sophisticated sanitary and medical resources. The major cause of the shorter life expectancy in the richer countries was the greater risk of cardiovascular heart disease resulting in a "heart attack." It also appeared that individuals in affluent communities were more subject to certain types of cancer.

Rich Diets

Among the factors considered to be potential contributors to this condition was the "affluent diet." Obviously, individuals' diets differed, but typical patterns in the more prosperous Western countries revealed considerably higher levels of sugar, salt, and fat than existed in diets elsewhere. Almost all recommendations up to that point had consisted of "at least so much of this" and "don't risk being short of that," particularly to encourage maximum growth in the young.

But now there is an entirely new type of research on dietary factors that could have adverse long-term effects when nutrients are consumed at high levels for long periods. One factor is total energy intake. People whose intake is not limited by a shortage of money and who burn fewer calories because they do not engage in much physical work or exercise tend to gain weight. Grossly obese people are, in general, poor health risks – for diabetes, for example, as well as for cardiovascular heart disease. One can calculate the number of calories a person needs to consume to maintain an ideal weight, but appetite can be compelling, and obesity is a problem for millions of people, in terms of both physical health and self-esteem. Nutritional science has not been able to provide a simple solution, though the dietary changes to be discussed next have been of some help in this regard. (It should be noted that health risks increase only with *severe* obesity. Many people feel compelled to become abnormally thin, and young women in particular may become seriously ill from anorexia, that is, "failure to eat.")

Cholesterol and Fat

Cardiovascular disease involves the blockage of arteries that provide oxygen within the muscular walls of the heart. The death of even a small portion of this muscle from lack of oxygen can result in the disorganization of the heartbeat and thus a failure of the heart to meet the body's oxygen needs. The plaques that build up in blood vessels and that narrow the flow of blood contain a high proportion of cholesterol. The typical diet of affluent Westerners

with their high intake of animal foods (i.e., meat, eggs, and dairy products) is rich in cholesterol. One recommendation, therefore, has been to lower cholesterol intake, in particular the intake of egg yolks (even though in the past eggs were regarded as the perfect food because they contained everything the rapidly growing embryonic chicks needed).

Cholesterol, however, is a vital constituent of cell walls, and we, like other animals, synthesize it continuously, regulating that synthesis (at least to some extent) according to dietary intake. Some studies indicated that people with high blood levels of cholesterol were at greater risk from cardiovascular heart disease. But evidence mounted that cholesterol levels in the blood were affected more by the dietary intake of saturated fat than by simple cholesterol intake. "Saturated," in this context, means saturated with hydrogen. In practice, saturated fats are those, like beef or mutton fat, butter, and some types of margarine, that are solid at room temperature.

In contrast, most vegetable fats, which are called "oils" because they are normally in the liquid state – for example, corn oil and olive oil – are more unsaturated. Margarines are made from vegetable oils that are saturated by hydrogen to various extents. Soft, or "tub," margarines are the least saturated. Of current interest is whether the fat content of the "affluent diet," in which fats typically provide 40 percent of the calories, should be reduced or whether there is something about unsaturated fat that counteracts the adverse effects of animal fats. In particular, the "omega-threes" found in fish oils are under intensive study. Also, strong evidence exists that people with high blood pressure (hypertension) are at increased risk from cardiovascular heart disease, and that a high salt intake promotes this condition.

Dietary Fiber

Modern food industries have been able to process seeds and vegetables so as to extract the fat and sugar or, in the case of grains, to mill off the outer branny layers to yield white rice or white wheat flour. The public, in general, prefers sweet foods that "slip down" easily because of their fat content and contain nothing "scratchy in the mouth." The fibrous residues from the processing of foods of this type have been used to feed farm animals. Ruminants, in particular, are able to ferment and utilize cellulose.

In the past it was thought that, because "roughage" apparently passed through the gut unchanged, the fiber had no significance as long as people had just enough not to become constipated. But in recent

years, a lower incidence of cancer of the colon among communities isolated from sophisticated Western food products has prompted the suggestion that these people are protected by the higher fiber content of their diets. Perhaps the greater volume of material in the colon dilutes any carcinogenic compounds present. It is thought that gut bacteria may produce such carcinogens by acting on bile acids.

Of course, differences among communities in the incidence of colon cancer can be explained by things other than diet. However, genetics does not appear to be one of them, because, in general, after two generations, emigrant groups seem to have a disease pattern similar to that of their hosts. Moreover, some studies have confirmed the importance of diet in colon cancer; there tend to be fewer cases among vegetarians than among other groups. Vegetarians obviously have a lower intake of fat and animal protein than do others, and they consume more vegetables and more fiber.

Vegetables are extremely complex mixtures of natural, "organic" chemicals. Some believe that, rather than fiber, the green and yellow vegetables that are the principal sources of carotenoids in our diet may provide protection against colon cancer. The protective factors could also be other chemicals found in some vegetables more than others. For example, there is a class of compounds, including pectins and gums, that are not digested in the small intestine along with starch, but are rapidly fermented by bacteria when they reach the colon. They are now subsumed within the overall term *dietary fiber,* though they may in some respects produce effects that differ from those of the largely unfermented cellulose.

Research in the field of nutrition is inevitably slow. Diseases appearing mainly in middle-aged humans cannot be modeled with certainty in short-term animal trials. In the meantime, nutritionists' most common advice, after the admonition to get more exercise and stop smoking, is to consume a "prudent" diet modeled on the traditional Mediterranean peasant diet, with a predominance of cereals, vegetables, and fruit, a sparing amount of meat, preference being given to fish and chicken, and a moderate amount of dairy products that are low in fat.

Summary

The first problem for nutritional science, to identify the chemicals required in a diet to support growth and maintenance, has been solved. The deficiencies involved in diseases such as scurvy and beriberi have been identified. The adequacy of diets can be

determined and the deficient nutrients supplied. The problems of malnutrition are now largely political and economic. Another problem for nutritional science is to ascertain which components of our foods either enhance or reduce our resistance to chronic disease. This work is still at an early stage.

III.4
Diseases of Infancy and Early Childhood

In ancient times physicians wrote primarily on the care of infants, and only incidentally about children's diseases, because their concept of medicine stressed the maintenance of health rather than the diagnosis of specific disease entities (for medical perspectives on children during antiquity, see Etienne 1973). The earliest of these "pediatric" texts known to us was that of Soranus of Ephesus (active around A.D. 100), *On Gynecology*, which included 23 chapters on infant care (see Soranus 1956; also Ruhräh 1925; Still 1931; Garrison 1965; Peiper 1966). First, Soranus gave instructions on sectioning the umbilical cord, feeding, swaddling, choosing a wet nurse (if necessary), bathing the baby, and other activities essential to infant care. Then he discussed the treatment of common disorders of infancy, including teething, rashes, and "flux of the belly," or diarrhea.

Soranus was a leader of the Methodist sect at a time when Greek medicine was enlivened by various contending schools of thought. Methodism taught that disease was due to excessive relaxation or contraction of internal pores of the body, leading to immoderate secretion and moisture in the first instance and to diminished secretion and dryness in the second. The cause of disease was considered unimportant, stress being laid instead on treatment that, crudely put, consisted of inducing the contrary state, drying the moist or humidifying the dry. In his section on infant management, Soranus concentrated on the practicalities of care and treatment without slavish adherence to the tenets of Methodism. The result was a pragmatic guide uncomplicated by theoretical or speculative overtones.

During the second century, Claudius Galen inaugurated a radical change in perspective by setting out his own complex theoretical synthesis. In so doing he established humoral theory, already several hundred years old, as the main guide to understanding health and disease. He was so successful that for the next 1,500 years humoral doctrine permeated most medical writings, including those on children and their diseases (for a guide to humoral theory, see Ackerknecht 1968).

According to this doctrine, the four elements, earth, fire, air, and water, were related to four quali-

ties, hot, dry, cold, and wet. These qualities in turn interacted with the four humors of the body, blood, phlegm, yellow bile, and black bile. Well-being depended on the humors being in balance. Illness came about when one or more humors became predominant either for internal, constitutional reasons or because of external strains, usually dietetic or climatic. To restore health required ridding the body of excess humors either actively, through drugs, purging, vomiting, or bloodletting, or passively, by maintaining the patient's strength while trusting nature to restore the natural humoral state. Hippocratic physicians had favored the latter, expectant method, whereas Galen advocated the former, more energetic course of action.

Book 1 of Galen's *Hygiene,* entitled "The Art of Preserving Health," contains five chapters on the care of the newborn and young child. Milk, according to Galen, was the ideal food for infants "since they have a moister constitution than those of other ages" (Galen 1951). Infants were also warm by nature, and "in the best constituted bodies," this quality would remain constant until adolescence, when it would increase in intensity. In contrast, the normal body would steadily dry out from infancy onward to reach desiccation in old age. In addition, there were individual differences, inborn divergences from the ideal constitution, that would require special management, but these were not specifically discussed in Galen's *Hygiene.*

However, the concept of constitutional change during growth and development, associated with that of innate differences in temperament or constitution, gave great flexibility to humoral theory and an almost limitless explanatory power. In part because the theory was so intellectually satisfying, its validity was not seriously questioned until about the sixteenth century. Even after the surfacing of doubts, humoralism survived, in various eroded forms, into the nineteenth century. In contrast to the modern ontological concept of diseases as specific entities (each with its own cause, natural history, and cure), under humoral doctrine illness was considered a personal manifestation of humoral imbalance due to environmental stress interacting with the individual's own special constitution. However, the dichotomy was not absolute, because ancient physicians recognized some diseases as specific entities and named them according to presumed anatomic site or to cause. Thus, the Hippocratic writings described phthisis (tuberculosis), pneumonia, and pleurisy, and in succeeding centuries such distinctions became more common. (For fuller discussions of histori-

cal conceptions of disease and its relation to health, see Riese 1953; Temkin 1977.)

The interplay between the humoral and ontological interpretation of disease can be illustrated by an examination of medieval and early modern descriptions of measles and smallpox. Rhazes, an Arab philosopher and physician at the turn of the tenth century, wrote a text on children, *Practica puerorum,* unusual for the times in that it dealt only with diseases and ignored infant management (for an English translation and analysis, see Radbill 1971). Rhazes also penned a treatise on smallpox and measles, which he distinguished between but considered to have the same cause: putrefaction and fermentation of the blood. Whether a person exhibited the symptoms of smallpox or those of measles depended on humoral constitutions (see Rhazes 1939).

Until about the seventeenth century, physicians followed Rhazes' example in describing the two diseases under the same heading. Thomas Phaire, a Welsh physician whose pediatric text, published in 1545, was the first to appear in the English language, began his chapter on smallpox and measles thus: "This disease is common and familiar . . . it hath obtained a distinction into two kinds: that is to say, varioli the measles, and morbilli, called of us the smallpox. They be both of one nature, and proceed of one cause, saving that the measles are engendered of the inflammation of blood, and the smallpox of the inflammation of blood mingled with choler [yellow bile]" (Phaire 1965).

In the following century an English physician, Thomas Sydenham, provided the first description of measles per se, as well as of scarlet fever and "chorea" (St. Vitus dance, Sydenham's chorea). He did so on the basis of clinical observation while retaining a humoral interpretation of cause and treatment. That Sydenham could be innovative while still adhering to humoral theory was due in part to his conviction that diseases could be classified into species, as were plants and animals. In giving advice on medical reform, he stated: "It is necessary that all diseases be reduced to definite and certain *species,* and that, with the same care which we see exhibited by botanists in their phytologies" (Sydenham 1848; Yost 1950). Sydenham himself never published a nosology, but his advice was repeatedly heeded in the eighteenth century, Carl von Linné (Linnaeus), the great plant and animal taxonomist, being one of the first to produce a classification of diseases.

Nosology did not prosper in pediatrics, where eighteenth-century physicians continued to list symptoms and diseases unsystematically. Yet it was

one of Sydenham's pupils, Walter Harris, who first diverged from classical humoral theroy. In his *Treatise of the Acute Diseases of Infants* (published in 1698 in Latin) Harris insisted that the prevailing cause of illness in infancy was excess acidity. Cure involved neutralizing and absorbing the acid with "testaceous powders" such as powdered oyster shell, crab's claws, egg shell, chalk, coral, mother of pearl, and burned ivory. The residue was then removed by purgation. Harris recommended rhubarb, a mild laxative by the standards of the time.

For the next 100 years, until the early nineteenth century, Harris's acid theory was predominant. George Still (1931) has suggested that its popularity was due to its simplicity. The old humoral pathology no longer seemed a reliable guide: it had become very complex because commentators felt free to amend it to suit themselves. In contrast, Harris supplied his readers with a simple cause and remedy for most early childhood ailments.

The late eighteenth century witnessed a revolution in chemistry. Owing to experimental input from many natural scientists and to Antoine Lavoisier's deductive genius, much time-honored knowledge was discarded. This included the Aristotelean doctrine of the four elements so intimately related to humoral theory, which was replaced by propositions that became foundational to modern chemistry. The revised science had swift repercussions in medicine, including pediatrics. Previously, physicians and others had evaluated the quality of milk on sight, by tasting, or through a nail test originally credited to Soranus that involved assessing the consistency of milk by pouring a drop on the fingernail and watching the rate of spread (Soranus 1895; Still 1931). Now, both human and animal milk could be subjected to chemical analysis. In the 1799 edition of his pediatric text, the English surgeon-midwife Michael Underwood (1806) discussed and tabulated the comparative properties of human and animal milk. Early in the nineteenth century, chemists were supplying information on the nitrogenous (protein), fat, carbohydrate, and mineral content of common foodstuffs. However, vitamin detection was delayed until the twentieth century with consequences that will be discussed in the section on deficiency diseases.

In the second half of the eighteenth century some medical men, notably Giovanni Morgagni and John Hunter, stressed the need to correlate clinical signs during life with later autopsy findings. This approach was occasionally used in the eighteenth-century pediatrics, by Robert Whytt, for example, in his observations on dropsy in the brain or acute hydrocephalus (reprinted and discussed in Ruhräh 1925). Whytt gave an excellent clinical account of this condition, which, however, would not be recognized as meningitis due to tuberculosis until the early nineteenth century. The regular practice of performing autopsies began with the advent of children's hospitals, which were introduced in Paris after the French Revolution. The Enfants Malades was established in 1802 for sick children over the age of 2 years and the ancient foundling hospital, the Enfants Trouvés, was reorganized to accommodate ailing babies as well as unwanted ones.

From contemporary reports one gathers that physicians were rarely refused permission to perform autopsies (Crosse 1815). With a relatively large number of children under their care, hospital doctors could also apply the so-called numerical method, a rudimentary statistical analysis by which mortality as well as complication and recovery rates could be assessed (Ackerknecht 1967). Under this system certain diseases, such as early childhood tuberculosis, could now be recognized and reported. Whytt's "dropsy of the brain" was classified as a manifestation of tuberculosis when it was discovered that the disease was associated with granular tubercular deposits on the membranes covering the brain (Papavoine 1830).

French pediatricians attempted to classify children's diseases, whereas, as already mentioned, earlier authors had dedicated chapters with complete impartiality to symptoms (e.g., nightmares, sneezing, hiccoughs) and to specific morbid conditions (e.g., mumps, measles, smallpox). In 1828 Charles M. Billard published a text exclusively on infant diseases, which he classified according to the site of the main lesion: skin infections, those of cellular tissue, of the digestive tract, of the respiratory and cardiac systems, of nervous or cerebrospinal origin, of the locomotor and generative systems, and finally congenital disorders. Frédéric Rilliet and Antoine Barthez, authors of a general pediatric treatise first published in 1843, used a different method. Diseases were classified primarily according to underlying pathology: phlegmasias (inflammations), hydropsies (accumulation of watery fluid), hemorrhages, gangrenes, neuroses, acute specific diseases, the various kinds of tuberculosis, and finally entozoan (parasitic, caused by various worms) diseases. Under these headings, further subdivisions were made according to the site affected (Barthez and Rilliet 1853).

In early-nineteenth-century Paris, with children's hospitals growing in number and size, pediatrics

emerged as a specialty inasmuch as physicians there could engage full time in the care of children. They published extensively, stimulating interest in pediatric research abroad, although in the United States and in Britain physicians continued throughout the nineteenth century to be generalists rather than specialists (for the history of pediatrics in the United States, see Cone 1979). At first, the concept of pediatric hospitals did not gain approval in English-speaking countries for a variety of reasons, some of which are remarkably consonant with modern opinion. It was said that children, especially babies, should not be separated from their parents and would have a better chance of recovering at home than in hospitals, where, as evident from the Parisian reports, cross-infection was rife (Anon. 1843). On Malthusian and moral grounds, Henry Brougham held that "the gratuitous maintenance of poor children, may safely be pronounced dangerous to society, in proportion as it directly relieves the parent from his burthen. It removes the only check upon improvident marriages, and one of the principal guards of chastity" (Brougham 1823). With Brougham, foundling hospitals were the prime but not the exclusive subject of contention. Nevertheless, by the 1850s opinion had changed sufficiently to allow for the establishment of pediatric hospitals, albeit small ones initially, in the United States and Britain. One reason for the change was pressure from physicians who argued that the intensive investigation of pediatric disease required a hospital base (Anon. 1849).

For the next hundred years, pediatric hospitals and clinics served as sites of further investigation and treatment of disease. After World War II, however, the earlier concept that babies and small children should not be separated from their mothers surfaced again with renewed intensity. Psychoanalysts in particular drew attention to the long-term emotional effects of maternal deprivation, most evident in children reared in orphanages but also demonstrable in babies hospitalized for acute disease or for surgery. Most influential perhaps was the 1951 report prepared by John Bowlby (1951) for the United Nations program on the welfare of homeless children, but as early as 1942 Harry Bakwin, a pediatrician, had drawn attention to apathy in babies confined to hospitals. Indeed, from the mid-nineteenth century onward some physicians had opposed the isolation of infants, but the dictates of hospital organization and fears of cross-infection severely restricted parental access to their children until the psychoanalytic concept of maternal deprivation was elaborated in the 1950s.

Cross-infection had frequently ravaged pediatric wards in the early nineteenth century; hence, with the discovery that microorganisms caused contagious diseases, the isolation of potentially infective patients seemed an obvious solution. As Harry Dowling (1977) points out, between 1880 and 1900, 21 microorganisms were identified as the causes of specific diseases, including the bacilii responsible for tuberculosis, typhoid fever, and diphtheria. Also discovered were the pneumococcus and meningococcus associated with the common forms of pneumonia and meningitis, and the streptococcus whose hemolytic form produced scarlet fever and rheumatic fever. Yet knowing the causes of these illnesses was not immediately helpful. More obvious benefits would have to await specific vaccines and antibiotics.

Babies continued to die at a steady rate. As historians have frequently indicated, in England the infant mortality rate did not decline during the nineteenth century, hovering between about 140 and 160 per 1,000 from 1839, when national vital statistics were first recorded, until 1900, even though all other age groups exhibited a falling death rate from midcentury onward (Logan 1950; McKeown 1976; F. B. Smith 1979; Winter 1982; Wohl 1983; Dwork 1987).

Most other countries that kept vital statistics were looking at similar trends. In Massachusetts, the earliest state to keep continuous records, the infant mortality rate was similar to that of England. During the second half of the nineteenth century, Massachusetts reported the highest infant mortality rate of 170 for the years 1870 to 1874 and the lowest of 123 for the years 1855 to 1859; for 1895 to 1899 the rate was 153 (U.S. Bureau of the Census 1960). The French and Germans reported even higher infant death rates; in 1895 the French infant mortality rate was 177, the German one 230 (Mitchell 1975). However, the Scandinavian countries and Ireland were doing much better, with lower and falling infant death rates during the second half of the century, demonstrating that much loss of life elsewhere was unnecessary. In 1895 the infant mortality rate in Norway was 96, in Sweden 95, in Denmark 137, and in Ireland 104 (Mitchell 1975). In England, regional statistics showed that infant mortality was often twice as high in industrial areas as in rural ones, which, together with the Scandinavian experience, suggested that predominantly agricultural societies exhibited conditions most favorable to infant survival (for contemporary discussions, see Jones 1894; Newman 1907). Industrial areas were more lethal, it was often concluded, because so many mothers went out to work, abandoning their babies to

casual care and bottle feeding. Dirt and environmental pollution, including food contamination, were seen as secondary to the damage caused primarily by a lack of breast feeding.

According to English vital statistics, the main killers of infants were "atrophy" and debility, pulmonary diseases (bronchitis and pneumonia), convulsions and meningitis, diarrheal diseases, and tuberculosis (Newman 1907). In the United States the picture was similar, except that diarrheal diseases accounted for a larger porportion of deaths, while pulmonary diseases were less prominent than in England (Cone 1976). By the last third of the nineteenth century, smallpox, which formerly had been particularly hazardous to babies, no longer accounted for many deaths, probably owing to widespread vaccination in the first months of life. But otherwise, medical progress, including the recognition of microorganisms as the cause of infectious diseases, seems to have had little relevance to the plight of infants. The diarrheal diseases, for example, included a variety of conditions that defied simple classification. Job Lewis Smith, a noted New York pediatrician, discussed simple diarrhea, intestinal catarrh or enterocolitis, the dreaded cholera infantum, enteritis, and colitis in the 1890 edition of his *Treatise on the Diseases of Infancy and Childhood.* Infantile cholera, the most acute and severe type, was so called because its symptoms were so similar to those of epidemic cholera. Diarrheal diseases were more common and fatal in the hot summer months, but the hot weather alone could not be responsible because summer diarrhea caused less harm in rural areas. Smith therefore subscribed to the time-honored view that the cause was related "to the state of the atmosphere engendered by heat where unsanitary conditions exist, as in large cities." Once, out of deference to germ theorists, he sent intestines from a child who had died of cholera infantum for examination by William H. Welch. The report was inconclusive because all kinds of bacteria were found on the surface of the intestines. Still, Victor C. Vaughan, professor of hygiene and physiological chemistry at the University of Michigan, was confident that the diarrheas were caused by toxin-producing bacteria. In his opinion, "there is not a specific micro-organism, as there is in tuberculosis, but any one or more of a large class of germs, the individual members of which differ from one another sufficiently morphologically to be regarded as distinct species, may be present and may produce the symptoms" (Vaughan 1897).

Recent historians, particularly Anthony S. Wohl (1983), have pointed out that maternal malnutrition probably contributed significantly to the high infant mortality. Chronically undernourished women gave birth to puny, sickly babies ill-equipped to withstand exposure to infection and the other hazards prevailing in a working-class environment, such as cold and damp housing and an inadequate diet. On the whole, however, Victorian physicians did not consider poverty and its consequences to be responsible for the unacceptably high infant mortality rate. Instead, they focused on the dangers of artificial feeding; influenced by middle-class expectations and standards, they berated women for going out to work, leaving their infants to be bottle-fed and possibly drugged by ignorant baby minders. It apparently did not occur to them that a mother's earnings might be essential for family survival, probably because a working mother was so contrary to the general Victorian image of womanhood.

By the onset of the First World War, infant mortality had fallen significantly in most European countries and in the United States. The infant mortality rate for Massachusetts dropped from 141 in 1900 to 116 in 1914 (Woodbury 1926). In England and Wales the reduction was from 154 in 1900 to 105 in 1914. Some of this abrupt change must be attributed to factors that had emerged in the nineteenth century but had taken time to prove beneficial, for example, better nutrition for the population at large leading to the birth of healthier babies (for discussions of the reasons for the decline of mortality at the turn of the century, see Woodbury 1926; McKeown 1976; Dyhouse 1978; F. B. Smith 1979; Dwork 1987). The contribution of direct medical intervention to the initial decline in mortality remains debatable, but progress in the understanding of disease began to exert observable effects on infant survival after World War I.

So numerous were the twentieth-century breakthroughs in understanding pediatric disease that only a brief summary can be attempted here. A listing of important disease categories is accompanied by a short discussion of how changes in traditional thinking gradually provided a new basis for remedial action.

Diseases Related to Infant Feeding

Infant nutrition is intimately connected with health. Breast feeding was always recognized as the ideal method of nourishing infants but was not always practicable. If a mother was unable or unwilling to suckle her baby, wet nursing was a socially acceptable alternative until the beginning of this century. In poorer families, however, nursing could be re-

placed only by artificial feeding. A fourth option, direct suckling from an animal, commonly the goat, was sometimes adopted on the European continent.

The literature on infant feeding is enormous (for comprehensive historical studies, see Wickes 1953; Cone 1976; Fildes 1986). By the nineteenth century, physicians in the United States and Britain tended to discourage wet nursing because of the adverse effects on the nurse's own infant, who was usually abandoned to foster care and the bottle. Efforts were directed toward increasing the safety of bottle feeding, perceived as the most important cause of high infant mortality. In 1867 Justus von Liebig, the renowned German chemist, marketed an infant food prepared on scientific principles (Drummond and Wilbraham 1958). It was not as perfect as he assumed (vitamins were then undreamed of), but it was the forerunner of an endless variety of proprietary infant foods. Many contained only powdered carbohydrates and thus, if not made up with milk and supplemented with other foods, could not begin to nourish an infant (for a discussion of interactions between physicians, infant food companies, and mothers, see Apple 1981).

A somewhat different situation prevailed in France, where it had become common practice by the eighteenth century for infants to be sent into the countryside to be wet-nursed together with the foster mother's own baby (Sussman 1982). Infant mortality was even higher than in English-speaking countries, the fertility rate was lower, and in part because of the threat of depopulation, concerned French physicians finally introduced novel methods for improving infant survival. In 1892 Pierre Budin, professor of obstetrics, organized a "Consultation de Nourrisons" at the Charité Hospital in Paris. Women who had been delivered at the hospital were advised on breast feeding and infant care; after discharge, the babies were examined and weighed weekly until weaned, then less frequently until they were 2 years of age. Great emphasis was placed on breast feeding, as well as on weight and height. Also in 1892 Gaston Variot, a pediatrician, organized the distribution of sterilized milk, at reduced prices, at the Belleville dispensary. Two years later, Léon Dufour, a medical practitioner in Normandy, opened a milk station, called the "Goutte de Lait," at Fécamp. Here also babies' growth was carefully supervised, and when breast feeding proved impracticable, sterilized milk was provided free or at reduced prices (McCleary 1935; Blake 1953).

At first there was friction between Budin and Dufour because the former felt that the Gouttes de Lait, rapidly being established all over France, encouraged artificial feeding. But soon the two men compromised and together organized the first international conference on infant welfare (Congrés International des Gouttes de Lait, 1905) held in Paris. Similar movements were developing in other countries. As early as 1893, the philanthropist Nathan Straus began organizing the distribution of pasteurized milk for children under 5 years of age in New York City (Straus 1917). At about the same time, Henry L. Coit arranged for the production of certified milk in Newark, New Jersey (Blake 1953). These pilot schemes demonstrated the possibility of ensuring a clean milk supply, although because of the expense involved city authorities only gradually adopted similar methods to ensure safe milk for all inhabitants. Rapidly disappearing, however, was the nineteenth-century conviction that breast feeding was the only safe way of nourishing infants. The new century ushered in greater professional acceptance of bottle feeding, spurred on by the availability of methods of checking the purity of milk and its bacterial content and of sterilization and pasteurization. Also novel was the awareness that incipient illness was often indicated by the failure of a baby's height and weight to increase, measures that were easy to monitor on a regular basis.

However, as will be discussed in the next section, not until the 1920s was it understood why infants fed sterilized milk, or proprietary foods, might not thrive unless also given supplements such as orange juice.

Deficiency Diseases

According to J. C. Drummond and Anne Wilbraham (1958), the earliest mention of rickets as a disease entity was made in a 1634 Bill of Mortality for the city of London. Between 1645 and 1650, at least three physicians, including Francis Glisson, gave accounts of the disease. Glisson's work, *De rachitide*, published in 1650, not only was the most extensive but also made reference to scurvy as a disease that could be associated with rickets in infants. Subsequently, most European pediatric texts discussed rickets, but no clear reference to infantile scurvy reappeared until the late nineteenth century. It would seem that rickets was commonplace in northern Europe, particularly in England, whereas infantile scurvy was rare until the advent of proprietary foods and the use of boiled or sterilized milk. In the United States, however, rickets was either unrecognized or had a low incidence until the late nineteenth century, for it was rarely discussed in the

earlier pediatric textbooks or, if mentioned, was dismissed as of rare occurrence (for the first North American monograph on rickets, see Parry 1872).

Thomas Cone and others have pointed out the lack of consensus on the cause of rickets by the end of the nineteenth century (Hess 1929; Cone 1979). Some believed it was due to an improper diet, others to a lack of sunshine or exposure to polluted air. Yet others regarded it as a degenerative disease. In this view, fortified by perceived similarities in the microscopic bony lesions of syphilis and rickets, parental syphilis could be expressed in offspring as rickets or as an increased liability to rickets (for a discussion of "hereditary" syphilis as the cause of other diseases in the offspring of syphilitics, see Lomax 1979).

As indicated by Kenneth Carpenter (1986) ideas about the cause of scurvy were just as confused. In 1883 Thomas Barlow described the clinical and pathological signs of infantile scurvy, a disease entity rarely recognized in babies. He also indicated that the best remedy was orange juice. Soon physicians in other countries were recognizing "Barlow's disease," but they could not agree as to the cause or even the cure. In 1898 the American Pediatric Society reported an investigation of infantile scurvy. Most physicians who had been consulted thought that proprietary foods, and perhaps sterilized milk, were responsible for the condition. One dissenter, August Caillé, considered the illness to be a form of ptomaine poisoning caused by the absorption of toxins (Cone 1979; Carpenter 1986). Epidemiology and clinical medicine could not produce decisive evidence in favor of any particular theory (see Wilson 1975).

Early in the twentieth century, researchers using animal models to establish dietary requirements came to the rescue. Administering modified diets to animals was not a new technique, but with improvements in chemical analysis it was becoming more precise. In 1907 scurvy was produced experimentally in guinea pigs, and further experiments led Casimir Funk to propose, in 1912, that scurvy, pellagra, rickets, and beriberi were caused by a dietary lack of essential factors, which he called "vitamines." The hypothesis was received with enthusiasm, deficiency diseases were induced in animals, and between 1928 and 1938, vitamins A, B_1, C, D, and E were isolated and chemically defined (Harris 1970).

Another type of deficiency was recognized when Cicely Williams (1933) drew attention to kwashiorkor, a disorder brought on by malnutrition in previously healthy West African toddlers after weaning.

Since then, physicians and nutritionists have sought to understand, prevent, and cure this and similar disorders and syndromes, collectively known as protein–energy malnutrition (PEM) and most commonly found in developing countries. (The research literature is very large; see, e.g., Trowell, Davies, and Dean 1954; Jellife 1969; Olson 1975.) At one extreme are marasmic infants, in whom growth failure is combined with wasting from starvation, as a result of a diet deficient in both calories and protein. At the other extreme is kwashiorkor, thought to be due to a diet with an adequate caloric content but deficient in usable protein. In between are less obvious forms of PEM, characterized by growth retardation and associated with a greater liability to infection than is found in well-nourished children. Infectious disease interferes with a child's appetite, thereby provoking or worsening malnutrition, and the latter state decreases resistance to infection. In former centuries, protein–calorie deficiency syndromes were probably responsible for much wasting, infection, and diarrhea in American and European babies, but the incidence would be difficult to estimate retrospectively because illness was perceived and described so differently at that time.

Congenital Abnormalities

In the past, a great deal of ingenuity was applied to explaining the occurrence of birth defects. In the sixteenth century the French surgeon Ambroise Paré suggested no fewer than 13 possible causes, including the wrath of God, imperfections in "the seed," the imagination of the pregnant mother, and injuries to the uterus during gestation (Paré 1982). The notion that maternal impressions during pregnancy could influence the developing fetus was very persistent. As indicated by Joseph Warkany (1977), a chapter entitled "Maternal Impressions" in J. M. Keating's 1889 *Cyclopedia of the Diseases of Children* recorded 90 cases of congenital defects, blaming mental trauma suffered by the mother during pregnancy for the abnormalities. Explanations of this sort were advanced in the late nineteenth century because the mechanism of inheritance remained a mystery. Most physicians and biologists, such as Charles Darwin, continued to believe that acquired parental characteristics could be transmitted to offspring under appropriate circumstances. This age-old concept was the basis not only of Jean Baptiste de Lamarck's theory of evolution but also of Darwin's theory of pangenesis (Zirkle 1946; Churchill 1976).

Change came in 1900 with the dramatic rediscov-

ery of Gregor Mendel's work on the laws of inheritance in peas. In 1902 an English physician, Archibald Garrod, voiced his suspicion that a rare disease in babies called alkaptonuria was hereditary and surmised that this "inborn error of metabolism" (Garrod's term) was due to the lack of a necessary enzyme and that genes (the Mendelian hereditary factors) produced enzymes (Garrod 1908). However, his hypothesis was not taken seriously until it was confirmed in 1941 by George Beadle and E. L. Tatum, who had investigated the genetic control of biochemical reactions in a mold – neurospora.

Apart from genetic anomalies, birth defects can be caused by chromosomal abnormalities, by a deleterious environment, or by a multiplicity of factors (Chudley 1985). Definite evidence of environmental action was not adduced until 1941, when N. M. Gregg reviewed 78 cases of congenital cataract, finding a history of maternal rubella infection during pregnancy in all but 10 cases. Twenty years later the "thalidomide scandal" concentrated attention on the teratogenic risk associated with drugs taken during pregnancy. This was followed by the equally dramatic recognition that specific congenital malformations, Kenneth Jones's "fetal alcohol syndrome," could result from maternal alcoholism during pregnancy (Jones and Smith 1973).

Since antiquity, maternal alcoholism had been associated with injury to offspring. But as indicated by Rebecca Warner and Henry Rosett (1975), concern about and research into the potential hazards of maternal alcoholism "virtually disappeared" between about 1920 and 1940. Many reasons can be adduced for this rather sudden change, including the effects of prohibition in the United States and the discrediting of the ancient belief in the inheritance of acquired characteristics. Especially in the nineteenth century, the latter concept was exploited to explain the appearance of many congenital diseases, including damage to an infant born to an inebriate woman. Alcohol was presumed to damage the germ cells, male or female, and hence to have an adverse effect on the offspring. To the nineteenth-century mind, this was an example of the hereditary transmission of disease leading to familial degeneration. By the 1920s such Lamarckian-type hereditary transmission had been largely discredited, and the phenomena it had allegedly explained were now usually ascribed to social and economic disadvantage. Furthermore, the uterine environment was not perceived to be a potential site of teratogenic action until the maternal rubella findings were published in the early 1940s.

Infectious Diseases

Although their cause was uncertain until the last third of the nineteenth century, childhood exanthemata and whooping cough were recognized by a majority of physicians as contagious. The responsible agent was thought to be a specific virus, or morbid poison, often undetectable by the senses. However, physicians who subscribed wholeheartedly to the miasmic theory of transmission did not accept the notion of a causal virus or physicochemical agent of infection. Instead, they believed that polluted air, or miasma, could excite a variety of fevers, the specific nature of any epidemic being determined by the geography of the locality, the season of the year, or the personal constitution. For example, William P. Dewees, author of the first U.S. pediatric textbook (1826), doubted that whooping cough, mumps, and measles were contagious. In his view they were epidemic diseases, that is, dependent on some condition of the atmosphere. In his words: "It is a rule, with few or no exceptions, that, where a disease can be traced to atmospherical influence, it does not prove contagious. Nature indeed can hardly employ two such opposite causes to produce the same effect" (Dewees 1829).

In 1798 Edward Jenner had advocated the use of cowpox (vaccination) as protection against smallpox, a disease particularly fatal to infants. In a remarkably short time, vaccination replaced inoculation as the means of providing immunity to smallpox (Edwardes 1902; Hopkins 1983). However, because the mechanism of protection was not understood, confirmed miasmatists continued until the end of the nineteenth century to protest vaccination, which contradicted their epidemic, nonspecific theory of disease (for antivaccinationist views, see Crookshank 1889; Creighton 1894; Tebb 1898). In their opinion, the decreased incidence of smallpox after mass vaccination was due not to protection afforded by vaccination, but to a natural decline in smallpox epidemics counterbalanced by an increase in other diseases such as measles and whooping cough.

Immunity began to be understood when Louis Pasteur discovered that the injection of an attenuated culture of chicken cholera protected laboratory birds from the effects of a subsequent inoculation of virulent culture (for a discussion of Pasteur's work on attenuation, see Bulloch 1938). Strategies of attenuation were enlarged to include dead organisms and prepared extracts; at the same time immunity began to be explained by the production of specific serum antibodies to bacterial antigens and of antitoxins that neutralized toxins. Scientists undertook the

preparation of specific protective sera with striking success in 1894, when Pierre P. E. Roux demonstrated the value of diphtheria antitoxin, which had been discovered earlier by Emil von Behring and Shibasaburo Kitasato.

Diphtheria antitoxin, although frequently lifesaving, conferred only passive, temporary immunity and could not prevent the spread of disease. Gradually a safe attenuated toxin (toxoid) was developed so that by the 1930s children could be actively immunized against diphtheria. By this time, a vaccine against pertussis had also been discovered, and passive immunization against tetanus, as well as certain types of pneumococci and meningococci, was possible. Research continued apace during the Second World War, when a safe tetanus toxoid was discovered (Dowling 1977). This was followed by the discovery of poliomyelitis vaccine in 1956 and, more recently, of vaccines for rubella, measles, and mumps. Today, a full immunization program during infancy eliminates, in large measure, the ill health, chronic disability, and mortality that were once associated with the common infectious diseases of childhood.

Conclusion

Unfortunately, it is impossible in the space allotted to discuss all of the novel concepts of early childhood illness that evolved during the twentieth century. Among these was an appreciation of the rapid debility and death that result whenever fluid is quickly lost and not replaced; this led to the development of methods for maintaining or restoring acid–base balance during rehydration. Also in the twentieth century were the recognition and treatment of hormonal disorders, of hemolytic disease of the newborn, and of numerous neurological and viral disorders.

In 1906 George Newman had already indicated that prematurity and immaturity at birth were among the largest contributors to infant mortality and were on the increase (Newman 1907). Today infection and malnutrition, the chief causes of infant death between the ages of 1 month and 1 year in Newman's time, are well understood and are rarely fatal, thus allowing pediatric medicine and research to concentrate on improving the premature infant's chance of survival during the neonatal period. Newman and his contemporaries would be gratified, perhaps amazed, that the current infant mortality rate in developed countries is one-fifteenth to one-twentieth the rate in their time. Even in Third World countries, where many more babies are subject to malnutrition and vulnerable to infection, the infant mortality rate is usually much lower than that which prevailed in western Europe and the United States at the turn of the century.

III.5
Famine and Disease

Famine can be defined as a failure of food production or distribution resulting in dramatically increased mortality. This increase is attributable to two, and very often three, orders of disease. First, there is the disease of general starvation characterized by wasting and inanition. Second, there are behavioral disorders and social disruptions, some a direct consequence of energy deficiency, others linked to mental disturbance. These can be lethal in their own right while at the same time contributing to the general starvation and to the spread of contagious illness. Third, there is epidemic infection, which is not always seen in mass starvation but which is frequent enough to be considered a classic concomitant. Facilitated by impaired individual and community resistance to pathogenic agents, contagions tend to run an exceedingly rapid course through famished populations, contributing in large measure to overall mortality.

General Starvation

Starvation, a condition in which the body draws on its own internal reserves for energy, arises from normal processes essential to survival. These processes lead to the disease of general starvation, or undernutrition, only after progressing beyond a threshold where damage resulting in functional incompetencies is done to active tissue. If starvation is not acute, that is, not rapidly induced, dysfunctions incompatible with heavy work are not apparent in nonobese people before the loss of 10 percent of prestarvation weight.

Ordinary starvation may be said to begin some 4 or 5 hours after a meal. It is then that the liver begins to release as glucose its store of glycogen. As this process continues, muscle and adipose (fatty) tissue, which otherwise rely on free glucose for fuel, gradually revert to the oxidation of fatty acids. This allows circulating glucose to be consumed primarily by the brain.

Liver glycogen alone in the absence of any food intake supplies glucose to the blood for roughly 12 to 16 hours before a number of metabolic changes begin shifting liver activity to gluconeogenesis, the conversion of muscle protein into glucose. Within 24 hours or longer, depending on the level of food intake, liver glucose output is fully dependent on imported protein. With the onset of gluconeogenesis, the liver itself burns fatty acids delivered from adipose tissue. As these arrive in increasing amounts, only partial oxidation occurs. This results in the liver sending ketones (incompletely burned fatty acids) into circulation. These become fuel for both muscle and brain as their level in the blood increases. In the case of rapidly induced starvation, keto acid concentrations can reach dangerous levels, resulting in dehydration and, eventually, in coma. This, however, can be avoided by the intake of small amounts of carbohydrate.

Gluconeogenesis continues for about a week before ketone production levels off. Muscle gradually ceases to be reliant on keto acids, making ever greater use of free fatty acids liberated from adipose tissue. The brain now takes ketone bodies over glucose for nourishment. This allows gluconeogenesis to shut down, eliminating the demands of this process on muscle protein. At this point, the body's metabolism is fully adjusted to draw on fat for almost all of its energy needs.

Protein catabolism and the destruction of active tissue is never totally eliminated, however. Wasting, loss of weight or body mass, the most obvious external manifestation of general starvation, is most precipitous during the first few days. It becomes less so over a longer period. If semistarvation extends over weeks or months, the rate of wasting will continue to decline. Fat accounts for the greatest portion of wastage after the first several days, but to the end there is a relatively slight but slowly increasing usage of protein.

This continuing attrition of protein, even as fat remains available, is not borne equally by all organs of the body. Heart and kidney tissue sustain slightly less loss than would be expected given their proportion of total body mass. The liver, intestines, and

skin incur more than their share of the loss. Postmortem examinations of starvation victims reveal no part of the body immune to atrophy except the brain.

During famine, starvation initially affects those who are physiologically the most vulnerable. Different forms of protein–energy malnutrition, kwashiorkor and marasmus, show up early in young children. Before gross weight loss is seen in older children and adults, there is a loss of endurance. Those who are afflicted require frequent rests from work. As general starvation becomes more advanced, there are complaints of weakness and muscle pains. Movement becomes sluggish. Individuals sit or lie down whenever possible. A slow, shuffling gait develops. Nocturnal sleep is interrupted, but total sleep progressively increases. An acute sensitivity to noise develops; the skin becomes extremely sensitive and bruises easily. There are complaints about feeling cold. Blood pressure and heart rate decline. A diarrhea attributed to visceral atrophy and malfunction occurs in individuals who are free of intestinal infection. Edema often appears, first in the face, then in the extremities, later in the abdominal and thoracic cavities.

Whereas the intellect remains largely unimpaired, the emotions are greatly affected. Victims' moods alternate between apathy and extreme irritability. The starving become discouraged and depressed but also display an exaggerated ill temper. Critical ability seems to fail. There is lack of concentration and lapse of memory. Speech becomes slow. Appearance and manners become matters of indifference. Interest in sex disappears. Women experience amenorreah; spermatogenesis declines in men. An inversion takes place: Light hair appears on women's faces, whereas men's beards stop growing. Both sexes lose hair from the top of the head and around the genitals. Victims think only of their diseased condition and food. But when starvation becomes acute, even appetite disappears.

The length of time a starving individual can survive on endogenous sources of energy varies, depending on fat reserves, the magnitude of caloric deficit (determined by energy intake and level of physical activity), and ambient temperature. Inactive individuals with normal weight for height can endure nearly total starvation for about 2 months. Semistarvation in active subjects consuming between 1,300 and 1,600 kilocalories per day has been studied under controlled conditions for up to six months. During a famine food intake may fall below this level but often for only brief periods of time at first. Hence, victims can endure for months. Once a 30

percent weight loss is incurred, however, the chances of survival are virtually nil without medical intervention. A 40 percent wastage during famine is almost certainly fatal.

Individuals suffering from advanced undernutrition can survive for prolonged periods owing to two remarkable means of accommodation that allow the energy budget to reach near equilibrium and permit weight loss to slow dramatically despite a very low level of caloric intake. The first is a decline in basal metabolism, which occurs because wasting reduces the number of metabolically active cells, accompanied by a decrease in the metabolic rate of the surviving biomass. The second is a decline in spontaneous movements and a decreased cost of movement. In other words, starving people reduce their actions to a minimum. Moreover, any activity that cannot be avoided becomes less expensive energywise because of reduced weight. Of these two factors, curtailed activity accounts for the greatest savings. In experiments conducted during World War II, volunteers restricted to a semistarvation diet for 6 months were observed to reduce movement-related energy expenditures by 71 percent. Approximately 60 percent of this was achieved by elective curtailment of activity. A reduction of anywhere near this magnitude during a famine is bound to have profound social implications.

Behavioral Disturbances and Social Disorders

People suffering inanition obviously find it impossible to maintain normal social relations. No matter what their cultural definition, ordinary interactions are also affected by the emotional correlates of starvation and by individual and collective efforts to survive under extreme conditions. Famine, as a net result, gives rise to a series of social transformations. Seen as variously altered patterns of interaction, these transformations progressively unfold under deteriorating conditions. For this reason, they have been viewed as broadly diagnostic of the prevailing level of want. This view is most certainly justified with respect to two dimensions of interaction, its frequency and the extent to which it involves positive reciprocities. Both of these indicators disclose the characteristic rise and fall of a stress–response curve as famine progresses from threat to full-fledged reality. Figure III.5.1 illustrates this in terms of the relationship between food supply and generosity.

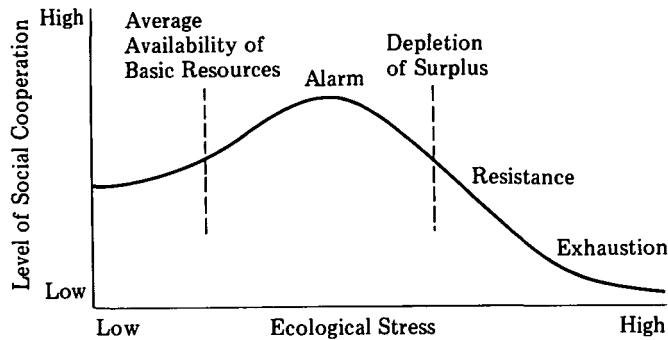
Social responses to famine develop through three phases. The first, the alarm phase, marked by general hyperactivity and intensified feelings of attach-


Figure III.5.1. Relation of social cooperation to ecological stress in a social action system. (Adapted from Laughlin and Brady 1978.)

ment, is triggered by the onset of an emergency. This reaction, also reported in the wake of sudden catastrophes such as floods and tornadoes, can create on the community level what has been called a "disaster utopia," a social environment of extraordinarily intense mutual care and assistance. Thus, the sharing of food and other resources among friends and neighbors actually increases, apparently irrespective of whether there is any prospect of outside assistance. Although accounts of local-level responses to this earliest phase of famine are relatively few, this phenomenon has been documented in a variety of cultural settings, including diverse urban and rural locations in Africa, western Europe (Ireland and the Netherlands), South Asia (India and Nepal), and Oceania (Yap and Tikopia). Hoarding at this stage does occur, but it appears to be limited to market economies and, more particularly, to those individuals least threatened by starvation.

Intensification affects virtually every sphere of life during the alarm stage. Market activity increases and, under certain conditions, may become chaotic. Food prices soar. Population movement increases, as individuals and families seek to relieve their mounting plight. Mystical efforts to find relief intensify; religious congregations swell. Political activity increases. Violence erupts, both spontaneous and concerted, frequently at sites where food and other commodities are in storage or transit.

As starvation begins to exact a physical toll and individuals become weaker and more easily fatigued, famine progresses beyond the stage of alarm and into a protracted phase of resistance. The question of available energy becomes paramount at this point. People turn to unusual sources, including foods known to be edible but normally ignored and species ordinarily regarded as inedible or abhorrent. Items of no nutritional value may be consumed

merely to assuage hunger. To conserve supplies, expenditures other than those immediately related to obtaining food are pared to a minimum. The extent of active social relations as indexed by food sharing shrinks considerably as a result.

This "social atomization" is the hallmark of the resistance phase. Essentially, it entails the closure of the household as a food-sharing unit. Generosity disappears; supplies are hidden; food preparation and consumption take place in secret. Visits from relatives and friends arouse suspicion and may be regarded as unfriendly acts.

Lawlessness, including physical aggression, continues to increase, but during the resistance phase of famine there tends to be less concerted and sustained violence, particularly after the average level of weight loss in a community begins to exceed 20 percent. The physical wherewithal for rioting or other active expressions of political unrest becomes practically nil beyond this point. Active expressions of any sort gradually disappear. Ritual observances are put off; religious attendance declines. People congregate only where there is promise of receiving food.

Exhaustion, the final phase of famine, comes with the disintegration of the household, the social bulwark of resistance. Its collapse is foreshadowed as food sharing within the household becomes increasingly discriminatory during the resistance phase. There is a distinct tendency to see the elderly as a drain on provisions. Tolerance toward younger dependents does not erode as quickly, but generally there comes a point when children too receive disproportionately small amounts of food. These types of discrimination – arguably adaptive insofar as they favor principal providers, those on whom eventual recovery will depend – show up in age-specific mortality rates. In the Punjab, for example, where in 1939 famine resulted in an overall increase in mortality of more than 52 percent, the elderly sustained a 288 percent increase in their rate of death and mortality among children under 10 rose by 192 percent. By contrast, among individuals between 10 and 60 years of age, mortality actually declined to a level 14 percent less than the average for the preceding 4 years.

Although exhaustion does not sweep over a famished population all at once, the appearance of neglected, wandering children is a certain sign that pockets of it exist within a region. The same holds for the abandonment and sale of children. Parents may take such drastic steps out of concern for their own survival or out of the hope that being in some other individual's or agency's custody will save their

offsprings' lives. But in either instance, as well as in the case of infanticide or parental suicide, an underlying cause is almost certainly the mental fatigue that comes from hearing ceaseless cries for food that cannot be stilled.

The final vestiges of cooperation in the worst famines are found only in the most instrumental relationships. Anyone promising to put a bite of food in one's mouth is a friend. The fact that people sometimes kill ruthlessly to acquire scraps of food suggests that anyone standing in the way of eating is an enemy. Cannibalism may occur during extreme famine, though its extent is impossible to gauge. Suicide, even in cultures where it is otherwise unheard of, becomes very common.

Exhaustion leaves an indelible mark on survivors. A significant incidence of gross stress reaction (acute situational maladjustment), a disease category that originally comprised the mental depressions of combat personnel whose disturbances could not be described accurately by existing psychiatric labels, has been documented among both European famine victims and Australian aborigines. Gross stress reaction is thought to arise from a severely disturbed interpersonal environment.

Relief-induced agonism is another postfamine syndrome worthy of note. It consists of a varied pattern of aggressive, exigent, and quarrelsome behavior, both verbal and nonverbal. It is seen during the course of relief operations, particularly after the refeeding of victims. Relief-induced agonism appears to be nonspecific in the sense that it is not directed at any particular target. The agonism expresses itself as a general irritability and a remonstrative or combative attitude toward anyone at hand, including relief personnel. What sometimes causes people who were heretofore wasted, inactive, and emotionally apathetic to become suddenly quite animated, clamorous, and contentious upon receiving ample nourishment is not known.

Famine and Infectious Disease

General starvation increases susceptibility to numerous pathogens. Conversely, infection accelerates the course of general starvation. This process is enhanced as declining health and increased mortality add to social disorder, creating greater impediments to the acquisition of food, increased undernutrition, and conditions ripe for the spread of disease.

This vicious circle can originate on the side of either pathogenic illness or undernutrition. Epidemic disease has the potential for ushering in general starvation, especially if infections debilitate or kill a large number of food producers. This is most liable to occur when a new disease is introduced into a region whose inhabitants have no acquired immunity. Many native American populations suffered severe famine upon first exposure to such commonplace Old World illnesses as measles and smallpox. Generally speaking, however, it is more often the case that infectious epidemics follow in the wake of starvation. The diseases that become epidemic tend to be familiar ones, long endemic to a region. Virtually any endemic illness has epidemic potential during famine, but certain of them have become notorious.

In the Western world, those diseases most disposed to reach epidemic proportions have been typhus, relapsing fever, smallpox, dysentery, tuberculosis, bubonic plague, influenza, and pneumonia. Changes affecting public health have altered the epidemic potential of these diseases at various points in history. Thus, typhus (famine fever, spotted fever), a louseborne infection that for centuries had been Europe's most dreaded famine disease, ceased to be a concern among most undernourished groups during World War II owing to the widespread use of DDT. However, with the disappearance of typhus, epidemic tuberculosis, which almost certainly had been present but undetected in previous famines, became a major problem.

As for the East, experience with famine-related epidemics has been much the same as that of Europe, with some exceptions. Typhus has not been seen in well-watered tropical and semitropical regions where people are accustomed to bathing daily. In contrast, waterborne disease such as dysentery and cholera have become virtually synonymous with mass starvation in such climates. Typhoid epidemics have been associated with famines in China. Acute malaria and heavy hookworm infestations have been observed in famished populations of India.

In Africa the effects of malaria do not appear to be aggravated by general starvation. However, contrary to experience in the rest of the Old World, including India, recent episodes of general starvation in Ethiopia, Nigeria, and the Sahel have been accompanied by epidemics of measles extremely lethal to children. Yet judging from records of the Great Ethiopian Famine of 1888–92, the greatest of all African famines, epidemic measles has not always been a problem in Africa in times of dearth. More common have been epidemics of cholera, smallpox, meningitis, dysentery, and pneumonia, and typhus outbreaks have also been reported in Ethiopia.

Two factors, often working together, facilitate the occurrence of epidemics under famine conditions.

The first is loss of community resistance to the spread of infection, and the second is loss of individual immune competence.

Loss of community resistance can be accounted for by a number of phenomena. These include population dislocations and the overcrowding of public facilities, both of which destroy barriers to the spread of infections. Transmission is further abetted by the behavioral economies that accompany inanition and undermine domestic hygiene and public sanitation.

Loss of community resistance is clearly illustrated in the case of typhus. Normally confined to isolated pockets of stark poverty, typhus often broke out over vast areas of Europe during starvation winters when a massive number of people, lacking energy and wrapped in thick layers of clothing to combat hypothermia, found it increasingly difficult to bathe or wash their clothes. This lapse opened the way to heavy louse infestations. Since dessicated louse feces clinging to unwashed garments were readily inhaled or rubbed into the eyes, the disease spread rapidly by casual contact wherever famished wanderers passed through a region or clustered to find relief from cold and hunger. During the Russian famine of 1919–22, the incidence of typhus in Leningrad showed a negative relationship not only with energy intake but with frequency of bathing. The death of nearly 193,000 people was attributed to typhus and relapsing fever, also louseborne, during Ireland's Great Hunger (1845–52). By comparison, approximately 20,000 died of starvation.

Starvation can undermine individual resistance at virtually every line of bodily defense. As protein is lost, protective anatomic surfaces such as skin and mucous membranes lose integrity as barriers against the invasion of pathogens. Flaky skin lesions, intestinal atrophy, and a reduction in tissue-healing capacity, frequently observed in children suffering from chronic protein–energy malnutrition, facilitate infection.

Once inside the body, infective agents encounter an impaired immune system. On the cellular side of this system, starvation has ill effects on both phagocytes and T-lymphocytes as the former lose efficiency as bacteria killers and the formation of the latter is depressed. On the humoral side, the complement system, a group of proteins that interact to form substances for the destruction of bacteria and viruses, functions poorly in undernourished children. Immunoglobulins, protein molecules secreted by B-lymphocyte-derived plasma cells and a principal element of the humoral immune system, are often found in serum at high levels among mal-nourished populations. Reflecting the high incidence of infection that such populations experience even in the best of times, the buildup of immunoglobulin levels in children is especially rapid. Despite this, when confronted with certain antigens, including the pathogens of typhoid, influenza, mumps, diphtheria, and yellow fever, the immunoglobulins appear hypoactive. Secretory immunoglobulin A (IgA), which prevents bacteria from adhering to mucosal surfaces, is found at abnormally low levels in the undernourished, which helps to explain why starvation is generally associated with high rates of respiratory and gastrointestinal infection. What remains unknown, and this applies to all of the foregoing functional impairments, is the degree of depression of immunoglobulin levels that can be withstood before the onset of clinical disease.

Nutritional balance is adversely affected by a number of reactions to infection. These include higher caloric expenditure resulting from greater mobilization of protein due to increased stress and adrenocortical activity; decreased food intake owing to general malaise, increased secretion of mucus, and appetite loss; and intestinal changes leading to reduced absorption of ingested foods. With regard to energy expenditure, relatively little is known beyond the fact that, if infection involves fever, basal metabolism increases. Nevertheless, it is suspected that even in the absence of fever virtually all infections increase the demand on energy sources. The effects of illness on protein nutrition have received a great deal of attention. Protozoal and helminthic diseases such as malaria and hookworm have adverse affects on nitrogen balance proportional to parasitic load. Most bacterial and viral infections have negative effects on nitrogen balance. Bacterial and viral infections of the intestinal tract are of major significance in most developing countries where diarrhea constitutes a major disease, particularly in infants and young children. Intestinal infections impair the absorption of nitrogen, but more significant in creating a nitrogen imbalance is an abnormally high excretion of that element in urine, much of this coming from an increased breakdown of muscle tissue. Considerable nitrogen is also lost through fever-induced sweating. Making up for nitrogen loss is difficult given the decline in appetite that typically accompanies intestinal illness.

History and Geography

Food production and distribution in every society are enmeshed in human ecologies of great complexity. Because of this, untoward conditions and events of

many sorts can lead to famine. These include natural disasters such as drought, flood, volcanic eruption, frost, and pestilence. In addition, there are social factors such as war, revolution, political policy, general economic collapse, speculation in food commodities, administrative decision or indecision, inadequate transportation, runaway population growth, and gross social inequality. Despite the popular inclination throughout history to blame food disasters on one or another of these phenomena, close analysis of specific cases invariably reveals multiple causes. Efforts to untangle general factors have led to the creation of various classification schemes and models of famine development. They have also resulted in regional studies of outstanding quality. To date, however, little headway has been made in explaining famine in a way that would account for its historical and geographic incidence on a global scale.

One large-scale pattern awaiting explanation is seen in the proportional number of famines suffered in regions of the Old World over the past 6,000 years. Beginning about 4000 B.C. and until 500 B.C., existing records point to the Middle East and northeast Africa, especially the valleys of the Tigris and Euphrates rivers and the Nile, as extraordinarily famine prone. Over the next 1,000 years, the region of disproportional incidence shifted to Rome and the eastern parts of its empire, including Greece, Asia Minor, Syria, and Judea. Western Europe became the major locus about A.D. 500. Eastern Europe assumed this grim distinction after 1500, but about 1700 the high frequency of famine moved further eastward. From that year until 1974, periods of dearth occurred with greatest frequency among peoples residing within a huge belt extending from regions of Russia south of Moscow, across the southern Asian steppes, into India and China. More recently, African regions, especially the East and the Sahel, have been the scene of a disproportionate share of food emergencies.

The several published lists of the world's major famines, all compiled before the 1970s, contain little mention of catastrophic food shortages among the peoples of sub-Saharan Africa, Oceania, and the New World. These omissions grossly underrepresent the experiences of "peoples without history," leaving vast sectors of the world a blank map and much of the information required to chart the occurrence of famine beyond Eurasia unassembled. What truly universal patterns might be discovered once the temporal and spatial distribution of famine has been more broadly mapped can be glimpsed from a preliminary analysis of unpublished data drawn from the Standard Cross-Cultural Sample (SCCS), a representative, worldwide sample of the world's known and well-described societies. The SCCS, developed by George P. Murdock and Douglas R. White, includes 186 communities dependent on a wide variety of subsistence systems. Each community is precisely located at a point in time, the sample as a whole spanning history from ancient civilization to the twentieth century. The incidence of famine recorded in SCCS bibliographic sources reveals no remarkable differences in the frequency of unexpected food shortages among the world's major geographic regions. Climatically, data show no more than a mildly positive relationship between the incidence of starvation and aridity. With respect to persistent famine (i.e., its occurrence more than once per generation) the sample does show, as many would predict, a rather strong association with endemic hunger. Finally, statistics indicate a global tendency for the severity of food shortages to increase with both increased societal complexity and dependence on food importation.

Detection of Famine

Possibly throughout history, most certainly in the nineteenth and twentieth centuries, the term *famine* has been used loosely. Hungry seasons, annual periods of dearth afflicting societies just before harvest, have been called famines. To add to the semantic confusion, there have been allegedly deliberate misapplications of the term by some governments in order to elicit aid when it was not warranted. Moreover, some governments have avoided using the term when it ought to have been used. The concept of famine has clearly been politicized. Nevertheless, one must admit that famines, unlike sudden physical catastrophes such as earthquakes and hurricanes, are not always easy to detect. Often unannounced by any violent event, famine can develop insidiously, remaining invisible for a protracted period to members of the privileged classes, especially if they are inured to the sight of poverty, endemic undernutrition, and disease. One can perhaps better comprehend the tendency for famine to escape notice by reflecting on the fact that during the Ethiopian famine of 1973–5 it was estimated that at any one time not more than 8 percent of that country's population was starving to death. In a nation where as many as 20 million people are perpetually hungry, the threshold at which suffering becomes perceived as an emergency stands relatively high.

For this reason, historical sources bearing on the study of famine, whether official, academic, or popu-

lar, must be read with caution. A rigorous historical detection of famine should include the following:

1. evidence of a dramatic increase in mortality;
2. evidence that such an increase occurred in several adjacent communities at once;
3. consideration of the possibility that lethal disease unrelated to general starvation bears responsibility for increased mortality;
4. data showing a correlation between mortality curves and the price of food;
5. information indicating disproportional mortality among the economically marginal;
6. evidence of a depression in live births; and
7. statements contained in contemporary accounts referring to dearth, misery, or death owing to want.

III.6
A History of Chiropractic

Chiropractic is a system of healing that holds that disease results from a lack of normal nervous function caused by a disordered relationship between the musculoskeletal and nervous systems. Controversial from its inception, chiropractic has grown into the largest nonallopathic healing profession in the United States, with nearly 35,000 active practitioners. Although considered by many a "marginal" group, chiropractors are licensed in all 50 states, are reimbursed by Medicare, Medicaid, and many third-party payers, and in 1984 earned an average yearly net income of $55,000. The recent defeat of the American Medical Association (AMA) by chiropractors in a major lawsuit dramatically emphasizes chiropractic's current strength. The public image of chiropractic has significantly improved, and opposition from medical organizations has abated. Chiropractic has successfully established itself as an alternative healing profession.

At first glance, it seems an unlikely system to have achieved such success. Chiropractic was founded in 1895, just as medicine was being transformed into a dominant profession. Successfully uniting disparate elements of the medical community, the AMA reorganized in the early 1900s and developed into a powerful force, influencing nearly every aspect of the U.S. health care system. The homeopathic and eclectic sects, important mid-nineteenth-century competitors, virtually disappeared during the first decades of the twentieth century. Physicians actively and effectively suppressed competition from patent medicine vendors with pure food and drug legislation. Yet despite the impressive strength of the medical profession, chiropractic thrived. Whereas nearly every other form of unorthodox healing was being suppressed, banned, or co-opted, this system of healing established itself as an independent profession. By 1930 it was already the largest nonallopathic sect in the United States, with nearly 16,000 practitioners.

This extraordinary development does not fit easily into current historiographic models. Broadly speaking, two models have been offered to explain medicine's enormous growth during the late nineteenth and early twentieth centuries. According to the first, medicine benefited from scientific developments, which provided a new rational basis for medical prac-

tice and offered effective treatments. Proponents of this model point to the establishment of the germ theory of disease, the development of diphtheria antitoxin, the creation of salvarsan (for use against syphilis) and the discovery of insulin as evidence of how scientific progress fueled medicine's expansion. According to the second model, political organization and lobbying were the critical factors behind medicine's new strength. Proponents of this model point to demographic data suggesting that medical practice had little impact on morbidity and mortality and to the aggressive political maneuvering of the AMA to support their argument.

Despite their differences, these two schools share the assumption that allopathic medicine established hegemony over health care during the early twentieth century. Neither approach provides a particularly useful framework for discussing chiropractic, because each virtually ignores unorthodox medicine. Although medicine clearly wielded the greatest influence on the U.S. health care system, the success of chiropractic demonstrates that there are important limits to medicine's authority. A close examination of chiropractic history helps identify those limits and the forces that define them.

The Critical Early Years, 1895–1924

In 1895 Harvey Lillard visited the offices of Daniel David Palmer. "D.D.," as he is nearly always referred to, had recently opened his practice in Davenport, Iowa, after a varied career that included stints as a schoolmaster and grocery clerk. Lillard, a janitor, complained that ever since he had received a blow to his neck 17 years ago he had been deaf. Palmer examined the patient and noted a lump in the cervical region. He manipulated Lillard's spine and, much to the delight of both patient and practitioner, restored his hearing. Chiropractic was born.

Therapeutic manipulation was not unknown to late-nineteenth-century North Americans. They were aware of the long tradition of massage as a healing modality. Bohemian immigrants to the Midwest practiced a special form of massage, napravit. Bonesetting, a form of manipulation involved primarily in treating orthopedic problems, had flourished in some areas. Finally, in Kirksville, Missouri, in 1874, Andrew Taylor Still had founded osteopathy, a school of healing that utilized spinal manipulation.

These diverse healing techniques shared more than their emphasis on manual manipulation. Drugless healing was an important theme in many nonallopathic systems in the mid-nineteenth century. It was part of a larger response to the excesses

of "heroic" therapies (i.e., vigorous cathartics, emetics, and bloodletting) and in fact, mid- and late-nineteenth-century healers, both inside and outside the medical profession, increasingly began to emphasize milder interventions. They shared a growing recognition that the worth of many conventional remedies had never been scientifically proved and placed a new emphasis on the healing power of nature. Their skepticism about heroic medicine was epitomized by the words of Oliver Wendell Holmes when he proclaimed in 1860 that, with the exception of a few specific remedies, "if the whole materia medica, *as now used*, could be sunk to the bottom of the sea, it would be all the better for mankind and all the worse for the fishes."

Nonallopathic healers took advantage of this climate arguing against any pharmacological therapy, and host of drugless alternatives developed, among them hydropathy, osteopathy, and magnetic healing. As a drugless system that emphasized the body's natural healing powers, chiropractic fit easily into this important nineteenth-century trend.

Briefly stated, Palmer's chiropractic fused magnetic healing with therapeutic manipulation. Palmer believed that subluxations of the spinal column caused disease by impinging on the nervous system and inhibiting the flow of the body's vital "fluid," which Palmer called "innate intelligence"; disease resulted from either a deficiency or an excess of this fluid. By examining the patient's spine, a chiropractic could detect the malalignment responsible for the patient's ailment, manually manipulate the vertebrae, and restore normal alignment, allowing the return of proper nervous function. Once the normal flow of "innate intelligence" resumed, the body's inner healing powers ensured a return to health.

Palmer argued that his chiropractic approach offered the world an important new philosophy. He believed that God had created a balanced, ordered universe and that equilibrium was the fundamental organizing principle of life. "Innate intelligence" represented God's presence in human beings. Subluxations created disequilibrium, and the inevitable sequela of this violation of natural law was disease.

Palmer's vision was consonant with cultural and intellectual assumptions that were prevalent in the United States at the turn of the century. It linked health care to a worldview in which God was benevolent and ruled the universe through natural laws. It emphasized that there should be no conflict between religion and science; science served religion by demonstrating the Creator's natural laws.

This view of science was a critical component of chiropractic and contrasted sharply with the view of medicine's new research elite. Increasingly secular, the science of medicine was located in university laboratories, required special training, and was based on a reductionist philosophy. Deductive reasoning and the manipulation of nature in an experimental setting were its hallmarks. In contrast, chiropractors emphasized a different scientific approach. A scientist observed nature, collected facts, classified these facts, and thereby gained insights into the laws of nature. Furthermore, science linked the physical and spiritual worlds and reemphasized the perfection of the Creator. In his seminal 1910 work, *Textbook of the Science, Art and Philosophy of Chiropractic,* Palmer explained:

Chiropractic is the name of a systematized knowledge of the science of life . . . an explanation of the methods used to relieve humanity of suffering and the prolonging of life, thereby making this stage of existence much more efficient in its preparation for the next step, a life beyond.

Palmer believed that science ought to serve a subordinate and supportive role in relation to religion. A significant portion of U.S. society shared that view as the popularity of fundamentalism in the 1920s and the Scopes monkey trial dramatically demonstrated. Thus, the chiropractic approach to science remained a powerful model well into the twentieth century, with its legitimacy resting heavily on the assumption that science should reflect God's grandeur.

Ironically, chiropractors also sought to benefit from the growing prestige of science. They deflected allopathic attacks on chiropractic as quackery by arguing that their system of healing was a truly scientific way of dealing with disease. In fact, they even launched their own offensive by ridiculing physicians for adopting a scientific approach that epitomized the corrupt "atheistic materialism" that was destroying the United States.

Their efforts to reconcile science and religion by emphasizing the primacy of God attracted support at a time when the appropriate relationship between science and religion was hotly contested. They argued that by using drugs and surgery as therapies, and by failing to appreciate the importance of the spiritual in health and disease, physicians rejected the healing power of nature, and implicitly rejected the beneficence and wisdom of God Himself. When surgeons began to perform an increasing number of appendectomies in the early twentieth century, chiropractors sarcastically noted that it seemed odd that the creator of the universe had made the mistake of giving humans a useless appendix. By focusing on

the appendix, an organ presumed to be a vestigial remnant of the evolutionary process, chiropractors highlighted their allegiance with antievolutionists.

Chiropractic's appeal extended beyond the scientific and philosophical. Important turn-of-the-century social and political themes also reverberated in the chiropractic literature. Chiropractors repeatedly characterized the AMA as a trust, invoking a familiar and powerful image central to this era of reform. They pointed to the growing public health movement as an indication that medicine, like all trusts, manipulated government to its own profit. Compulsory allopathic examination of schoolchildren and the armed forces' refusal to use nonallopathic healers, they contended, demonstrated the power of medicine over government.

Like all trusts, medicine was ruled by a narrow circle of conspirators. It was not the trustworthy, rural general practitioners who were responsible for medicine's monopolistic excesses; they too were being duped by a small group of eastern, elite intellectuals. This argument sought to capitalize on the disgruntlement of those physicians who resented the AMA's increasing emphasis on research science. Furthermore, it allowed individuals to condemn the medical profession but to retain confidence in their personal physician.

Chiropractors accused medicine of dominating the media, another characteristic of monopolies. They cited AMA boycotts of newspapers that contained "quack" advertisements and the explosive increase in the number of press releases by physicians' organizations.

The chiropractic solution to the problem of the medical trust was simple: open competition. The United States was built on rugged individualism. The merit of each practitioner and each healing profession should be established solely by a jury of patients. Individuals should determine whether their health care was adequate; government regulation was unnecessary and demeaned the "common man" by suggesting that he was incapable of assessing the quality of his health care. Physicians had no right to expect governmental protection or to hold themselves up as elite members of the healing profession. Rather, they were a wealthy aristocracy attempting selfishly to protect their interests. AMA efforts at educational and licensing reform were guaranteed to exclude the honest poor from the medical profession. By requiring collegiate training before medical school and the use of Latin prescriptions, the AMA had erected artificial barriers designed to elevate the physician and intimidate the patient. In contrast, chiropractic colleges required no formal educational background and no foreign languages. Anyone with common sense who was willing to apply himself or herself could become a chiropractor.

Although necessary, the congruence of chiropractic's social, political, cultural, and scientific appeals with early-twentieth-century beliefs was not sufficient to ensure the system's survival. To be successful, chiropractic needed more than a coherent message; it needed a leader. The man who responded to this need was Bartlett Joshua Palmer.

B.J., as he is invariably referred to, was D. D. Palmer's son. When the elder Palmer was jailed in 1906 for violating the medical practice law, B.J. took over the reigns of the Palmer School of Chiropractic (P.S.C.). Under his charismatic leadership both the school in Davenport, Iowa, and the general focus of chiropractic expanded enormously. B.J. began to market this system of healing aggressively, and enrollment at the P.S.C. increased from a trickle, to a stream, to a flood. There had been a total of 15 graduates in the decade before B.J. inherited the school. Starting in 1921 the P.S.C. graduated more than 1,000 students per year. Although the number of graduates soon declined into the hundreds, the Palmer School remained a major chiropractic institution throughout B.J.'s career.

B.J. did not limit his efforts to the development of the P.S.C. He tirelessly proselytized for all of chiropractic. Establishing a printing office at the Palmer School, he turned out a flood of chiropractic literature. He opened one of the first radio stations in Iowa, over whose powerful airways he proclaimed the benefits of chiropractic healing. B.J. went on lecture tours, organized the Universal Chiropractors Association, lobbied legislators, and appeared at trials. A nearly cultlike atmosphere developed around him and few could be neutral about the man. Nonetheless, B.J.'s forceful advocacy of chiropractic created more publicity, which was necessary to the development of the field. Indeed, it began to flourish as his efforts combined this system of healing with a philosophy of health and disease that resonated with important concerns for many North Americans. The growing influence of chiropractic arguments and chiropractors is suggested by their ability to convince legislators that chiropractors deserved licensure. In 1913 Kansas passed the first law recognizing chiropractors, and several other states in the Midwest soon did the same. By the 1930s, despite vigorous medical opposition, chiropractors had obtained some form of legal recognition in 32 states. Despite the skepticism

and outright hostility of physicians, millions of North Americans were consulting chiropractors.

Parallel Evolution, 1920–60

The rapidly changing medical, social, and political landscape of the 1920s to the 1960s challenged chiropractic's ability to adapt and thus to survive. On the one hand, an excessive reliance on beliefs and theories developed in the 1890s might render this system anachronistic. On the other, chiropractic risked losing its distinctive character if it underwent radical reform and became "medicalized." An examination of the changing role of technology in chiropractic, the modification of its criticisms of the germ theory, and the stiffening of chiropractic educational standards will demonstrate how it successfully responded to the challenge.

Mixers versus Straights: Technology in Chiropractic

At the 1924 annual homecoming of the P.S.C., B. J. Palmer made a startling announcement: Henceforth the "neurocalometer" would be a vital component of the chiropractic system. Touted as a breakthrough for scientific chiropractic, the neurocalometer was a machine designed to help diagnose subluxations by registering differences in heat alongside the spinal column. It could be obtained only from the Palmer School for $500 and a $1.00 per month service charge.

Chiropractors were stunned, and with good reason. Since chiropractic's earliest years, the use of technology had engendered enormous controversy. B. J. Palmer himself had argued strenuously that diagnosis and treatment should be performed only by manual manipulation. In fact, he claimed that the Palmer School taught chiropractic "P, S, and U" – pure, straight, and unadulterated – and scornfully labeled any practitioners who utilized other modalities as "mixers."

For "straight" practitioners, chiropractic was a natural system of healing that allowed the body to manifest its intrinsic restorative powers. The use of machines implied that natural methods of diagnosis and treatment were inadequate. By avoiding the use of machines, chiropractic buttressed its argument that it was fundamentally different from medicine, which relied increasingly on new technologies during the early years of the twentieth century. By rejecting technology, chiropractic also avoided regulation under medical practice laws.

On a deeper level, the rejection of technology reflected the ambivalence of many Americans toward machines. Machines created change, and although change could be positive, it also caused uncertainty and upheaval. As industrialization proceeded during the late nineteenth and early twentieth centuries, many were uncertain whether the changes induced by modern technology were improvements, and straight chiropractors were able to tap into this wellspring of concern.

Conversely, the "mixers" utilized the positive image of technology to foster their growth. Machines were new and exciting, the wave of the future, and chiropractic needed to take advantage of modern technology in order to see that future. Many mixer schools, led by the National School of Chiropractic of Chicago, advocated using diagnostic and therapeutic adjuncts. As if to emphasize its differences with the straight chiropractors, the National School of Chiropractic had several physician-chiropractors on its faculty by 1916.

As the leader of straight chiropractic, B. J. Palmer had rarely declined an opportunity to ridicule the mixers. When he suddenly declared that the neurocalometer was not only acceptable but central to chiropractic practice, many ardent supporters were outraged. Four key members of the Palmer School faculty resigned. Palmer was accused of betraying his colleagues, and because the neurocalometer could be obtained only from Palmer, many thought he had been motivated by greed. The neurocalometer debate signaled an important change in chiropractic. Although advocates of straight practice continued to play an important role, their strength waned and gradually most chiropractors incorporated adjuncts into their practice. The introduction of the neurocalometer in 1924 reflected a shift in U.S. attitudes toward technology, for the prosperity of the 1920s had eased earlier fears about it while highlighting its economic benefits. B. J. Palmer's acceptance of machines is best seen in this light. As machines became firmly enmeshed in the fabric of U.S. life, it became untenable for this system of healing to reject them, although the distinction between straights and mixers, while increasingly blurred, would endure for some time.

The Germ Theory and Chiropractic

Another milestone in the evolution of chiropractic was an increasing acceptance of the germ theory of disease. At first many chiropractors had rejected the notion that bacteria could cause disease. However, as germ theory achieved widespread acceptance, they realized that rejection of the association between bacteria and disease would make chiropractic

seem retrogressive. Accordingly, chiropractors no longer insisted that bacteria could not cause disease but instead argued that bacterial infection was a secondary phenomenon that occurred only in persons whose ability to resist disease had been vitiated by a spinal subluxation. This stance allowed chiropractors to highlight a major problem with germ theory: If the key to disease was simply infection with pathogenic organisms, why didn't everyone exposed to a germ become ill? Or why did some people infected with the same organism die and others experience only a mild illness? By emphasizing resistance as the key to health and disease, chiropractors retained their explanatory model while continuing to challenge formal medicine.

Educational Reform in Chiropractic
Education provides another window on the development of this system of healing. During the earliest years of chiropractic, disagreements developed over what, if any, formal education should be required. One group of practitioners, commonly referred to as "field-men," opposed any formal training, arguing that it was elitist. They felt that chiropractors should reject the medical model of education with its emphasis on "book-learning" and instead rely on the practical training that an apprenticeship provided. Although the field-men's arguments were heavily influenced by their concern that licensing legislation would exclude practitioners who lacked a chiropractic diploma, their stance also highlighted the ideological commitment to egalitarianism that many chiropractors felt their field should embody.

Competition among chiropractic colleges also inhibited the adoption of educational standards. Each institution vied for students and wanted to be recognized as the "true" standard bearer of the profession. Each had a slightly different definition of chiropractic, typically dividing along the "mixer–straight" axis. Each wanted its own diploma to be the exclusive prerequisite for a chiropractic license. Attempts to block the legislative recognition of rivals occasionally resulted in open warfare among the schools.

Despite this contentious beginning, the conviction that there was a need for minimal educational standards gradually gained wider acceptance. Exposés of mail-order chiropractic "colleges" had tarnished the reputation of the entire profession, and the dramatic reform of medical education in the early twentieth century had opened a wide gap between the training standards of regular physicians and those of chiropractors. Physicians exploited this difference by frequently ridiculing the standards of chiropractic

schools, many of which had curricula that required only 18 months of schooling.

Chiropractors responded by gradually embracing a professional model of training and reducing 79 schools in 1920 to only 21 by 1932. Those that remained increased the period of training and strengthened their faculties, and schools that had previously emphasized how rapidly one could become a chiropractor increasingly stressed the advantages of their clinical facilities, eminent faculty, and comprehensive curricula. In 1935 the National Chiropractic Association (NCA), the mixers' professional organization, established a Commission on Educational Standards. This led to the adoption of formal accrediting procedures, and the International Chiropractors Association, the straight chiropractics' representative, followed suit. Spurred by the tireless efforts of John Nugent, director of education of the NCA, a continual strengthening of educational standards occurred in the 1940s and 1950s.

The adoption of technology, reconceptualization of the relationship between bacteria and disease, and educational reform were all ways in which chiropractors responded to a changing environment. Chiropractic's ability to retain its distinct identity while undergoing this evolution helps explain how it has avoided the fate of other alternative healing sects. The evolutionary trajectories of medicine and chiropractic can be conceived of as two parallel lines, and the ability of the latter to maintain a constant distance from medicine is perhaps the most remarkable quality in its historical development. If the distance between the two professions had narrowed, as in the case of homeopathy and osteopathy, chiropractic would have risked losing its identity. If the distance had widened, chiropractic would have risked becoming anachronistic. Instead, it flourished as it adroitly maneuvered between the Scylla of convergence and the Charybdis of divergence.

From Marginally Acceptable to the Acceptable Margin: The 1960s through the 1980s
The 1950s and 1960s were a golden age for medicine. Federal support for biomedical science expanded enormously after World War II, and impressive diagnostic and therapeutic advances aided medicine's emergence as the most highly regarded profession in the United States. Federal subsidies for hospital construction helped create an enormous health care industry.

Simultaneously, chiropractic seemed to stagnate. It received no significant federal support, and indi-

rect subsidies, in the form of support to veterans under the G.I. bill to finance their chiropractic education, were small indeed in comparison with the massive investment in orthodox medicine. Perhaps more than ever before, medicine dwarfed chiropractic, and in the early 1960s the AMA set out to destroy it. The motives for its assault ranged from concern that chiropractic was gradually achieving acceptance to the conviction that chiropractors were unscientific cultists who were detrimental to the public health. The assault was launched by the AMA Committee on Quackery, created in 1963.

The committee mounted an intensive campaign. Under its direction, the AMA adopted a resolution calling chiropractic an unscientific cult, distributed publications critical of its practice, and discouraged medical organizations from condoning interactions between physicians and chiropractors, even declaring consultation with chiropractors unethical.

Despite this remarkable onslaught, chiropractic not only survived but thrived. During the tenure of the committee (1963–74), chiropractic greatly expanded as schools opened, the number of chiropractors grew, and licensing was granted in the few states that had withheld it. Chiropractic achieved federal recognition when it became incorporated into the Medicare and Medicaid programs.

The ability of chiropractic to resist AMA's assault rested on four important developments: (1) a new social climate, (2) improved intraprofessional cohesion, (3) shrewd political maneuvering, and (4) jettisoning of its one cause–one cure hypothesis. A new social climate had come about with the extraordinary upheavals of the 1960s. The civil rights movement, the women's movement, the antiwar movement, and the environment movement, among others, rejected the status quo. What had previously been held to be authoritative was now condemned as authoritarian. Science and technology were no longer accepted as unalloyed good, critics argued that physicians had lost touch with the art of medicine, and conventional health care came to be viewed as impersonal, costly, and inefficient. Long critical of organized medicine, chiropractors began to find an increasingly receptive audience as tolerance for, and interest in, alternative medicine expanded enormously. Chiropractic benefited greatly from this new openness and yet, as a well-established profession, simultaneously avoided the appearance of being a fad. The criticism that medicine was too reliant on technology led chiropractors to reemphasize their reliance on "natural" healing. (Ironically, the use of technologies like diathermy

again became controversial in chiropractic, and a new "superstraight" faction emerged that eschewed nearly all machinery.) The AMA's antichiropractic efforts may have paradoxically created new support for this system of healing.

Chiropractic witnessed much more cohesion among its practitioners, for efforts by the medical profession to eradicate it had the effect, despite the persistent argument between mixers and straights, of unifying chiropractors. Certainly, the tangible manifestation of chiropractic unity was adept political maneuvering. From their earliest struggles to obtain state licensure at the beginning of the twentieth century, chiropractors have demonstrated a considerable mastery of the U.S. political process and thus, despite opposition from the vaunted AMA lobby, they have shrewdly combined personal appeals, mass mailings, and the efforts of paid lobbyists to promote their goals.

Finally, chiropractic began explicitly to limit its claim of effectiveness and increasingly emphasized its role in the management of musculoskeletal disorders. In 1969 both major chiropractic associations rejected the "one cause–one cure" tenet of chiropractic. This freed chiropractors from having to respond to medical hecklers who ridiculed them for believing that cancer, diabetes, and other ills were caused by spinal subluxations. Growing evidence supported chiropractic's contention that it was an effective therapeutic modality for low back pain. The prevalence of this condition combined with orthodox medicine's paucity of effective treatments for back problems helped chiropractors define a niche for themselves in the U.S. health care system.

By the mid-1970s chiropractic occupied a new and greatly strengthened position. In the face of a changing social climate and numerous antitrust lawsuits instituted by chiropractors, opposition from organized medicine began to abate. The AMA and other medical organizations grudgingly recognized that there might be some benefits from spinal manipulation, and of course the inclusion of chiropractic in the Medicare and Medicaid programs helped legitimize the profession. In 1979 a conference sponsored by the National Institute of Neurological and Communicative Disorders and Stroke of the National Institutes of Health addressed the research status of spinal manipulative therapy. At this meeting, medical doctors, osteopaths, scientists, and chiropractors exchanged information. Although the scientific basis for manipulative therapy remained a subject of debate, a consensus emerged that this therapy was of clinical value in the treatment of back pain. The

fact that chiropractic was seriously discussed by a branch of the National Institutes of Health – one of the cathedrals of scientific medicine – symbolizes how far chiropractic had traveled.

Although, as this essay has shown, chiropractic has become more acceptable to the mainstream of U.S. society, it has not become widely accepted as a conventional therapy. The majority of Americans have never visited a chiropractor, and considerable confusion exists about what chiropractors do. However, the number of people who have been treated by a chiropractor is gradually increasing, and chiropractic's public image is improving. The periphery of the U.S. health care system is perhaps the ideal position for chiropractic. It provides legitimacy while allowing for the distance from conventional medicine that is fundamental to chiropractic's identity.

III.7
Concepts of Addiction: The U.S. Experience

</div>

Addiction has remained a vague concept in spite of efforts to define it with physiological and psychological precision. The word's Latin root refers to a legal judgment whereby a person is given over to the control of another. In recent centuries the meaning has ranged from a simple inclination toward an activity or interest to an uncontrollable desire to take opium, which historically was viewed as the most addictive of drugs. Opiate addiction is characterized chiefly by the repeated use of the drug to prevent withdrawal symptoms, which include muscle and joint pains, sweating, and nausea. The extreme discomfort of withdrawal passes away after one to three days, although a yearning for the drug may last for a very long time. Some attempts to define addiction in medical terms (e.g., restricting it to opiate withdrawal phenomena) have led to confusion among members of the public because cocaine, according to that restricted definition, would be considered nonaddictive and, by implication, safer than the opiates.

For the sake of brevity, this essay considers chiefly opium and coca and their constituents and derivatives. The chemicals that could be discussed range from the barbiturates to lysergic acid diethylamide (LSD), but the models of control and therapy commonly applied to these other substances evolved in the past two centuries from experience with the coca bush, opium poppies, and their powerful alkaloids.

Opium

The opium poppy appears to be indigenous to the eastern Mediterranean area. The manner of producing crude opium is to scratch the surface of the poppy pod and scrape off the juice that exudes, collecting and drying the material until it is solid. This crude opium can be taken alone or in combination with other substances. Mithradatum, theriac, and philonium are three ancient and renowned medicines that contained opium, among other substances, when compounded during the early centuries of the Roman Empire, although in subsequent eras opium was not invariably a constituent.

The smoking of opium, so closely associated with China in the nineteenth and early twentieth centuries, appears to have been introduced to the Chinese in the seventeenth century by Dutch traders who had

earlier supplied tobacco for smoking. The Chinese government attempted to outlaw the practice as early as 1729, but through much of the nineteenth century, as supplies came from the region of Turkey and Persia and later mostly from India, the attraction of smoking opium grew. The attempts of some Chinese administrators to cut off foreign opium importation were frustrated by the defeat of China in the so-called Opium War of 1839–42. Near the close of the century, young reformers blamed widespread addiction to opium and consequent lethargy and inefficiency for China's defeat by Japan in 1895. In response to a growing antagonism to opium use, the dowager empress Tzu Hsi instituted a program to eliminate domestic opium production and to seek a reduction in the importation of opium from India. This action was one of three crucial events in 1906 that led to a worldwide effort to control the production and distribution of opium and the opiates.

The second event was the Liberal Party's victory in the British parliamentary elections. The Liberal Party had long taken a stand against sending opium from India to China against the will of the Chinese people and government, although treaty rights to do so had been established by the British military. Complicity in facilitating Chinese addiction to opium deeply offended many Britons, especially those who promoted Christian missionary efforts in China. Previous British governments had argued that opium was not particularly harmful, being the equivalent of distilled spirits among Westerners, and that the opium trade was needed to pay for the British administration in India. After 1906, however, cooperation between the British and Chinese governments in curbing opium production was theoretically possible.

The third major antiopium event of 1906 was the U.S. decision to convene the Shanghai Opium Commission, a decision that reached fruition in 1909, as is discussed in the section on the origin of international control.

Morphine and the Hypodermic Syringe

The isolation of morphine from opium by F. W. A. Sertuener in 1805 marked the beginning of a new era in opium use. Physicians now had access to a purified active ingredient; hence, they were no longer uncertain of the strength of a dose and could investigate the effect of a specific amount. Commercial production followed the isolation of morphine and by the 1830s morphine was commonly available in any area touched by pharmaceutical trade with Europe and the United States. Morphine was administered by mouth, clysis, or absorption through denuded skin, as after blistering. The refinement of the hypodermic syringe and needle at midcentury created a mode of delivery as revolutionary in the history of addiction as had been the isolation of morphine.

Hollow needles and syringes had been employed long before the appearance of the familiar syringe and needle in the nineteenth century, but the growing number of purified chemicals, such as morphine, that could be directly injected into the body stimulated the pace of development and production. At first, injected morphine was considered less likely to be addictive than oral morphine because a smaller amount was required for equivalent pain relief. But by the 1870s this assumption was found to be erroneous, although many physicians continued to use injected morphine for chronic ailments, such as arthritis.

Restrictions

In most European nations, the central government controlled the practice of medicine and the availability of dangerous drugs through legislation. In addition, by the mid-nineteenth century, European physicians and pharmacists had organized themselves on a national level. By contrast, in the United States the federal government relegated to the individual states control over the health professions, and the professions themselves were poorly organized nationally. No laws controlled the sale of, contents of, or claims for "patent medicines," and there were few local laws restricting the availability of opium, morphine, and, later, cocaine. The result was a thriving and open market in these substances until late in the century, when some states began to enact laws preventing the acquisition of opiates and cocaine except with a physician's prescription. The U.S. Constitution grants the regulation of commerce among the states to the federal government, so no state law could affect the sale of drugs or products across state lines. The consequence was a higher per capita consumption of opium and opiates in the United States than in other Western nations and even, a government official claimed in 1910, more than the legendary consumption of opium in China.

Addiction and Its Treatment

The model of addiction to opium and opiates is the one to which addiction to other substances has been compared. Such addiction has long been viewed in moral terms, with the addict seen as "vicious" or

"degenerate," driven by a "sinful" desire for plea-
sure. But as drugs were increasingly used to treat
illnesses it was also understood that an individual
could inadvertently become addicted to them – an
understanding that has helped to give rise to the
biological concept of addiction as an illness.

The investigation of addiction has experienced a
decided shift over the past two centuries or so from
the moral view of addiction as "sin" to the biological
concept of addiction as disease, prompting some to
argue that the "disease" in question was invented
rather than discovered. Yet as more and more have
adopted the view of addiction as a disease, the ques-
tion of susceptibility has arisen, with biologists oscil-
lating between the conviction that everyone is
equally susceptible and the belief that only some are
susceptible for psychological as well as physiological
reasons.

Such ambivalence can also be found in legal sys-
tems that attempt to distinguish between morally
"superior" and morally "inferior" addicts and in the
medical profession, where physicians for a century
have tried to find among their patients signs that
would warn of addictive liability. These questions are
still relevant to contemporary addiction research.

During the nineteenth century, once opiate addic-
tion became familiar to physicians, a debate ensued
over whether the continuous use of opium was a
habit or a disease over which the patient had little
control. The debate was complicated by a belief that
abrupt withdrawal from opium could cause death.
Three options were proposed and vigorously de-
fended. The first was abrupt withdrawal, recom-
mended almost exclusively as a hospital procedure.
The addict was considered to be ingenious in obtain-
ing drugs and to have a will so weakened by addic-
tion and craving for opium that, unless he or she was
securely confined, withdrawal would not be success-
ful. It could be assisted by the administration of
belladonna-like drugs that counteracted withdrawal
symptoms such as sweating. These drugs also caused
delirium, which, it was hoped, would have the effect
of erasing the addict's memory of the withdrawal.
(Scopalamine is given today just before general anes-
thesia for a similar reason.) The high rate of relapse
in the weeks after treatment brought into question
the value of detoxification.

The second option was gradual withdrawal, recom-
mended because of the presumed ease of the treat-
ment as well as the fear that sudden termination of
the opiate would result in death. The idea that
abrupt withdrawal could cause death was not widely
refuted in the United States until about 1920. Grad-

ual withdrawal was a technique that favored outpa-
tient care and self-treatment by over-the-counter ad-
diction "cures." Critics of this method argued that
many addicts could lower their opiate intake only to
a certain level below which they could not comfort-
ably descend. An example of this threshold is the
case of William Steward Halsted, a physician at
Johns Hopkins Medical School who had to take a
daily amount of morphine, about two to three grains,
for the last 30 years of his life.

Halsted's experience suggests the third option, in-
definite opiate maintenance. Of course, the strong,
and for some the invincible, hold that opiates had
over a user is what led to popular and professional
fear of narcotics. Perpetuating addiction was the
opposite of curing it, and initially the reason for
doing it was simply the difficulty of stopping. Early
in the twentieth century, however, scientific reasons
for maintenance were advanced. Influenced by the
rise of immunology, some researchers theorized that
the body produced antibodies to morphine. If the
level of morphine dropped below that required to
"balance" the antibodies, the antibodies would pro-
duce withdrawal symptoms. Thus, unless the anti-
bodies and every vestige of morphine could be re-
moved from the individual, maintenance would be
required to create a normal physiological balance.

Research produced no evidence of antibodies to
morphine, but a less specific claim found adherents
around the time of World War I. The hypothesis was
that continued exposure to a substance like mor-
phine caused a pathological change in the body's
physiology that could not be altered by any known
treatment, but required indefinite maintenance for
normal functioning. This hypothesis was rejected in
the antiaddiction fervor just after World War I in the
United States, although it was revived by Vincent
Dole and Marie Nyswander in the 1960s as a justifi-
cation for maintenance by methadone, a synthetic,
long-acting opiate.

A treatment for addiction that found wide accep-
tance in the first two decades of the twentieth cen-
tury, especially in the United States, was described
by Charles B. Towns, the lay proprietor of a hospital
for drug and alcohol abusers, and Alexander Lam-
bert, a respected professor of medicine at Cornell
Medical School and later president of the American
Medical Association. An insurance salesman and
stockbroker, Towns purchased from an anonymous
person a general treatment for addictions. Lambert
became convinced of the treatment's efficacy, and he
and Towns published it jointly in the *Journal of the
American Medical Association* in 1909. The reputa-

tion of the Towns–Lambert treatment can be gauged by the fact that the U.S. delegation attempted to persuade the Shanghai Opium Commission to approve the treatment formally. The commission declined to do so.

The treatment, which combined various medical theories of the time, was based on the belief that morphine or other addicting substances had to be eradicated from the body. Therefore, a powerful mercury-containing laxative, called "blue mass," was administered several times, culminating in the passing of a characteristic stool that brought a profound sense of comfort. During the latter part of the therapy a formula, chiefly belladonna and hyoscine, which presumably counteracted the symptoms of withdrawal, was given at half-hour intervals. In the early years of this treatment, prominent physicians such as Richard C. Cabot of Boston allowed their names to be closely associated with that of Towns. In the years immediately after World War I, however, Lambert rejected the treatment as worthless and adopted the position then becoming popular that there was no specific treatment for addiction. Towns, by contrast, continued to operate his hospital in New York, applying the same treatment to alcohol addiction. "Bill W." received the inspiration to found Alcoholics Anonymous while undergoing treatment at the Towns Hospital in 1934.

In subsequent years, the treatment of opiate addiction has focused on achieving abstinence following detoxification, or maintenance using heroin, morphine, or methadone. Even when abstinence is achieved, however, relapses are common. In the 1970s pharmacological research led to the development of naltrexone, which blocks the effects of opiates, and several new drugs, most prominently clonidine, that lessen the discomfort of withdrawal.

The popularity of treatment and the growing emphasis on law enforcement to curb supply and punish users reflect social attitudes toward drug use. These attitudes have, in the course of a long span of drug consumption, evolved from toleration of use during the decades immediately following the introduction of new substances, such as cocaine, to extreme hostility toward drugs and drug users as the "epidemic" wears on. In the United States, medical and therapeutic approaches initially found favor but have since given way to law enforcement in response to the public's belated fearful reaction to the effect of drugs on individuals and society. Some countries, such as Indonesia, employ the death penalty against drug suppliers, whereas others rely on less stringent controls.

Cocaine

Cocaine, a central nervous system stimulant, offers a contrast to the opiates, although both have been subject to extreme praise and condemnation. Coca bushes are native to South America, and the leaves have been chewed there for millennia. The amount of cocaine extracted by chewing was increased by the addition of an alkaline substance to the wad of leaves, but the tissue level of cocaine obtained in this way was small compared with that obtained from the purified alkaloid cocaine, identified and named by Albert Niemann in 1860. Cocaine was not commercially available until the early 1880s. Before it was introduced to the market, extracts of coca leaves, often in a wine solution such as Vin Marianni, found favor as a tonic both with physicians and with the public.

Pure cocaine proved extraordinarily popular. Within a year of its introduction in the United States in 1884, Parke, Davis & Co. offered cocaine and coca in 14 forms. Cocaine was expensive, but soon became an ingredient in the new drink Coca-Cola and was found to be a specific remedy for hay fever and sinusitis. Within a few years, reports appeared in medical journals and the popular press telling of ruined careers and bizarre behavior among some users, but eminent experts such as William A. Hammond, a professor of neurology in New York medical schools and a former surgeon-general of the U.S. army, reassured the profession and the public that cocaine was harmless and the habit no more severe than that of drinking coffee.

Within 10 years, however, observers raised serious doubts that cocaine was as safe as had been asserted by Hammond and by cocaine's chief advocate in Europe, Sigmund Freud. By the first decade of the twentieth century, cocaine was no longer considered an ideal tonic but an extremely dangerous substance. In the United States, this new image, now associated with uncontrolled consumption, violence, and distorted thinking, provided powerful impetus to establish a national antinarcotic law, despite constitutional restrictions. In most other nations cocaine production and distribution was already regulated by national pharmacy laws. Through a complex series of events, the United States placed a national prohibition on narcotics use except for medical purposes and initiated an international campaign to control the production and distribution of opiates and cocaine.

The U.S. Response to Addiction

The per capita consumption of narcotics in the United States was officially described in the late

nineteenth century as much higher than that of any comparable Western nation, perhaps even that of China. This may well have been the case, but reliable comparisons are often difficult to make, partly because drug use and addiction have been topics relatively neglected by historians.

Concern in the United States over opiate addiction and the rise in consumption, which reached a peak in the 1890s, led to state laws that in most instances made morphine available only by a physician's prescription, although there was no restriction on interstate commerce. Cocaine use increasingly worried the public, who associated it with the underworld and assumed that its use by blacks was a cause of unrest among them in the South. The latter association exemplifies the linkages so easily made by the public between drugs and social problems.

Some of the unusual factors associated with extensive narcotics use in the United States (i.e., late professionalization of medicine, an open drug market, and constitutional restrictions on national legislation) began to change in the late nineteenth century. A domestic movement to control dangerous drugs, especially patent medicines, led to passage of the Pure Food and Drug Act of 1906, which required accurate labeling of the narcotic contents of products sold in interstate commerce. The acquisition of the Philippine Islands in 1898 and the necessity of dealing with the opium problem there spurred the most important decision making on narcotics by the federal government. The Philippine experience not only accelerated the passage of national laws but, of broader significance, led directly to a U.S.-inspired treaty to control narcotics worldwide, as well as to the international antiaddiction effort that persists to this day.

Origin of International Control

Under Spanish rule, there had been an opium monopoly in the Philippines from which opium smokers could obtain supplies. The newly arrived U.S. government decided to reinstitute the monopoly and use the profits to help support universal education there. However, U.S. missionary and political leaders strongly rejected the proposal. The impasse led to the creation of an investigating committee appointed by the Philippine government that included Charles Henry Brent, Protestant Episcopal bishop of the Philippines, who would become the key figure in establishing an international campaign against narcotics. The committee examined control measures used in other areas of the Orient and recommended a gradual reduction approach for opium users in the

Philippine Islands. The U.S. Congress took a more severe stance, mandating total prohibition of opium and derivatives, except for medical purposes, for Filipinos in 1905 and all other groups (mainly Chinese) in the Islands in 1908.

It was obvious to the U.S. government that its meager enforcement could not prevent the smuggling of opium into the Philippines. Conflict with China over the treatment of Chinese aliens in the United States along with the crucial events of 1906 in China and the United Kingdom provided Bishop Brent with a rare opportunity. He wrote President Theodore Roosevelt urging that the United States convene a meeting of relevant nations to assist China with its antiopium crusade. Successful control of narcotics traffic would aid the Philippines and the United States, and might also placate China. The acceptance of Brent's idea resulted in a survey of the U.S. domestic drug problem and the convening of the International Opium Commission at Shanghai in February 1909. Brent was chosen to preside over the 13 nations that gathered there. The commission's rather noncontroversial resolutions were used by the United States to convene the International Opium Conference, a treaty-making body, at the Hague in December 1911. The dozen nations represented at the conference, again chaired by Brent, adopted an International Opium Convention in January 1912. This treaty also included provisions for the control of cocaine. Control would be enforced primarily through the domestic legislation of several nations: However, the treaty would not come into force until every nation on earth had ratified. This difficult requirement arose out of the fear of some producing and manufacturing nations that, without universal adoption, the nonadhering nations would be able to dominate a lucrative market.

At a conference in June 1914, it was decided that any nation ratifying the treaty could put it into effect without waiting for unanimity. The United States chose to do so, and enacted the Harrison Narcotic Act in December 1914. World War I slowed ratification, but when the fighting ended, several of the victorious nations, including the United Kingdom and the United States, added the Hague Convention to the Versailles Treaty, mandating that ratification of the Peace Treaty include the Opium Convention. It was as a result of this requirement, and not of any domestic drug crisis, that the United Kingdom enacted the Dangerous Drugs Act of 1920. In later decades, especially in the United States, the origins of this act were forgotten, and the provision of opiates to some addicts allowed under the act was claimed to have solved a

serious addiction problem in the United Kingdom. This is an example, common in the area of drug policy, of trying to base solutions to an addiction problem on the laws or practices of another nation without taking into consideration differences in history and culture.

The Establishment of an International Bureaucracy

The League of Nations assumed responsibility for the Hague Convention in 1920. In 1924 the First Geneva Opium Conference addressed the gradual suppression of opium smoking. This was soon followed by the Second Geneva Opium Conference, which expanded international control over drugs by establishing a system of import and export certificates, creating the Permanent Central Opium Board (PCOB) to oversee the new provisions, and adding coca leaves and cannabis to the list of controlled substances. The United States, because it did not recognize the League, relinquished leadership of the international movement, and went so far as to walk out of the Second Geneva Opium Conference because, in its view, the other nations were unwilling to take meaningful steps to curb opium production and refused to ban the manufacture of diacetyl-morphine, more commonly known by its generic name, heroin. Heroin had been introduced by the Bayer Company in 1898 as a cough suppressant and within two decades had replaced morphine as the drug of choice among youth gangs in New York City. Heroin had an advantage over morphine in that it could be sniffed as well as injected and became the most feared of the opiates in the United States. In 1924 the United States banned domestic production of heroin.

In 1931 a conference was held in Geneva on limiting the manufacture of narcotic drugs, and in 1936 another Geneva conference dealt with suppressing the illicit traffic in dangerous drugs. After World War II the United Nations accepted responsibility for narcotics control, and in 1961 the various treaties were combined into the Single Convention on Narcotics. A significant addition to the older treaties was the prohibition of cannabis production.

The United Nations placed drug control under the Economic and Social Council (ECOSOC). The UN Commission on Narcotic Drugs meets annually to review the drug problem and make recommendations on policy to ECOSOC. The commission is the successor to the League's Advisory Committee on Traffic in Opium and Other Dangerous Drugs (1921–40). Also under ECOSOC is the International Narcotic Control Board (INCB), which oversees the ongoing functioning of treaty obligations and provides technical assistance in the form of statistics and chemical analyses. INCB, established by the Single Convention, succeeds the League's PCOB (1929–67) and the Drug Supervisory Board (1933–67).

The appearance in the 1960s of problems with newer drugs, such as LSD, barbiturates, amphetamines, and tranquilizers, prompted a new treaty, the Convention on Psychotropic Drugs (1971), which aims to expand international supervision beyond the traditional substances linked to opium, coca, and cannabis. In 1988 a convention intended to improve criminal sanctions against international traffickers was submitted to members of the United Nations for ratification.

Recent Responses to Drug Use

Research into the mechanisms of drug addiction and dependence has greatly increased in the past quarter-century. In the nineteenth century, research centered on modes of delivery, the development of the hypodermic syringe, and the nature of opiate addiction. The pattern of withdrawal was described and treatment for opiate addiction sought. Cocaine was offered, for example, as a cure for morphinism and alcoholism. Other cures were drawn from popular medical theories of the time, autointoxication, and other aspects of immunological response.

Confidence in treatment was equaled only by enthusiasm for research, until after World War I when, especially in the United States, a powerful reaction against drug use caused both professionals and the public to reject current treatments – which, in fact, were of little value – and to lose interest in research. The battle against drug abuse came to rely primarily on law enforcement. Research again found support in the late 1960s and the 1970s when consumption rose and there was a certain toleration of "recreational" or "experimental" drug use among youth. However, as fear of drugs and drug users increased, the public grew impatient with treatment and toleration of any drug use and, again, funding for research fell. In recent decades, significant advances have included the discovery of opiate receptor sites in the brain, of the existence of naturally produced opiates, endorphins, and of the existence of chemicals that block opiate receptor sites. Specific treatment for cocaine dependence has eluded investigators.

On an international level, attempts have been made to interdict drugs coming from producing areas; persuade local growers of poppies, coca bushes,

and marijuana to grow other crops; arrest local dealers; and spray illicit crops with herbicides. Crop substitution as an international policy dates to the 1920s, when the League of Nations sought to persuade opium growers in Persia to grow other crops, and continues today in major opium-producing areas, such as the "Golden Triangle" in northern Burma. This scheme has not yet cut into the world supply of opium and coca and, of course, is irrelevant to the control of manufactured drugs such as synthetic opiates and stimulants like amphetamine. Spraying the crops of producing nations and other policies advocated by consuming nations raise sensitive questions of sovereignty. Furthermore, producing nations claim, as they did during the first U.S. campaign to control production before World War I, that the problem is not production but the consuming nations' demand for drugs.

In its worldwide campaign against addiction, the United States early in this century asserted that the use of narcotics for anything other than strictly medical treatment was dangerous and morally wrong. This attitude represented the thinking of most North Americans at the time, but it was not a universal view and is not a view always held by the United States. The vicissitudes of moral attitude toward addiction over the past two centuries illustrate that the response to addiction is intimately bound to the social history and mores of a nation or region at any given time. The history of addiction has a medical element, but it is also a reflection of nations' characteristic approaches to individual and social problems. Integration of the history of addictive substances with the social history of nations and regions remains a fertile area for research.

Tobaccosis

The term *tobaccosis* in this essay denotes, collectively, all diseases resulting from the smoking, chewing, and snuffing of tobacco and from the breathing of tobacco smoke. They include cancers of the mouth, nasopharynx, larynx, trachea, bronchi, lungs, esophagus, stomach, liver, pancreas, kidney, bladder, prostate, and cervix, as well as leukemia. They also include atherosclerosis of the cardiovascular system – coronary heart disease (with ischemia and infarction), cardiomyopathy, aortic and other aneurysms, cerebrovascular hemorrhages and blockages; renal failure and peripheral vascular disease; emphysema and chronic obstructive pulmonary diseases; peptic ulcer disease and regional ileitis; cirrhosis of the liver; immunological deficiencies and failures of endocrine and metabolic functions; and fetal diseases and perinatal disabilities.

Tobaccosis is the foremost plague of the twentieth century and thus joins the most fearsome plagues that devastated humanity during this millennium such as the Black Death, smallpox, malaria, yellow fever, Asiatic cholera, and tuberculosis. But unlike microparasitic plagues, whose victims experienced pathognomonic disease manifestations within days or weeks of exposure, tobaccosis is an extraordinarily insidious disease entity of long latency resulting from exposure to tobacco for many years or decades and manifested by increased occurrence of any of a broad spectrum of neoplastic and degenerative diseases ordinarily associated with advanced age. Thus, the powerfully malignant nature and magnitude of the tobaccosis pandemic went largely undetected during the first four centuries of its global march; and it is only late in the fifth century of the post-Columbian world's exposure to tobacco that the extent of tobacco's depredations is being fully revealed. Because of its leadership in the production, marketing, and use of tobacco, the United States has borne much of the brunt of the tobaccosis pandemic. Hence, this historical account deals mainly with the U.S. experience.

Origin and Peregrinations of Tobacco

Tobacco is native to the Americas and was extensively cultivated and smoked by the aborigines there. The addictive weed was first encountered by Christopher Columbus and crew on the island of Cuba in November 1492. For some years it was known as *paetun* and by other names before it was given its common name, *tobacco*, from the pipes in which it was smoked on the island of Santo Domingo.

Increasingly cultivated and used by Spaniards and blacks in the West Indies and by Portuguese and blacks in Brazil during the early decades of the sixteenth century, tobacco was introduced to many European countries during the latter decades of that century. In 1559 tobacco seeds obtained in Lisbon by Jean Nicot, the French ambassador, from a Dutch trader just returned from the New World were sent as a medicinal to Queen Catherine de Medici and the House of Lorraine, thereby initiating tobacco cultivation and use in France and gaining lasting fame for Nicot.

Tobacco was brought to England in 1565 by John Hawkins, returning from a second voyage to Florida, but it did not gain immediate popular use. Two decades later, Walter Raleigh established a colony on Roanoke Island in Virginia. When Francis Drake visited the ill-fated colony in June 1586, the governor and others returned with him to England, bringing with them the tobacco and pipe-smoking practices soon popularized by Raleigh and others at Queen Elizabeth's court. By 1600 tobacco was widely used in all the maritime nations of Europe.

Meanwhile Portuguese traders carried tobacco in the latter 1500s to African ports and to India, the Spice Islands, Japan, Macao, China, and elsewhere in the Orient; and Spanish traders carried it to the Philippines. Other European merchants trading in the Levant took the weed with them throughout the East. Thus, by the end of the seventeenth century, tobacco was widely available and used in virtually all trading nations of the world.

Tobacco in Europe

Among American Indians, from Canada to Brazil, tobacco was widely smoked for its intoxicating effects, as a medicinal, and for ceremonial purposes. The spread of tobacco use from the New World gave rise to the first great drug controversy of global dimensions. From the onset, opinions regarding tobacco differed radically. Used by Indians as a remedy for aches and pains, snake bite, abdominal and chest pains, chills, fatigue, hunger and thirst, tobacco was extolled by European purveyors for its miraculous curative powers.

Yet the popularity of tobacco in England was challenged by James I, who became monarch of the British Isles after the death of Queen Elizabeth in 1603. His "Counterblaste to Tobacco," published anonymously in 1604 and considered extreme and rather quaint during intervening centuries, can now be appreciated as somewhat prescient:

And now good countrey men let us (I pray you) consider, what honour or policie can move us to imitate the barbarous and beastly manners of the wild, godlesse, and slavish Indians, especially in so vile and stinking a coustome? . . . A custome lothesome to the eye, hateful to the nose, harmfull to the braine, dangerous to the lungs, and in the black stinking fume thereof neerest resembling the horrible stigian smoke of the pit that is bottomless. (Quoted in Austin 1978)

The following year he organized, at Oxford, the first public debate on the effects of tobacco, at which – to get his point across – he displayed black brains and black viscera allegedly obtained from the bodies of smokers. To discourage tobacco sales and use, James I increased the tax thereupon 40-fold; but when use and smuggling increased, he reduced the tax in 1608 to one shilling per pound of tobacco and sold the monopoly right to collect it. With the establishment in 1607 of his namesake colony on the James River in Virginia and on the initiative of John Rolfe, tobacco quickly became its principal crop and export. In 1615, 2,300 pounds were exported, in 1618, 20,000 pounds, and by 1620, 40,000 pounds.

An outbreak of plague in London in 1614 gave further impetus to smoking, in that doctors declared that steady smokers were not as subject to infection as others and recommended tobacco as a disinfectant. At that time, 7,000 shops were selling tobacco in London, with use spreading among the poor despite high prices. By 1615 tobacco imports had risen to such an extent that James revoked his 1608 monopoly grant and reassigned it at a higher price. In 1620 he ordered that all tobacco bear the government seal, and in 1624 he decreed that only Virginia tobacco be imported. Thus, despite the high costs and discomfort of smoking, chewing, and snuffing and despite intense repressive actions of such sovereigns as King James I of England, King Christian IV of Denmark, Tsar Michael Romanov of Russia, and Sultan Murâd of Turkey, tobacco continued to increase in popularity.

Snuffing Cancer

Among the lower classes, pipe smoking was the common method of tobacco consumption; among the Eu-

ropean upper classes during the 1700s, pipe smoking was largely supplanted by snuffing (the practice of sniffing tobacco dust). Within a few decades the widespread practice of snuffing generated the first clinical reports of cancer caused by tobacco – cancer of the nasal passages, as described by an English physician, John Hill, in 1761:

This unfortunate gentleman, after a long and immoderate use of snuff, perceived that he breathed with difficulty through one of his nostrils; the complaint gradually encreased 'till he perceived a swelling within. . . . It grew slowly, till in the end, it filled up the whole nostril, and swelled the nose so as to obstruct the breathing . . . he found it necessary to then apply for assistance. The swelling was quite black and it adhered by a broad base, so that it was impossible to attempt to the getting it away . . . and the consequences was the discharge of a thick sharp humor with dreadful pain, and all the frightful symptoms of cancer . . . and he seemed without hope when I last saw him. (Quoted in Whelan 1984)

Also in 1761, the Italian anatomist Giovanni Battista Morgagni described lung cancer at postmortem without identifying its cause. A few years later, in 1775, Percival Pott described a scrotal cancer epidemic among London chimney sweeps, documenting the carcinogenicity of chimney *smoke,* which should have alerted many to the pathogenic implications of chronic exposure of respiratory tissues to tobacco smoke.

Although tobacco-induced lung cancer must have produced many thousands of deaths from the sixteenth to the nineteenth century, all such progressive chest diseases were lumped under the rubric of *phthisis* or *consumption* until the late-nineteenth-century scientific advances of histology, bacteriology, and X-ray. At that time, because of the often obvious relationships between snuffing and nasal cancer, pipe smoking and lip cancer, tobacco chewing and cancer of the mouth, cigar smoking and cancer of the mouth and larynx, there was a growing realization that tobacco use produced cancers of directly exposed topical tissues.

Nineteenth-Century Wars and Tobaccosis

British soldiers returning from campaigns on the Iberian Peninsula during the years 1808–14 introduced cigarettes to England. Likewise, veterans returning from the Crimean War (1853–6) increased cigarette smoking in Britain – a practice soon brought to the United States by returning tourists, including New York society women.

During the U.S. Civil War (1861–5) the use of all kinds of tobacco, including that of cigarettes, in-

creased, and after the war tobacco factories mushroomed. By 1880, with a population of 50 million people, the United States consumed 1.3 billion cigarettes annually, 500 million made locally and the rest imported. Nonetheless, chewing tobacco – a U.S. concoction of tobacco and molasses – remained the leading form of tobacco in the United States throughout the nineteenth century. Along with a great increase in tobacco consumption during the nineteenth century came increasing reports of tobaccosis, especially cancers of directly exposed tissues. Although medical science was still in its infancy in the nineteenth century, occasional astute clinical observations gradually increased people's awareness of the pathogenicity of tobacco.

In 1851, for example, James Paget saw a patient with leukoplakia ("smoker's patch") on the tongue where he always rested the end of his pipe, and "told him he certainly would have cancer of the tongue if he went on smoking" (quoted in Whelan 1984). And in 1857 *Lancet* commented:

Tobacco . . . acts by causing consumption, haemoptysis and inflammatory condition of the mucous membrane of the larynx, trachea and branchae, ulceration of the larynx; short, irritable cough, hurried breathing. The circulating organs are affected by irritable heart circulation. (Quoted in Whelan 1984)

In 1859 a French physician reported a remarkably thorough study of 68 cases of cancer of the oral cavity in a French hospital. Ascertaining the habits of 67 of these patients, he found that 66 smoked tobacco and the other chewed tobacco. He also noted that cancer of the lip ordinarily occurred at the spot where the pipe or cigar was held.

In 1882 the *Boston Medical and Surgical Journal* offered this prescient view of cigarettes:

The dangers, then, which are incident to cigarette smoking are, first, the early age at which it is taken up; second, the liability to excess; and, third, the bad custom of inhaling the smoke. These are dangers super-added to those attendant upon the ordinary use of tobacco, and should be considered by all medical men.

Despite such examples, however, leading physicians of the late nineteenth century were generally oblivious to the hazards of tobacco. In the monumentally detailed *Medical and Surgical History of the War of the Rebellion,* prepared under the direction of Surgeon General of the Army Joseph K. Barnes by J. J. Woodward and colleagues and published in six huge volumes from 1875 to 1888 under the authority of the U.S. Congress, there are only two comments about tobacco: that tobacco clyster may be

used for the treatment of zymotic disease and that abuse of tobacco may cause "irritable heart." Nor was tobaccosis frequently mentioned by John Shaw Billings, founder of the *Index Medicus*, the National Library of Medicine, and author of voluminous analyses of late-nineteenth-century U.S. mortality. William Osler in his classic 1892 text, *The Principles and Practice of Medicine*, devoted only three sentences in 1,000 pages to the effects of tobacco.

With the advent of cigarette-making machines, which made possible the nearly unlimited production of cigarettes, and portable "safety" matches (introduced at the turn of the century), which enabled smokers to light up whenever and wherever they wished, the stage was set for a vast increase in cigarette consumption. However, as tobacco companies intensified promotional activities, a powerful antitobacco movement developed, led by Lucy Page Gaston and the Women's Christian Temperance Movement, which substantially curbed cigarette sales during the 1890s and early 1900s.

Twentieth-Century Cigarette Tobaccosis

A comprehensive view of evolving tobacco use patterns in the United States during this century is presented in Table III.8.1, which documents the progressive trend from cigar smoking and the use of "manufactured tobacco" (pipe tobacco, chewing tobacco, and snuff) to cigarette smoking. Annual production of manufactured tobacco increased from 301 million pounds in 1900 to a peak of 497 million pounds in 1918 and subsequently decreased to 142 million pounds (1988). During the twentieth century, cigar production oscillated between 4 and 10 billion annually, with more cigars produced in 1900 (5.6 billion) than in 1988 (3.2 billion).

Meanwhile, cigarette production and consumption increased more than 100-fold, with consumption increasing from 2.5 billion cigarettes in 1900 to 640 billion in 1981, then decreasing to 562 billion in 1988. On a per capita basis in the United States, annual cigarette consumption increased from 54 per adult in 1900 to a peak of 4,345 per adult in 1963. Since then it has decreased to 3,096 cigarettes per adult in 1988.

The foremost determinants of national cigarette consumption can be inferred from the trend changes seen in Figure III.8.1. Cigarette consumption doubled during World War I, when cigarettes were included in soldiers' rations sent to France. It doubled again during the 1920s, propelled by innovative advertising campaigns and augmented by radio and cinema. But then it decreased during the early years
Figure III.8.1. Annual consumption of cigarettes by U.S. adults (18 years of age and older), 1900–88. (Data from the Economic Research Service, U.S. Department of Agriculture.)

of the depression of the 1930s, only to increase during the latter part of the decade, presumably in response to intensified advertising in magazines, on billboards, and on radio as well as in response to the incessant smoking of popular film stars and other famous personalities.

During World War II, when cigarettes were made freely available to many military and some civilian groups, consumption almost doubled again – from 1,976 cigarettes per adult in 1940 to 3,449 in 1945. After the war, cigarette consumption continued upward until 1950, when scientific findings showed smoking to be the principal cause of a rapidly increasing epidemic of lung cancer. However, tobacco sales soon recovered.

Intense wrangling over the validity of research findings on the harmful effects of tobacco generated so much confusion that in 1962 Surgeon General Luther Terry established the Advisory Committee of Experts, whose landmark report on 11 January 1964 rendered an authoritative verdict: "Cigarette smoking is causally related to lung cancer in men; the magnitude of the effect of cigarette smoking far outweighs all other factors. The data for women, though less extensive, point in the same direction."

Again the tobacco industry took vigorous defensive action with intensified advertising; but when a fairness doctrine required that advertising messages on radio and television be balanced by antismoking messages, tobacco advertising was discontinued in the broadcast media.

Table III.8.1. *U.S. tobacco production and consumption, 1900–88*

Year	Mfg. tobacco (lbs. × 10^6)	Tobacco products produced Total in billions Cigars	Cigarettes	Cigarette consumption Total in billions	Per adult (18+ years)

Despite these setbacks for the tobacco industry, sales ascended during the early 1970s. During the late 1970s, however, consumption began to decline under Joseph Califano as Secretary of Health, Education, and Welfare, a trend that fortunately has continued, for several reasons. Among these are increasing evidence of the harm to persons who are chronically

exposed to smoke generated by others and stronger antitobacco activities by official and voluntary agencies at national, state, and local levels, as well as the vigorous campaign mounted by Surgeon General C. Everett Koop.

World Tobacco Trends

During recent decades, as antitobacco movements have hobbled tobacco promotion and sales in some of the affluent countries and as income levels have risen in many less developed countries, the multinational tobacco companies have intensified their advertising efforts in the less developed world, resulting in the global tobacco consumption pattern seen in Table III.8.2.

The leading countries in the production and consumption of tobacco are China, the United States, the Soviet Union, Japan, the Federal Republic of Germany, the United Kingdom, Brazil, India, Spain, France, and Italy. World production and consumption of cigarettes now exceed 5 trillion annually – more than enough to raise the world tobaccosis death toll substantially above the current level of about 3 million annually. Fortunately, during the 1980s the World Health Organization began to exercise forthright leadership in supplying information on this difficult issue, though it had not yet applied financial and personal resources commensurate with the nature and magnitude of the tobaccosis pandemic.

Nature of the Tobacco Hazard

Addictive Pleasures

Although it has always been obvious that tobacco contains a substance (nicotine) that yields psychic

pleasures not obtained by the smoking of other plant leaves, only during the 1980s did a strong scientific and societal consensus emerge that nicotine is truly addictive – just as addictive as heroin or cocaine and much more addictive than alcohol.

Indeed, cigarette smoking is now the most serious and widespread form of addiction in the world. The proportion of adult men and women who have smoked cigarettes in the United States during the past half-century is indicated in Table III.8.3. Half of adult men smoked at midcentury, this proportion decreasing to 33 percent in 1985 and 30 percent in 1987. Likewise, smoking by adult women decreased from 34 percent in 1965 to 28 percent in 1985 and 27 percent in 1987.

Lethal Poisons

The smoke of burning tobacco contains several thousand chemicals and a number of radioisotopes, including hydrogen cyanide, nitriles, aldehydes, ketones, nicotine, carbon monoxide, benzopyrenes, aza-arenes, and polonium 210, an alpha-particle emitter and therefore *the* most powerful contact mutagen, more than 100 times more mutagenic than equivalent RADs of gamma radiation. The combination of an addictive substance (nicotine) and more than 50 potent mutagens (especially polonium 210) has made tobacco the foremost human poison of the twentieth century.

Pathogenic Mechanisms

When tobacco smoke is inhaled deeply into the lungs, most of the tars contained therein are cap-

tured and retained by the respiratory mucous blanket. Soluble components are then promptly absorbed into the pulmonary circulation and conveyed by the systemic circulation throughout the body. Less soluble tars trapped by the mucous blanket are raised by ciliary action and coughing to the pharynx, then swallowed; thereafter, they pass to the esophagus, stomach, small intestine, portal circulation, and liver. Hence, chronic inhalation of tobacco smoke exposes the entire body – every tissue and cell – to powerful mutagens and carcinogens, thus hastening the malignant cellular evolutionary process and accelerating the development of the broad spectrum of neoplastic and degenerative diseases constituting tobaccosis (Table III.8.4).

The differences in mortality among smoking and nonsmoking U.S. veterans amply confirm the pioneering findings of Raymond Pearl, published in 1938, showing a great decrease in the longevity of smokers. In fact, the life-shortening effects of smoking are now so obvious that it seems incredible that they were generally overlooked for four centuries. Among persons who start smoking in adolescence and continue to smoke a pack of cigarettes daily, the *average* loss of life is roughly 8 years – approximately equal to the cumulative time actually spent smoking.

The most surprising finding of prospective and pathological studies – that the *majority* of tobaccosis deaths are caused by diseases of the cardiovascular system – initially generated incredulity, and indeed the phenomenon is still not well understood or fully believed by many. It nonetheless deserves full credence and is central to understanding the nature and magnitude of tobaccosis.

The fabric of evidence that cigarette smoking is a major cause of atherosclerosis is woven of these evidential threads:

1. The epidemic increase in ischemic heart disease in the United States during the twentieth century followed the rise in cigarette smoking and occurred particularly among those age–sex subgroups most exposed.
2. Individual studies document a close relationship between heavy cigarette smoking and early coronary disease.
3. There is a plausible pathogenic mechanism by which tobacco smoke could damage vascular tissue: The absorption of inhaled tobacco smoke results in the circulation of polonium 210 and other toxins, with injury to endothelial and other cells, causing cellular damage, clonal proliferation, intramural hemorrhage, lipid deposition, fibrosis,

Table III.8.4 *Deaths and mortality ratios among smoking U.S. veterans, 1980*

and calcification. Though often overlooked, ionizing radiation is a powerful cause of atherosclerosis and premature death from cardiovascular disease.

4. Prospective studies of heavy smokers matched with nonsmokers for numerous confounding variables have consistently shown the relative risk of death from atherosclerosis to be much higher for smokers and directly related to the number of cigarettes smoked.

5. Members of certain religious groups that eschew the use of tobacco, such as Seventh-Day Adventists and Latter-Day Saints, have markedly lower morbidity and mortality rates from atherosclerotic disease.

6. Quitting smoking is ordinarily followed by a reduced incidence of coronary heart disease, among specific groups and for the entire population.

7. Experimental studies in animals have demonstrated that tobacco constituents are potent causes of atherosclerotic disease.

The evidence is clear, consistent, and compelling that tobacco smoke is a major cause of atherosclerotic disease and death.

Epidemic Curves

Temporal relationships between twentieth-century epidemic curves for cigarette smoking and death from coronary heart disease, lung cancer, and emphysema/COPD (chronic obstructive pulmonary disease) are presented in Figure III.8.2. The figure shows the massive epidemic of coronary heart disease beginning in the 1920s – a few years after the World War I doubling of cigarette smoking; followed by epidemic lung cancer beginning in the 1930s – 20 "pack years" or 150,000 cigarettes after World War I; followed by epidemic emphysema/COPD beginning in the 1940s – the third decade after World War I. Furthermore, as tar content and per capita cigarette smoking decreased during the last 2.5 years, mortality from coronary heart disease and cerebrovascular disease decreased.
Figure III.8.2. Cigarette consumption and tobaccosis mortality in the United States, 1900–87. The asterisk indicates that the population exposure to tobacco tars is decreasing faster than the cigarette curve. (From Economic Research Service, U.S. Department of Agriculture; Vital Statistics of the United States; WCHSA Archives [personal communication]; Ravenholt 1962; Walker and Brin 1988; U.S. Department of Health and Human Services.)

Magnitude of the Hazard

Although some astute observers attributed lung cancer to smoking during the 1920s, 1930s, and 1940s, there was little general awareness of this relationship until the publication of case-control studies in 1950 showing that almost all (more than 90 percent) of lung cancer patients were smokers. The association of smoking with cancer of the lung was so obvious, consistent, and understandable that many scientists were readily convinced that smoking was the main cause of that disease. But when a number of prominent statisticians (who were themselves smokers) criticized these studies because of possible biases inherent in retrospective studies, massive prospective studies of morbidity and mortality differentials among smokers and nonsmokers were launched about the same time by the British Medical Association, the American Cancer Society, and the American Veterans Administration. (Among the many publications resulting from these studies were those by Doll and Hill [1952], Hammond and Horn [1958], Dorn [1959], and Rogot and Murray [1980].) The studies showed that smokers not only died from cancers of directly exposed tissues of the mouth, larynx, and lungs, but also died at a greatly accelerated rate from a bodywide spectrum of diseases, especially cardiovascular diseases (Table III.8.4) – thus confirming the finding of Raymond Pearl in 1938 that smoking exerted a profound life-shortening effect.

Furthermore, a matched-pair analysis of American Cancer Society prospective data by E. C. Hammond (1964) enabled this author to construct a Lung Cancer Index to total tobaccosis mortality and the estimate of *a quarter million U.S. tobaccosis deaths in 1962* – equal to the sum of all deaths from accidents, infection, suicide, homicide, and alcohol. Truly, for those who smoke a pack or more of cigarettes daily, tobacco is an environmental hazard equal to all other hazards to life combined. In 1967 this estimate was updated to 300,000 deaths for 1966.

During two ensuing decades, U.S. lung cancer deaths alone more than doubled from 48,483 in 1965 to 137,000 in 1987. In 1984, with the help of the Multi-Agency Working Group at the National Institute on Drug Abuse, seeking to achieve an updated, realistic estimate of U.S. tobaccosis mortality during the 1980s, this author applied proportionate analytic methods to 1980 U.S. mortality data; 485,000 tobaccosis deaths from cigarette smoking were estimated that year (Table III.8.5), as were

Table III.8.5 *Estimated number of deaths caused by cigarette smoking in the United States, 1980*

Anatomic site or nature of disease or injury (ICD number)	No. of deaths
Malignant neoplasms (140–209, 230–9)	147,000
Diseases of the circulatory system (390–459)	240,000
Ischemic heart disease (410–14)	170,000
Other vascular diseases	70,000
Diseases of the respiratory system other than cancer (460–519)	61,000
Emphysema (492)	13,000
Chronic bronchitis and other respiratory diseases	48,000
Diseases of the digestive system (520–79)	14,000
Diseases of the esophagus, stomach, and duodenum (530–7)	2,000
Cirrhosis and other diseases of digestive system	12,000
Certain conditions originating in perinatal period (760–79) (caused by maternal smoking, low birth weight, and other congenital disabilities)	4,000
External causes of injury (E800–E999)	4,000
Injuries caused by fire and flames (E890–E899)	2,500
Other accidental injuries	1,500
Miscellaneous and ill-defined diseases	15,000
Total	485,000

more than 500,000 tobaccosis deaths from all forms of tobacco use.

This estimate was accepted and used by the American Council on Science and Health and the World Health Organization, but not by the U.S. Office of Smoking and Health (OSH), which preferred a more "conservative" estimate of 320,000 tobacco deaths in 1987, raised to 390,000 in 1988.

Suffice it to say that the annual tobaccosis death toll – whether the OSH "conservative" estimate of 390,000 or the more complete estimate of 500,000 tobaccosis deaths – is far greater than mortality from any other preventable cause of death in our time and more than 25 times greater than current mortality from the acquired immune deficiency syndrome (AIDS), which emerged during the 1980s as a newly recognized and formidable disease entity (Figure III.8.3).

Conclusion

Tobacco owes much of its destructive power to the fact that its lethal effects are not immediately discernible. Initial reactions to smoking like nausea and respiratory distress usually subside, and many persons continue smoking, chewing, or snuffing tobacco for several decades without apparent serious injury or death. When serious illness does occur, it assumes such diverse forms that few comprehend the common cause.

Only recently, during the fifth century of post-Columbian tobacco experience, has medical and epidemiological science advanced sufficiently that the diffuse nature and great magnitude of tobacco's depredations have become fully evident. In the twentieth century alone, we tally these numbers:

In the United States the smoking of 26 trillion cigarettes and 556 billion cigars and the consumption of 25 billion pounds of "manufactured tobacco" (pipe tobacco, chewing tobacco, and snuff) have produced:

more than 2.9 million deaths from lung cancer,

more than 7 million deaths from cardiovascular disease, and

more than 14 million deaths from all forms of tobaccosis.

During the 1980s, the U.S. tobaccosis death toll was roughly 500,000 annually, for a total of 5 million deaths in the decade. Moreover, even if all tobacco use ceased immediately, many millions would still die of tobaccosis in ensuing decades.

In 1989 the world's inhabitants were smoking 5 trillion cigarettes annually and consuming millions of tons of tobacco as cigars, bidis, chewing tobacco, and snuff, as well as in pipes and hookas. The tobaccosis death toll was more than 2.5 million, and that in the twentieth century more than 50 million.

Considered a global entity with an extraordinarily diffuse, subtle nature and with lifetime latencies, tobaccosis poses the ultimate challenge to epidemiology and to world public health and political leadership.

III.9
Occupational Diseases

In recent years, occupational diseases have become an area of intense interest to medicine, public health, industry, and labor. Whole new areas of medical and public health specialization have developed since the end of World War II, partly in response to the detection of carcinogens in the workplace, dust in the air that workers breathe, and human-made chemicals that workers touch, taste, or inhale. Black lung (coal workers' pneumoconiosis), brown lung (byssinosis), and white lung (asbestosis) are three industry-specific diseases that have gained international attention and highlighted the role of occupation in the creation of illness. Laborers as well as physicians have become acutely aware of the dangers posed by substances and materials at work in a host of industries from steel to petrochemicals.

The growing attention to the hazards of the industrial workplace has alerted workers even in "clean" worksites to occupational disease. Physical dangers are posed to office workers by video display terminals, poorly designed furniture, noise, and vibrations. Stress at the workplace is now seen as important in the creation of the modern epidemics of high blood pressure, heart disease, and stroke. The very definition of disease has been altered by a rising popular and professional consciousness of the importance of occupation as a source of illness.

Occupational Diseases through the Industrial Revolution

Despite the recent concern, however, attention to the worksite as a source of disease is not new. Even the ancients recognized that certain occupations presented special risks of disease and injury. Hippocrates described lead poisoning among metal miners. Pliny the Elder was the first to describe the dangers that dust posed to tradesmen. Decimus Junius Juvenalis (Juvenal) wrote of the dangers that blacksmiths faced from the soot of "glowing ore." Over the course of the next two millennia a variety of observers remarked on the health hazards faced by specific tradesmen, artisans, and common laborers. But it was not until 1700 that Bernardino Ramazzini wrote his classic text, *De Morbus Artificum Diatriba* (Diseases of workers). This manuscript, the result of a lifetime of study and observation, was the first systematic treatment of the relationship between the workplace and the occurrence of disease. Ramazzini wrote of the health problems of common laborers and skilled artisans as well as of scribes, scholars, tradesmen, and others in the growing commercial classes. He alerted physicians to the significance of the workplace in identifying the sources of a patient's illness.

The Industrial Revolution fundamentally changed the methods of production and work relationships throughout the world. The factory system, which displaced workers from their land and homes, created new dangers. In addition to accidents caused by machinery, a faster pace of production, and long hours, new diseases plagued the working classes. Because England was the first industrial nation, English reformers and physicians quantified, measured, and documented the effects of industrialism and urbanization on the lives of the English working classes. Edwin Chadwick, Thomas Percival, and William Farr were among a group of Benthamites, Tories, and social reformers who sought to use statistical and quantitative analyses to impose order and expose the horrible working and living conditions that were closely linked to the development of the factory system. Charles Turner Thackrah, a physician in Leeds, paid particular attention to the diseases of various trades and, in 1832, wrote *The Effects of Arts, Trades, and Professions on Health and Longevity*. Thackrah organized his text by occupation, listing the diseases and disabilities associated with each trade. Diseases of operatives, dealers, merchants and master manufacturers, and professional men were itemized. Among the operatives who were exposed to harmful substances at work were corn-sillers, maltsters, coffee roasters, snuff makers, rag sorters, papermakers, flock dressers, and feather dressers. Dangers listed in the section on merchants and manufacturers were "anxiety of mind" and "lack of exercise." Despite the obvious impact of new industrial and urban conditions on the life of the workers and their families, much of this early work is remarkable for its emphasis on the responsibility of individual workers to both remedy and control those forces destroying their lives.

The growing European socialist movements interpreted the disintegration of workers' health as confirmation of the unacceptable social costs of industrial capitalism. In the mid-nineteenth century, Frederick Engels wrote his classic treatise, *The Condition of the Working-Class in England*. In this work he devoted two chapters to the conditions of work in a variety of industries, specifically noting the effects of these conditions on the health of workers. He was

especially concerned with the impact of child labor on the health of children pointing to its relationship with child mortality and disablement:

> In the manufacture of glass, too, work occurs which seems little injurious to men but cannot be endured by children. The hard labor, the irregularity of the hours, the frequent night-work, and especially the great heat of the working place (100 to 190 Fahrenheit), engender in children general debility and disease, stunted growth, and especially affections of the eye, bowel complaint, and rheumatic and bronchial affections. Many of the children are pale, have red eyes, often blind for weeks at a time, suffer from violent nausea, vomiting, coughs, colds, and rheumatism. . . . The glass-blowers usually die young of debility of chest infections. (Engels 1980, reprint 1892 publication)

By the mid-nineteenth century, physicians, sanitary and social reformers, and radicals recognized a wide variety of occupational diseases that afflicted industrial populations. The medical literature was filled with articles about dust diseases and heavy-metal poisonings closely linked to the high temperature, poor ventilation, and bad lighting of the early factories. Consonant with much medical theory that associated disease with the social and moral environment of different populations, the medical literature noted the explicit relationship between disease and the work environment. Health was understood to be a reflection of the balance between people and nature. Disease was seen as a reflection of the imbalance between humans and the unnatural environments that they created for themselves. Cities, factories, slums, and other manifestations of industrialism were creating this imbalance. Hence, physicians and public health workers writing about treatments, diagnoses, and cures for disease often framed their arguments in the personal, moral, and social terms that infused medical theory. For example, throughout most of the nineteenth century, impure air, "miasmas," and dust were considered sources of disease; industrial dust was seen as the source of one form of "phthisis" or consumption, a chronic condition that affected broad cross sections of western European and U.S. populations. Popular and medical opinion coincided in that both used the terms *phthisis* and *consumption* to denote a set of symptoms of diverse social origins. The symptoms of wasting away, coughing, spitting, and weakening appeared in victims from various classes and social strata. The root of a worker's disease could be found by looking at a host of variables including race, ethnicity, personal characteristics, home life, and work.

By the last third of the nineteenth century, however, the growing acceptance of germ theory moved the medical and public health communities away from this social explanation of disease. This was illustrated most directly by the effect of Robert Koch's discovery of the tubercle bacillus on the history of industrial lung disease. By the time of Koch's discovery in 1882 an enormous literature about the effect of dust on the health of workers had developed, especially in Europe. But with the discovery of the bacillus, the study of its relation to industry ceased, according to Ludwig Teleky (1948), a noted industrial physician and author of the first modern history of industrial hygiene. In Europe, researchers "mocked at all those 'curiosities' of quartz lungs, coal lungs, and iron lungs, 'all of which belong in a cabinet of curiosities.' " Until the beginning of the twentieth century all consumption or phthisis came to be understood as tuberculosis, caused by a specific organism and spread like other infectious diseases.

The United States in the Early Twentieth Century

In the United States the medical community also narrowed its focus, which set back the study of occupational disease for a generation. Others outside of the medical community developed a broader conception of the relationship between the work environment and health. In the late nineteenth and early twentieth centuries, reformers concerned with the plight of the urban poor saw that the terrible conditions of their lives and their work could not be separated. Charity and settlement-house workers, for example, documented that in nearly one of every four dwellings in New York City in 1890 there was a death from consumption. In the poorer neighborhoods, it was clear, the toll was much higher, leaving those communities devastated by the disease. The Progressive Era (1890–1920) analysis that intimately linked social conditions and disease led reformers and public health workers to emphasize the connection between work and disease as well.

In industrial sections of the United States, individual physicians and state public health officials participated in reform movements for workmen's compensation legislation, and John B. Andrews and the American Association for Labor Legislation led campaigns against such problems as lead poisoning and "phossy jaw" (necrosis of the jaw caused by exposure to phosphorus, as in the making of matches). But occupational disease was not yet seen as an intrinsic part of the mandate of public health.

It was only in 1915 that the U.S. Public Health Service was granted authority to investigate "occupational diseases and the relation of occupations to

disease." It organized an Industrial Hygiene and Sanitation section, and shortly thereafter the American Public Health Association also formed its own Industrial Hygiene section. In addition, a few of the state departments of health took an active and sustained interest in occupational diseases, most notably in Ohio under the leadership of Emery R. Hayhurst.

Even those reformers and physicians who were concerned with diseases of occupation focused mostly on acute poisonings, especially heavy-metal and phosphorus exposure. In the early years of the twentieth century, such investigators as Alice Hamilton, Florence Kelley, Andrews, and Hayhurst carried out detailed studies of lead, phosphorus, and mercury in such states as New York, Illinois, and Ohio. In 1911, following the tragic Triangle Shirtwaist fire in New York, in which scores of immigrant women were killed, the state sponsored a massive study of factory conditions led by Robert Wagner and Frances Perkins, among others. In the 1920s and after, industrial hygienists and occupational physicians investigated chronic diseases in workers in a number of occupations, especially painters and battery workers exposed to lead, watch-dial makers exposed to radium, and miners exposed to coal, silica, asbestos, and other dusts. The problem of lead had been known since antiquity, but the widespread introduction of lead into paint and gasoline and the increased smelting of ores associated with the Industrial Revolution heightened the awareness of the danger of lead to workers and the public alike.

During the early 1920s, workers in various petrochemical plants and research centers developed signs of acute lead poisoning. This alerted the public health community to the potential environmental damage that the recently introduced leaded gasoline posed. The Workers' Health Bureau argued that oil refinery workers were being "used like canaries in the coal mines" to test for the presence of poisonous substances. A major national conference was convened by the U.S. Public Health Service to discuss public policy regarding the use of organic lead in gasolines. However, it was not until the late 1960s and early 1970s that systematic efforts were made to eliminate lead from both indoor paint and gasoline.

It was also in the 1920s that women who worked in factories producing luminous watch dials in New Jersey were found to have symptoms of chronic radiation poisoning. This prompted occupational disease researchers and local physicians to undertake one of the first studies on the dangers of radium exposure. But again, it took until well after World War II for the U.S. government to act on their warnings about the deleterious effects of radiation.

Medical and public health interest in occupational diseases gave rise to new professions, such as that of industrial hygienist, and new specialties, such as occupational medicine. They were dominated in the 1920s by private companies, which supplied financial support, research facilities, and even patients. Indeed, in the United States hundreds of corporations hired their own physicians, nurses, and engineering and medical personnel as part of company welfare and health plans. But there were very few industrial agencies that were concerned with industrial health and only a few universities, such as Harvard, Yale, and New York University, organized departments that addressed industrial hygiene specifically. Thus, the control of workplace hazards was in the hands of professionals associated largely with private industry and therefore was not really associated with the broader perspectives of the Progressives and labor reformers.

The Problem of Dust and the Emergence of Chronic Disease

While a host of investigators began to study particular acute diseases caused by specific industrial toxins, the problem of dust in the closed environments of factories and mines galvanized the attention of the health community and work force. Dust was a potential problem in virtually every industrial setting. There were mineral and metal dusts in coal and metal mines, foundries, steel mills, and rubber factories, and vegetable and animal dusts in granaries, bakeries, textile mills, and boot and shoe factories. In the early twentieth century, the work of Thomas Oliver and a series of British governmental studies were instrumental in revitalizing interest in the industrial etiology of lung disease and the problem of chronic occupational diseases in general. In 1902, in his famous treatise *Dangerous Trades,* Oliver cited four specific dust diseases: chalicosis or silicosis, siderosis, anthracosis, and byssinosis.

In the first half of the twentieth century, labor and business focused mostly on silica dust, and though this diverted attention from the other dust diseases, it did lead to the formulation of general public policies that were applicable to other chronic industrial diseases. Politicians, labor, management, insurance company representatives, physicians, and lawyers all raised questions of responsibility for risk in the new industrial workplaces.

The central questions of the debate were: What was an industrial disease? How could occupational

and environmental diseases be distinguished? How should responsibility for risk be assigned? Should a worker be compensated for impairments or for loss of wages due to occupational diseases and disabilities? Should industry be held accountable for chronic illnesses whose symptoms appeared years and sometimes decades after exposure? At what point in the progress of a disease should compensation be paid? Was diagnosis sufficient for compensation claims, or was inability to work the criterion? Who was to define inability to work – the employee, the government, the physician, or the company? In short, the questions and arguments addressed the problem of who defined what today we would call latency, time of onset, and the very process of disease.

Shortly after the Boer War, silicosis gained wider public notice, as English miners who had worked in the South African gold mines returned to Great Britain. Oliver described the fate of "young miners in the bloom of health" who, after working in the gold fields for only a few years, "returned to Northumberland and elsewhere broken in health." Because of the hardness of the rock from which gold was extracted, dry drilling and blasting created special hazards both for native workers and for their English overseers. In 1902 a British governmental commission was appointed to study the nature and prevalence of lung diseases in these mines. Investigators such as Edgar Collis, H. S. Haldane, and the Miners' Phthisis Commission demonstrated clearly that victims of "Rand Miners' phthisis" were primarily suffering not from tuberculosis, but from silicosis. This was the first systematic study of the hazard of exposure to silica dust.

In the United States, the British findings were employed by Frederick L. Hoffman in his study *The Mortality from Consumption in Dusty Trades* (1908). It began with the observation that "no extended consideration [was required] to prove that human health was much influenced by the character of the air breathed and that its purity is a matter of very considerable sanitary and economic importance."

The study built on the clinical evidence presented in the British material as well as on progressive social analysis. But it was also significant because Hoffman used statistical data drawn from insurance company records and census materials from both Great Britain and the United States. Although the British (especially Thomas Oliver) had also used statistical and epidemiological data in their investigations, Hoffman was the first American to use such methods. In so doing he documented the prevalence and scope of industrially created lung diseases and also used the statistical materials for their implications about the work environment. Although the case for the significance of dust as a cause of pneumoconiosis was building, Hoffman's focus in this 1908 report remained on industrial dusts and tuberculosis.

The dust hazards for metal miners and other workers had become sufficiently apparent that, in 1911, the U.S. Public Health Service and the Bureau of Mines were asked by the National Association for the Study of Tuberculosis to conduct a thorough investigation of lung diseases of metal miners. In 1914 the two federal agencies initiated the first such epidemiological study in the tristate lead- and zinc-mining region of Missouri, Kansas, and Oklahoma. The study exposed the horrendous toll that metal dusts were taking on miners in the area and graphically described the suffering that many of the miners experienced as the disease progressed: "If we can imagine a man with his chest bound with transparent adhesive plaster, we can form a mental picture of how useless were the efforts at deep inhalation made by these patients" (Lanza 1917a).

In Europe, as well as in the United States, the introduction of power hammers, grinders, cutting instruments, and sand blasters at the turn of the century had exposed large numbers of industrial workers to massive quantities of fine silica dust, which could penetrate deeply into their lungs. By the time of the Great Depression, many of these workers had developed symptoms of silicosis and, under the financial strains created by massive unemployment, began to bring their claims for disability benefits into the workers' compensation and court systems of the industrialized nations. Thus, silicosis emerged as a major political, social, and economic issue in the mid-1930s.

In the United States this produced a massive number of lawsuits which ultimately led to the convening of national conferences and the revision of workers' compensation systems. In this process, the issue of chronic industrial disease was forced onto the agendas of the medical and public health communities, and the debate began over responsibility for risk as well as over definitions of the technical and medical means of distinguishing and diagnosing chronic conditions. In the ensuing years the problem of noninfectious chronic diseases created by industrial work processes would become the centerpiece of industrial medicine.

Although the relationship of dust exposure to cancer was noted by the 1930s, it was only during the 1950s and 1960s that the medical and public health

communities acknowledged its significance and such investigators as Wilhelm Heuper, Harriet Hardy, Irving Selikoff, and Lorin Kerr began to link exposure to dusts and toxins at the workplace to a variety of cancers. The investigations by Irving Selikoff of asbestosis, mesothelioma, and lung cancer were particularly effective in galvanizing popular and professional attention; the widespread dispersal of asbestos throughout the general environment caused profound awareness of the dangers of industrial production to the nation's health.

Occupational health was also a matter of concern for many social, labor, and political movements and this concern focused on industrial hazards. During the Progressive Era, for example, such unions as the Bakers' and Confectioners' Union, the International Ladies Garment Workers Union, and the Amalgamated Clothing Workers joined middle-class reform groups such as the National Consumers' League to press for reform of working conditions. During the 1920s, activist organizations like the Workers' Health Bureau of America sought to aid labor unions in investigations of workplace hazards and joined painters, hatters, and petrochemical workers to demand reform of factory conditions. During the 1930s various unions within the Congress of Industrial Organizations used deplorable health and safety conditions as a focal point for organizing workers in heavy industry. In the next two decades, other unions, such as the International Union of Mine, Mill and Smelter Workers, pressed for national legislation to protect their members from dust hazards. In the 1960s safety and health became major activities for such unions as the Oil, Chemical and Atomic Workers' Union (OCAW) and the United Mine Workers (UMW). Leaders like Lorin Kerr of the UMW and Anthony Mazzochi of the OCAW were involved in lobbying for national legislation to protect miners and other workers, and the UMW was also active in urging special legislation to compensate victims of coal workers' pneumoconiosis.

All of these activities culminated in the Coal Mine Health and Safety Act of 1969 and the Occupational Safety and Health Act of 1970. The latter act mandated the creation of both the Occupational Safety and Health Administration (OSHA) in the U.S. Department of Labor and the National Institute of Occupational Safety and Health (NIOSH) in the Department of Health and Human Services (previously Health, Education and Welfare). OSHA was to set and enforce national standards of safety and health on the job, and NIOSH, the research arm, was to determine safe levels of industrial pollutants.

With the decline of heavy industry after 1960 and the rise of white collar and service industries, many people argued that occupational disease was a legacy of the industrial era. Yet the problem of occupational diseases has merely taken on a new form. The emergence of a strong environmental movement has once again focused attention on the dangers of industrial production at the same time that it has broadened the scope of what was once seen as a problem for the industrial work force alone. The emergence, for example, of a nuclear power industry – whose domain ranges from the production of atomic weapons to nuclear medicine – has heightened awareness about the danger that radiation poses for workers even in the most highly technical professions. Furthermore, the problems of industrial and atomic waste disposal have forged a link between those who are concerned primarily about protecting workers and environmentalists.

Moreover, as international economic competition intensifies and workers and professionals alike experience intense pressure to increase the speed of production and improve the quality of products, the scope of the definition of occupational disease continues to broaden. Stress, for example, which was once considered a problem of executives, is now a major reason for compensating claims in California. And some miscarriages have been linked with exposure to low-level radiation from video display terminals.

In conclusion, the history of occupational diseases reflects the broad history of industrial production and changing relationships between capital, labor, and the state. Professionals such as physicians, industrial hygienists, and engineers, who have addressed the problem of industrial disease, have often also played auxiliary roles in the political and social conflict over the value of workers' lives. But control of industrial diseases has been accomplished largely through political activities and changing economic conditions rather than through medical or engineering interventions. Professionals have usually played an important technical role after an issue has been forced upon the public's agenda because of an industrial or environmental catastrophe or because of concerted political activity.

Until the 1950s, the history of medicine was often understood to be the history of infectious disease. However, with the evolution of chronic, noninfectious disease as a major public health problem, industrial illnesses have taken on a new importance and are no longer mere oddities in a "cabinet of curiosities." Indeed, industrial disease may prove to be a

model for understanding all noninfectious illness, for those physicians, government agencies, and professionals who study it will be forced to address a host of questions regarding social and political responsibility for society's health. In fact, ultimately, industrialized countries will be forced to ask what level of risk is acceptable for industrial progress and who should bear the cost.

Throughout most of the past, ideas about the means and necessity of providing for the health of the general community were based on notions of what ensured an individual's well-being. At this personal level, measures that we might consider motivated by aesthetic choices (rather than fully developed ideals of cleanliness and the health necessities of personal hygiene) were interwoven with practices designed to minimize exposure to disease and injury. In a narrow sense, public health practices refer only to the organization of care for the sick of a community and the implementation of epidemic controls. Public sanitation includes all collective measures taken to protect the healthy from disease. Yet even today many believe that what ensures the health of an individual should be reflected in the rules for maintaining the public's health.

Through much of the past and present, the view of "public" health has involved a compromise between available community resources and the ideals of health maintenance at the individual level. Thus, in order to examine the history of public health and sanitation before the 1700s, it is necessary to include some discussion of the ideas and ideals of personal hygiene along with the development of concepts that led to genuine public health practices. "Basic" sanitary organization largely comprised rudimentary sanitation and sanitary law, care of the sick poor, provision for public physicians, and epidemic controls.

Sanitation

Archaeological records testify to the antiquity of communal efforts to provide clean water and dispose of human and animal wastes. The engineering achievements of some peoples, such as the ancient Peruvians in the Western Hemisphere and the Etruscans in Europe, were most impressive. They managed extensive systems for refuse drainage and clear water conveyance. However sophisticated the outcome, the motivation for these projects probably lay in fears common among tribal societies – for example, the fear of pollution offending a god or gods, who in turn could send disease and disorder. Reflecting these aboriginal values, natural springs and wells

were sites of religious activity for millennia. But independently of the health benefits, the maintenance of a reliable water supply and efficient drainage of agricultural lands permitted larger human settlements, and thus, whether or not the health benefits were perceived, these practices were copied or reinvented in all the early civilizations of the Mediterranean, in the valleys of the Yellow, Indus, Tigris, Euphrates, and Nile rivers, and in the Incan and Mayan civilizations.

The most celebrated early sanitary engineering achievements were those of republican and imperial Rome, c. 300 B.C. to A.D. 200. In fact, many of the conduits built by the Romans remained in use until the twentieth century. Basing drainage projects on the successes of Etruscan predecessors, who were able to construct extensive underground drainage channels because the loose, volcanic soil of southern Italy was easily worked, early Romans developed systems of wells, rainwater cisterns, and irrigation ditches that promoted rural, agricultural development. Before 300 B.C., the Romans seem to have associated the assurance of clean and abundant water with ordinary life, an ideal never specifically related to the maintenance of health, public or private. But when they began to build cities, aqueducts became a public symbol of the Roman way of life, as well as a symbol of Roman power and sensitivity to the general welfare. Frontinus, in *On Aqueducts* (c. A.D. 100), says that the first one was constructed in Rome in 312 B.C.

In rural areas, the prosperity of the "farm" or villa seems to have been the inspiration for securing a reliable water supply, a favorite topic for the pragmatic and aristocratic authors of treatises on Roman agriculture and medicine (Scarborough 1981). These authors fastidiously detailed the benefits and drawbacks of using plants and drugs, differentiated harmful from benign bugs, and analyzed myriad substances that promoted or undermined the well-being of the farm and the farmer. For Cato, Columella, Frontinus, Vitruvius, Varro, and Celsus, health benefits were the natural harvest of the well-managed farm, a pastoral ideal of Roman life that survived through the urban, imperial centuries.

Although Romans generally welcomed practical advice, the adoption of the Greek ideals of personal hygiene was delayed until after the period of early republican growth – a time of rapid development of architectural and administrative models for aqueducts, cisterns, cloacae, drains, and wells. Greeks and Romans, however, shared a passion for the details of personal hygiene, including a fondness for baths, cleansing agents for the skin, and oils, soaps, unguents, and other cosmetics used to maintain a good personal appearance and skin tone. Moreover, concern for personal hygiene went far beyond the realm of attracting sexual partners or performing religious cleansing rituals. Greeks and Romans worshiped health and consequently elevated in importance to their life-style the technical knowledge they believed would promote individual health and longevity.

Galen's *Hygiene,* written shortly after the death of Emperor Marcus Aurelius in A.D. 180, represents the acme of professional health theory and advice through which Greek medical thought and pragmatic Roman farm hygiene were united in late Mediterranean antiquity (Sigerist 1956). The Hippocratic theory of the four humors, describing health as a balance of the humors, which in turn represented the four elements of all material substance, dictated the fundamental ways of preserving equilibrium through an individual's natural changes in age, diet, season, and exposure to noxious influences. The emphasis was on prevention, and the health seeker needed to learn which foods were right for his or her constitution, when baths promoted or jeopardized health, what exercise was appropriate, when purgation was needed, and what substances and influences were lethal. Attention was to be focused on the fine details and management of the individual's environment.

Nonetheless, despite the foregoing, which seems an idealistic portrayal of health practices in antiquity, the stark reality is that 25 years was the average life expectation for most Greeks, Romans, Egyptians, and others in the vast ancient Greco-Roman Empire. Roman elites recognized the importance of effective disposal of human wastes and so constructed miles of sewers and cloacae, as well as public and private latrines, and collected the waste for use as fertilizer in rural areas (Scarborough 1981). However, an enormous gulf separated the privileged and the poor. The hovels and lean-to shacks of the destitute, homelessness, and severe crowding (all of which mimic life in modern Western and Third World slums) dominated Roman life (Scobie 1986). The ideals promoted by the wealthiest citizens apparently had little impact on the public's health. De facto, the drainage systems installed in individual homes were seldom connected to street drains and sewers, as archeology at Pompeii has shown, and latrines were not provided with running water. Alex Scobie (1986) has detailed the multiple health problems attending the practical aspects of Roman public hygiene, observing that a city the size of Rome with a population of approxi-

mately 8 to 10 million in early imperial times would have produced about 40,000 to 50,000 kilograms of body waste per day. Arguing that only a fraction of that output reached the "public" collection sites, he shows that the emphasis in Roman public hygiene was the maintenance of the farm and an aristocratic life-style, whatever the adverse health costs to the general population. The emptying of public and private facilities enhanced agricultural productivity and provided a livelihood for armies of unskilled workers. The collection of urine aided the cloth industry, because fullers used urine as a mordant for certain dyestuffs. Roman literature does not adequately testify to the horrors of Roman cesspits "nauseating mixture(s) of the corpses of the poor, animal carcasses, sewage, and other garbage" (Scobie 1986).

Nor have the marvels of the aqueducts fared well under recent historical scrutiny. Frontinus sang the praises of the nine aqueducts that daily supplied the city of Rome (scholars have calculated that they provided about 992,000 cubic meters of water each day), but he tells us little about the distribution of water and whether there were any mechanisms to stem the flow of water into basins and tanks. Because of their malleability, lead pipes were commonly used in the plumbing of aristocratic homes, but we do not know whether the water they carried was soft or hard. (Hard water would have prevented much of the lead from seeping into the drinking water.) Ancient pastoral fondness for rainwater probably protected many Romans outside the great city from the multiple health hazards attending advanced urban sanitary technology.

The best and worst features of Roman public health, and of the Greek traditions and theories of personal hygiene, were passed along in the books and physical artifacts that survived the piecemeal dismantling of the Roman Empire. Thus, the strong aristocratic voice that determined the ideals of public and private health and their implementation remained relatively unchanged in the societies that inherited Roman custom, such as the Byzantine and Islamic empires. But in western Europe, retreat to a rural economic base, the effective disappearance of cities and market economies, and the introduction of Germanic customs interrupted the Greco-Roman public health tradition. It is true that in Benedictine monasteries upper-class monks constructed infirmaries, baths, latrines, *caldaria,* or steam rooms, and cold rooms in the best of Roman aristocratic tradition. (St. Gallen monastery in Switzerland, built in the eighth century, is one of the best surviving examples of this tradition.) But most Roman sanitary

practices were adopted and gradually transformed only as Christian Mediterranean cities began to grow again in the eleventh and twelfth centuries.

In the European Middle Ages, cities grew to a maximum of 100,000 to 150,000 individuals by the early fourteenth century, only one-tenth the size of ancient Rome. The Roman legal principles holding individual property owners responsible for cleaning the streets in front of their homes dominated "public" sanitary intervention. Medieval Italians were far more willing than the Romans to specify what individual behaviors put others at risk and therefore to write new legislation prohibiting the pollution of public streets with animal carcasses, human refuse, and other noisome substances. Yet we do not know to what extent laws were actually enforced, and it is probable that medieval cities were even more squalid than those of antiquity. Nonetheless, there seems to have been a new ethic of communal, collective responsibility for public health. Some of the change may have come about with the Christianization of Europe, which among other things emphasized the physical and spiritual dangers of evil. Roman baths were used in common by the wealthier classes, but medieval laws dictated strict segregation of the sexes, treating as prostitutes, for example, women who strayed near the baths on a day when only men could use the facilities.

During the Middle Ages, urban dwellers could empty chamber pots into the streets as liberally as aristocratic Romans might have done, but medieval lawmakers often prescribed the times at which such wastes could or could not be evacuated or ordered that words of warning be shouted to passersby below. For example, thirteenth-century residents of Siena were enjoined to cry "Look out!" three times before tossing the contents of a pot onto the street, and fines were specified for those who were found noncompliant. Medieval city governments, like their Roman predecessors, hired laborers to clean streets, cisterns, and sewers and to evacuate garbage. But unlike Roman officials, who appear to have adopted a laissez-faire attitude toward enforcement, they elected or appointed district supervisors to patrol both these employees and citizen behavior, and to report infractions to judicial authorities. The medieval belief that humans were sources of pollution (by the fourteenth century, lepers were forced to wear yellow to symbolize their danger to the community) had profound consequences for the development of epidemic controls, as will be discussed in a later section.

Leading the way for the rest of Europe, Italian and

probably Spanish cities appropriated detailed Roman law and customs regulating the trappings of public sanitation – baths, sewers, fountains – as well as sanitary personnel and marketplace regulations, leaving most of these features unchanged, at least on paper, for hundreds of years. Public hygiene laws in 1700 strongly resembled those of 1300, with even the fines little changed. Those who could afford to follow all the recommendations of Galenic personal hygiene did so without questioning the basic premises of health maintenance, public or private. Only the creation of boards of public health, a very important late-medieval contribution to public health, and, late in the seventeenth century, medical attention to occupational disease represented significant advances in modern public health philosophy and practice.

Care of the Indigent and Public Physicians

The organization of basic health services within a community involves the provision of medical care to all members of that community and a conscious attempt to prevent or minimize disease. A relatively recent innovation is the appropriation of communal resources for hospitals devoted principally to *medical* intervention, that is, to hospitals that are something other than a refuge for the sick, the poor, or pilgrims. The earliest hospital in the modern Western sense was probably the Ospedale Maggiore of Milan. It was built in the mid-fifteenth century, funded by church properties, and managed by a lay board of governors, who in turn were appointed by state officials. Most medieval cities acknowledged the need for city hospitals, symbols of good Christian governance, and thus hospitals became as characteristic of this society as the aqueducts had been of Rome.

The public employment of physicians was another significant development in the history of public health before 1700. Even ancient Greece, where many physicians were itinerant healers forced to wander in search of patients, established political and economic centers and provided salaries and other privileges to individuals who would agree to minister to their populations (Nutton 1981). Yet wherever a settlement grew large enough to support ethnic, linguistic, or even economic diversity, it was more difficult to ensure a sufficient number of healers.

In some places, such as Mesopotamia, the provision of physicians could extend the power of rulers or of a religion if people were assured that the proper gods would be summoned when intervention was necessary. With politically or religiously less important illnesses, a patient's family could post the patient at their doorway or in the marketplace, giving passersby the opportunity to make a diagnosis or offer therapeutic suggestions.

In Egypt, India, and China where political upheaval was not as common as in Mesopotamia and Greece, highly individualized solutions to the communal responsibility for providing physicians were devised. Thus, Egypt may have developed a state system for the use of doctors as expert witnesses and provided a living allowance to all physicians, and by the period of the New Kingdom had established a formal hierarchy of doctors, the chief palace physician at its pinnacle. Similarly, in ancient India the king and other extremely wealthy individuals were obliged to provide medical care for their people by underwriting the services of priestlike Ayurvedic physicians (Basham 1976).

It was the Greek tradition that was ultimately transmitted to western Europe. From as early as the fourth century B.C., the Greeks had established a network of salaried physicians throughout the Hellenistic world. The terms of their contracts to individual communities varied widely, but the arrangement assured healers of some measure of personal stability. Unlike physicians in the more monolithic Egyptian society, who were natives subject to the same legal privileges and restrictions as their patients, physicians in the mobile Greek world were often foreigners who received salaries as well as tax immunities and special privileges (e.g., citizenship, the right to own land, rent-free housing, or even choice theater tickets) in return for contractual service to a community. This "system" – if indeed one can so call a functional solution to the provision of medical care – was adopted by the Romans in the designation of *archiatri,* or public physicians, whose duties were extended and to some extent redefined over the centuries. Later Renaissance European elaborations of the concept of public health mediated by public physicians was a rediscovery of ancient practices lost during the Middle Ages.

By the second century of the common era, large Roman cities designated up to 10 *archiatri,* their salaries set by municipal councilors, to minister to the poor. Physicians often competed for these communal posts, suggesting that there were financial rewards beyond the salary itself – most likely access to a wealthy patient population. Public physicians seem to have been selected by laymen. Sources are largely silent on how their performance was assessed or how they typically sought access to their clientele. It is unlikely that they had any responsibility for the maintenance of public health in other

respects, such as epidemic control or sanitation. Other salaried physicians in the Roman Empire included physicians to gladiators (Galen began his professional career in such an assignment), to baths, and to courts or large households.

The financial privileges and immunities granted to public physicians may have ensured the survival of the office well into the early Middle Ages, for with inflation and the heavy fiscal demands on Roman citizens around A.D. 200, these inducements were considerable. In the early fourth century, the emperor Constantine the Great extended state salaries to teaching doctors irrespective of their medical services to the community, thus linking the interests of public physicians to those of local medical personnel. That association would become paramount in the later Middle Ages, leading to the monitoring and licensing of medical practice, ostensibly for the public good but equally obviously for the financial benefit of particular groups of healers. Under Emperor Theodoric, in the early sixth century, Roman doctors were given an overseer, an imperial physician called "count of the *archiatri*," who may have formed the first formal link between lay interests and medical elites because he could nominate and appoint physicians to a college of medicine. Specialized medical services, such as those of official public midwives, may also date from this period. The Islamic state, which replaced most of the Roman Empire in the Middle East, brought regulatory power over physicians under the control of the state, which paid the salaries of physicians appointed to hospitals and even administered licensing examinations (Karmi 1981).

The medical institutions of late Rome did not persist through the early Middle Ages, even in relatively urbanized Italy and Spain. The practice of community hiring of salaried physicians was not reestablished until the twelfth and thirteenth centuries. Vivian Nutton (1981) argues persuasively that early Italian interest in jurisprudence and their editions of Roman law texts led to the reestablishment of public physicians in Italy. Thus, the office acquired legal responsibilities not typical of the ancient world. Perugia's first *medicus vulnerum* (before 1222) probably had to provide expert testimony in cases of assault and battery. Public physicians in succeeding centuries typically had to judge whether a wound or injury had caused death. By the end of the fifteenth century, the system of hiring physicians was almost universal in Mediterranean western Europe, a system undoubtedly reinforced by the recurrence of plagues, which necessitated state interven-

tion to ensure medical care. Yet public physicians were not true public health physicians or medical officers of health, positions that Renaissance Italians seem to have invented. The institutions addressing communal medical responsibility for health surveillance arose instead from epidemic controls.

Richard Palmer (1981) has demonstrated that in large metropolitan areas the system of *medici condotti*, the Italian medieval name for *archiatri*, fell into disuse by the sixteenth century. But in small towns the system continued or even increased in popularity because it was a means of securing quality medical care without being at the mercy of itinerant quacks or "specialists."

The system of rural public physicians was able to absorb the late medieval expansion in the number of medical professionals, which brought about a more equal distribution of medical goods and services. Cities no longer needed to import physicians. The financial benefits they offered, the opportunities they provided for other, similarly trained practitioners, and often the presence of a university provided ample inducements for urban medical practice.

The major cities of Italy and Spain provided the prototype in medicine for the northern European cities of the seventeenth and eighteenth centuries: They developed local medical colleges dedicated to defending professional standards, restricting practice to the "qualified," regulating pharmacies, and mediating the state's charitable obligations to the poor in areas the church had abandoned (Lopez Piñero 1981; Palmer 1981). Tightening the restrictions on membership became common in Italy, foreshadowing the mercantilistic objectives of state medicine.

Epidemic Controls

Refuse disposal and the provision of clean water were regarded as aesthetic problems for growing cities as much as they were means to improve health. Nevertheless, by the thirteenth century, all Italian cities with statutes of laws had incorporated a system of sanitary provision modeled on ancient Roman patterns. The hallmarks of this system were maintenance of clean water sources, patrolling refuse disposal, and the posting of gatemen to identify potential sources of infection in the city. Two explanatory models underlay this approach to public health. The first was based on the assumption that polluted air caused disease by altering the humoral balance of humans and animals. The second was based on the knowledge that some diseases, such as leprosy, could be transmitted from one person to another.

The first of these two models was influential among public physicians when boards or offices of public health were created. The second model of contagion was not widely accepted during antiquity and the Middle Ages, at least among the educated elite. One exception, the practice of isolating lepers in special hospitals (*leprosaria*), is noteworthy because the custom was later adapted and justified as a means of epidemic control. Strict social isolation of individuals designated as lepers, whatever conditions may have been responsible for cases of advanced skin infection and/or physical deformities, was a practice derived from the Jews of antiquity. In biblical times priests identified those suffering from "leprosy" and used their authority to cast these people out of a settlement. Drawing on this practice, medieval Christian communities permitted priests to identify lepers and, at least in northern Europe, subject them to a ritual burial and banish them from the community.

Unlike Jews, medieval Christians accepted a communal responsibility for providing lepers with organized care – food, clothing, shelter, and religious services – but rarely medical care. The church and state cooperated in the construction and maintenance of residential hospitals for lepers. The peak of this building activity occurred in the period from 1150 to 1300.

Nonetheless, lepers were ostracized. Guards often kept them outside city gates. Those formally identified as lepers were made to wear symbols of their infection and perhaps to carry a bell or clapper to warn those who might get too near them. They could shop at markets only on designated days and hours, and could touch things only with a long pole. Moreover, practices such as these survived throughout the early modern period even when *leprosaria* were turned to other uses.

In other societies (e.g., Chinese and Muslim) in which leprosy was considered to be a communicable disease, social restrictions were often linked to legal restraints on lepers' activities. In Muslim lands, "mortal" illnesses, including both leprosy and mental illness, cast their victims into a state of dependency, somewhat like that of a child or slave. They lost the right to make and maintain contracts, including the right to continue a contract of marriage. Though a wide variety of behavioral responses to lepers existed across Islamic society, ranging from pity, to aggressive medical assistance, to isolation of the sufferers in leper hospitals, Michael Dols (1983) emphasizes the distinctiveness of Western Judeo-Christian tradition. In Europe, but not in the Middle East, lepers were considered diseased in soul as well as body, were ritually separated from the community, were deemed fiercely contagious to others, and were subjected to religious penance and other punishments even after diagnosis and isolation.

Apart from exaggerated responses in the West to lepers (as well as to prostitutes, homosexuals, heretics, and Jews), collective action to protect public health was, as a rule, crisis-oriented. Plague and other epidemics may not have been the most important manifestations of disease in earlier societies in terms of mortality, but they were certainly the most visible. Recurrent bubonic plague epidemics evoked the greatest response, making plague what Charles-Edward Winslow (1943) called the "great teacher." Beginning with the wave now called the Black Death, plague appeared in Europe at least once every generation between 1348 and 1720. At the first outbreak of the disease, fourteenth-century government officials in Florence, Venice, Perugia, and Lerida called on medical authorities to provide advice on plague control and containment. Of these, only Lerida's adviser, Jacme d'Agramont, seems to have articulated a contagion model for the spread of disease. The Florentine and Venetian approaches to epidemic control may have been the most sophisticated: aggressive cleanup of refuse, filth, offal, and other sources of corruption and putrefaction on the city streets. They applied traditional health practices to meet an emergency, but created a novel bureaucratic unit to orchestrate public efforts. In these two republican city-states, small committees of wealthy citizens were appointed to oversee the administration of ordinary sanitary laws, to hire physicians, gravediggers, and other necessary personnel, to maintain public order and respect for property, and to make emergency legislation. These communities saw no need for the direct intervention of the medical guilds. By contrast, in Paris, which lacked a tradition of lay involvement in public health control, members of the university medical faculty collectively offered advice about surviving pestilence, a practice individual doctors elsewhere followed in providing counsel to their patients.

For whatever reason, during the following century there seems to have been no deliberate reappraisal of the sanitary methods used in the earliest plague epidemic, and no temporary re-creation of boards of health other than in Milan, the only northern Italian city not stricken during the 1348 epidemic. Most cities relied instead on maintaining order, particularly in the burial of bodies, acquiring information about cities that were havens from disease (or, con-

versely, cities that were stricken with plague), providing physicians and other service personnel, and transferring property and goods after the plague to heirs or to the state. Rarely, however, did cities specifically address the technical problems of public or community-level measures for containing plague even though the "corruption of the air" theory presumably should have dictated intervention. Purifying bonfires, the disinfection or destruction of the goods and clothing of plague victims, and fumigation or other cleansing of infected dwellings were practices first employed aggressively in Milan in the late fourteenth century. Elsewhere and later, antiplague measures based on either the contagion or the corruption model of plague were adopted. *Cito, longe, tarde* – "Flee quickly, go far, and return slowly" – was the advice most wealthy city dwellers followed during the first century of plague experience, thereby eschewing costlier and more direct measures against the disease.

The tiny Dalmatian colony of Venice, Ragusa (now Dubrovnik), invented the quarantine in 1377. This was a response to impending plague whereby a temporary moratorium on travel and trade with the town was decreed. The Ragusan practice, actually then a *trentino,* or 30-day waiting period, became standard maritime practice by the sixteenth and seventeenth centuries. Although the quarantine in common parlance has acquired a more aggressive meaning, in the maritime context it was a passive measure designed to prevent incursions of plague rather than to segregate active cases. Through reproduction of a typographical error in the early nineteenth century, many surveys of quarantine and public health have credited Marseilles with the use of the quarantine by 1483. In reality the Ragusan maritime quarantine was not widely used until the sixteenth century.

Another feature of what was to become regular plague control, the pest house, or *lazaretto,* was used during the first plague century, 1350 to 1450, but chiefly as a means of delivering medical care to the poor. After the 1450s both quarantine (passive, preventive isolation of the healthy) and active hospital isolation of the ill became more popular antiplague measures in city-states, which can be taken as evidence for the increasing acceptance of a contagion theory of plague. Finally, official boards of health were reestablished. Throughout the early modern period, these bureaucracies identified and handled human cases of plague and acted as arbiters of standard public health controls (Cipolla 1976; Carmichael 1986).

Only during the fourteenth century do descriptions of plague note the loss of many principal citizens. After that period, elites seem to have worked out effective patterns of flight, so that only those who remained in the cities were exposed to danger. Unfortunately, in urban areas, plague control measures may have inadvertently augmented the death tolls. Standard practices developed in Italian cities during the fifteenth century – practices that would be followed by northern Europeans during the late sixteenth and seventeenth centuries – included the house arrest or hospital confinement of all family members of plague victims as well as others who may have had contact with them, whether or not the others were sick. This led to the construction of ramshackle buildings, *lazarettos,* that could segregate as many as 5,000 to 10,000 individuals at a time. By the sixteenth century, larger urban areas were quarantining the still-healthy contacts of plague victims in one place, isolating the ill together with immediate family members in a medically oriented hospital, and placing those who recovered in houses or hospices for a second period of quarantine.

By 1500 many of the principal Italian city-states had created permanent boards of health to monitor urban sanitation and disease threats even when no crisis arose. Rarely were physicians members of these aristocratic boards, though in many cities the lay directors employed medical officers of health. Nevertheless, local colleges of medicine and university medical faculties assumed the responsibility of providing diagnostic and therapeutic advice when crises threatened. By the second half of the sixteenth century, boards of health routinely consulted members of the medical establishment, one group helping the other in publication efforts to dispense both health advice and sanitary legislation and in the provision of public "debriefings" after a plague had passed. During the sixteenth and seventeenth centuries, these basic principles of public health surveillance and epidemic control were adopted by states north of the Alps.

In Italy and the Mediterranean, generally, the boards of health developed into tremendously powerful bureaucracies, commanding sizable portions of state resources and the cooperation of diplomats in securing information about the health conditions in other states. Carlo Cipolla (1976) identifies both vertical and horizontal paths of transmitting such information, emphasizing the aristocratic character of health boards and their successes in superseding any authority that merchants might claim from the state. Detailed information about plague or other

diseases thought to be contagious was gathered from the reports of ambassadors as well as from broad networks of informants and spies at home. Armed with these data, health magistracies could impose quarantine at will, confiscate goods, and impound, fumigate, disinfect, or burn them. Though they usually agreed to reimburse the owners at half to two-thirds the value of their property, dire necessity and heavy expenditures during great epidemics left many boards of health bankrupt in all but their broad judicial authority. In fact, despite all efforts and a rigorous interpretation of the contagion theory of plague, the plagues of the late sixteenth and seventeenth centuries were catastrophic in the Mediterranean countries, in terms of both human and financial losses.

Not surprisingly, with the sweeping powers Italian boards of health were given, permanent magistracies required greater justification for their existence and their policies than the control of plague. They could argue that plagues would have been even worse without their efforts, but the economic costs of quarantine and isolation policies were more than early modern populations could bear without the creation of widescale human misery. Yet as strong monarchies emerged, legislators, physicians, and concerned aristocrats of the seventeenth and early eighteenth centuries were able to weave some public health controls into the evolving theories of mercantilism. Apart from epidemic surveillance, medical "police" extended state medicine into the licensure of midwives, the control of drugs and markets for drugs, stricter control of nonlicensed practitioners, and a variety of other matters. The results were optimistically summarized at the end of the eighteenth century by an Austrian state physician working in Lombardy, Johann Peter Frank (Sigerist 1956).

Outside the Italian sphere, where state medicine and public health carried the longest and strongest tradition, public health boards and epidemic controls did not evolve into permanent magistracies concerned with all aspects of public health. As Caroline Hannaway (1981) has indicated, at the beginning of the eighteenth century, the French, British, German, and, ultimately, U.S. traditions of public health relied mainly on the traditional Galenic–Hippocratic discourse about what ensured an individual's good health. Superimposed on those interests was makeshift machinery of epidemic control borrowed from the Italians. Concern for the health of "the people," however, spurred by general mercantilist goals and the early Enlightenment passion for

order and reason, was pan-European. During the eighteenth century, the impetus for change and reform in public health thus moved northward. Rejecting the political bases for state medicine that had led to the Italian boards of health, northern Europeans turned their energies to the production and consumption of health information: popular handbooks and manuals, such as those by William Buchann and S. A. Tissot; the proliferation of foundling homes, hospitals, and infirmaries; and the earliest efforts at systematic information gathering. As we move closer to the modern world, the rhetoric and rationale on which sanitation, care for the indigent, provision of public physicians, and epidemic controls were based before 1700 are blended into a new campaign for cleanliness and order, public and private.

III.11
History of Public Health and Sanitation in the West since 1700

The nature and role of public health are constantly changing, and its definition has been a major preoccupation of public health leaders in the twentieth century. Essentially, public health is and always has been community action undertaken to avoid disease and other threats to the health and welfare of individuals and the community at large. The precise form that this action takes depends on what the community perceives as dangers to health, the structure of government, the existing medical knowledge, and a variety of social and cultural factors. From the beginning, communities, consciously or not, have recognized a correlation between filth and sickness, and a measure of personal and community hygiene characterized even the earliest societies.

By the eighteenth century, personal and community hygiene were becoming institutionalized. A wide variety of local regulations governed the food markets, the baking of bread, the slaughtering of animals, and the sale of meat and fish. These regulations were motivated by a concern for the poor, a desire for food of a reasonable quality, and commercial considerations. Bread was always a staple of the poor, and regulations in the Western world invariably set the weight, price, and quality of loaves. For economic reasons, merchants shipping food abroad promoted regulations on meat and grains in order to protect their markets and save themselves from dishonest competition.

The American colonial laws and regulations, which were patterned after those of English towns and cities, illustrate the ways in which communities protected their food. Most of the regulations were enacted in the first century of colonization and strengthened in the second. For example, when New York City received a new charter in 1731, the old bread laws were promptly reenacted. Bakers were required to stamp their initials on loaves, the mayor and aldermen determined the price and quality of bread every three months, and bread inspectors were appointed to enforce the regulations. Butchers could be penalized for selling putrid or "blowne" meat, and a series of regulations governed the town markets, with special attention to the sale of fish and meat.

Slaughterhouses, which could be both public nuisances and potential sources of bad meat, were among the earliest businesses brought under town control. The term *public nuisance* in the eighteenth and nineteenth centuries embraced a great many sources of filth and vile odors. Wastes, rubbish, and garbage were simply dumped into the nearest stream or body of water, except in major cities, which generally had one or more covered sewers. Some foul-smelling open sewers characterized all cities and towns. The water closet was rare until the late nineteenth century, and the vast majority of residents relied on privies. In the poorer areas they were rarely emptied, with the result that their contents overflowed into the gutters. The work of emptying privies was handled by scavengers, sometimes employees of the municipality, but more often private contractors. They slopped human wastes in open, leaking carts through the streets to the nearest dock, wharf, or empty piece of land.

Street cleaning and garbage collection were left largely to private enterprise and were haphazard at best. The malodorous mounds of manure in the dairies and stables and the equally foul-smelling entrails, hides, and other materials processed by the so-called nuisance industries attracted myriad flies in addition to offending the nostrils of neighboring residents. The putrefying odors from these accumulations of entrails and hides, particularly in summer, must have been almost overwhelming.

Early U.S. towns were spared the worst of these problems because they were smaller and their residents more affluent. The small size of communities

and the cheapness of land made it easier for the town fathers to order the slaughterers and other nuisance industries to move to the outskirts. By 1800, however, the growing U.S. cities were beginning to experience the major sanitary problems faced by their British and European counterparts. The great bubonic plagues beginning in the fourteenth century had taught Europeans the value of quarantine and isolation, but by the eighteenth century, the major killer diseases had become endemic. Smallpox, one of the most deadly, was largely a children's disease by the second half of the eighteenth century, and no longer aroused alarm. On the Continent, occasional resurgences of bubonic plague led governments to establish quarantines on their eastern borders, but even this threat diminished toward the close of the century.

The one area where quarantines were applied with some consistency was the North American colonies. Because of the colonies' sparse population and geographic separation from Europe and one another, great epidemic diseases could not establish themselves permanently until late in the colonial period. The two most feared disorders were smallpox, brought from Europe or by slaves from Africa, and yellow fever, usually introduced from the West Indies. Smallpox appeared only occasionally in the seventeenth century, but it struck the colonials with devastating effect. By 1700 all of the colonies had enacted quarantine laws of various degrees of effectiveness and most of the port towns had established "pesthouses" in which to isolate smallpox patients.

Yellow fever did not enter the colonies until the end of the seventeenth century. Unlike smallpox, which was obviously spread from one individual to another, yellow fever was a strange and unaccountable pestilence that brought death in a horrible fashion to its victims. It struck the colonies only occasionally, but news of its presence in the West Indies led authorities in every coastal town to institute quarantines against vessels from that area. A series of epidemics, which struck the entire eastern coast beginning in 1793, led to the establishment of permanent quarantine officers and temporary health boards in nearly every major port. The limited sanitary and quarantine laws of the eighteenth century, many of which dated back several hundred years, were to prove inadequate under the impact of rapid urbanism and industrialism after 1750. Fortunately, that eighteenth-century period of intellectual ferment, the Age of Enlightenment, created a new awareness of the need for a healthy population. The earlier theory of mercantilism had argued that population represented wealth, and the emergence of political arithmetic or population statistics in the seventeenth century provided a crude means of measuring the health of a given population. John Locke's *Essay on Human Understanding,* emphasizing the role of environment, encouraged intellectuals, particularly in France, to advocate improving the lot of human beings through social reform. In his *Encyclopedia,* Denis Diderot discussed medical care, hospitals, and a wide range of topics related to health.

Economic changes led to a population explosion in Europe beginning in the mid-eighteenth century, and one result was an enormous infant mortality rate in the crowded cities and towns. A second result was the emergence of a socially conscious middle class out of which grew the British humanitarian movement. An important aspect of the movement was a concern for infant welfare, a concern that stimulated the rise of voluntary hospitals in Great Britain and ultimately led to an awareness of the deplorable health conditions of all workers. The eighteenth century, too, saw the publication of Bernardino Ramazzini's classic study on the diseases of workers, *De Morbus Artificum Diatriba.*

Even more significant than the writings of Ramazzini, the French philosophers, and other intellectuals in bringing government action was the work of Johann Peter Frank. In 1779 he published the first volume of a comprehensive nine-volume study instructing government officials on how to maintain the health of the people. Stimulated by the prevailing intellectual ferment, the enlightened despots of Prussia, Austria, Russia, and other states made tentative attempts to impose health regulations on their subjects. At that time, however, the governing structures were inadequate for the task, and the upheavals of the French Revolution and Napoleonic Wars temporarily ended efforts at health reform.

In Great Britain the seventeenth century had seen the execution of one king and the deposing of a second in the course of the Glorious Revolution of 1688. The resulting distrust of the central government meant that, for the next century and a half, a high degree of authority remained at the local level. Hence, until the mid-nineteenth century, efforts to improve public health were the work of voluntary groups or of local governments. Although some progress was made at the local level – most notably in terms of infant care, the mentally ill, and the construction of hospitals – public health was of little concern to the national government. Probably the most significant development was the rapid increase

in hospitals and asylums and the appearance of dispensaries or outpatient clinics. In England the majority of these were funded by private charity, whereas on the Continent they were largely municipal or state-supported.

It was no accident that England, which was in the vanguard of the Industrial Revolution, took the first effective steps toward establishing a national public health program. The original charters of most English towns and cities gave the municipal government only limited powers, and these proved totally inadequate to meet the needs of their increasing populations. The first local health board in Great Britain came into existence in Manchester in 1796. A series of typhus epidemics among the overworked cotton mill employees, who lived and worked in crowded, filthy conditions, led Thomas Percival, John Ferriar, and other physicians to organize a voluntary board of health. In Liverpool, James Currie and a small group of other physicians assumed the same responsibility. Owing to the haphazard structure of English local government and the prevailing laissez-faire sentiment, little was accomplished in the following half-century.

Atrocious factory conditions, particularly as they affected child and female workers, provided the next stimulus to public health. Through the agitation of socially minded physicians, and in particular the work of Sir Robert Peel, a socially responsible textile manufacturer, the first English factory law, the Pauper Apprentice Act of 1802, was pushed through Parliament. Changing circumstances made the law meaningless, and it took years of agitation by Peel, Robert Owen, and numerous others before a relatively effective factory act in 1833 limited the working hours of children in textile mills. The most significant feature of the act was a provision for four officers to inspect, report on, and enforce the law. This measure marked the first time that the central government broke away from a laissez-faire policy and assumed a limited responsibility for health and welfare. Equally important, the reports of the factory inspectors proved invaluable to Edwin Chadwick, Southwood Smith, Lord Ashley, and other reformers seeking to make the public aware of the brutal and degrading conditions in which workers labored and lived.

At least as important as the horrible factory conditions in promoting government action on behalf of health was the first of the three great pandemics of Asiatic cholera to strike the Western world in the nineteenth century. This disease, which devastated the poor, who were crowded in filthy, miserable slums, convinced public health pioneers that sanitary programs were the solution to the problems of disease and ill health. Consequently, in the prevailing argument over the value of quarantine versus sanitation, the sanitationists, represented by Chadwick in England, won out. The panic and disruption in Great Britain caused by the first epidemic in 1831 undoubtedly contributed to the general unrest in England and, indirectly, was responsible for a number of major reforms. Among the significant legislative measures enacted in these years were the Parliamentary Reform Bill of 1832, the Factory Act of 1833, the Poor Law Amendment of 1834, and the Municipal Corporations Act of 1835. The last act was particularly important because it strengthened the authority of town officials and gave them wider powers in the areas of health and social services.

In 1834 Chadwick was made secretary of the new Poor Law Board, and the board's investigations under his direction laid the basis for his great *Report on the Sanitary Condition of the Labouring Classes.* Its publication in 1842 led to the appointment of a Royal Commission on the Health of Towns, and the grim reports of this commission eventually forced Parliament to enact the first major national health law, the Public Health Act of 1848, which created the General Board of Health. This board ran into immediate difficulties, since the medical profession was strongly opposed to it, and local officials were still reluctant to surrender any of their authority to a central board. In 1858 the board was dismissed, and its public health responsibilities were transferred to the Privy Council. Despite its weakness, the board was successful in spreading the gospel of cleanliness and sanitation.

During these years a series of sanitary laws, such as the Nuisances Removal Act, Common Lodging House Act, and the Adulteration of Food Act, were shepherded through Parliament. In addition, beginning in 1847, medical officers were appointed in a number of cities. The culmination of almost half a century of health education was the passage (helped along by the third cholera pandemic) of the Sanitary Act of 1866. This measure broadened the health and sanitary areas under the jurisdiction of the national government and authorized its officials to compel municipalities and counties to meet minimum sanitary standards. Within the next nine years successive legislative action gradually strengthened the 1866 law. In 1875 a comprehensive health law consolidated the many pieces of legislation relating to health and sanitation and gave Great Britain the best national health program of any country in the world.

The Industrial Revolution was much slower in coming to France and other countries, and the energy devoted to improving social conditions in England was dissipated on the Continent in wars and struggles for political freedom and national independence. Yet the French Revolution and the Napoleonic Wars gave France leadership in medicine and public health by destroying much of the old order and releasing the energy of the lower classes. Among its contributions in these years was the publication of the first public health journal, the *Annales d'hygiéne publique et médecine legale,* which appeared in 1829. The outstanding public health figure in France during these years was René Louis Villermé, whose studies in the 1820s clearly demonstrated the relationship between poverty and disease. His major report in 1840 on the health conditions of textile workers led to the enactment the following year of a limited child labor law.

Continued appeals for reform by Villermé and health reformers achieved a measure of success following the Revolution of 1848. The new French government under the Second Republic established a system of local health councils (*conseils de salubrité*). Despite the hopes of public health leaders, these councils, which met every three months, were purely advisory and exercised no real authority. Any further chance of immediate health reform was dashed in 1851 when Napoleon III overturned the Second Republic. The system of weak advisory health councils remained in effect until the end of the nineteenth century, and public health in France continued to lag far behind that of Britain.

On paper, the public health regulations of the Russian imperial government seemed quite advanced, and because the government was autocratic, it had the power to enforce its laws. Unfortunately, as the successive Asiatic cholera epidemics revealed, these regulations were seldom exercised with any degree of effectiveness. Quarantine measures against cholera were belated, haphazard, and applied too ruthlessly. The widespread poverty and ignorance of the Russian people made many of them resent even the most well intentioned government actions. Whereas the cholera outbreaks in the West aroused demands for health reform, particularly in Britain and the United States, the autocratic government in Russia and the lack of a socially conscious middle class prevented any meaningful reform before the twentieth century. The development of public health in the United States closely followed that of Great Britain, although the sheer expanse of the nation reinforced the belief in local control and delayed action by the

federal government. Spurred on by epidemics of Asiatic cholera and yellow fever, U.S. cities began appointing permanent quarantine officers at the beginning of the nineteenth century. New York City, which tended to assume leaderhsip in public health, created the Office of City Inspector in 1804. The office was designed to gather statistics and other information relating to the city, but under the leadership of such men as John Pintard and John H. Griscom, it became a significant force for social change. Their annual reports as city inspectors were damning indictments of the poverty, misery, and squalor that characterized the life of so many New Yorkers.

Nonetheless, the prevailing spirit in the nineteenth century was laissez-faire, and except when epidemics threatened, government officials felt little responsibility for health. The threat of an epidemic or its presence usually aroused the quarantine officials from their lethargy and stimulated the city council to appoint a health board, open temporary hospitals, and initiate a campaign to clean up the worst sanitary abuses. Once the epidemic was over, the quarantine was relaxed and city hall returned to politics as usual. When a particular abuse, such as an unusual number of putrefying dead animals in the streets or a particularly odorous canal or sewer down the main street, became an outrage, public opinion would demand action, but the relief was usually temporary.

While the public worried about the two great epidemic diseases of the nineteenth century, yellow fever and Asiatic cholera, and to a lesser extent about smallpox, the major causes of morbidity and mortality in both Europe and the United States were pulmonary tuberculosis and other respiratory infections, enteric disorders, malaria, typhoid, typhus, and such perennials as measles, diphtheria, scarlet fever, and whooping cough. These were familiar disorders that killed young and old alike, and in an age when almost half of the children died before the age of 5 and sickness and death were omnipresent, the public attitude was one of quiet resignation.

One explanation of this passive acceptance of endemic disorders was that before the bacteriological revolution little could be done about them. Another is that, until the accumulation of reasonably accurate statistics, it was impossible to gauge the significance of these diseases. Beginning in the 1830s, individuals in Great Britain, on the Continent, and in the United States began collecting a wide range of statistical information. The studies of William Farr in England and Villermé and Pierre Laplace in

France were duplicated in the United States by Lemuel Shattuck, Edward Jarvis, and others. These early statistics, however, brought few immediate results in the United States. The same can be said of three classic public health studies published in the years before the Civil War – Griscom's *Sanitary Condition of the Laboring Population of New York City,* Shattuck's *Report of a general plan for the promotion of public and personal health* (1850), and McCready's essay (1837) on occupational diseases. Nonetheless, these men laid the basis for substantial progress in the post–Civil War years.

Their work also contributed to arousing an interest in public health and sanitation in the United States during the 1850s. Devastating yellow fever outbreaks from 1853 to 1855 raised fears throughout the country and led to a series of National Quarantine and Sanitary Conventions from 1856 to 1860. The major issue at these meetings was whether yellow fever could be kept at bay by quarantine or by sanitation. The sanitationists won the day. By 1860 they were preparing to turn the conventions into a national organization of health officers and sanitary reformers, but the outbreak of civil war brought the project to a sharp halt.

All was not lost, however, because the hygienic problems engendered by crowding thousands of men into army camps and the movements of troops throughout the country stimulated the public health movement. As evidence of this, in 1866 the Metropolitan Board of Health was established in New York City, the first permanent municipal health department. It was followed in 1869 by the first effective state board of health in Massachusetts. By the end of the nineteenth century, most major cities had established some type of health agency. Many of them, particularly the state boards, were only nominal, but the principle of governmental responsibility for public health was firmly established.

In the meantime the work of Joseph Lister, Robert Koch, Louis Pasteur, and a host of scientists working in microbiology was changing the whole basis for public health. Sanitation and drainage, the chief preoccupation of health officials in the nineteenth century, were replaced in the twentieth century by specific methods of diagnosis, prevention, and cure. Yet the sanitary movement had brought remarkable advances in life expectancy and general health. A higher standard of living, the introduction of ample and better city water, and large-scale drainage and sanitary programs all contributed to a sharp reduction in the incidence of urban disorders. Although the basis for the sanitary movement, the miasmic theory, was invalid, the movement itself achieved notable success in improving the public's health.

The major drive in all Western countries during the early twentieth century was to reduce or eliminate the major contagious diseases. With the aid of new diagnostic techniques, antitoxins, and vaccines, the major killer diseases of former times gradually were brought under control. Tuberculosis, probably the most fatal disease in the West during the nineteenth century, was greatly reduced, in part by improved living conditions and in part through concerted action by voluntary associations and governments to identify, isolate, and cure all cases. In addition, large-scale educational campaigns informed the public about the disease, and visiting nurses and social workers helped families of victims. As was true of drives against other contagious disorders, large-scale screening programs were used for the early identification of cases. Recognition of the role of vectors made it possible to drive malaria and yellow fever virtually from the Western world through antimosquito campaigns. The greatest success against disease has been with smallpox. With the help of the World Health Organization and massive vaccination programs, the disorder literally has been eliminated from the world.

Even as the fight against contagious diseases was getting underway, health officials began moving into other health areas. Among the more obvious social problems in the late nineteenth century was the enormous infant death toll. In western Europe, where nationalism was the real religion and the military power to defend that religion was equated with population, the birthrate was falling, increasing pressure to improve maternal and child care. The movement to do so began in England and France, where voluntary organizations began promoting dispensaries for child care. In the United States a New York philanthropist, Nathan Straus, opened a pure-milk station in 1893 to provide free or low-cost milk to the poor. The idea was picked up in other U.S. cities and soon spread to western Europe. Over the years, these stations gradually evolved into well-baby clinics and maternal and child health centers.

A major step forward in the movement for child care was taken in 1908 when New York City, in response to the urging of Sara Josephine Baker, became the first municipality to establish a Division of Child Hygiene. The success of Baker's program in New York encouraged Lillian Wald and Florence Kelley, who had long been advocating a children's bureau at the national level, to redouble their efforts. Four years later, in 1912, President Theodore Roosevelt signed a bill establishing the Federal Chil-

dren's Bureau. The next action at the national level was the passage of the Sheppard–Towner Act of 1921, a measure that provided matching federal grants for states to encourage maternal and child health programs. Although this act was allowed to lapse in 1929, the New Deal Program of Franklin Roosevelt in the 1930s firmly established a role for the national government, not only in maternal and child care, but in all aspects of public health.

Another important health area that had its origins in Europe in the late nineteenth century was school health. Smallpox vaccination appears to have been the entering wedge, because compulsory vaccination of school children was relatively easy to enforce. The discovery of so many other contagious disorders among children led to the introduction of school inspectors and school nurses around the turn of the century. The early twentieth century saw the beginning of physical examinations for school children, and these in turn created a need for school clinics and other remedial measures. As living standards were raised, particularly after World War II, school health programs declined in importance.

The discovery of vitamins (so named by Casimir Funk in 1912) opened up the field of nutrition, and a substantial effort has been made by health officials to educate the public on matters of diet. Commercial firms, capitalizing on public ignorance of scientific matters and the popularity of food fads, have managed to confuse the issue of what constitutes a well-balanced diet, thus negating much of the educational work. Despite this, however, food and drug regulations have generally improved the quality of the food supply.

An effective autocracy can mandate public health, but health officials in the Western democracies have been forced to rely largely on health education. The United States, which has the oldest tradition of mass education, was the first to recognize the value of information and persuasion in changing people's way of life. By the 1890s, a number of state and municipal health boards were publishing weekly or monthly reports and bulletins. Originally, these publications were intended for physicians and other professionals serving as health officers, but by the early twentieth century a variety of pamphlets and bulletins were being distributed to the general public. By this time, too, health education was given a formal status in the organization of health departments. Lacking the U.S. penchant for public relations, European health departments have not given as much emphasis to health education, relying much more on private groups to perform this task.

The education of public health workers originated in Great Britain in the second half of the nineteenth century. It was essentially a practical course to train food and sanitary inspectors. Early in the twentieth century, courses in public health were offered by the University of Michigan, Columbia, Harvard, and the Massachusetts Institute of Technology, and in 1913 Tulane University established a School of Hygiene and Tropical Medicine. The latter survived only briefly, and the first permanent school of public health was opened by Johns Hopkins University in 1918. Rather than an institution designed to train general health workers, it was essentially a research organization intended to educate the highest echelon of public health professionals. This pattern has been followed by all subsequent U.S. public health schools.

Although the term *public health* implies government action on behalf of the community, from the beginning voluntary work by individuals, groups of citizens, and philanthropic foundations has played a major role in promoting the general health. Citizens' sanitary organizations were very active in the late nineteenth century, and their counterparts in the twentieth have been voluntary groups fighting against particular disease and medical problems. These associations are found in nearly all Western countries, but they are most active in the United States. One of the best examples is the National Tuberculosis Association, founded in 1904, which had an active part in reducing the incidence of this disorder in the United States. Of the many foundations working in the health area, the Rockefeller Foundation is the best known. Along with the Carnegie Foundation, it has given major support to medical education. It is equally well known for its contributions to public health, particularly with respect to the drive against hookworm in the southern United States, the Caribbean, and Brazil and yellow fever in Latin America and Africa. The efforts of the Rockefeller Foundation also helped lay the basis for the Pan American Health Organization and the World Health Organization.

Since World War II, public health agencies, having won control over most of the contagious infections that formerly plagued the Western world, have turned their attention to chronic and degenerative disorders and to the problems of aging. Veneral diseases appeared to have been relegated to a position of minor significance with the success of antibiotics in the 1950s, but resistant strains and the appearance of genital herpes and AIDS have drastically changed the picture. An area where some success

has been achieved is that of community mental health, but progress has been slow.

With the success of the sanitary movement and the emergence of bacteriology in the early twentieth century, health departments tended to assume that care for the environment was largely an administrative matter. Since the 1950s, they have come to recognize many subtle, and not so subtle, forms of air and water pollution and dangers from pesticides, harmful factory wastes, and radiation. They have also sought to deal with problems of alcoholism, drug addiction, occupational hazards and diseases, and a major source of death and disability, automobile accidents.

The twentieth century has seen public health shift from an emphasis on the control of contagious diseases to the broader view that public health should concern itself with all factors affecting health and well-being. Whereas an original aim was to increase life expectancy, today public health also seeks to improve the quality of life. The current view of public health is that it should actively promote health rather than simply maintain it. Achieving a longer life expectancy is still a major aim, but it is equally important to improve the quality of life.

Measuring Health

IV.1
Early Mortality Data: Sources and Difficulties of Interpretation

The subject of early (for our purposes, pre—World War II) data on mortality is a vast one, and thus this treatment is quite broad. The emphasis is on identifying classes of data, sources of ambiguity, and general approaches to problems of interpretation. Wherever possible, citations are made to critical surveys of the literature, rather than to the literature itself. Some of the points discussed here can be extended, with appropriate caution and revision, to the equally important, but much less tractable area of early morbidity data.

Protostatistical Populations

There are rich opportunities for studying death and disease in populations for which vital statistics in the modern sense are nonexistent. Primary data sources include faunal evidence obtained by archaeological excavation, epigraphic evidence from funerary monuments, and information contained in parish records and family genealogies. In most cases, however, although these data allow inferences to be made regarding overall mortality among specific and highly localized populations, they contain little information on national-level populations and, with the exception of some faunal evidence, on causes of death. We can address the first shortcoming merely by assuming that the population studied accurately represents the total population, an assumption that is probably robust in very high mortality populations. The second difficulty – the lack of information on causes of death – is irremediable in the main. Furthermore, these data are rarely complemented by accurate population statistics, which are essential for computing rates and probabilities. Because of the dearth of early census data, genealogies and parish records, which provide a link between birth and death records, are especially important for estimating life expectancy (e.g., Henry 1956; Hollingsworth 1964; Wrigley 1968).

Early Statistical Populations

A key date in historical demography is 1532, when it was mandated that London parish priests compile weekly "Bills of Mortality," which were in turn the primary source of the first known life table (Graunt 1662). As this ecclesiastical registration system expanded, it provided the basis for Thomas Short's early study (1750) of geographic variation in British mortality. Not until 1837, however, was a national civil vital registration system established in England, and not until 1875 did registration of vital events become mandatory.

The English system was antedated by compulsory national civil vital registration systems in Scandinavia: Finland (1628), Denmark (1646), Norway (1685), and Sweden (1686). In Sweden the ecclesiastical registration system dates from 1608, slightly antedating the English Bills of Mortality. By the end of the nineteenth century, civil registration was compulsory in virtually all European countries, North America, Japan, and a host of other countries such as Egypt (1839), Mexico (1859), and Brazil (1885). Unfortunately, not all of these early registration systems, enumerated by Henry Shryock and Jacob Siegal (1980), contain cause-of-death data.

In addition to the registration systems, a number of important compilations and secondary sources exist. The International Statistical Institute of the League of Nations published its *Annuaire international de statistique* in 1916, 1917, 1919, 1920, and 1921 and its *Aperçu de la demographie des divers pays du monde* in 1922, 1925, 1927, 1929, and 1931. Publication of the latter series was suspended until 1939, when a volume covering 1929–36 was published. The U.S. Bureau of the Census and Library of Congress collaborated on a compilation of interwar European demographic statistics (U.S. Bureau of the Census and Library of Congress 1946), and to this may be added an earlier effort of the U.S. Bureau of the Census and Library of Congress (1943a,b). The standard compilation of historical mortality statistics for Latin America is that of Eduardo Arriaga (1968). Other national and international data compilations, as well as secondary studies of pre–World War II (mostly European) vital rates, are cited by Shryock and Siegal (1980) and, in the European case, by E. A. Wrigley (1969).

In the United States, although the availability of early church records, genealogies, and epigraphic evidence is impressive, particularly in New England (Vinovkis 1972) and Mormon Utah, vital registration got off to a late start. Beginning with the seventh census of the United States in 1850, questions regarding deaths in the household during the previous year were included in the compilation (a similar system was adopted in nineteenth-century Canada). The decennial U.S. Censuses of Mortality are the main source of nationwide mortality data from 1850 to

1890, but they are seriously incomplete (Condran and Crimmins 1979). This is in contrast to the situation in the United Kingdom, where civil registration data, including cause-of-death and limited socioeconomic data, are quite accurate from the mid-nineteenth century forward. A few states, such as statistically precocious Massachusetts, initiated state registration systems during the nineteenth century, and some cities published local mortuary records. In 1900 the federal government began collecting and publishing mortality data from a Death Registration Area consisting of the 10 states (plus the District of Columbia) in which it was judged that at least 90 percent of all deaths were registered. Under federal urging, more and more states initiated and improved compulsory registration systems, until by 1933 all of the present states except Alaska were included in a national vital registration system.

Among a number of compilations of U.S. vital statistics, the most noteworthy are volumes prepared by the U.S. Bureau of the Census (1933, 1943a,b); the U.S. Public Health Service (1961) has also published in a single volume comparable U.S. life tables for 1900–59. The fifteen volumes of the Vital and Health Statistics Monograph Series of the American Public Health Association, together with the final summary volume, *Mortality and Morbidity in the United States* (Erhardt and Berlin 1974), present a comprehensive view of the U.S. case. The emphasis of the series is on the 1960s, but a wealth of twentieth-century statistics, as well as some comparative international data, are presented in many of the volumes.

Statistics collected and special studies prepared by life insurance companies represent an underutilized body of data for nineteenth-century mortality in the United States and Europe. Because of the financial incentive to maintain accurate death records, these data may be quite accurate, and they contain considerable cause-of-death detail. The greatest drawback is that, because such data deal with only the insured population, they may underestimate the true extent of mortality among the broader population. To these data sources should be added the life tables calculated by eighteenth- and nineteenth-century actuaries such as Edward Wigglesworth, the accuracy of which has been the subject of intense scrutiny (Vinovkis 1971; Haines and Avery 1980).

One straightforward approach to setting a lower bound on the availability of early mortality data is simply to enumerate the pre–World War II multiple-decrement life tables in the work of Samuel Preston, Nathan Keyfitz, and Robert Schoen (1972). The criteria for inclusion in this authoritative compilation were stringent: Only populations for which accurate mortality statistics, including cause-of-death detail, and accompanied by reliable population data, are represented. These are daunting barriers to entry, but nevertheless the number of pre–World War II populations included is quite large: Australia (1911, 1921, 1933, 1940); Canada (1921, 1931); Chile (1909, 1920, 1930, 1940); Czechoslovakia (1934); Denmark (1921, 1930, 1940); England and Wales (1861, 1871, 1881, 1891, 1901, 1911, 1921, 1931, 1940); France (1926, 1931, 1936); Greece (1928); Italy (1881, 1891, 1901, 1910, 1921, 1931); Japan (1899, 1908, 1940); the Netherlands (1931, 1940); New Zealand (1881, 1901, 1911, 1921, 1926, 1936); Norway (1910, 1920, 1930); Portugal (1920, 1930, 1940); Spain (1930, 1940); Sweden (1911, 1920, 1930, 1940); Switzerland (1930); Taiwan (1920, 1930, 1936); and the United States (1900, 1910, 1920, 1930, 1940).

Problems of Interpreting Early Mortality Data

As already mentioned, relatively few sources of early mortality statistics can satisfy the Preston–Keyfitz–Schoen criteria. The deficiencies of such data are easily enumerated (Shryock and Siegal 1980):

1. *Definition of death.* This is an issue mainly in the case of stillbirths and neonatal deaths.
2. *Misallocation of deaths by place of occurrence.* In cases where large hospitals serve an extended catchment area, it is common for death notices to be listed incorrectly, indicating the residence of the deceased to be the metropolitan area in which the hospital is located rather than the outlying areas.
3. *Misallocation of deaths by time of occurrence.* Deaths are commonly tabulated on a year-of-occurrence basis, and mistakes in reporting are inevitable.
4. *Age misreporting.* This is a problem mostly at the older end of the age spectrum, where there is a tendency for reported ages to exceed actual ages significantly. It is also a problem in the case of children.
5. *Completeness of registration.* This is a problem involving both the *extent* and the *accuracy* of registration. In many countries, national registration systems were not in fact national, as in the United States with its original 10-state Death Registration Area. In other countries, certain populations were explicitly excluded from early registration

systems, such as Maoris of New Zealand and persons residing in the Yukon and the Northwest Territories of Canada. Even assuming that the entire population of a nation was included in the registration process, some degree of undercounting was inevitable. This tends to be the most serious problem in the case of infants, children under 5, and persons over 65.

6. *Cause misreporting*. Preston, Keyfitz, and Schoen (1972) have categorized problems in this area into errors in diagnosing cause of death and errors in translating an accurate diagnosis into an entry on the death registration form. The latter include errors in categorizing deaths according to international vital statistics convention (e.g., brain tumors were once classified under diseases of the nervous system, but are now grouped with neoplasms) and, more important, errors arising from complex issues in the case of multiple causes of death. To these two areas of difficulty should be added biases arising from the extent and accuracy of registration. Even an incomplete death registration system can, in theory, reflect accurately the population's cause-of-death structure. Unfortunately, differential completeness of registration can skew the cause-of-death structure. For example, if deaths among the elderly are systematically underreported, the resulting cause-of-death structure will understate the role of chronic and degenerative diseases, among them neoplasms and cardiovascular disease.

Among these problems, the fifth and sixth typically are of greatest concern, and it is to these that the remaining pages of this essay are devoted.

Estimating Completeness of Death Registration

Direct Approaches

There are two broad approaches to estimating completeness of death registration: direct and indirect. In the direct approach, the true level of mortality is independently estimated and compared with the level reported in the registration system. Household surveys of child survival, often performed in conjunction with census enumeration, are examples of the direct approach, but few such surveys are available for the pre–World War II era. Of more interest to social scientists are "matching" studies, in which deaths appearing in one tabulation (e.g., a parish register) are matched with deaths tabulated in the civil registration system during the same period (Marks, Seltzer, and Krotki 1974). It can be shown

that, if inclusion in the civil registration system and inclusion in the alternative tabulation are statistically independent, then completeness of civil registration, say C, is equal to the ratio of deaths recorded in both systems, say D(Both), to deaths recorded in the alternative system, say D(Alt):

$$C = D(\text{Both})/D)\text{Alt}). \tag{1}$$

It is important to note that, given statistical independence, it is unnecessary to assume that the alternative recording system is complete. The main advantage of matching studies, which have had extensive historical application (e.g., Crimmins 1980), is their conceptual simplicity. They are also well suited to the study of highly disaggregated mortality data, such as deaths in a given city from a given cause among a given segment of the population. The main difficulties, in addition to violations of the independence assumption, are empirical, particularly in deciding what constitutes a true match. It should be added that the matching-study approach is inherently labor intensive.

Indirect Approaches

Most indirect approaches to estimating completeness of civil registration are of comparatively recent development. The basic data requirement for all such methods is a reported age distribution of deaths in a given year. Other requirements, depending on the method employed, include population by age in the study year and age-specific population growth rates (calculated from two censuses, neither of which need have been taken during the study year). Most indirect methods require either the assumption of a stable population (i.e., one that is closed to migration and in which rates of birth and death have been constant for a long period of time) or, at a minimum, the assumption of no migration. In some cases, the methods are fairly robust to violations of these assumptions.

Some notion of the indirect approach can be gained by looking briefly at one of the earliest and simplest of these methods developed by William Brass. (The present section is based on the discussion in MacKellar 1987.) The Brass method is based on the fundamental population change accounting identity:

$$r(x+) = b(x+) - d(x+) + m(x+). \tag{2}$$

Here $r(x+)$ is the actual growth rate of the population aged over x, and $b(x+)$ is the actual birthrate of the population aged over x; that is, the number of xth birthdays celebrated in a given year divided by the

number of person-years lived in a state of being aged
over x in that year. $d(x+)$ is the actual death rate of
the population aged over x, analogously defined; and
$m(x+)$ is the actual net migration rate of the popula-
tion aged over x, analogously defined.

Setting x equal to zero, we find that (2) reduces to
the familiar identity whereby the growth rate of the
total population equals the crude birthrate minus the
crude death rate plus the crude rate of net migration.

The population is assumed to be stable, and since
the age distribution of a stable population is invari-
ant, $r(x+)$ is constant for all x. Let this constant
growth rate be r. Since there is, by assumption, no
net migration, we have $m(x+) = 0$ for all x. The
completeness of death registration is assumed to be
constant with age over age x. Let the proportion of
actual deaths enumerated be C. Then (2) can be
rearranged to yield the following:

$$b(x+) = r + (1/C)\ d'(x+), \qquad (3)$$

where $d'(x+)$ is the *recorded* death rate over age x.

If $N(x+)$ is the recorded population aged over x
and $N(x, x + n)$ is defined as the population aged
between x and $x + n$, $b(x+)$ can be estimated by a
statistic such as the following:

$$b(x+) = (N(x - n, x) + N(x, x + n))/2nN(x+). \qquad (4)$$

Thus, given a set of observed age-specific death
rates and a single population census for the calcula-
tion of $b(x+)$, linear regression or any other curve-
fitting procedure can be used to estimate the popula-
tion growth rate and the completeness of death reg-
istration (see United Nations 1983 for a discussion
of estimation issues).

The primary advantages of indirect approaches
are, first, that their data requirements are modest,
and second, that as a result, they are much less
labor intensive than direct methods. However, indi-
rect methods are applicable almost exclusively to
national-level populations and allow no disaggre-
gation by cause of death, residence, socioeconomic
status, and so on.

The Accuracy of Cause-of-Death Data

Errors in ascertaining true cause of death may arise
from inaccurate diagnosis by the attending physi-
cian (if any), failure to perform an autopsy, inaccu-
rate autopsy results, including inability of the pa-
thologist to specify multiple causes of death, and
failure of the death certifier to take into account the
results of autopsy. In the last case, problems arise
from changing vital statistics conventions and the

inevitable resulting misassignments of correctly di-
agnosed deaths. There is a large volume of postwar
research on the accuracy of reported cause of death
(Preston et al. 1972; Manton and Stallard 1984).
This literature is useful not only for isolating princi-
pal themes in the misdiagnosis of cause of death, but
also in setting upper bounds on the accuracy of pre-
war statistics.

Prewar populations present special problems. Spe-
cific clinical problems of diagnosis and pathology are
outside the scope of this essay, but several general
points are important. First, because of intracategory
misassignment (e.g., strokes due to cerebral hemor-
rhage being misassigned to strokes due to cerebral
thrombosis), there are significant gains in accuracy
from aggregating individual causes of death into
broader categories (Preston et al. 1972). The more
fine-grained the category, the higher the likely de-
gree of error.

Second, any death wrongly excluded from the cor-
rect category, if it does not escape the registration
system entirely, represents an incorrect addition to
another category; problems of overattribution, in
other words, may be as serious as problems of un-
derattribution.

Third, as death has increasingly occurred at older
ages from chronic and degenerative diseases, re-
searchers have been forced to replace the traditional
underlying-cause model, in which one disease or con-
dition is assumed to have resulted in death, with
more complex multiple cause-of-death approaches
(Manton and Stallard 1984). In the case of historical
populations of low life expectancy, however, use of
the simple underlying-cause model is more defensi-
ble than in the case of modern populations. Of
course, it is frequently inappropriate for the case of
aged persons, and the contributory role of chronic
conditions such as nutritional deficiency and low-
level diarrheal disease may be significant.

Finally, because of the improving state of medical
knowledge, increasing presence of an attending phy-
sician, and increasing frequency of competent au-
topsy, the overriding problem of the proportion of
deaths attributed to unknown, ill-defined, and bi-
zarre or nonsensical causes in cause-of-death statis-
tics has been in steady decline (Preston et al. 1972).
Among ill-defined causes, we include old age, senil-
ity, debility, fever, teething, dropsy, and so on. How-
ever, even in compilations as early as the 1850 U.S.
Census of Mortality, the proportion of deaths as-
signed to bizarre causes is tiny, and attributions to
unknown and ill-defined causes are confined largely
to deaths of persons over 65.

Moreover, we are not totally ignorant of the underlying nature of many deaths assigned to unknown and ill-defined causes. There is an a priori reason to believe that historical cause-of-death data systematically underreport causes of death most common in old age because of the inherent difficulty of correctly diagnosing chronic and degenerative conditions. The most likely scenario is that these deaths ended up in the *unknown* and *ill-defined* categories, a hypothesis in support of which Preston (1976) has adduced strong statistical evidence. In particular, most deaths attributed to old age and senility can, with some confidence, be attributed to cardiovascular disease and cancer.

Thus, there are further compositional advantages, in addition to the enhanced validity of the underlying-cause mortality model, to dealing with low-life-expectancy historical populations. Calculations indicate that in a population with a life expectancy of 30, of the men 52.9 percent eventually die from causes falling into fairly robust categories: respiratory tuberculosis, other infectious and parasitic diseases, diarrheal disease, the influenza–pneumonia–bronchitis complex, and violence. In a population with a life expectancy of 70, by contrast, the corresponding figure is only 14.6 percent (Preston et al. 1972; Preston 1976). Partially vitiating this compositional advantage of low-life-expectancy populations is the relatively large proportion of deaths from diseases of infancy and early childhood that are difficult to diagnose. Nevertheless, it appears that nineteenth- and early-twentieth-century mortality statistics give a fairly accurate picture (excluding problems related to chronic and degenerative disease) of the actual cause-of-death structure.

> IV.2
> Maternal Mortality:
> Definition and Secular
> Trends in England and
> Wales, 1850–1970

Maternal mortality signifies the deaths of women that take place during pregnancy, labor, or the puerperium, once frequently referred to as "deaths in childbirth." Despite past claims, in the context of total deliveries, maternal death was a rare event compared with death from disease. Even in the worst periods of the eighteenth and nineteenth centuries, the mother survived in at least 98 percent of deliveries. Nonetheless, a death rate of 1 to 2 percent is high when the average number of deliveries *per day* is about 2,000, as it was in England and Wales by the end of the nineteenth century. In the United States during the 1920s, for example, death in childbirth claimed some 15,000 to 20,000 lives a year, and it was second only to tuberculosis as a cause of death in women of childbearing age.

This essay is about the historical epidemiology of maternal mortality – the distribution and determinants of maternal mortality in different populations at different periods. The epidemiological approach to the history of maternal mortality is not, of course, the only one, but it is the method that makes the greatest use of statistics to attempt to discover why the mortality rate changed at different periods, and why one region or one country suffered more maternal deaths than another. It is

necessary to examine a broad range of clinical, social, political, economic, and geographic factors, all of which affected childbirth in different countries and at different times. Although this is a historical exercise, some of the answers are undoubtedly relevant to obstetric problems in certain parts of the Third World today.

To illustrate how maternal mortality is determined, the trend in England and Wales will be examined first. Maternal deaths and other data are shown in Table IV.2.1 for certain selected decennia and in Figure IV.2.1 for successive decennia from the 1850s through the 1970s.

In England and Wales the population of women of childbearing age more than doubled between the 1850s and the 1970s, but the birthrate more than halved, so that the average number of births per day (or per decade) was almost exactly the same in the 1850s and the 1970s. But the risk of childbirth had been enormously reduced. Total maternal deaths, as shown in Table IV.2.1, rose from an average of 8.5 per day in the 1850s to a peak of 12 per day in the 1890s before descending to the present level of about 1 per week. In the nineteenth century, a woman would most likely have known of at least one death in childbirth among her friends or neighbors, if not her own family. Today, maternal deaths are so rare that very few people have personal knowledge of such a tragedy.

There is a certain pattern of mortality with which historians and epidemiologists are familiar. It consists of a general decline in deaths dating either from the mid-nineteenth century or from the beginning of the twentieth. This decline was seen, for instance, in death rates from all causes, deaths from the common infectious diseases, and infant mortal-

Table IV.2.1. *Birthrates and maternal deaths in England and Wales, 1851–1980*

Decennium	Population of women aged 15–44 (millions)	Birthrate[a]	Average number of births per day[b]	Average number of maternal deaths per day[b]	Average annual maternal deaths per million women aged 15–44	Maternal deaths per 10,000 births
1851–60	4.60	144.8	1,775	8.5	675	47.0

ity. The reasons for the decline have been debated for a number of years. In the past it was attributed to advances in scientific medicine. It is now generally accepted that the decline in mortality rates before the Second World War had little to do with advances in medical or surgical therapy, but a great deal to do

with a general improvement in health and hygiene associated with a rising standard of living.

Figure IV.2.1 shows maternal deaths per million women of childbearing age. The graph appears at first sight to conform to the general pattern, because it shows that maternal deaths declined from the 1870s onward. However, this decline is seen only when the birthrate is ignored and maternal mortality is measured solely in terms of the total number of women of childbearing age. In fact, the population at risk is not *all* women of childbearing age; it is only women during pregnancy, labor, or the puerperium. Maternal mortality has to be measured in terms of births, not total population, and Figure IV.2.1 shows clearly that the birthrate was declining alongside deaths in childbirth.

The maternal mortality rate (henceforth, the MMR) is therefore calculated by dividing the total number of registered maternal deaths (the numerator) by the total number of registered births (the denominator). The quotient is then multiplied by 1,000, 10,000, or, as is usual today, 100,000. Deaths per 10,000 births is the most convenient when one is working with historical data and is used here. The ideal denominator for the calculation of maternal mortality would, of course, be pregnancies rather than births; but total pregnancies cannot be recorded when there are no statistics on abortions or multiple births from single pregnancies. Total births (or live births before stillbirths were registered) are therefore used instead.

When the MMR is calculated in terms of births rather than women of childbearing age, the graph is very different (Figure IV.2.2). Between the 1850s and
Figure IV.2.2. Maternal mortality rates for England and Wales, 1851–1980 (logarithmic scale). Maternal mortality rates expressed as maternal deaths per 10,000 births. (From Annual reports, Decennial Supplements and Statistical Reviews of the Registrar General for England and Wales.)

1930s the MMR, far from declining, remained on a plateau while other major causes of death were declining. This plateau, and the steep and sustained decline that started in the mid-1930s, are the two prominent features of the graph. The plateau suggests that the factors that caused a general decline in death rates between the 1870s and the mid-1930s had no effect on the MMR. This is especially surprising when one recalls that obstetrics differed from the use of medicine in surgery in that, starting in the 1880s, certain measures were introduced into obstetric practice that should have reduced mortality. These included antisepsis and asepsis, the compulsory regulation and training of midwives, and the growing importance of antenatal care. But it appears that at the national level they had no effect. There is yet another unusual feature of maternal mortality: the correlation with social class. For most of the common causes of death in the past, social-class gradients existed, with the highest mortality rates among the poor and lowest among the well-to-do. In the case of the MMR, the gradient was reversed.

From the mid-1930s, the abrupt and sustained decline in mortality is as striking as the previous absence of any decline. Maternal mortality is puzzling and fascinating because of these unexpected features. Were England and Wales, however, unusual in these respects, or were similar trends found in other countries?

International Comparisons of Maternal Mortality

Few countries published vital statistics before the mid-nineteenth century. The exception was Sweden, where, as Ulf Högberg (1985) has shown, the MMR fell from about 100 per 10,000 births in 1750 to about 50 in the mid-nineteenth century, followed by a rise to about 63 in the 1870s. Work by R. Schofield (1986) suggests that the MMR in England probably fell from about 100 per 10,000 births during 1700–50 to around 80 during 1750–1800 and to between 50 and 60 in the first half of the nineteenth century. The MMR in Europe in the late eighteenth and early nineteenth centuries may have been about 100 deaths per 10,000 births, but this is speculative.

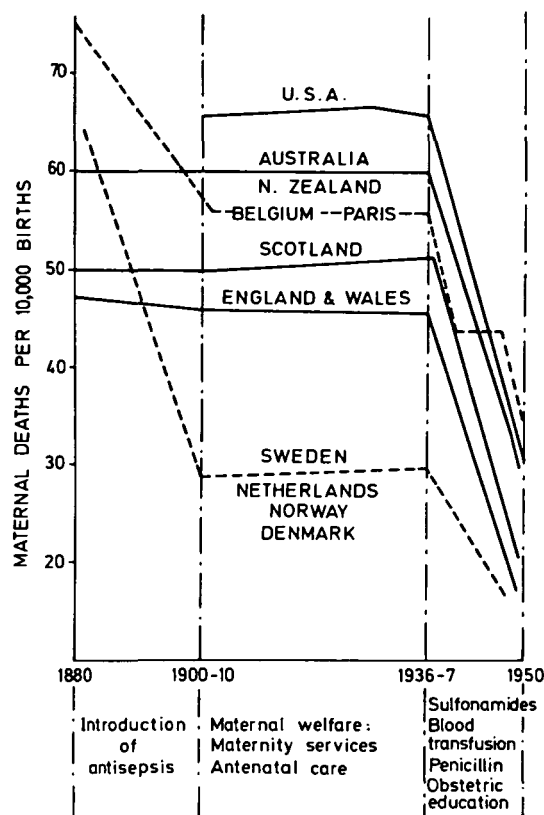
Data on maternal deaths were not always included in early lists of causes of death, but they were usually included in vital statistics (with various degrees of reliability) from the 1850s in European countries, from about the 1880s in Australia and New Zealand, and from 1900 in the United States (except for the state of Massachusetts, where statistics on maternal mortality can be obtained from 1850).


Figure IV.2.3. Changes in maternal mortality rates in different countries, 1880–1950. (Based on the vital statistics of the countries shown.)

Data from the United States as a unit present a special problem because they were based on the expanding Death Registration Area, established in 1880. Initially this consisted of the states of New Jersey and Massachusetts, the District of Columbia, and nineteen cities. Other states were added year by year. The process was completed by 1933 with those states that recorded the highest MMRs coming last and to some extent accounting for the rising MMR in the United States between 1900 and 1933. In spite of this complication, however, there is little doubt that the United States experienced one of the highest MMRs in the developed world during the first four decades of the twentieth century.

Figure IV.2.3 is a schematic representation of the secular trend in the MMR in various countries between 1880 and 1950. In 1880 the MMR in most developed countries lay somewhere in the range of 50 to 100 deaths per 10,000 births. Between 1880 and 1910, some countries (e.g., Sweden and Belgium) showed a substantial reduction in the MMR, which Högberg (1985) has suggested was almost certainly the result of the effective use of antisepsis and asepsis. (Although different, both techniques are de-
Figure IV.2.4. Maternal mortality rates in Scotland, England, Wales, and Sweden, 1870–1950. (From Annual Reports of the Registrar General for England, Wales, and Scotland. For Sweden, 1860–1910: Ulf Högberg, Maternal mortality in Sweden, Umeå University Medical Dissertations, New Ser. 156 [Umeå, 1985], 1911–1950: *Sveriges officiella Statistik,* Stockholm.)

noted by the term *antisepsis* in this essay). However, other countries (e.g., Britain and Australia) failed to reduce mortality significantly, a difference that is hard to explain but one that suggests poor antiseptic practice. An example of this difference can be seen in Figure IV.2.4, which shows the secular trends in the MMR in Scotland, England and Wales, and Sweden.

That antiseptic techniques, rigorously employed, could be very effective in reducing maternal mortality was beyond doubt. Before 1880, the experiences of lying-in hospitals all over the world were appalling and MMRs of 200 or more were common. By 1900 such hospitals as the Rotunda Hospital in Dublin, the York Road Lying-in Hospital in London, the Maternity Hospital in Basle, and the Women's Hospital in Sydney reported very low MMRs and a virtual absence of deaths from puerperal sepsis. Such success, however, seems to have been confined to a minority of hospitals, the implication being that those standards of care were the exception before the twentieth century. This was certainly the belief of the Australian Committee on Maternal Mortality of 1917, which said in no uncertain terms:

Puerperal septicaemia is probably the gravest reproach which any civilised nation can by its own negligence offer to itself. It can be prevented by a degree of care which is not excessive or meticulous, requiring only ordinary intelligence and some careful training. It has been abolished in hospitals and it should cease to exist in the

community. It should be as rare as sepsis after a surgical operation.

From 1900 to the late 1930s, almost everywhere the MMR stayed level or rose slightly, although there were wide differences among national MMRs. The United States showed the highest and the Netherlands and Scandinavia the lowest. Between 1929 and 1935, the MMR declined slightly in the United States and New Zealand. Elsewhere the trend was level or rising.

When it became obvious that maternal deaths, and especially those from puerperal sepsis, were not being prevented, concern about maternal mortality increased. In many countries, including Britain, Australia, New Zealand, and North America, radical reforms were suggested. These eventually led to improvements in the education and regulation of midwives (except in the United States, where abolition of the midwife was recommended), to better obstetric training for physicians (although in practice little improvement occurred), and an increasing number of specialist obstetricians (with the inevitable tendency for obstetrics to become a branch of operative surgery). Also suggested were the encouragement of routine antenatal care (which seems to have had little effect before the 1940s) and the establishment of new obstetric institutions (clinics, maternity hospitals, and maternity departments in general hospitals in spite of the danger of cross-infection). There were repeated exhortations to use antisepsis properly (which were largely ignored), and local and national governments were urged to improve both the quality and availability of maternal care to women at all levels of society (their actions were usually weak but occasionally effective).

Some medical authorities were optimistic. Maternal mortality, it was felt, was not a difficult problem. Methods of preventing maternal death were known, and reforms based on them would reduce the tragic and unnecessary loss of so many young women in the prime of their lives. Yet national MMRs showed an obstinate refusal to fall, and a number of studies revealed wide and disturbing regional differences within nations.

Map IV.2.1 shows regional variations for England and Wales, and Map IV.2.2 the same for the United States. In England and Wales there was a well-marked northwest and southeast divide along a line from the Severn to the Wash, which persisted from the late nineteenth century until the 1930s. Most counties above the line suffered an above-average,

Rates higher than that of England and Wales by an amount which is definitely significant

Rates higher than that of England and Wales by an amount which is very probably significant

Rates which do not differ significantly from that of England and Wales

Rates lower than that of England and Wales by an amount which is very probably significant

Rates lower than that of England and Wales by an amount which is definitely significant

Map IV.2.1. Differences in maternal mortality rates in England and Wales, 1924–33. (From Ministry of Health 1937.)

and those below the line a lower-than-average, MMR. The explanation is neither simple nor certain, but it probably lies in the standards of obstetric care rather than standards of living (see the section on determinants).

In the United States the divide was geographically the opposite. Maternal mortality was highest in the South. The states with a high MMR lay along the curve stretching down from Wyoming, Colorado, New Mexico, and Arizona across to the states of the Deep South – Louisiana, Mississippi, Alabama, Florida, Georgia, North and South Carolina, Tennessee, and Virginia. In the Northeast, only Maine showed a persistently high MMR.

The secular trend for the United States as a whole can be seen in Figure IV.2.5. The striking features are the high MMRs and the very large difference between white and all mothers, a difference that persisted at least to the 1970s. The high MMR in the South was due largely, but not entirely, to the concentration of the black population. For white mothers as

well as black, the MMR was highest in the southern states, but the differential was relatively slight.

In the United States before the Second World War, maternal mortality was usually lower in rural than in urban areas. By the 1960s this situation had been reversed. Remote rural areas, however, often experienced special problems, and wide variations in the provision of maternal care in different parts of the same state were not uncommon. In mountainous areas with deep ravines and few roads, often no trained birth attendants of any kind were available. In other areas, low mortality might be achieved by small homogeneous populations of European origin, which included midwives trained in Europe. Yet other remote areas might possess small local hospitals where nearly all deliveries would be performed by physicians. In many developed countries, a lack of uniformity was the rule rather than the exception as far as factors affecting the MMR were concerned. It was true of Britain, for instance, but most extreme in the United States. In the years 1938–40, when the

Woodbury, *Maternal mortality: The risk of death in childbirth and from all the diseases caused by pregnancy and confinement,* Rept. no. 152 [1921]; Elizabeth Tandy, *Comparability of maternal mortality rates in the United States and certain foreign countries,* Rept. No. 229 [1935].)

average MMR for the United States as a whole was 37.6 per 10,000 births, it ranged from 17.5 per 10,000 in North Dakota to 67.8 in South Carolina, a ratio of lowest to highest of 1 to 3.9. In England and Wales in the same period, the average MMR was about 28 per 10,000 and the range between regions was probably about 17 to 38, a ratio of 1 to 2.2.

All this was known to the authorities who made policy in Britain and the United States. Both countries were concerned about their unacceptable MMRs and the obstinately persistent regional differences. But they devised quite different policies. In the United States it was thought that maternal mortality could be defeated by an increase in the proportion of hospital deliveries performed by specialist obstetricians. The midwife and the general practitioner with her or his "kitchen-table midwifery" should be abolished except in remote rural areas.

In Britain it was felt that the backbone of obstetric care should continue to be home deliveries by midwives and general practitioners. Hospital care should increase, but on the whole it should be reserved for complications of labor and high-risk cases. New Zealand tended to follow the U.S. pattern, Australia, the British, and the Netherlands and Scandinavia also pursued a successful policy of home deliveries by midwives backed up by a minimum of hospital deliveries. It is interesting that, in spite of such divergent policies, none of these countries experienced a significant fall in the MMR between 1910 and the mid-1930s.

The Causes and Determinants of Maternal Mortality

Three conditions – puerperal sepsis, toxemia, and hemorrhage – caused the majority of maternal deaths throughout the developed world from the mid-nineteenth century until the mid-1930s, and the proportion of total deaths contributed by each was remarkably constant in different countries during this period.

Puerperal sepsis usually accounted for about 40 percent of deaths. At first, the term *puerperal sepsis* was synonymous with puerperal fever ("childbed fever"), an infection that appeared after delivery. Later, it included septic abortion as well, but in most countries the two were not distinguished until the late 1920s, when deaths from septic abortion were increasing, although to a widely different extent in different countries. By the early 1930s, the death rate from septic abortion had reached a high level in the United States. In New Zealand, deaths from septic abortion actually exceeded those from full-term sepsis. The contribution of septic abortion to mater-

nal mortality in different countries is an extremely complex subject. But it is likely that the increase in the MMR in the Netherlands and Sweden in the late 1920s and early 1930s was the result of an increase in deaths from septic abortion superimposed on a more or less constant rate of deaths from puerperal fever.

Unlike deaths from septic abortion, those from puerperal fever were largely preventable. The risk of puerperal infection, however, was much greater in the past than it is today because of the prevalence and virulence of the organism known as the B-hemolytic streptococcus, Lancefield group A (*Streptococcus pyogenes*), which was responsible for the vast majority of deaths from puerperal fever. Before the Second World War, this organism was frequently carried in the nose or throat of a large proportion of the healthy population ("asymptomatic carriers"). It was also common not only as the cause of scarlet fever and erysipelas, but as an infection in people suffering from such minor complaints as sore throats, whitlows, and minor abrasions, so that the risk of cross-infection was high. The prevalence of the virulent streptococcus and the inadequacy of antiseptic procedures contributed to the high MMR. Today, asymptomatic carriers are rare, scarlet fever has become a minor disease, and rheumatic fever and acute nephritis have virtually disappeared. The reasons for the change are uncertain.

Deaths from toxemia (eclampsia and preeclampsia) accounted for about 20 to 25 percent of total maternal deaths and hemorrhage (antepartum and postpartum) for about 20 percent. Each of the remaining causes, such as "white leg" (deep-vein thrombosis) and embolism, ruptured uterus, ectopic pregnancy, hyperemesis gravidarum, puerperal mania, and so on, contributed 5 percent or less to the total.

Determinants of Maternal Mortality

Although the immediate causes of maternal deaths are not disputed, the factors that determined MMRs are much more debatable. They fall broadly into two groups: clinical factors and socioeconomic, political, and geographic factors.

Clinical factors were associated with the type and standards of obstetric care provided by the birth attendant. Standards of obstetric care were determined by a number of factors, including the status of obstetrics and thus the quality of education and training, the type of birth attendant (specialist obstetrician, general practitioner, trained or untrained midwife, etc.), the place of delivery (home or hospi-

tal), and current fashions in the management of normal and abnormal pregnancies and labors.

Nonclinical factors included the attitudes and expectations of women about the conduct of childbirth, together with socioeconomic considerations: family income, nutrition, housing and hygiene, the ability to command and pay for obstetric care where private care predominated, and the provision of maternal welfare schemes by local and national government or charities where they existed.

Some historians have suggested that high MMRs in the past were due largely to social and economic deprivation. Others have asserted that the responsibility lay not with poverty per se, but with the standards of obstetric care available to the poor. Poor standards of care might result from ignorance and lack of training. Poor practice might also, and often was, caused by negligence, laziness, hurrying, and dangerous, unnecessary surgical intervention by trained practitioners. Poor practice, therefore, was not confined to untrained midwives or even to the often-maligned general practitioners; it was often found among specialist obstetricians following the procedural fashions of their time.

Clinical and nonclinical factors were not mutually exclusive. They overlapped, and both could affect the outcome of childbirth. In any particular case, maternal risk was a reflection of the complex interplay of traditional, social, economic, and clinical features that surrounded the birth of a baby and where the baby was born. Obviously, the risks of a mother giving birth in midwinter in Montana or Maine, North Wales or the Highlands of Scotland were different from the risks experienced in the middle of London, Paris, or Boston.

Yet in spite of bewildering variety, it is the task of the historian to generalize, and to try to assess the relative importance of all such factors in different populations at different times, allowing for differences in the ways that populations are described. Europeans tend to describe populations in terms of social class; North Americans in terms of nationality, race, and color. One can suggest with reasonable confidence, however, that black mothers as a whole in the United States would have shared with the lower social classes in Britain a greater than average likelihood of suffering from malnutrition, chronic disease, and the general ill-effects of poverty. Did they suffer a high MMR as a consequence? Two lines of evidence suggest that social and economic factors were much less important determinants of maternal mortality than might be expected.

A series of reports from cities in Britain, dating

from the 1850s to the 1930s, revealed that MMRs were higher among the upper classes than the lower. These findings were confirmed by the Registrar General's analysis of maternal mortality by social class for England and Wales for the years 1930–2. This showed that the MMR for social classes I and II (professional and managerial) was 44.4, while for social class V (unskilled workers) it was 38.9.

In the United States there was no doubt that the MMR was much higher (usually by a ratio of 3 to 1) among black women than white. A few investigations were carried out on the relationship between income and maternal mortality. Most showed a higher MMR among the lowest income groups, but they generally concluded (the Massachusetts report of 1924 is an example) that inability to pay for obstetric care, not poverty per se, was the explanation.

The second line of evidence might be called experimental. It came from programs in which a high standard of obstetric care was provided in regions of social and economic deprivation. The classic example was the *Rochdale experiment*. In 1929 Rochdale (a town in Lancashire) had an exceptionally high MMR of slightly more than 90 deaths per 10,000 births. Andrew Topping, a physician serving as the new officer of health, undertook a vigorous reform of obstetric care during a period of severe economic depression. The MMR was reduced in a few years from one of the highest in England to one of the lowest. There was no change in the social and economic environment during the experiment.

A similar experiment was the establishment of the Kentucky Frontier Nursing Service by Mary Breckinridge in the 1920s. Highly trained nurse-midwives, traveling on horseback, delivered babies of women who lived in great poverty in isolated mountain terrain and suffered from a high rate of chronic illness and malnutrition. An astonishingly low MMR was achieved solely by good obstetric practice – about one-tenth of the rate among women delivered by physicians as private patients in the hospital in Lexington, the nearest town.

The countries showing the lowest MMRs – the Netherlands and Scandinavia – ran maternity services based on a strong tradition of home deliveries by highly trained midwives. In Britain a very low MMR was achieved by a similar group, the Queen's Institute Midwives. The records of outpatient charities in Britain and the United States showed repeatedly that the establishment of a free or low-cost obstetric outpatient service in areas of severe socioeconomic deprivation could result in low MMRs, even when deliveries took place under appalling con-

ditions. Therefore, although there were maternal deaths in which anemia, malnutrition, and chronic ill-health must have been contributory factors (and it seems likely that they contributed to the high MMR in the Deep South of the United States), the weight of evidence suggests that the standard of obstetric care was usually the most important determinant of the MMR. Because hospital delivery carried the danger of cross-infection as well as the likelihood of surgical interference in normal labor, it was usually safest before the mid-1930s to be delivered at home by a trained midwife or by a medical practitioner who was conservative in his or her attitudes toward obstetrics and meticulous in antiseptic practice. The irony is that the rich often sought what they considered the "best" obstetric care in plush private hospitals and paid for it with the added risk of iatrogenic maternal mortality.

Conclusion

The fall in MMR that began in the late 1930s was due to a number of factors, which followed one another but at slightly different rates in different countries. In England and Wales these were, in succession, the sulfonamides, blood transfusion, better obstetric care (in part associated with wartime organization), penicillin in 1944, and after the war a marked improvement in obstetric education. The National Health Service hastened the adoption of a standard of obstetric care for everyone, which was available only to a minority before the war. The fact that this decline in MMR occurred throughout the developed world at much the same pace is a strong endorsement of the notion that clinical care is the main determinant of MMR. Some, however, would still maintain that the low maternal mortality today is due to good health, not medical technology. In this respect the experience of a religious group in Indiana in the 1970s is informative. This group rejected all orthodox medical care while engaging in the same middle-class occupations and earning the same incomes as their orthodox neighbors. Mothers received no prenatal care and were delivered without trained assistance. Their MMR was 100 times higher than the statewide rate.

We have noted the high MMRs between 1900 and 1935. We may ask with the benefit of hindsight whether it would have been possible for countries such as Britain and the United States to have reduced their MMRs significantly. The answer is almost certainly yes, although it is probable that the MMRs seen in the 1950s would have been out of reach in the 1930s, because of the virulence of streptococcus and the absence of sulfonamides and penicillin.

A significant reduction in maternal mortality might have been achieved, however, through education. The medical curriculum should have attached as much importance to obstetrics as to anatomy, physiology, and biochemistry. It would have been essential to demonstrate the need for a very high standard of antiseptic practice at every delivery. It would have been wise for every developed country to have established a national or regional maternity service based largely on the work of trained midwives undertaking the majority of normal deliveries at home. Maternity hospitals were necessary, of course, for the management of dangerous complications and high-risk cases, but they were not the best place for normal deliveries. The work of hospitals, general practitioners, and midwives should have been monitored by local maternal mortality committees, and care taken to establish close cooperation between all parts of the maternity service. Some of these reforms were beginning to be implemented by the late 1930s in Britain. None required knowledge that was not then available. The examples of the Kentucky Nursing Service, the Rochdale experiment, and the numerous successful outpatient charities and services were well known. The success of Scandinavia and the Netherlands, where most of the principles just outlined were in operation, was no secret.

If such simple but potentially effective changes were not adopted, it was partly because no clear consensus existed as to the way obstetric care should be delivered. Even if there had been a consensus, it would have been impossible to compel medical personnel to change their ways.

Appendix

The Problems of Comparative Statistics

Certain statistical problems surround the interpretation of the statistics on maternal mortality and international comparisons. In England and Wales before the compulsory registration of stillbirths in 1927, the denominator *births* meant *live births* only. After 1927, stillbirths were included and the term *total births* replaced *live births* in the calculation of the MMR. The difference was relatively small. In 1933, for example, the MMR was 45.2 per 10,000 live births and 43.2 per 10,000 live births plus stillbirths. The failure to take multiple births into account produces a slight distortion in the other direction, because births rather than deliveries are used as the denominator. Again, the distortion is slight.

The use of the classification based on the International List of Diseases was important when it was adopted by England and Wales in 1911. Previously, deaths due to toxemia of pregnancy (but not deaths from eclampsia) were entered under diseases of the kidney; after 1911 they were entered as maternal deaths. Subsequent revisions of the international list made little difference to the calculation of total maternal mortality, but an appreciable difference in the way maternal deaths were classified.

A major problem in international comparisons was that of *associated,* or, to use the modern term, *indirect* deaths. Simply stated, should the death of every pregnant woman be recorded as a maternal death, regardless of the cause? There was no difficulty in identifying "true" maternal deaths such as those due to postpartum hemorrhage, puerperal fever, or ectopic gestation; and deaths that had nothing to do with the pregnancy or general health (e.g., the death of a pregnant woman in a road or railway accident) were generally excluded. Difficulties arose, however, when a woman died in the course of an otherwise normal pregnancy or labor from influenza, or some preexisting condition such as heart disease, tuberculosis, or nephritis. It was argued that such deaths were due to the combination of general disease and the strain of pregnancy or labor; if the woman had not been pregnant, she might have survived. Should such deaths be entered under maternal or general causes of death? Different opinions were held. In the United States, Australia (but not New Zealand), Denmark (but not Norway or Sweden), and Scotland (but not England and Wales), indirect deaths were usually included in the estimation of maternal mortality. There were always borderline cases, and the way they were treated could also differ, but these differences were statistically negligible. Those countries that included associated deaths often believed that they were more honest and commented angrily that, if their MMRs seemed high, it was due solely to this difference in method. This was understandable, but wrong. Elizabeth Tandy of the Children's Bureau showed in 1935 that, although some differences could be attributed to differences in method, they were only slight in comparison with the wide international differences that existed. An example can be found in Figure IV.2.5, where the MMR for the United States as a whole is shown twice: once with associated deaths included in the U.S. manner and once with associated deaths excluded in the English manner.

Perhaps the most difficult problem is that of "hidden" deaths – deaths from puerperal fever and abor-

tion that are hidden because of the opprobrium surrounding them. A death from puerperal fever was, above all other deaths, one for which the physician or nurse was likely to be blamed. There were therefore strong motives for a physician to register a death like this in such a way that the authorities would not know it was a maternal death. In the late nineteenth and early twentieth centuries, it was not unusual for doctors to certify a death from puerperal sepsis as being due to peritonitis or septicemia without mention of childbirth. These conditions were cited because they were, in fact, the immediate causes of death in puerperal sepsis.

The true cause of death in cases such as these could be determined, however, both by asking the offending doctor outright whether childbirth had been involved or by searching the death records for an excess of deaths from peritonitis or septicemia among women of childbearing age. Deaths from both causes ("peritonitis of unstated origin" and "septicemia") were more common in men than women once deaths from puerperal sepsis were excluded. This complicated statistical exercise was carried out by government statisticians in Britain and the United States in the 1920s. Indeed, this author has carried out in some detail the same exercise using the lists of causes of death from the 1880s to the 1950s. In England and Wales, in the period from 1900 to 1930, apparently incorrect certification led to an underestimation of the true number of deaths from puerperal sepsis by about 12 percent. The MMRs described by this essay for the period up to the mid-1930s are therefore likely to be an underestimation; they are certainly not an exaggeration of the true figures. Needless to say, the exact MMRs of the past can never be known. Nevertheless, the extent of statistical distortion can to a large extent be estimated. It is then reasonable to believe that a generally correct picture of MMRs in most developed countries since the 1880s can be obtained and that the picture becomes increasingly accurate through the present century.

IV.3
Infant Mortality

The infant mortality rate (which is commonly calculated as the number of deaths among infants under 1 year of age in a calendar year per 1,000 live births in that year) measures the probability that a newborn baby will survive the hazards of infancy and live to celebrate his or her first birthday. Whether a given infant survives this crucial first year of life is influenced in part by certain biological characteristics (e.g., genetic makeup, nature of the birth outcome, susceptibility to particular diseases). But a voluminous body of research over the past century has clearly identified the major determinants of the overall infant mortality rate to be, first, the nature of the physical environment, especially the state of sanitation, and, second, the nature and availability of health care facilities. Although the health of persons of all ages is affected by these conditions, the newborn infant is most susceptible and most likely to be adversely affected by the absence of appropriate sanitary and health care facilities.

It has also been solidly established that within any society infant mortality rates are strongly related to family income, which in turn is an indicator of both the nature of the environment in which an infant is born and raised and the family's ability to provide the infant with optimal health care. The basic aim of this essay is to review briefly some of the relevant research and to present empirical justification for designating the infant mortality rate as the most sensitive indicator of the overall health status of any population group.

Historical Evidence
Although precise statistical data are lacking, the little that scientists have been able to compile from various anthropological and archaeological sources clearly indicates that throughout most of its existence humankind has had to contend with an extremely high death rate. At least 20 percent and

probably more of all newborn babies died before their first birthdays, and for most there was no more than a 50 percent chance of surviving to adulthood. More specific estimates of mortality in antiquity are limited to occasional estimates of *average life expectancy,* the number of years lived, on the average, by the members of a given population. This average life expectancy, or average age at death as it is sometimes crudely defined, is influenced most strongly by the mortality rate in infancy (Shryock et al. 1976); hence, where conventional birth and death statistics are not available, this measure can be used as something of a proxy for the infant mortality rate. Available historical estimates indicate that, while some of our primitive ancestors surely attained extremely old ages, the average life expectancy in ancient times among most groups was probably not much more than 25 or 30 years, and in some populations it was even lower (Russell 1958).

Although overall survival improved somewhat over the years, average life expectancy had not greatly improved as recently as the start of the present century. Estimates for England and Wales, for example, indicate that average life expectancy for the period 1891–1900 was only about 45 years (44 for men and 48 for women) (Dublin, Lotka, and Spiegelman 1949), and in the United States in 1900 it was only about 50 years (48 for men and 51 for women) (U.S. Bureau of the Census 1960). Moreover, it was still common at that time for as many as 15 percent or more of all newborn babies to die before their first birthdays. Data for the United States, for example, indicate an infant mortality rate for 1900–2 of 162 per 1,000 live births (U.S. Bureau of the Census 1960); and rates of comparable magnitude (between 150 and 170) have been estimated for this period in a number of other western European countries (Woods, Watterson, and Woodward 1988).

Contemporary scholars, concerned with the high levels of infant and childhood mortality, were clearly aware of their causes. Some were environmental factors, such as foul air, contaminated water, and poorly ventilated, overcrowded housing, which contributed to the high incidence of a variety of infectious, respiratory, and parasitic diseases. Other causes were related to poor child care, including inadequate and unsanitary delivery conditions and improper feeding practices, notably a lack of breast feeding and the associated consumption of contaminated milk, all of which led to high rates of mortality from diarrheal diseases (Woods, Watterson, and Woodward 1989). Moreover, it had generally been known since at least the mid-nineteenth century

that these detrimental health conditions were differentially distributed among the population and that the lower social classes experienced much higher infant death rates than the middle and upper classes (Woods et al. 1989). As previously mentioned, research over the years has clearly established that family income is the most significant determinant of the physical well-being of all family members, and particularly that of infants and young children. Arthur Newsholme, for example, one of the best-known investigators of this topic in the late nineteenth and early twentieth centuries, identified poverty as a major corollary of poor sanitation and high infant mortality. In England nearly 80 years ago he wrote, "No fact is better established than that the death rate, and especially the death rate among children, is high in inverse proportion to the social status of the population" (Newsholme 1910).

Similarly, in summing up his classic study of infant mortality in the United States during the first quarter of this century, Robert Woodbury (1925) noted that infant death rates were "highest when the father's earnings were low and lowest when the father's earnings were relatively high." Although Woodbury's findings suggested that several other variables bore a causal relation to infant mortality (e.g., race, physical condition of the mother, age of mother, type of feeding, length of interval between pregnancies), all of these were highly correlated with the earnings of the father. Thus, in summing up the interrelationship between infant mortality, father's income, and the other causative factors, he concluded:

The analysis indicated that low earnings of the father exerted a potent influence over the prevalence of these factors and therefore must be regarded as primarily responsible for the greater mortality associated with them. The presence of intermediate factors in the chain of causation does not lessen the responsibility of low earnings as a primary cause. (Woodbury 1925)

Twentieth-Century Mortality Declines

Mortality rates have fallen dramatically in much of the world since the early days of the twentieth century, although life expectancy values are still lower than 50 years in a number of the lesser developed countries, particularly in Africa. Recent estimates for the more developed countries of North America and Europe place the average life expectancy between a low of 73 years for Ireland and a high of 77 to 78 years for Iceland, the Netherlands, Sweden, and Switzerland (Population Reference Bureau 1989). The primary causes of this enormous mortality de-

cline in the Western world lie in the unprecedented measure of control gained over those infectious and parasitic diseases that until quite recently took such a heavy toll, especially among the younger elements of the population (Stockwell and Groat 1984). Indeed, the most significant mortality trend of the twentieth century has been an extremely pronounced decline in the death rate among children under 1 year of age. In the United States, for example, there has been a 50 percent reduction in the total death rate since 1900 (from 17.2 to 8.6), but the infant mortality rate during the same period declined by approximately 94 percent (from 162 to 10 per 1,000). Moreover, there is evidence that declines of a similar or even greater magnitude have occurred in a number of western European countries since the beginning of the twentieth century (Woods et al. 1988). In contrast to the situation at the turn of the century, when infant mortality rates were of the order of 150 or more, a number of western European countries today have single-digit infant mortality rates; and in three countries (Finland, Iceland, and Sweden), out of every 1,000 babies born only 6 fail to survive until their first birthdays (Population Reference Bureau 1989). In addition, an infant mortality rate of less than 6 per 1,000 is found in Japan, the first non-European country to achieve a high level of modernization.

In sharp contrast to these single-digit infant mortality rates, or even those approaching 15 throughout more or less developed regions of the globe, infant mortality rates of the order of 100 or more per 1,000 live births are still fairly common in the less developed countries of the Third World. Today they are highest in the least developed countries of Africa: 18 countries on that continent have rates of 125 or more, and in at least 4 countries (Ethiopia, Guinea, Mali, and Sierra Leone) the infant mortality rate continues to exceed 150 per 1,000 live births (Population Reference Bureau 1989).

The high life expectancy values and corresponding low infant mortality rates of the more developed countries stand as an impressive testimony to the success of those countries in improving the quality of life of their populations. Conversely, the low life expectancies and corresponding high infant mortality rates in the less developed countries are, as was the case in Europe a century ago, a reflection of the poor quality of life available to the bulk of the population. In particular, they reflect the inability of existing public health programs to deal with evolving health problems, many of which are related to widespread malnutrition resulting, at least in part, from a decline in social and economic progress

(Gwatkin 1980). In other words, on an international level there remains a clear and strong association between level of modernization and the infant mortality rate. In fact, the association is so strong that the infant mortality rate is generally regarded as a much more accurate indicator of the level of socioeconomic well-being of a people than is its per capita gross national product or any of the other more conventional indices of economic development.

Family Income and Infant Mortality in Modern Societies

The infant mortality decline in the Western world described in the preceding section represents one of the truly outstanding achievements of the twentieth century. At the same time, however, it is very clear that this decline has not altered the nature of the traditional socioeconomic differential. Rather, the findings of a wide variety of studies have consistently shown that the lower income groups in all societies have been and continue to be extremely disadvantaged in the probability that their newborn infants will survive to adulthood. According to a recent effort directed by the present author, the existence of a general inverse association between infant mortality and socioeconomic status has been documented by a great many studies based on widely different population groups, covering different points in time, and using a variety of methods, not only in the United States but in a number of western European countries (Stockwell and Wicks 1981). Moreover, a follow-up investigation documented the existence of such a relationship for all race–sex groups and for all major causes of death (Stockwell, Swanson, and Wicks 1986).

This later study entailed an analysis of infant mortality differentials in a metropolitan aggregate comprising eight of the larger cities in the state of Ohio covering the years 1979–81. The general design of the research was an ecological one in which the primary analytic unit was the census tract of the mother's usual residence. (Census tracts are small geographic areas used in the United States to delimit neighborhoods composed of people possessing relatively homogeneous characteristics. They have no political basis, but are merely statistical aggregates that are used primarily for various planning programs and for research.) The independent variable was defined as the percentage of low-income families in each census tract at the time of the 1980 decennial census. An annual income of $10,000, or roughly 50 percent of the median family income, was selected as the low-income cutoff point.

Table IV.3.1. *Infant mortality rates for income areas in metropolitan Ohio, 1979–81*

Income area	Infant mortality rate		
	Total	Neonatal	Postnatal
All areas	16.6	10.6	6.0
I (high income)	8.9	6.3	2.6
II	14.3	9.2	5.1
III	16.4	10.8	5.6
IV	19.7	12.6	7.1
V (low income)	24.3	14.4	9.9

Source: Stockwell, Swanson, and Wicks (1986, 74).

The dependent-variable data consisted of the number of live births in each census tract during 1980 and the number of infant deaths, by age, in the three years centering on the census date (1979–81). The analysis first used the income variable to aggregate the census tracts of the study cities into five broad groups in such a way that an approximately equal number of tracts fell into each income status group. The resulting aggregates were then ranked and compared in terms of infant deaths – total, neonatal (under 1 month), and postneonatal (1 month to 1 year). The results of these comparisons are presented in Table IV.3.1. Inspection of the data clearly reveals the existence of a consistent and pronounced inverse association between infant mortality and family income, with the differential being especially marked for postneonatal mortality, or for those deaths generally considered to be most influenced by the nature of the environment.

Similar observations can be made with respect to both men and women and for both whites and nonwhites (Stockwell et al. 1986). There are occasional deviations from a consistent linear pattern, but they are not sufficient to detract from the validity of the overall conclusion of the research: The traditional inverse association between infant mortality and family income, first documented in the United States in 1925 (Woodbury 1925), continues to be very pronounced; and it characterizes both the neonatal and postneonatal components of infant mortality, for both sexes and for both major racial groups.

Cause of Death

To understand more fully the association between income status and levels of infant mortality it is necessary to undertake a cause-specific analysis to see if the general inverse nature of the relationship can be explained largely in terms of a few selected causes or groups of causes, or if it more or less characterizes all the major causes of death. In this analysis, the census tracts were grouped into three rather than five income aggregates. A preliminary examination of the data indicated that a larger number of groupings would introduce a serious problem of rate instability because of smaller cell frequencies in the more detailed cross-tabulations. Even with only three areas, small frequencies became a problem when specific causes of death were considered; hence, this analysis was confined to the total population, and most of the comparisons were limited to two broad categories of causes of death. These are *exogenous* causes of death (those whose origin is farthest removed from the actual birth process) and *endogenous* causes of death (those whose origin is most closely associated with the physiological processes of gestation and birth). The specific cause groups, along with their identification codes from the ninth revised edition of the *International Statistical Classification of Diseases and Causes of Death,* are as follows:

Exogenous causes
Infectious and parasitic causes (001–139, 320–3, 460–6, 480–7, 500–8, 771)
Injury or poisoning (800–999)

Endogenous causes
Congenital anomalies (740–59)
Conditions originating in the perinatal period (760–70, 772–9)
Residual endogenous conditions (390–459, 470–8, 490–6, and all causes not elsewhere classified)

The overall exogenous and endogenous death rates for the three income areas, by broad age category, are shown in Table IV.3.2. As is conventional with cause-specific rates, the rates in the table are expressed in terms of 100,000 rather than 1,000 live births. Two conclusions are immediately suggested by these data. First, the vast majority of infant deaths today are caused by the endogenous conditions that are most closely associated with the physiological processes of gestation and birth. Second, both the exogenous and endogenous cause-specific death rates are inversely associated with family income. Not surprisingly, perhaps, the strength of the relationship, as measured by the difference between the death rates of the highest and lowest areas, is much greater for the environmentally related exogenous causes such as infections, accidents, and poisonings. The exogenous death rate in Area III is nearly three times greater than that in Area I. By contrast,

Table IV.3.2. *Infant mortality rates (per 100,000 live births) by broad cause-of-death group for income areas in metropolitan Ohio, 1979–81*

Income area	Exogenous causes			Endogenous causes		
	Total	Neonatal	Postneonatal	Total	Neonatal	Postneonatal
All areas	227	69	158	1,432	990	443
I (high)	129	57	72	998	703	295
II (medium)	201	61	140	1,453	1,023	429
III (low)	363	92	271	1,881	1,262	618

Source: Stockwell, Swanson, and Wicks (1986, 87–93).

the Area III endogenous death rate is only twice as great as that of Area I.

There is a tendency for the exogenous causes to account for an increasing proportion of total deaths as income decreases: 11 percent of the infant deaths in Area I compared with 16 percent in Area III were due to exogenous causes. Thus, it is clear that, despite the much lower absolute death rate, the increased risk of an infant dying as the economic status of its parents declines is relatively much greater from environmentally related exogenous causes than it is from endogenous causes. It is true that the inverse association between infant mortality and economic status seems largely due to conditions that can generally be regarded as amenable to societal control. However, this should not lead one to minimize the significance of a consistent and pronounced inverse relationship for those endogenous conditions less resistant to control, which account for the vast majority of infant deaths.

Inspection of the exogenous–endogenous rates for the neonatal and postneonatal ages reveals that the pronounced inverse association with economic status characterizes both of the causal groups for both segments of infant mortality. The more interesting point here, however, is perhaps the challenge these data pose to the traditional distinction between neonatal–endogenous as opposed to postneonatal–exogenous mortality. In the past, demographers and other epidemiological researchers have commonly used the neonatal and postneonatal death rates as proxies for endogenous and exogenous mortality (Bourgeois-Pichat 1952). Yet while the Ohio data show a clear preponderance of endogenous causes in the neonatal period (93 percent), they also reveal a preponderance of endogenous causes among postneonatal deaths (74 percent). The increasing importance of the endogenous causes in the latter period likely reflects the nature of the technological progress made in recent years in enhancing the surviv-

ability of high-risk births. In other words, many infants who a generation ago would have died within a few days or weeks after birth now have a much greater chance of surviving. For some, this change will mean a chance to survive infancy and grow to adulthood leading relatively normal lives. For others, however, it will mean surviving the neonatal period only to succumb later in infancy; the frequency of deaths due to endogenous causes in the postneonatal period thus increases (Miller 1985). In any case, these findings indicate that there is no longer any basis for assuming an age–cause proxy relationship in infancy such as may have existed in the past (Stockwell, Swanson, and Wicks 1987).

Our results demonstrated that the same general conclusions apply to both sexes as well as to the two racial groups: Endogenous causes clearly predominate in all categories, and both cause-specific rates are inversely related to income status for all sex–color groups (Stockwell, Swanson, and Wicks 1988). Moreover, this pattern was also strongly apparent in those few instances where the numbers were sufficiently large to permit a comparison based on more specific causes of death (Stockwell et al. 1988).

Overall, the results of our research show that the basic inverse relationship between infant mortality and socioeconomic status cannot be attributed solely, or even largely, to either group of causes. Although more deaths are due to endogenous than to exogenous causes, and more deaths occur in the neonatal period regardless of cause, the variations in the death rates for both broad cause groups are characterized by a similar marked inverse differential for all major subgroups in the society.

Conclusion

In spite of significant progress in maternal and infant care and an associated substantial decline in infant mortality in this century, our research, as well as that of many other contemporary scholars,

points to the persistence of a strong inverse association between economic status and the probability that a newborn infant will survive the first year of life. Although there are occasional exceptions or various degrees of deviation from a perfectly linear pattern, the overriding conclusion is that infant mortality rates among lower income groups continue to be substantially above those of higher income groups.

This conclusion implicitly assumes that causality runs solely from low income to high infant mortality. But though such an assumption can be justified on the grounds that we are dealing with infants rather than adults, we cannot rule out the possibility that the general inverse relationship reflects two-way causality. That is, the poor health of parents may contribute to lower income, which is such a potent determinant of infant life chances. This possibility does not detract, however, from the validity of the overall conclusion, namely that the infant mortality rate is a powerful indicator of the general health status of a population group.

The fact that infant mortality rates have declined at all income levels obviously indicates that the benefits of new and improved infant health care programs do reach all segments of the population eventually. However, the persistence of the strong inverse association between infant mortality and income status points to the existence of a social class differential in access to health care services and facilities. The first to benefit from advances in medical technology and other health care improvements are those in the highest income classes, and only gradually do the fruits of such progress filter down to the economically deprived groups. This is indicative of an elitist approach to the delivery of health care, and in the Western world, where it is supposed that adequate health care is a basic right for all citizens, and not just an expensive privilege for those who can afford it, this situation presents a major challenge to society.

Efforts to meet this challenge must, of course, be guided by the knowledge that a wide variety of factors associated with a low economic status contribute to the observed differences in mortality, and that each of these factors will require very different kinds of programs to bring them under control. In the past, major efforts focused on those factors that exerted a direct influence on the survival chances of infants, including the adequacy of their diet; the quality of housing, water, and home sanitary facilities; and their immunization status.

These factors, which directly influence exogenous causes (e.g., parasitic diseases and respiratory infections), have already been brought fairly well under control by various public health programs, and what were once the major killers of infants and young children now account for a very small fraction of the total deaths under 1 year of age. Nevertheless, because the exogenous-disease death rates continue to vary inversely with economic status, it is clear that the progress made in the prevention and treatment of these diseases has not benefited all groups equally. There is an obvious need to continue and even accelerate efforts to extend the full benefits of advances in medical knowledge and health care practices to the more economically deprived segments of the population.

By far the biggest challenge today, however, concerns endogenous conditions, which account for about 80 percent of all infant deaths in the United States. These causes, which have traditionally been regarded as less amenable to societal control, reflect such things as social class differences in reproductive behavior (age at childbearing, length of interval between pregnancies), differences in the amount and quality of prenatal care (timing of first prenatal examination, frequency of visits), and other maternal characteristics such as adequacy of diet during pregnancy, amount of weight gain, smoking habits, and the use of drugs or alcohol. These factors generally have an indirect impact on infant mortality through their effect on pregnancy outcome – particularly on birth weight.

It has recently been recognized that a low birth weight seriously impairs an infant's chances for survival. A major policy goal, therefore, should be the prevention of low birth weights. Evidence suggests that efforts to do this must go beyond simply providing more and better prenatal care and concentrate on enhancing the overall quality of life and general health status of low-income mothers (Wise et al. 1985). A similar conclusion applies to less developed countries, where it is also recognized that reducing high infant mortality rates will depend more on general socioeconomic development than on the implementation of conventional health strategies (Gwatkin 1980). In the meantime, we will continue to live in a world where the level of infant mortality serves as a major barometer of the quality of life in any given environmental setting and the overall health status of the population.

IV.4
Measuring Morbidity and Mortality

Sickness and death are individual- and population-level phenomena. At the individual level, they are best understood in terms of their causes. In illness the best prognosis derives from what is known about the cause and about the individual. At the population level, sickness and death can also be understood in terms of incidence. Future rates of sickness and death can be forecast from experience, taking into account the trend and likely variations from it. Population-level statements about sickness and death – morbidity and mortality rates – can be considered statements of comparison. As such, they underlie many judgments about health and health care.

Morbidity and mortality are also structural phenomena, which is to say that, considered for a sizable number of people, they display certain regularities. The most important of these relate to age and appear as curves or schedules when morbidity and mortality data are arranged by age. Age-specific sickness and death rates should not be expected to be identical in any two populations, but their structure – their distribution by age – should be similar. This makes it possible to make estimates for missing data and to compare individual- and population-level experience with sickness and death over time. This essay summarizes the basic method of analysis, which employs a life table, and suggests some ways in which the problem of incomplete information can be overcome with various estimation procedures.

Quantity of Life

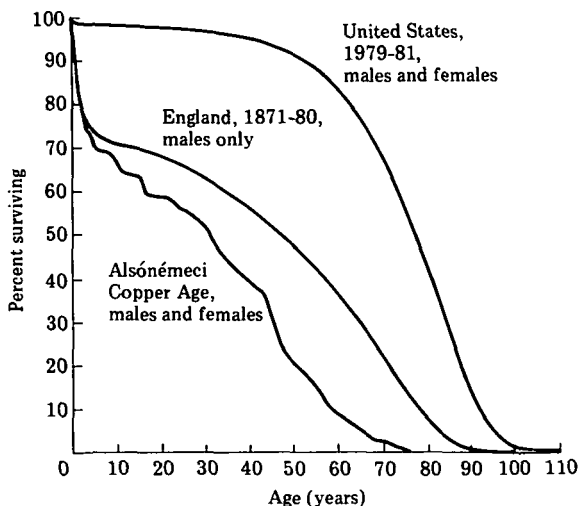
Like other life forms, humans have a characteristic life span, a maximum number of years over which individuals might survive if protected from all hazards. The span is currently unknown. Our only direct evidence about it derives from the age at death of exceptionally long-lived people, and the reliability of this evidence is often marred by poor memory, poor records, and misrepresentation. A few people have lived longer than 110 years, and the number of people surviving to extreme ages has increased over time. But it is not clear – because the evidence is inadequate – whether there has been a change in the maximum age to which individual members of the species survive. Given the very small number of


Figure IV.4.1. Survival curves. (From Acsádi and
Nemeskéri 1970; Commons Sessional Papers 1884–5;
U.S. Decennial Life Tables for 1979–81.)

people who survive to even older ages, the life span
is often estimated at 110 and sometimes at a lower
round number, 100 (Preston 1982).

An alternative procedure for estimating longevity
is based on the attempt to measure the most advanced
age to which people survive in significant numbers. It
can safely be suggested that over most of human
existence the modal age at death – the age at which
more individuals died than at any other – was during
the first year. Among people surviving early child-
hood, however, the modal age at death occurred in
adulthood. Apparently it has advanced over time. A
life table based on skeletal evidence for a Copper Age
population indicates that the number of postinfant
deaths peaked at age 46, but late-twentieth-century
life tables show a much later peak. For example, a
U.S. life table for 1979–81 indicates a postinfant
modal age at death of 83 (Acsádi and Nemeskéri
1970; U.S. National Center for Health Statistics
1985). Estimates of the species-specific life span or
values for the modal age at death are used to show
capacity for survival. Often expressed as a rectangle,
this capacity is a statement about how many years of
life individuals born at the same time might accumu-
late if they avoided hazards.

These estimates have been less important in mea-
suring and comparing health experience than they
will become. The transition can be attributed to a
major change in the pattern of human survival. For
most of the history of the species, the space of life –
the area represented by the survival rectangle –
contained more years of life lost to premature death
than years survived. Figure IV.4.1 illustrates this

history with survival curves for some populations,
the curves showing the number of individuals who
lived at each age.

For most of human history most deaths were pre-
mature, and the survival curve remained concave. It
first became convex in a few advantaged societies in
the nineteenth century. Since then, it has bowed out
in these and some other societies, approaching a
rectangular form. The concave curve can be identi-
fied with the traditional mortality regime, a regime
in which the risk of death was high at every age. The
convex curve is a characteristic of the modern mor-
tality regime. And the convexity itself indicates how
the transition from one mortality regime to the
other has altered the problems associated with mea-
suring mortality. For most of human history, expecta-
tions or hopes about survival have been expressed by
reference to birth. The rectangularized survival
curve directs attention instead toward life span,
modal age at death, or another value intended to
represent a survival goal. In other words, how many
of the people living at the same time can be pro-
tected from premature death, and how long can they
be protected?

The survival curve captures the concepts needed
to compare mortality experiences. The data neces-
sary to plot it are drawn from the life table, initially
developed as a way to set insurance premiums, but
subsequently put to use in epidemiology, biology,
and demography. The estimation of survival curves
and other elements of the life table are commonplace
in historical discussion, although they are more of-
ten implicit than explicit because historians seldom
work with periods and populations for which life
tables exist.

One useful estimate of mortality experience is the
crude death rate, the ratio of deaths in a given year
to the mean population during that year. This rate is
a function of the age distribution as well as the
number of deaths at each age. Consider, for example,
the crude death rates for the United States and
Costa Rica in 1977 – 8.6 and 4.3, respectively. The
lower rate for Costa Rica means a lower probability
of death, but it is lower because the age structure
was different in the United States rather than be-
cause the risk of death was lower at each age. In fact,
Costa Ricans faced a higher mortality risk at most
ages, but the younger average age offset the differ-
ence in risk of death.

The crude death rate is also influenced by migra-
tion. For example, populations receiving immigrants
of a certain age group, say young adults, will appear
to have higher life expectancies based on the record

of deaths than will more stable societies. Although there is often no more than fragmentary information about age structure or migration, the effects of these variables may require that the crude death rate be qualified by a statement concerning its possible distortion. In addition to reasons already mentioned, the crude rate may be misleading if, in a regime prone to epidemics, it is not averaged over several years.

Age-specific death rates can be compared (over time and space) in the form of the survival curves in Figure IV.4.1. Comparisons can also be made on the basis of age-standardized death rates, which adjust age-specific rates for a standardized population (this procedure and others are explained by Shryock et al. 1973). The reason for making these calculations of death rates is to compare two or more populations on the same terms, eliminating the effects of differences in age structure. (This procedure can also be applied to other characteristics according to which mortality or morbidity rates may differ, such as sex, residence, occupation, and marital status.)

With information about the size of a population,

the age of its members, and the number who die at each age – or plausible estimates of these quantities – it is possible to build a life table such as the one for Sweden during 1751–90 presented in Table IV.4.1. The table begins with a radix, or base population – in this case 10,000. The probabilities of death at each age, the basic quantities of the life table, are derived from age-specific death rates. Both the death rate and the probability of death at an age have the same numerator – the number of deaths at that age within a specific time period. But their denominators differ. For the death rate, the denominator is the mean population at that age over the period studied, and for the probability of dying, it is the population at that age at the beginning of the period under study. This difference is usually minor, except when one is considering the probability of death between two ages that are separated by a number of years (e.g., from 5 to 10) and except for infants.

A current, or period, life table makes use of death rates for all ages at a given time to provide a cross-sectional picture of a stationary population. Its val-

ues for life expectancy and other quantities are termed hypothetical because the death rates used to construct it apply to people at each age in the current population; the history it relates refers to a hypothetical cohort, because the people alive at this time may have been subject to different death rates in past years and may be subject to differences again in the future. A cohort, or generation, life table follows the experience of one cohort from birth to death. Its values are not hypothetical, but a cohort table cannot be constructed until all members of a cohort have died. Thus, a current table, like that in Table IV.4.1, is preferred for many uses.

When populations are small, as Sweden's population was in the eighteenth century, and when death rates fluctuate from year to year, it is customary to average experience over several years. Table IV.4.1 is also an abridged table, meaning that it provides values only for benchmark ages. Those in between can be interpolated. Because the number of years lived by the cohort at high ages is so small, the custom is to close the life table at an age that is lower than that of the oldest survivor and to sum the years lived at all higher ages. The accumulated years lived by the actual or hypothetical cohort, which is the sum of years lived in each interval, provides the information necessary to calculate life expectancy. From Table IV.4.1 life expectancy at birth (35.2) is the sum of all years lived by the hypothetical cohort (351,935) divided by the radix population (10,000); life expectancy at age 20 (38.3) is the sum of years lived after 20 (222,369) divided by the number surviving to 20 (5,807).

What makes the life table so useful for historical investigation is its capacity to represent a sequence of events over a long span. Thus, the life table has been used to estimate changes in the prevalence of specific diseases over time. Although the events of interest in this essay are mortality and episodes of morbidity, other events, such as marriage and divorce, can also be followed, as can conditional events, such as deaths among people already ill. Age-specific death rates are conditional because they depend on survival to each age. The population whose experience is followed over time may be select in the sense that its members differ in significant ways from the general population. The life table need not begin at birth or be limited to single events. More complex models treat contingent events that occur in stages, such as the evolution of cancer, with its various outcomes and probabilities at each stage. The concept can also be applied to the longevity of political regimes or credit instruments.

Because historians often know or can reliably estimate the death rate at a few ages but not throughout the life course, it is helpful to employ model life tables to make inferences about other ages or to estimate the overall structure of mortality. Model tables are based on the observation that mortality risks show some regularities over time. Populations that have low death rates at one age are likely to have low death rates at other ages, and vice versa. The regularities can be seen by plotting the mortality schedule, which consists of a line linking age-specific probabilities of death. (When the change from one benchmark to another is high, it is convenient to plot values on paper with a vertical logarithmic scale. On this scale an exponential rate of change appears as a straight line.) Figure IV.4.2 shows that the form of the mortality schedule resembles a misshapen W across the survival rectangle. Over time the W-curve has usually shifted down, so that at each age lower mortality rates are reported for recent, as opposed to past, populations.

Close scrutiny of life tables from a variety of populations shows that the W-shape is preserved across time, but that it displays some irregularities. In some populations the risk of death is greater at some ages than it is in other populations. In Figure IV.4.2, for instance, the angle of change in the mortality risk varies among the three populations, most evidently at adult ages. As can be seen, the U.S. 1979–81 schedule is lower than the other two, yet its rate of increase between ages 40 and 80 is steeper. But for these variations, model life tables would suggest all other age-specific mortality rates when only one was known. Because of these variations, demographers have fashioned groups or "families" of model life tables, each representing a variation on the basic form. One widely used collection of model tables provides four families, styled West, North, South, and East, and a variety of mortality schedules or levels (Coale and Demeny 1966; McCann 1976). With model tables, which are most readily conceived from their survival curves, incomplete information about mortality experience in a given population can provide the basis for a plausible estimate of complete experience.

Life expectancy, which incorporates age-specific death risks, is a convenient value for making historical comparisons. Over time, life expectancy at birth has advanced, and the story of that advance is part of the history of mortality and the mortality revolution. Whereas life expectancy is most commonly used as an estimate of the average remaining lifetime at birth, it also captures changes in death rates
Figure IV.4.2. Mortality risk for medieval Hungary, England (1871–80), and the United States (1979–81). (From Acsádi and Nemeskéri 1970; Commons Sessional Papers 1884–5; U.S. Decennial Life Tables for 1979–81.)

at different ages. During the modern period of mortality decline, which began in the eighteenth century and has not yet ended, the risk of death did not decline in a uniform way across the age spectrum (Perrenoud 1979, 1985; Imhof 1985). In northwestern Europe, for example, the decline during the eighteenth century was concentrated among infants, youths, and young adults. Other age groups joined the shift toward declining risks later.

Life expectancy commonly appears to increase to a greater extent when measured at birth than when measured at higher ages. That is, the risk of death has declined more in infancy (up to age 1) than at any later age. It is often reported that life expectancy at higher ages, especially in adulthood, has changed relatively little over time. In some ways this is misleading. Thinking once more in terms of the survival rectangle, a disproportion is apparent in the time at risk. At birth some members of a population might be expected to live 110 years. But at each higher age their potential survival time is bounded by the human life span; it diminishes as age rises. In short, life expectancy can also be construed as an indication of how much of the available space of life has been used.

By turning our attention toward both birth and

some representation of maximum survival and by reporting an age-specific measure of mortality at several points within the life course, we obtain means of detecting more subtle changes in mortality experience. Whereas life expectancy represents the average remaining lifetime, another measure, years of potential life lost (YPLL), compares the average span achieved with the number of years that it can plausibly be supposed a population might survive. Because that value is indefinite, no convention yet exists for measuring YPLL. The U.S. National Center for Health Statistics presently uses a base of 65 years. That gauge assigns greater weight to causes of death the earlier those causes intervene, and no weight to causes that intervene at ages above 65.

Although not yet applied extensively to historical investigations, the YPLL provides a way to think about the degree to which different societies succeed in controlling mortality. If the YPLL is not adjusted for changes over time, more modern societies will systematically appear more successful than earlier societies because they have higher life expectancies. But judgments about success need not depend on the assumption implicit in this comparison, the assumption that all societies have the same potential for increasing the years its members can expect, on average, to live. If the ceiling is adjusted – perhaps using changing modal age at death – different interpretations of changes in survival may emerge. If the ceiling is adjusted with an eye on one or a few causes of death of particular interest, societies can be compared according to the efficacy of their control over leading diseases (see Preston, Keyfitz, and Schoen 1971).

Quality of Life

Mortality rates and other statistics derived from them imply that we have measures for the number of years survived. Yet equally measured mortality levels may represent quite different qualitative experiences. In search of ways to capture the quality of life, researchers have selected mortality indexes believed to be more revealing, such as infant or maternal mortality, and have combined vital and economic statistics. One index, used widely to compare the quality of life in Third World countries, is the Physical Quality of Life Index, which uses a weighted average of several demographic and economic statistics (Morris 1979). It has some possibilities for application to historical societies for which equivalent data are available.

A more promising approach to the quality of life draws on health statistics. Unlike mortality, ill health – morbidity – is not an unambiguous quantity. Individuals and societies make different decisions about the threshold between health and ill health, and these decisions raise problems concerning definitions and measurements of ill health. Some standard gauges rely on diagnostic evidence; these are encountered in reports of the number of cases of specific diseases identified in a given region and period. Other gauges are based on contact with health institutions or personnel (hospitalizations, physician visits). Still others depend on evidence about individual performance, such as restricted activity, bed disability, or work time lost; these measures are often encountered in insurance records and health surveys. Because different sources provide different forms of evidence, the important point is to find a gauge whose definition is consistent (Riley 1989).

Morbidity also differs from mortality in its complexity. Different questions are at issue. A morbidity rate may express the number of times members of a population fall ill during a period (incidence), the proportion of the population ill at a given time (prevalence), or the amount of time spent in illness by a population during a given period (duration). To take only the two extreme cases – incidence and duration – the age-specific risk of falling sick (incidence) is concave and resembles the inside of a shallow bowl, and that of being sick (duration) looks like the misshapen W identified earlier. Figure IV.4.3 provides examples of these morbidity curves, using Friendly Society records from nineteenth-century Britain (Riley 1987). Like the mortality schedule, the morbidity schedule may move up or down over time, a factor influenced by objective health experience and by subjective decisions about the threshold between health and ill health. Individual curves are likely to vary from these forms, especially when the characteristics of the population under observation change over time. For example, the National Health Interview Survey shows a morbidity schedule with a slower rate of increase at higher ages, a factor attributable in part to the exclusion of institutionalized members of the population from the survey (National Center for Health Statistics). More investigations of health experience in historical societies will help identify the causes of variation (Larsen 1979; Beier 1985; Pelling 1985).

Morbidity rates in turn can be used in association
Figure IV.4.3. Morbidity rates for nineteenth-century Britain. (From Nelson 1982.)

with mortality rates to estimate the number of ill-health episodes to be expected in the average remaining lifetime or, alternatively, the proportion of lifetime remaining to be spent in ill or good health. The technique makes use of age-specific morbidity rates in combination with mortality risks in the life table. The health expectation, sometimes called the active life expectation, uses the age-specific risks of mortality and being sick to estimate the remaining lifetime and the portion of that time to be spent in good health (Riley 1989).

If changes in ill-health rates paralleled those in mortality rates, the two rising or falling together, then morbidity risks and health expectation could be estimated from mortality risks. But investigation of the association between mortality and morbidity suggests that the straightforward form of this tie – deaths are attributed to ill health – belies the statistical and population-level associations. Rates of falling sick and being sick change independently of mortality rates, which is to say that the risk of dying once one is sick changes over time. The association is conditioned by environmental forces, such as therapeutic regime or standard of living, and by changes in the composition of the

population that can be attributed to mortality. For example, insurance records and health surveys show that the mortality decline of the twentieth century has been accompanied by increased duration of ill health at each age (Alter and Riley 1989).

In other words, the proportion of people dying from a given disease or injury – the case fatality rate – has shifted. Changes have occurred in the percentage of people surviving, a concept dramatically illustrated by the history of diseases that vary in virulence or that cause death much more often among people with no prior contact with them than among people relatively resistant to them, and familiar also in terms of changes in the efficacy of therapies. The case fatality rate is a useful way to measure the severity of diseases that have a short course. For chronic diseases, however, it is necessary to consider the prolonged duration of an ailment and the likelihood of death from another cause during its course. A related notion, which might be termed case duration, is the time between onset and resolution. That period may change as diagnostic practices shift or as a population's view of the ill-health threshold or its recognition of ill-health episodes changes. And it may also shift when new therapies are introduced. Because, with notable exceptions, case fatality rates as high as 50 percent have been rare, it is apparent that most ill-health episodes are resolved in recovery. Even in acute diseases, duration has been an important element in the disabling effects of illness, injury, and collective violence.

Variations

Some leading causes of variations in mortality and morbidity include sex, income, residence, season, and disease profile. Separate tables are usually calculated for each sex because of differences in male and female experience, which are partly biological and partly environmental in origin. Figure IV.4.4 shows two forms of this variation by exhibiting mortality curves for men and women in Sweden during 1816–40 and 1979–83. In recent centuries male mortality has exceeded female mortality at most ages, a characteristic that seems to suggest a biological advantage for the latter (Verbrugge 1985).

Socioeconomic status is another well-recognized cause of variation in mortality. Wealthier members of a population, in the aggregate, face lower health risks, although the causation appears to operate in
Figure IV.4.4. Mortality schedules for Sweden, 1816–40 and 1979–83. (From Sundbarg 1970; *Statistisk årsbok för Sverige* 1986.)

both directions: Greater wealth is partly an effect of lower health risks and partly a cause.

Disease-Specific Measurements

Mortality records identifying cause of death lend themselves to disease-specific measurements and to analyses of trends of individual diseases and disease profiles (Preston et al. 1971; McKeown 1976). Although the size of the population at risk of death is often unknown for periods before the twentieth century, the annual number of deaths constitutes a denominator.

Heterogeneity

Average experience within a group can be a useful indicator, but there are many instances in which the average, and variations on it, are misleading. These occur when the distribution of vital events within a population is uneven. Thus, life expectancy at birth is a misleading measure of survival in seventeenth-century Europe because deaths occurred with two modes, infancy and late adulthood. This example is well known, and authorities regularly point to the rapid increase in life expectancy among people who survived infancy and early childhood. Irregular distributions – those taking a form

other than the normal or bell curve – are often encountered. They signal something called heterogeneity – incompatible or nonproportionate elements. For example, future health is in part a function of prior health, so that some authorities suggest that a cohort divides itself into two modes, one with a high and the other with a low propensity to be sick. Thus, an average figure – such as the average age for retirement, 65 – may misstate cohort experience in such circumstances.

Members of the same cohort may have disparate health experiences, in ways just suggested, but the likelihood of disparity is greater still when different cohorts are compared. The health experiences of a cohort are shaped by the circumstances encountered at each stage in life, so that each cohort accumulates a unique health history. In modern advantaged societies these differences remain, but their magnitudes are such that they have little measured effect on basic vital statistics. Thus, life expectancy at a given age varies little in the short run. But in historical populations the disparity may be marked. In seventeenth-century England, life expectancy at birth shifted dramatically from cohort to cohort. The population alive in 1750, for example, included individuals who had survived such disparate events as the plague of 1665 and the as yet incompletely identified forces of the mid-eighteenth century favoring mortality decline. Sporadic epidemics caused the number of deaths and the death rate to fluctuate, with the result that the number of years lived by each cohort varied between wide boundaries (Wrigley and Schofield 1981). This shifting cohort pattern is a historical rhythm that deserves recognition.

IV.5
Stature and Health

In conventional terms the standard of living has become practically synonymous with a material standard, and consequently the concept has most often been equated with and measured by per capita income. Yet it can be interpreted much more broadly to encompass the psychological and biological dimensions of human existence (i.e., the quality of life in all of its manifestations). Distinguishing among these components of well-being would not add much that is conceptually meaningful to our understanding of the past if they all correlated positively and perfectly with one another. But recent empirical evidence has tended to show the importance of not conflating them into one concept.

Historians have begun to explore ways to illuminate this issue from another perspective, namely by considering the biological standard of living as an equally valid measurement of human well-being (Komlos 1989). One approach has been to study the health of historical populations, though

this avenue is obviously limited by the scanty systematic evidence at our disposal (Riley and Alter 1986). Another approach has been to consider mortality an integral component of welfare and, in fact, to incorporate mortality into the conventional index of the material standard of living (Williamson 1981, 1982; Davin 1988). Yet this attempt to collapse the biological and material standards of living into a single index is vexed by the inherent difficulty of gauging the monetary value of human life.

Still another promising approach, and one with an abundant evidential basis from the seventeenth century onward, is anthropometric history, meaning the analysis of secular changes in human height, weight, and weight for height (Tanner 1981; Fogel 1987; Komlos 1987; Ward 1987; Riggs 1988; Cuff 1989; Floud and Wachter 1989). This way of looking at the issue acknowledges outright the inherent multidimensionality of the standard of living, and furthermore assumes that the several dimensions might be orthogonal to one another, which is to say that they generally cannot be collapsed into one indicator. The agenda of this research program is to construct indexes of the biological standard of living of various populations over time, by social class and gender if possible, and to ascertain how this indicator correlates with the material standard of life conventionally conceived.

Anthropometric measures are an important part of this research program, because they enable one to quantify nutritional status, which hitherto has eluded historians. This line of reasoning is based on medical research, which has established beyond doubt that the net cumulative nutritional intake of a population has a major influence on its average height, with maternal nutrition also playing a significant role (Fogel, Engerman, and Trussel 1982; Falkner and Tanner 1986). Thus, height at a particular age, as well as the terminal height attained by a population, is a measure of cumulative net nutrition: the food consumed during the growing years minus the claims on the nutrients of basal metabolism, of energy expenditure, and of encounters with disease (Tanner 1978). As nutritional status increases, more calories and protein are available for physical growth, and the closer individuals and populations come to reaching their genetic potentials of height.

The terminal height an individual reaches in a given population is also influenced by genetic factors, but this consideration does not affect studies of

the evolution of human height as long as the genetic composition of the population is not dramatically altered by large-scale migration.

Holding the genetic composition of the population constant, nutritional status, measured by height, is at once an indicator of exposure to disease and of health in general. It correlates positively with food consumption and with life expectancy, and consequently shows how well the human organism thrives in its particular economic, epidemiological, and social environment (Friedman 1982). Consequently, height is a much more encompassing variable than are real wages and has the advantage in a historical context of being available for groups, such as subsistence peasants and aristocrats, for whom real wages are not pertinent.

Food consumption in prior centuries was the major component of total expenditure (Cipolla 1980), and therefore height can also be used as a proxy for real income. The positive relationship between height and income has been amply documented for twentieth-century populations, for which both variables are available (Steckel 1983; Brinkman, Drukker, and Slot 1988). Yet some caveats are in order. The distribution of income has been found to affect the mean stature of a population. Furthermore, the composition of the food consumed is also of some consequence, because the mix of calorie and protein intake is important to the growth process. This question of mix is complicated by the fact that protein is made up of many amino acids, and it is the combination of amino acids, not only their absolute quantity, that ultimately influences growth and physical well-being. Finally, food consumption obviously depends not only on real income, but also on the price of food relative to all other products. In a society in which commercialization has not proceeded very far, the availability of industrial products might be limited and therefore their prices are high. Once the availability of industrial goods increases through market integration, the structure of food consumption might change discontinuously and rapidly as a consequence of substitution. Economic development might also lead to the introduction of new products, such as coffee, tea, or sugar, that could be perceived as substitutes for some nutritious food items. This, in turn, may lead to shifts in the demand for food independently of any changes in income per capita. These constrictions indicate clearly that the analysis of the stature of a population is not a mechanical exercise.

In spite of these caveats, the results of anthropo-metric research have been quite revealing. Height has been shown to correlate positively with socioeconomic variables. For instance, the height of French recruits born in the late 1840s depended on their education and wealth. Illiterates averaged 164.3 cm, whereas those able to read and write were 1.2 cm taller. Presumably literate men were wealthier and spent more time at education and less at labor than did illiterate men (Le Roy Ladurie and Bernageau 1971). Another interesting finding is that by the early eighteenth century the height of the colonial North American population was already well above European norms, which implies that the ecological (and nutritional) environment of the New World was especially favorable from the human–biological point of view (Sokoloff and Villaflor 1982). Although slaves appear to have been neglected as children, even they benefited from the abundance of food in colonial North America, because as adults their height was close to that of the white population and above that of the European peasantry (Steckel 1986). In contrast to that of early North Americans, the nutritional status of the poor boys of London seems to have been truly miserable at the end of the eighteenth century. They were shorter than practically all modern populations, with the possible exception of such groups as the Lume of New Guinea (Eveleth and Tanner 1976; Floud and Wachter 1982).

Yet there were several instances in which the trends in heights and in per capita incomes diverged from one another. They occurred during the early stages of rapid economic growth: in east central Europe during the second half of the eighteenth century, in late-nineteenth-century Montreal, and in the antebellum United States. In the United States, the stature of army recruits declined by more than 2 centimeters beginning with the birth cohorts of the 1830s, even though according to conventional indicators the economy was expanding rapidly during these decades. Between 1840 and 1870 per capita net national product increased by more than 40 percent (Gallman 1972; Fogel 1986; Komlos 1987). In the Habsburg monarchy the decline in stature during the course of the second half of the eighteenth century was at least 3 but more nearly 4 centimeters. A similar pattern was found for industrializing Montreal. The birth weight of infants there fell after the 1870s, indicating that the nutritional status of the mothers was declining. Such anthropometric cycles were not known to exist previously (Ward and Ward 1984; Komlos 1985).

Determining the extent to which these episodes were accompanied by a deterioration in the epidemiological environment requires further study, but it is already clear that all three were, in fact, characterized by a decline in per capita nutrient intake. In the New World, periods of nutritional stress were accompanied by rapid economic growth, during which, by conventional measures, the material standard of living was rising. This might be considered an anomaly because an increase in per capita income normally implies that food consumption, too, is rising. It becomes less anomalous, however, once one notes that although income determines the position of the demand curve for food, an individual who purchases food at higher market prices might consume less of it than a self-sufficient peasant isolated from the market by high transport and information costs, even if the measured income of the former is larger than that of the latter. Moreover, contemporaneously with the decline in human stature in the antebellum United States, the crude death rate was increasing even as per capita income was rising, supporting the notion that the biological standard of living was declining (Pope 1986).

The divergence in biological and conventional indicators of well-being can be explained by several other factors. The examples of economic growth already provided were accompanied by rapid population growth and by urbanization. This increased the demand for food at a time when the agricultural labor force was growing more slowly than the industrial labor force and the gains in labor productivity in agriculture were still small. Hence, supply did not generally match the increased demand for food, and food prices rose relative to those of all other goods.

The relative price of food also rose because rapid technological change in the industrial sector brought with it a decline in all other prices. The rise in the relative price of food was greatest in areas that had previously been isolated from industrial centers. Early stages of growth were generally accompanied by market integration, and this meant that in some regions the price of food, relative to that of all other goods, rose sharply. This brought with it the potential for large movements along the demand curve for food in these regions. In addition, new products changed consumers' tastes and might also have been seen as substitutes for traditional food products. Thus, although the real wage might have risen in the industrial sector, it did not rise as fast as food prices. Even farm operators

whose income rose as fast as food prices decreased their food consumption because the price elasticity of demand for food was greater than the income elasticity.

In east central Europe the fall in nutritional levels was initiated not by sectoral shifts from the agricultural to the industrial sector, but by rapid population growth pressing on scarce resources. In contrast to the situation in the United States, in Europe the quantity of land was fixed, and therefore population growth ran into Malthusian ceilings (Komlos 1985). The subsequent limited quantity and the rise in food prices meant a fall in consumption, particularly of meat products, because the price of a calorie is much greater if purchased through meat than if purchased through grain. This fall in the intake of animal protein, an important component of nutritional status, made it more difficult for the body to fight off nutrition-sensitive diseases. Of course, during the early stages of economic growth, individuals were usually not well informed about the importance of a balanced diet and therefore were unaware that changing their food habits would impinge on their nutritional status and health.

To be sure, not all members of the society experienced nutritional stress during the early stages of economic development. In the United States the income of the urban middle class rose sufficiently in the 1830s and 1840s to keep pace with the rise in the price of foodstuffs and, at least initially, to permit that group to maintain its nutritional status. Not until the Civil War disrupted the flow of nutrients did their biological well-being begin to suffer as well. In a similar fashion, Habsburg and German aristocrats were not affected by the Malthusian crisis of the eighteenth century, but rather increased their height advantage considerably compared with the lower classes (Komlos 1986, 1990).

Height therefore correlates positively with social class. In Germany, aristocrats were 3 to 7 centimeters taller than middle-class boys throughout adolescence. The latter in turn were about 8 centimeters taller than boys with lower social standing of the same age. Boys attending prestigious military schools in Austria, England, France, and Germany were all much taller than the population at large. For instance, adolescents of the English gentry were at least 20 centimeters taller than the nutritionally deprived slum boys of London (Floud and Wachter 1982; Komlos 1990).

Yet another pattern is that propinquity to nutri-

ents is a crucial determinant of nutritional status in preindustrial societies and in societies caught in the early stages of economic development. In such circumstances per capita income is not as important a determinant of human stature as is the availability of food. In the eighteenth-century Habsburg monarchy, recruits from areas with a large agricultural sector, even if the economy was relatively underdeveloped, were well nourished by the standards of the time compared with those from industrially more advanced provinces. Being isolated from markets by high transportation and transactions costs had its advantages as long as population density did not exceed the carrying capacity of the land, because the subsistence peasant families had little choice but to consume all of their own food output. Once they became integrated into a larger market, however, rising food prices and their sales of agricultural commodities tended to impinge on their own food intake.

Similarly in the antebellum United States, white southern men were 1.5 centimeters taller than their counterparts in the more industrial North, even though per capita income was greater in the latter region (Margo and Steckel 1983). The same pattern held between England and its colonies. Although in the eighteenth century England had a higher per capita income, perhaps by as much as 25 percent, its soldiers were considerably shorter than their counterparts in the British colonies of North America. A century later, Irish-born recruits into the Union army during the Civil War were also taller than soldiers born in England, although English per capita income was certainly higher than that of the Irish (Mokyr and O'Gràda 1988).

Indeed, the importance of remoteness for nutritional status can be seen from the fact that in 1850 the tallest population in Europe was probably found in Dalmatia, one of the least developed areas of the Continent. This relationship reappears in an astounding form at the end of the century: Although Bosnia-Herzegovina was certainly among the least developed parts of the Habsburg monarchy, its population was nonetheless the tallest (Austrian Bureau of Health 1910).

All of this evidence corroborates the notion that being close to the supply of food during the early stages of industrialization had a positive effect on nutritional status, possibly because the costs of obtaining food were lower. In addition, rural populations doubtless benefited from a lower exposure to disease than those crowded into an urban en-

vironment. Another probable reason for the difficulty of maintaining nutritional status during the initial phase of economic development is that income distribution is more uneven during such phases than at other times. The changes in entitlement to goods, with the rise in food prices, cause many to lose their ability to "command food" (Sen 1981).

In summary, because height is a good proxy for nutritional status, it is employed to measure the biological well-being of populations of the past. The biological standard of living indicates the extent to which ecological circumstances are favorable to the functioning of the human organism. The concept encompasses such aspects of human biology as life expectancy, morbidity, and public health. Moreover, in the developed economies of the twentieth century, height correlates positively with per capita income not only because of the rise in food intake, but also because of improvements in public health and medical technology.

Yet the evidence presented here also implies that economic growth can be accompanied by a fall in nutritional status. Hence, the biological standard of living can diverge from real incomes during the early stages of industrialization. This pattern is not anomalous, because gross national product has generally grown more rapidly than the agricultural sector, and in some cases per capita food consumption has fallen. But it does mean that per capita income can be an ambiguous measure of welfare during the early stages of economic development. A rise in average per capita income is of ambiguous benefit if it is distributed unevenly and if some members of the population lead less healthy lives as a by-product of economic change. Of course, in the long run the ambiguity disappears, because the productivity of the agricultural sector improves and relative food prices decline. Hence, the share of food in consumer budgets fell in Europe from about 75 percent to about 25 percent, or even less, of income. Yet for the early stages of industrialization recent anthropometric research indicates that the conventional indicators of welfare are incomplete; they must be supplemented with a measure, such as human stature, that illuminates the biological well-being of a population.

PART V

The History of Human Disease in the World Outside Asia

V.1
Diseases in the Pre-Roman World

In the past 15,000 years, epochal social and cultural changes have created fundamentally different relationships between humankind and the environment. One of the most important innovations has been the domestication of plants and animals, a major factor in the gradual establishment of agriculture as the world's predominant economic base. The development of agriculture brought an increase in sedentism, in which human groups lived in more or less permanent communities.

Associated with farming was the domestication of animals and, in some societies, nomadic pastoralism. By about 6000 B.C., animal husbandry provided a relatively widespread and stable source of high-quality protein in the Near East. Moreover, the protein was typically produced in ways that did not compete directly for agricultural land resources. Domestic herds grazed on agricultural land after the harvest (Bentley 1987) or on land that was fallow, marginal, or inadequate for farming.

The greater control that agriculture and the domestication of animals gave people over food production resulted in food surpluses. Surplus food created the potential for the emergence of specialists such as craftsmen, merchants, and a ruler class, which are essential components of urban society, another major social change. Urbanism began in the Near East during the Chalcolithic Age (c. 4000–3200 B.C.) but had its major efflorescence during the Early Bronze Age (c. 3200–2000 B.C.)

The advent of agriculture, the domestication of animals, and the development of urbanism had a significant impact on human health. Although agriculture dramatically increased the calories that could be produced by a given individual, the emphasis on a few cultigens increased the vulnerability of agricultural societies to famine and malnutrition (Cohen 1984a). Innovations associated with agriculture, such as irrigation, greatly heightened exposure to some infectious diseases. Plowing the soil itself probably increased the risk of acquiring fungal diseases. Sedentary communities, unlike hunting and gathering societies, which usually changed their living areas often, lived amid their own detritus with its inherent risk of causing disease (Wells 1978). The domestication of animals brought the

potential of contracting animalborne diseases (zoonoses). Urbanism brought increased population sizes and densities and a greater likelihood of exposure to dropletborne infectious agents. Extended trade and commerce, activities associated with urban society, enhanced the spread of infectious organisms between geographic areas (Cockburn 1963).

However significant these changes were, direct evidence of their having caused disease is difficult to obtain. Paleopathology, the study of ancient disease, is hampered by several limitations. Two of the most important of these are the nature of our sources and the way in which we study and interpret the data.

Our current sources of data on disease in the pre-Roman world include ancient texts that describe disease, archeological cultural artifacts that portray the effects of disease on the human body, and human skeletal and mummy remains recovered from archeological sites. There are many difficulties in utilizing some of these sources.

Although skeletal and mummy remains would appear to be a promising source of information, most diseases suffered by individuals in antiquity, and many that caused death, leave no evidence in soft-tissue remains or in bone as observed by gross or microscopic methods. In addition, attributing the relatively few conditions that do occur in the skeleton to a specific morbid syndrome is often difficult. These problems make the interpretation of the biological significance of skeletal disease difficult. However, although our sources may have limitations, much can be learned if these restrictions are kept in mind. Even tentative observations can provide the basis for further clarification and/or debate. We are hopeful that current avenues of research will provide new data and stimulate the development of new methods. For example, the work of M. Y. El-Najjar and colleagues (1980) and that of N. Tuross (1991) suggest the possibility of recovering immunoglobulins from archeological tissues, including bone.

The second and perhaps most serious limitation to the study of prehistoric human disease is that imposed by the methodological and theoretical inadequacies of current research. There is no universally accepted descriptive methodology that ensures comparability between published sources, which hampers any attempt to integrate the data presented in the literature. In addition, as will be discussed in relation to infectious diseases, paleopathology has not yet reached a theoretical consensus on the significance of many skeletal diseases.

In spite of the limitations and problems in the field of paleopathology, we have attempted some in-

terpretation of the data. In addition, we have included findings of other researchers who have sought evidence of trends of certain conditions for sites in specific geographic regions. However, we strongly emphasize the tentative nature of these findings and the need for greater methodological rigor in future research.

In this essay, we focus on research involving human physical remains from the Old World, beginning with the Mesolithic period (about 10,000 B.C. in the Near East) and ending with the emergence of the Roman Empire. Because of the considerable chronological and geographic scope of the essay, and because of the complexity of understanding disease in antiquity, particularly in relation to modern medical experience, we briefly discuss some relevant concepts, trends, and factors.

First, it must be emphasized that the transitions between hunter-gatherer, agricultural, and urban societies occurred at various times in different areas of the Old World. For example, while the Near East was in the early stages of farming with some town life (c. 8000–5000 B.C.), Europe was still at a hunter-gatherer subsistence level. Therefore, at a specific point in time the health problems encountered by the human populations in these two areas were different.

Second, the relationship between humans and disease is continually evolving. Over time, the virulence of infectious organisms tends to become attenuated, while the human host population tends to evolve a more effective immune response to infectious organisms (Cockburn 1963). The implication of these two trends is that with the passage of time a given infectious disease is likely to become a less serious threat to life and develop a more chronic pathogenesis.

Third, the expression of disease can be influenced by many factors (e.g., age and environment). In general, the risk of disease increases with the age of the individual. With the exception of many Third World countries, people today live 30 to 40 years longer than they did in antiquity. This greatly increased longevity is a very recent development in human history and means that the prevalence of many diseases common among modern Western peoples, such as cancer and heart disease, is probably much greater than it was in antiquity. Environmental conditions, both geographic and cultural, can also influence the expression of disease. For example, exposure to smoke from wood-burning fires may be a factor in the prevalence of nasopharyngeal tumors in archeological skeletons (Wells 1977).

Finally, a helpful distinction can be made between specific and nonspecific disease (Buikstra 1976). *Specific disease* refers to those conditions in a skeleton that can be attributed to one of a fairly limited number of disease syndromes (e.g., anemia or leprosy). *Nonspecific disease* is an abnormal condition of a skeleton (e.g., periostitis, dental hypoplasia, and Harris's lines) that cannot be attributed to a discrete morbid syndrome. In a sense, specific and nonspecific diseases represent the polar extremes of a conceptual gradient.

In samples of archeological human skeletons, approximately 15 percent show evidence of significant disease. The incidence of specific disease syndromes varies among geographic areas and cultures, as does the expression of diseases, but generally the most common pathological conditions seen in archeological human skeletons include trauma, infection, arthritis, and dental disease. These conditions will be the focus of our discussion. In addition, because of current interest, we will briefly discuss anemias and tumors. Most of the other general categories of disease (e.g., dysplasias and metabolic diseases) are represented by at least one syndrome that affects the skeleton, but archeological evidence for these syndromes tends to be rare. Differential diagnosis is often difficult, and low frequencies create severe limitations in reaching paleoepidemiological conclusions.

Trauma

Trauma is a pathological condition that varies in type and frequency depending on culture and physical environment. Trauma to the skeleton can be divided into two categories: (1) accidental or unintentional trauma, such as fracture that results from a fall, and (2) intentional trauma or injury purposefully caused by another human being. Intentional trauma includes injury resulting from violence (Figure V.1.1) in warfare or interpersonal conflict, which may result in broken long bones or a fractured skull, as well as trauma induced by a therapeutic procedure.

One of the most remarkable forms of trauma in antiquity was a surgical procedure known as trephination, whereby a portion of the skull was removed, great care being taken to avoid penetration of the underlying dura. Trephination was first reported for Paleolithic Poland (Gladykowska-Rzeczycka 1981). The procedure apparently became more common in the Neolithic period, in France, England, Denmark, Germany, Italy, and Russia, and it continued into the Middle Ages (Steinbock 1976). Trephined skulls have also been reported from the Near East for the Neolithic period through

Figure V.1.1. Probable unhealed ax wound in an adult male skull from a rock tomb at Lisht in Upper Egypt dated between the Twentieth and Twenty-fifth Dynasty (c. 1100–655 B.C.). Bone fragment produced by the blow at the time of death is reflected to the right. Note the lack of remodeling on the cut surface indicative of death at the time of or shortly after the trauma. (From Catalog no. 256384, National Museum of Natural History, Washington, D.C.)

the Iron Age (Wells 1964a; Lisowski 1967; Ortner and Putschar 1981; Rathbun 1984) and from the eastern Mediterranean for the Bronze and Iron ages (Ortner and Putschar 1981; Grmek 1989); however, in the Near East and eastern Mediterranean the practice apparently was not common.

Evidence of healing, as indicated by antemortem remodeling of cut edges in trephined skulls, is common. But even when there is no evidence of healing, death may have been caused by factors other than the surgical procedure, such as a blow to the head, to which the trephination was a therapeutic response (Lisowski 1967; Ortner and Putschar 1981).

Although it may not be possible to determine all the reasons that trephination was performed, among some populations treatment for trauma seems to have been a common objective. Perhaps mental illness and epilepsy served as additional reasons. In Danish skulls trephination is found almost exclusively in male specimens, with the left side being the one most commonly operated on (Bennike 1985). This pattern suggests that trephination was the therapeutic procedure for a blow to the cranium, resulting from violence among men and usually inflicted by a right-handed opponent.

Other types of trauma found in archeological skeletal remains reveal information about early lifestyles. In general, male skeletons show a higher rate of trauma, especially violent trauma, than do female skeletons. In the eastern Mediterranean, from the

Early Neolithic (c. 6500 B.C.) to the Roman period (A.D. 120), the frequency of skull wounds in men ranged from a high of 20 percent in the Early Neolithic to a low of 3 percent in the Classic period (650 B.C.). For women, the frequencies were 3 to zero percent for the same periods (Angel 1974). In Iran between 5000 and 500 B.C., there was a much higher rate of head wounds among men than among women (Rathbun 1984). At the site of Hissar in Iran, occupied from the Chalcolithic through the Early Bronze Age (4000–2000 B.C.), W. M. Krogman (1940) noted that men suffered three times more head wounds than women. In contrast, for the same time period in neighboring Iraq, T. A. Rathbun (1984) found no difference in rates of head trauma between the sexes. In fact, the postcranial material he studied for both Iran and Iraq revealed no differences between the sexes. Yet a Late Period site (664–323 B.C.) in Egypt revealed cranial trauma in 20 percent of the adult males and 8.3 percent of the adult females (Strouhal 1986).

Another pattern in the early skeletal material is the rarity of evidence of fracture or trauma in children (Grmek 1989). Specifically, this has been noted for Bronze Age Greece (Angel 1957), Denmark from the Mesolithic period through the Middle Ages (Bennike 1985), Mesolithic western Europe (Meiklejohn et al. 1984), and Late Period Egypt (Strouhal 1986). These observations, however, pose a potential methodological problem. Remodeling associated with growth generally obliterates any evidence of fracture in children, particularly if it occurs in early childhood. Thus, evidence of fracture or other trauma in children is often not seen in skeletal remains unless the child died shortly after the traumatic event.

One of the fractures most frequently seen in the pre-Roman world was caused when an individual, in attempting to protect the head, absorbed a blow with the forearm. This injury, called a *parry fracture,* most often involved the left ulna.

There have been several surveys of the incidence of forearm fractures. J. Angel (1974) found that, in prehistoric Greece and Turkey, forearm fracture was the most common form of injury. F. Wood-Jones (1910a) reported that, in pre-Dynastic through Byzantine Nubia, 31 percent of all fractures occurred in the forearm, with the ulna being broken more often than the radius and the left side more often damaged. In a British Neolithic to Anglo-Saxon series (c. 3500 B.C. to A.D. 600) fracture of the forearm bones (radius and ulna) was the most common form of postcranial injury, representing almost 49 percent of all fracture cases (Brothwell 1967).

In the eastern Mediterranean the next most common fracture site was the lower thoracic vertebrae. Fracture of the vertebral region also showed the least amount of difference between men and women (Angel 1974).

Fractures of the lower extremity are uncommon in the eastern Mediterranean (Angel 1974). In Nubian skeletons from the pre-Dynastic to Byzantine periods fractures of the foot are rare, and those of the leg are less frequent than those of the arm (Wood-Jones 1910a). In Mesolithic to medieval Danish skeletal material, fracture of the lower extremities is rare (Bennike 1985).

A review of the literature on trauma reveals several chronological trends. For the Mesolithic period through Iron Age, the rate of trauma generally seems to decrease. However, this decrease is related primarily to accidental trauma; the incidence of violent trauma appears to remain the same. For example, Angel observed that, in the eastern Mediterranean, the general rate of fracture decreased with the development of civilization but the rate of violent injury to the head remained the same (Angel 1974). Although P. Bennike (1985) did not find any time-related pattern for the postcranial Danish material, her data reveal that cranial trauma decreased over time. She also found that trauma to the skull was more common in the Mesolithic (8300–4200 B.C.) than in the Neolithic (3200–1800 B.C.), and more common in the Neolithic than in the pre-Viking Iron Age (c. 500 B.C. to A.D. 800). Bennike did not differentiate between accidental and intentional trauma.

The tendency for the incidence of trauma to decrease through time was also noted for western Europe (Meiklejohn et at. 1984) and for Iran and Iraq (Rathbun 1984). C. Meiklejohn and colleagues (1984) tentatively hypothesize that the reduction in trauma, in Mesolithic and Neolithic Europe, which in their sample was a reduction in overall accidental trauma, was due to a more sedentary existence. Rathbun (1984) observed an apparent tendency for trauma in material from Iran and Iraq to decline from the preagricultural to the urban phases several thousand years later. Although he could not differentiate between accidental and intentional trauma in the earlier skeletal material, he noted that much of the trauma of the later periods appeared to be due to human violence.

Infection

Infectious diseases are caused by bacteria, fungi, viruses, and multicellular parasites (e.g., worms). The health significance of each of these agents is affected by many variables, some of which were important factors during the history of human disease. For example, parasites may have become a greater problem for human groups after the domestication of animals, which are common vectors of diseases associated with these organisms. Airborne viruses, which require fairly large host populations (Fiennes 1978), may have become a significant health problem with the rise of urbanism. Fungi may have become a more serious problem with the advent of agriculture, particularly among groups who were under- or malnourished. Because fungi tend to be opportunistic, they are a greater problem in individuals who are immunologically compromised.

Perhaps the most interesting observation about infectious disease during the Mesolithic through the Metal Ages is its apparent low incidence in skeletal samples from most geographic areas (e.g., Wood-Jones 1910b; Martin et al. 1984; Rathbun 1984; Strouhal 1986). This low frequency has been observed both for localized infection resulting from trauma in general (Domurad 1986) and fracture in particular (Wood-Jones 1910b; Bennike 1985) and for skeletal lesions (Martin et al. 1984), which may develop as a result of systemic disease. In fact, skeletal evidence of systemic infection appears to be quite rare, and differential diagnosis often poses a great challenge even to experienced paleopathologists or orthopedic specialists.

Even though skeletal studies report a low incidence of infection, interpreting this observation requires caution and reflects some of the theoretical problems involved in paleopathology. Most serious, acute infectious diseases leave no evidence in gross skeletal remains. The lack of skeletal evidence of infection may mean that the population was healthy, but it may also mean that people were dying from acute infectious disease before the skeleton could be affected (Ortner and Putschar 1981; Rathbun 1984; Ortner 1991).

Several surveys have detected possible trends in infection rates. Rathbun (1984) notes that in Iraq and Iran there appears to have been an increased frequency of infectious-type lesions in the Neolithic and Chalcolithic periods. These rates declined significantly in the later Bronze and Iron ages. Although these trends may be real, they may also reflect stochastic effects of inadequate samples. As Rathbun (1984) suggests, however, the decline in percentage of cases exhibiting infectious lesions from the Chalcolithic to the later Bronze and Iron Age periods may be the result of people dying before bone was involved. Elsewhere in a study of Euro-

pean skeletal material, Meiklejohn and colleagues (1984) noted an increase in cranial infections from the Mesolithic to the Neolithic period. Dental evidence of disease in the eastern Mediterranean suggests to Angel (1984) that new diseases, including epidemics, emerged with the increased population sizes of the Middle Bronze Age.

Evidence from surveys of archeological skeletal material, site reports, and individual case reports has pointed to the existence of a number of infectious diseases in the pre-Roman era – specifically, tuberculosis, leprosy (in Egypt), osteomyelitis, and periostitis.

There is strong evidence that tuberculosis may have developed and/or become a problem with the beginning of farming. Although no unequivocal cases of destructive lesions of the spine have been reported thus far for the prefarming Mesolithic, there are numerous descriptions of lesions of the spine for Neolithic Europe (c. 4200–1500 B.C.; Bartels 1907; Patte 1971; Sager et al. 1972; Dastugue and de Lumley 1976; Formicola, Milanesi, and Scarsini 1987) and pre-Dynastic Egypt (c. 4800–3100 B.C.; Strouhal 1991), for which one possible diagnosis is tuberculosis. However, one must caution that several disease conditions other than tuberculosis produce destructive lesions of the spine, including infection by staphylococcus bacteria and fungi.

There were several cultural changes during the Neolithic that would have influenced the development of diseases affecting the spine. In the Near East the use of domestic animals became an important part of the economy. Proximity to domestic animals, particularly bovids, was likely to have been a significant factor in the development of tuberculosis (Manchester 1983). In addition, a more sedentary life-style and increased population density in the Neolithic and subsequent periods would have been likely to increase its incidence. However, farming was also likely to have increased the incidence of fungal diseases. It is thus probable that spinal lesions attributable to both bacterial and fungal infection increased in the Neolithic period. The current skeletal evidence supports this expectation, although the specific etiology for the destructive lesions remains problematic.

Reported cases of tuberculosis show wide geographic distribution. K. Manchester (1984), basing his opinion on iconographic as well as on skeletal evidence, believes that the earliest undisputed evidence for human tuberculosis comes from Egypt and that the disease spread out from a near eastern center (Manchester 1983, 1984). Although there is considerable controversy regarding the exact dating

Figure V.1.2. Partial antemortem destruction of the fourth lumbar vertebral bone from the skeleton of a young adult from the Early Bronze Age cemetery (c. 3100 B.C.) at Bab edh-Dhra', Jordan (Tomb A100E). Note the reactive bone formation on adjacent vertebral bodies, particularly the fifth lumbar vertebra. (Unaccessioned specimen, National Museum of Natural History, Washington, D.C.)

and diagnosis of the purported cases of spinal tuberculosis in Egypt (Morse 1967; Grmek 1989; Strouhal 1991), it appears that skeletal samples from this region contain at least 32 possible cases in the pre-Christian era (Strouhal 1991). Donald Ortner (1979) reports two possible cases of tuberculosis in Jordan (Figure V.1.2) in a sample of about 300 from the Early Bronze IA (c. 3100 B.C.) tombs at Bab edh-Dhra'. In central and southern Europe, in addition to the Neolithic cases already cited, five cases have been reported between the Bronze Age and 100 B.C. (Dastugue and de Lumley 1976; Steinbock 1976; Angel 1984). Manchester (1984) believes that in Britain the disease was present by the Roman period. Evidence of tuberculosis is also reported for northern Europe, where it may have begun later than the rest of Europe; most skeletal evidence is post-Roman (Brothwell, as cited in Manchester 1984).

Leprosy is another infectious disease for which there is skeletal evidence. In a review of the history of leprosy, Manchester (1984) cites the earliest evidence as that from Ptolemaic Egypt (second century B.C.). Skeletal evidence for leprosy occurs later in Europe. D. Brothwell (1961) argues that leprosy was probably not established there before the first or second century A.D. and did not become a serious problem until after the seventh century. By the Mid-

Figure V.1.3. Chronic inflammation of the left tibia and fibula resulting from an overlying ulcer in a skeleton of an adult woman probably over 50 years of age at the time of death. Specimen is from Tomb A100E in the Early Bronze Age cemetery at Bab edh-Dhra', Jordan. Note the large, oval, circumscribed area of reactive bone associated with the ulcer. Chronic inflammation involves all bone tissue and resulted in fusion of the tibia and fibula. (Unaccessioned specimen, National Museum of Natural History, Washington, D.C.)

dle Ages, the disease had become a serious problem but virtually disappeared by the end of the fifteenth century. Manchester (1991) notes that the reduced frequency of leprosy is associated with an increase in the prevalence of tuberculosis. He speculates that a factor in the decline of leprosy may have been cross-immunity induced by the closely related disease of tuberculosis.

Both osteomyelitis and periostitis have been reported in ancient skeletal material. Although their frequencies show some degree of variability (e.g., Wells, as cited in Sandison 1980; Strouhal 1986), these conditions generally are not common. Descriptions of cases are encountered in the literature. For example, Wood-Jones (1910b) describes a humerus from ancient Nubia with evidence of inflammatory bone formation. He attributes the inflammation to an infectious complication of an injury. Ortner (1979) reports a case of reactive bone formation on the tibia and fibula of a skeleton (Figure V.1.3) dated to about 3100 B.C. The specimen is of an old woman with an overlying skin ulcer of the lower leg that stimulated the inflammatory bone reaction.

Research on mummy remains has provided useful information on the antiquity of many other infectious diseases. An early case of poliomyelitis was reported in a pre-Dynastic mummy from Egypt (Mitchell 1900) dated to 3700 B.C. The leg deformity in the mummy of Pharaoh Siptah from the Nineteenth Dynasty (c. 1200 B.C.) has also recently been recognized as having been caused by polio (Fleming et al. 1980; Whitehouse 1980). Further possible evidence of this disease has been reported in Middle Bronze Age Greece (Angel 1971b) and sixth- to second-century B.C. Italy (Mallegni, Fornaciari, and Tarabella 1979).

Mummy material has also provided information on parasites (Tapp 1986). Schistosomiasis is documented in two mummies of the Twentieth Dynasty (c. 1100 B.C.) in Egypt (Sandison 1973) but probably became a problem much earlier. The practice of irrigation, which may have begun in the Near East as early as the Neolithic, would have facilitated the spread of this disease. The roundworm, *Ascaris,* was found in an Egyptian mummy dating to around 170 B.C. (Fleming et al. 1980), as well as in coprolite material from Bronze Age Britain (Jones and Nicholson 1988) and Iron Age Europe (800–350 B.C.; Aspöck, Flamm, and Picher 1973). The liver fluke was found in two mummies of the Twelfth Dynasty (Fleming et al. 1980). The tapeworm *Echinococcus granulosus* is associated with the mummy Asru dated to about 700 B.C. (Tapp and Wildsmith 1986).

Arthritis

Arthritis is a disease of the joints that includes many syndromes. The term *arthritis* implies an inflammatory condition of the joints, and inflammation is a major factor in several syndromes. One general category of arthritis, and its most common syndrome, is osteoarthritis. Inflammation may occur in osteoarthritis, but it is usually neither the initial nor the most significant factor. Although genetics, physiology, trauma, and other factors appear to play a role, the most important condition contributing to osteoarthritis is mechanical stress. Furthermore, the effect of stress in stimulating arthritic change is cumulative and thus the presence of osteoarthritis is highly correlated with age. There is also a strong association between the type and degree of physical stress and the severity of osteoarthritis. For example, relatively frequent but low-level stress over a long period of time probably has a different effect than severe intermittent stress (Ortner 1968; Jurmain 1977).

Because evidence of osteoarthritis is so common in

archeological human skeletons, the potential for discerning different patterns of joint stress that may be linked to variation in culture exists. However, the current descriptive methodology for conducting such research is poorly developed, and most of the published observations on osteoarthritis do not permit any comparative anaylsis. In addition, mean age of population is often not carefully controlled. Because of the strong association between age and development of osteoarthritis, mean age is crucial to any comparison among populations.

Osteoarthritis of the spine has received the most systematic attention in paleopathological reports. Many surveys have found that the spine is more frequently affected than any other area of the skeleton (Brothwell 1960; Gray 1967; Gejvall 1974; Meiklejohn et al. 1984; Rathbun 1984). Other surveys, although offering no comparisons among areas of the skeleton, have noted the very frequent occurrence of spinal osteoarthritis (Meiklejohn et al. 1984; Bennike 1985), particularly among Egyptians and Nubians (Wells 1964a; Dawson and Gray 1968; Vagn Nielsen 1970).

A variant of spinal degenerative arthritis known as spondylosis (spondylitis) deformans is reported among some populations, such as the Late Stone Age inhabitants of the Baltic Coast (V. Y. Derums 1964), as well as those of Neolithic Jericho (Kurth and Röhrer-Ertl 1981), Neolithic Greece (Dastugue 1974), Third Dynasty Egypt (c. 2750–2680 B.C.; Ruffer and Rietti 1912; Ruffer 1918), and Bronze Age Latvia, USSR (c. 2000–1000 B.C.; V. J. Derums 1987).

Detecting time related trends from the many surveys of vertebral osteoarthritis remains problematic. Reports for Denmark (Bennike 1985) and Egypt (Wells 1964a) indicate no significant changes in the frequency and severity of the condition. Angel (1971a) reported that evidence of osteoarthritis of the spine in the eastern Mediterranean changed little from the Upper Paleolithic (c. 60 percent) until the Classic period, when there may have been a decline (47 percent). In a later paper, however, the estimated frequency of the disease during the Classic period (76 percent) was as high as or higher than that at previous time periods (Bisel and Angel 1985). The incidence of vertebral osteoarthritis in western Europe was reported to be higher in the Neolithic than in the Mesolithic (Meiklejohn et al. 1984).

The mixed conclusions of these surveys may be reflective of methodological problems. However, the importance of physical stress as a factor in vertebral osteoarthitis means that variability in sex roles, type of subsistence, and environmental factors is likely to be great. Perhaps a better understanding can be obtained with a detailed comparative study at the site level such as was undertaken by E. Strouhal and J. Jungwirth (as cited in Aufderheide 1985). They found that in two contemporary Nubian skeletal populations dating to c. 1784–1570 B.C., agriculturists had more spinal osteoarthritis than did hunter-gatherers.

In surveys of the incidence of osteoarthritis in other areas of the skeleton or of the overall rate of general osteoarthritis, the same methodological problems exist. However, some tentative trends have been reported. Meiklejohn and colleagues (1984) found that the overall rate of arthritis in western Europe was higher in the Mesolithic than in the Neolithic, suggesting greater biomechanical stress in the earlier period.

Cultural factors and differences in physical environment have been proposed as explanations for changes in the incidence of the disease. Rathbun (1984) found an overall decrease in osteoarthritis in Iran and Iraq from the earlier periods to the later Metal Ages, which he related to the change in economic activities accompanying urban life. He also found that the Iranian material typically showed more osteoarthritis than the Mesopotamian samples – a difference that may be related to terrain. Brothwell (1961) found that in Great Britain the joints of the upper extremities exhibited more osteoarthritis in the Neolithic period through the Iron Ages than they did in modern times. Manchester (1983) attributes this difference to much greater physical stress in the earlier periods.

Sex-related roles also seem to affect the frequency and severity of osteoarthritis. Male skeletons tend to have a higher rate of the disease than female skeletons. Bennike (1985) found this to be true for the spinal column in an Iron Age sample from Denmark. Similar findings of male skeletons were reported for Bronze Age Greece (Angel 1971b), the eastern Mediterranean during the Chalcolithic through the Hellenistic period (Bisel 1980), Egypt during the Dynastic period (Gray 1967), and Sudanese Nubia during the Second Intermediate period (Strouhal and J. Jungwirth, as cited in Aufderheide 1985).

Although greater male involvement is common, there are exceptions. In the Chalcolithic–Early Bronze Age (4000–2000 B.C.) material from Kalinkaya in Anatolia, osteoarthritis was more common in women according to S. Bisel (1980), who attributes this to greater physical stress from hard work. Female skeletons also show more arthritis at Early Neolithic Nikomedeia in Greece (Angel 1973).

A second general category of arthritis is that of the inflammatory erosive joint diseases. This category includes such syndromes as Reither's syndrome, psoriatic arthritis, and three that are examined in this paper: rheumatoid arthritis, ankylosing spondylitis, and gout. Some syndromes of inflammatory erosive joint disease have a known association with bacterial infection of the bowel or genitourinary track. Lyme disease, for example, is initiated by a tick bite that introduces a bacteria (spirochete) into the host. If untreated, the disease produces severe erosive joint destruction in some patients. The prevailing theory is that other erosive arthropathies are probably initiated by infectious agents as well. Inflammatory erosive joint disease occurs in some people when an infectious triggering agent operates in combination with an individual's defective immune response. The major problem in inflammatory erosive joint disease is that the immune response to the infectious agent is not turned off after the triggering organisms are eliminated. Because of both the infectious and genetic/immune components in inflammatory erosive joint disease syndromes, their time depth and geographic range are of particular interest in the context of human adaptation and microevolutionary biology.

Differential diagnosis of some syndromes of inflammatory erosive joint disease in dry bone specimens is likely to be difficult. Statements in the literature attributing inflammatory erosive joint disease in an archaeological specimen to a specific syndrome should be treated with caution. Even distinguishing these syndromes from septic arthritis and osteoarthritis can be problematic in some cases.

There is currently a debate in the medical and anthropological literature on the antiquity of rheumatoid arthritis. B. Rothschild, K. R. Turner, and M. A. Deluca (1988) have argued that, in the New World, the disease has a history extending back at least 5,000 years. They further argue that rheumatoid arthritis may have been derived from New World pathogens or allergens. However, reports in the anthropological literature indicate that rheumatoid arthritis may have begun as early as the Neolithic in the Old World. Brothwell (1973) suggests the possibility of its presence in Neolithic skeletal material from Great Britain. Rheumatoid arthritis has also been reported in skeletal material from Neolithic Sweden (2500–1900 B.C.; Leden, Persson, and Persson 1985–6), Bronze Age Denmark (c. 1800–100 B.C.; Bennike 1985; Kilgore 1989), Fifth Dynasty Egypt (2544–2470 B.C.; May 1897), and Iron Age Lebanon (500–300 B.C.; Kunter 1977). A specimen from Iron Age Sicily (300–210 B.C.; Klepinger 1979) may represent a case of erosive joint disease with skeletal manifestations including features of both ankylosing spondylitis and rheumatoid arthritis. More recently, L. Kilgore (1989) has suggested a diagnosis of rheumatoid arthritis for a case of erosive joint disease from Sudanese Nubia dated to between A.D. 700 and 1450.

As mentioned earlier, a diagnosis of rheumatoid arthritis should be viewed with caution. However, given the number of cases mentioned by different authors, it does seem that rheumatoid arthritis may be of some antiquity in the Old World. Although the assignment to a specific syndrome of inflammatory erosive joint disease may be incorrect, it seems likely that erosive joint disease was present by at least the Neolithic period. Further clarification of the antiquity of rheumatoid arthritis will have to await additional study of Old World archeological skeletons.

Another syndrome of inflammatory joint disease that occurs in archeological skeletal samples is ankylosing spondylitis. There is general agreement that this syndrome has a history extending for several thousand years (e.g., Resnick and Niwayama 1988). Skeletal evidence is reported in material from Neolithic France (Pales 1930; Torre and Dastugue 1976), Neolithic Sweden (Zorab 1961), and pre-Roman Germany (Zorab 1961). C. Short (1974) has concluded that there were 18 recorded cases in Egypt dating between 2900 B.C. and A.D. 200. G. Morlock (1986) has noted that cases of ankylosing spondylitis (as well as some severe forms of vertebral osteophytosis) have been misdiagnosed. He contends that some cases represent a syndrome of hypertrophic arthritis called DISH, whose antiquity therefore dates to pre-Roman Egypt, Greece, and Europe.

A third syndrome of inflammatory erosive joint disease, gout, is well known in ancient historical accounts. The Old Testament, in a passage dated to between 915 and 875 B.C., provides a graphic description of the painful symptoms of this disease (Resnick and Niwayama 1988). There are few good descriptions, however, of gout in ancient human remains. A mummy from a Christian cemetery in Egypt exhibits erosive destruction of the first metatarsals. Substance removed from the lesions produced a reaction typical of uric acid crystals (Elliot-Smith and Dawson 1924; Rowling 1961). In addition, C. Wells (1973) has reported a possible case of gout in a Roman period skeleton from a site in Gloucester, England.

Other syndromes of inflammatory erosive joint

Figure V.1.4. Dental caries of the upper left second molar in an adult male skull from Tomb A100N in the Early Bronze Age cemetery at Bab edh-Dhra', Jordan. (Unaccessioned specimen, National Museum of Natural History, Washington, D.C.)

disease may exist in ancient Old World human remains. The diagnostic criteria for evaluating the presence of these syndromes are now being developed and refined. We should have a better understanding of the historical dimension of these syndromes in the near future.

Dental Disease

Teeth and supporting tissues can be affected by many disease conditions. The size and shape of teeth can be affected by systemic diseases (e.g., infection and malnutrition) that occur during fetal, infant, and childhood dental development. Systemic diseases can also leave observable defects (hypoplasia) in the enamel. Tooth surfaces can be destroyed by bacteria, a process resulting in caries (Figure V.1.4). Caries can destroy the tooth to the point where the pulp cavity is exposed to infectious agents that can invade the bone and produce inflammation and abscess. Finally, teeth can be traumatized by gritty materials in food, by violence, and by the use of teeth as tools.

Other areas of the mouth can be affected by disease. Gums may become inflamed due to irritation from plaque or infection, resulting in periodontal disease and resorption of alveolar bone. The subsequent exposure of tooth roots with alveolar recession can result in root caries and tooth loss. Supporting bony tissues of the jaw are subject to inflammation just as bone is in other parts of the body.

In an archeological context, the dental pathologies most commonly seen are caries, periodontal disease, dental abscess, antemortem tooth loss, dental attrition, and enamel hypoplasia. Unfortunately, there are two major difficulties in extracting meaningful

data from dental remains. First, like bone, teeth and their supporting tissues react to different disease conditions in similar ways, so that one may be unable to attribute an abnormal condition to a specific disease. Second, the methodology for analyzing these dental pathologies is inexact, often making comparisons among observations hazardous. For these reasons, we will examine in detail only enamel hypoplasia, a condition that has been carefully studied (e.g., Goodman, Martin, and Armelagos 1984; Molnar and Molnar 1985; Rose, Condon, and Goodman 1985; Goodman 1991). Although there is a considerable body of data on caries, methodological problems hinder interpretation. Basically, variation in caries rate appears to be attributable to two dietary factors: presence of carbohydrates and sugar, and presence of gritty food. (Gritty substances remove the crevices in the dental crown, thereby eliminating the locations for bacterial activity.)

Enamel hypoplasias can reveal a number of aspects about the health of an individual or population during childhood. If tooth surfaces have not been worn away, enamel hypoplasias can be used to estimate both the timing and severity of stress. The presence of enamel hypoplasias in the deciduous teeth indicates the occurrence of stress during the last 5 months in utero through the first year of postnatal life (Goodman et al. 1984). In the permanent incisors and canines, the teeth most commonly studied for enamel defects in adult dentitions, enamel hypoplasias reflect stress between birth and 7 years (Goodman 1991). The onset of stress can be determined in half-year intervals (Goodman 1991).

Enamel hypoplasias represent a disturbance lasting from several weeks to 2 months (Rose et al. 1985). Many sources attribute these disturbances to infection or nutritional deficiencies (y'Edynak and Fleisch 1983; Goodman et al. 1984) such as those that can occur with weaning (Rathbun 1984; Smith, Bar-Yosef, and Sillen 1984).

A general survey of the literature on enamel hypoplasia reveals several interrelated patterns. First, there seems to be a general rise in the frequency of hypoplasia from the Mesolithic to Roman period in many areas of the Old World (y'Edynak and Fleisch 1983; Rathbun 1984; Smith et al. 1984; Molnar and Molnar 1985; Formicola 1986–7; Angel and Bisel 1987). This rise seems to be related to general changes in the human environment.

P. Smith and colleagues (1984) found that in Palestine the frequency of enamel hypoplasias increased from the Natufian period (c. 10,000 to 8500 B.C.) to the Neolithic, and rose again in the later Chalco-

lithic and Bronze ages. They postulate that the slight rise in dental pathology in the Neolithic may have been due to changes in diet. However, they attribute the more definite increase in frequencies in the later periods to a marked decline in health due to chronic disease (Smith et al. 1984).

The Palestinian material also revealed interesting changes in the onset of childhood stress. In the Natufian period enamel hypoplasias indicate that a major period of stress occurred between 3 and 4 years of age and was probably associated with weaning (Smith et al. 1984). However, during the later Chalcolithic and Early Bronze Age periods, stress appears to have occurred earlier in life with deciduous teeth commonly affected. This suggests to Smith and co-workers (1984) that weaning took place earlier in life in these later time periods – a pattern that reflects a presumed decrease in birth spacing.

Angel's findings in the eastern Mediterranean also reflect changes in the human environment. He linked the increased frequency of hypoplasia in the Middle Bronze Age (c. 2000–1500 B.C.) skeletal samples of that area to the beginning of childhood epidemics. Epidemics were not a significant problem until that time period because human population sizes were not large enough to support the disease organisms (Angel and Bisel 1986).

A second pattern in enamel hypoplasia research is the often wide variation in frequencies within a specific time period. For example, in Neolithic skeletal samples from Hungary (Molnar and Molnar 1985) and Sweden (Gejvall 1974), there was no evidence of enamel hypoplasia. Enamel hypoplasia was found to be relatively rare in Neolithic samples from West Germany (Schaefer 1978), whereas Brothwell (1973) reports that enamel hypoplasia in Great Britain occurred in 37 percent of Neolithic skeletons. V. Formicola and colleagues (1987) reported the frequency to be high for one Italian sample.

Inadequacies in the samples raise questions about the results, but it does seem that variation among sites within a period can be interpreted to mean that specific local conditions such as parasite load may be more important than the general economic subsistence base.

There is other evidence that differences in rates of enamel hypoplasia may be related to specific geographic factors, although it is not always clear what these factors may be. Rathbun (1984) found that skeletal samples from Iran dated during the period from the Neolithic through the Metal Ages had a significantly higher rate of enamel hypoplasia than did analogous samples from Iraq. These differences were generally limited to male skeletons, and Rathbun (1984) suggests that the greater frequency in males supports the contention that growing males are more vulnerable to stress than are females.

Finally, there is some indication that the severity of hypoplasia in subadult populations is inversely associated with age of death. Some researchers have suggested that stress, producing hypoplasia, may be linked with the factors resulting in the death of the individual (Rathbun 1984; Goodman 1991). In contrast, Smith and colleagues (1984) suggest that hypoplasia is indicative of individuals who survive stress, unlike individuals who die before their teeth can be affected.

Anemia

In archeological skeletal remains, evidence of two types of anemia, although not common, are well known and of considerable biological consequence. Genetic anemias, the less common of the two, are restricted to a few geographic areas of the world. Anemia resulting from malnutrition can occur anywhere. Because of the pitfalls in diagnosing anemia in skeletal material, an understanding of the biological processes involved in this condition is helpful.

In anemia there is an abnormal increase in the need for blood formation. This may be the result of several conditions, including excessive blood loss through chronic bleeding from intestinal parasites. In the genetic anemias, the hemoglobin in red blood cells is defective. This reduces the normal life span of the cells, which in turn creates an increased demand for new blood formation. Dietary iron deficiency can also result in abnormal hemoglobin with results similar to those that exist in the genetic anemias.

Because of the increased demand for blood formation, tissues that create blood occupy more space. The bone marrow spaces that in an infant or young child are normally required for blood formation are now inadequate, and hematopoietic marrow tends to expand at the expense of cortical bone. In the postcranial skeleton the marrow volume of the long bones increases at the expense of that of the cortex, which decreases in thickness (Ortner and Putschar 1981). In the skull the diploe enlarges primarily at the expense of the outer table; the skull becomes thicker, and the external appearance of the skull becomes porous. Although many descriptive terms have been applied to this condition in the skull, currently the most commonly accepted one is *porotic hyperostosis,* introduced by Angel (1966).

Unfortunately, there are other conditions that may be associated with porous lesions of the skull, including infection and metabolic diseases such as scurvy and rickets (Ortner and Putschar 1981; Ortner 1984, 1986). Thus, unless there is unambiguous evidence of an expansion of marrow space in at least some of the cases in the skeletal sample exhibiting porous lesions of the skull, a diagnosis of anemia should be offered with caution.

Angel (1966, 1972, 1977) proposed an intriguing connection between falciparum malaria and porotic hyperostosis in the eastern Mediterranean. He hypothesized that this condition in the skeletal remains of the region is indicative of thalassemia, one of the genetic anemias that may provide some immunity against malaria, and further proposed an association between the incidence of porotic hyperostosis and the cycles of malarial severity throughout the past 10,000 years. Malaria, he argues, did not become endemic until the population settlement and increase of the Neolithic period, when the frequency of porotic hyperostosis reached 50 percent (Angel 1972). After the Neolithic, porotic hyperostosis declined to 12 percent in the Bronze Age and 2 percent in the City State period (650–300 B.C.; Angel 1972). Angel attributes this decline in anemia, and presumably malaria, to changes in environment, including lowered sea levels and drained marshes. In a book of readings edited by M. Cohen and G. Armelagos (1984b), Cohen concludes, while reviewing data presented during a symposium, that porous lesions of the skull vault and eye orbit either appeared or increased in frequency with the advent of agriculture. He cautiously argues that this trend is indicative of an increase in anemia at that time.

Tumors

Tumors of the skeleton are classified on the basis of whether they arise in bone (primary) or invade bone from another tissue (secondary, malignant, or metastatic). Most of the primary bone tumors seen in archeological human skeletons are benign. Some primary benign tumors of bone, such as osteomas, are well known in archeological skeletons; other benign tumors, such as cartilaginous exostoses (Figure V.1.5), are less common but have been reported (e.g., Ortner and Putschar 1981). These benign tumors generally have minimal medical or biological significance.

Primary malignant tumors are uncommon in archeological skeletons and tend to occur in children and adolescents. The Celtic warrior (800–600 B.C.) from Switzerland with osteosarcoma or chondro-

Figure V.1.5. Benign tumor (cartilaginous exostosis) in the area of fusion between the pubic and iliac bones of a right innominate bone. Adult female from the Twelfth Dynasty (c. 1990 B.C.) Rock Tombs, Lisht, Egypt. (Catalog no. 256474, National Museum of Natural History, Washington, D.C.)

sarcoma of the humerus (Figure V.1.6) has been reported in several publications (e.g., Ortner and Putschar 1981). Secondary (metastatic) tumors of bone are more common than primary malignant tumors. However, because this type of tumor occurs most frequently in people over 50 years of age, it is also an archeological rarity. Until very recently in human history, few people lived long enough to acquire secondary tumors of bone.

Because tumors are so rare in archeological specimens, any statement on prevalence associated with geographic areas or time periods is likely to be
Figure V.1.6. Malignant tumor (osteosarcoma or chondrosarcoma) of the proximal left humerus of a Celtic warrior (c. 800–600 B.C.) from an archeological site near Münsingen, Bern, Switzerland. Each alternating band equals 1 centimeter. (Catalog no. A95, Natural History Museum, Bern, Switzerland.)

highly problematic. At present our data consist of case reports and surveys such as that provided by J. Gladykowska-Rzeczycka (1991) for tumors in European material. However, it seems reasonable to assume that carcinogens have been a problem for a long time. As previously mentioned, Wells (1964b) suggests that nasopharyngeal tumors seen in archeological human skeletons are associated with the open fires that have existed in human societies for millennia.

Conclusion

In this essay we have presented a broad overview of the specific diseases that may have existed in the pre-Roman Old World and outlined general patterns of health that may have been present as human society became increasingly complex. But because of the limitations imposed by the sources and the research methods used, the picture is incomplete.

From skeletal and mummy material we are fairly certain that, depending on geographic location, pre-Roman populations suffered from a number of infectious diseases (i.e., multicellular parasites, tuberculosis, poliomyelitis, periostitis, osteomyelitis, and, late in the pre-Roman era, leprosy). Most of these populations were also exposed to trauma, particularly in the form of head wounds and forearm fractures. Osteoarthritis, particularly of the spine, was prevalent, and some groups suffered from erosive joint disease. Anemia was present and apparently fairly common in some geographic locations and time periods. Tumors were rare. Determining the frequencies and geographic site of origin of some of these abnormal conditions will have to await future research.

One of the most intriguing ideas that has emerged from our review of infectious diseases is the possibility that tuberculosis became a problem in the Neolithic period. Greater population densities, sedentism, and close contact with domestic animals are all factors that, in theory, could have led to the emergence of tuberculosis as a serious health problem in the Neolithic. J. McGrath (1986) argues that large populations may not be needed for mycobacterial infections. This may be true, but it is equally true that some types of bacteria are more likely to be maintained in a host population when the population is large. A careful restudy of spines in Old World archeological skeletal samples would be most useful in clarifying this point.

Outlining general patterns of health has been equally elusive. With respect to nonspecific disease conditions (e.g., periostitis, osteitis, dental hypo-

plasia), the data seem inconsistent; there is variation among sites within the same time period, as well as among different time periods. In general, however, from the Mesolithic to the Neolithic there seems to be a trend toward increased frequencies of nonspecific disease conditions. Whether this trend is indicative of a decline in population health in the Neolithic is a question that remains, in our opinion, problematic. As we have suggested, an increased frequency of nonspecific lesions of bone may indicate a more effective immune response; individuals with nonspecific lesions of bone usually must have survived an acute phase to enter the chronic phase of a disease process.

For the urban periods, the same theoretical difficulties exist. In several areas the frequencies of enamel hypoplasias continue to increase from the Neolithic, indicating increasing childhood stress. However, the frequencies for nonspecific infectious skeletal lesions do not always increase.

Ascertaining the relation between skeletal disease and morbidity in antiquity requires great care. For example, is dental hypoplasia representative of an acute phase of a disease process occurring during late fetal life and childhood? Is periostitis indicative of chronic disease reflecting a good immune response? Issues of this type will have to be clarified before generalizations about population health can be made.

The epochal nature of the cultural change that took place between the Mesolithic and Roman periods offers an opportunity to study several important problems in human biocultural adaptation. Further research will require a much more effective descriptive and research methodology. We also need to give more careful thought to the meaning of our observations in a skeletal sample relative to the health of the living parent population.

Donald J. Ortner and Gretchen Theobald

V.2
Diseases of Western
Antiquity

</div>

There are good reasons for believing that diseases and complaints of various kinds and degrees of severity were as much a part of everyday life in classical antiquity as were the assorted battle wounds and injuries so dramatically portrayed from Homer onward. This is indicated not only by the surviving Greek and Latin medical texts and the fragments preserved in Greco-Egyptian papyri, but also by the large corpus of nonmedical Greek and Latin texts, some of which are still being read today. In poetry, tragedy, and comedy, in history and annals, in philosophy and theology, as well as in botanical, agricultural, and pharmacological texts, illness and health and life and death constitute distinctive motifs.

To be certain, the evidence, both written and nonwritten, has survived in different states of preservation. It permits us, nonetheless, to reconstruct in part the intellectual and technological achievements of our past. Large gaps, however, exist in our knowledge of that past, and the absence of crucial details has led to hypotheses and inferences that cannot be tested directly.

Our knowledge of the diseases of classical antiquity stands somewhere between demonstrative certainty and complete ignorance. There is, after all, a sizable body of Greek and Latin medical texts, and it, in turn, has generated an even larger body of secondary literature. But for all that, our knowledge of the diseases of classical antiquity is far from complete. There are several reasons for its incompleteness, but it is important to keep in mind the enormous differences between the conceptual bases of the modern medical sciences and those of antiquity. These differences have important consequences in any attempt to identify the diseases of classical antiquity and to understand their effects.

One significant consequence is primarily philological: Many Greek and Latin medical terms cannot be rendered adequately by any single term in most modern languages. A case in point is the specialized vocabulary denoting diseases, used primarily though not exclusively by the ancient medical writers. Obviously this has a bearing on the study of disease. Some ancient medical terms appear to cover an indeterminately wider range of meaning than is expressed by their modern equivalents. For example, *lepra* (λεπρα)

and *gonorrhea* (γονοϱϱηια), mean something more than the modern clinical entities whose names they bear; in fact, it is not altogether certain that *lepra* denoted Hansen's disease or that *gonorrhea* denoted the disease that today is positively diagnosed only by the presence of gonococcus.

A second consequence, far more formidable than the philological one just noted, concerns the very foundations of classical medicine. Beginning with Hippocrates, and accepted by the better medical writers throughout classical antiquity, was the notion of disease as a process. Regardless of the philosophical theory that supported the etiology, whether humoralism or solidism, a disease, theoretically, could be described as a series of stages with a predictable outcome. Each of those stages normally occupied a narrowly circumscribed period of time, such as 7, 14, or 20 days. Associated with the chronological development was a series of changes in the condition of the patient, each of which was described in specific, though not necessarily unique, terms representing the symptom or symptoms associated with that specific stage of the disease. It is with respect to the latter point that grave difficulties are encountered in an attempt to identify some of the diseases of classical antiquity. First of all, it was widely believed that some diseases were capable of passing into or changing into another disease. The latter was then characterized by its distinctive symptom or symptoms, which often were similar to the principal symptom or symptoms that characterized the original disease process. The newly arisen disease was then regarded as a species of the disease from which it originated at a certain stage in the morbid process. Then it too ran its predictable course, although therapeutic intervention (drug therapy, regiminary therapy, or surgery) might alter its course.

There was considerable discussion in antiquity concerning the proper nomenclature and, of course, therapy of these so-called species or varieties of a disease; and as one might guess, there was little agreement concerning details, especially with regard to their classification. On one issue, however, there was agreement and that was the widely adopted classification of diseases as acute or chronic. In the main, acute diseases were characterized by a sudden onset, a clearly circumscribed febrile stage, and the involvement of a specific localized area, frequently the respiratory or digestive system. As such, most of our infectious diseases were regarded as acute diseases in classical antiquity. Those disease processes in which a clearly demarcated febrile stage was absent and whose outcome could not be predicted on the basis of a

specified sequence of stages fell into the larger, less organized category of chronic disease (e.g., gout, lead poisoning, and scurvy).

Because it was not possible to base an etiology on specific microscopic, pathological organisms, close attention was paid to the description of symptoms at each stage of the disease process, from onset to outcome. Thus, many of the so-called species or varieties of a disease acquired distinctive names; these were based on a few of the salient symptoms or on a consistent clinical pattern, the latter resembling what later came to be called a syndrome (literally, a "running together" of symptoms).

It must be stressed, finally, that ancient therapeutics was almost wholly symptomatic. Consequently, the large body of literature surviving from classical antiquity must be used with due recognition of the fact that the illnesses for which the many hundreds of recipes and remedies were designed must be considered, in the main, to be symptoms and syndromes.

These caveats notwithstanding, some of the diseases of classical antiquity can be identified with assurance and others can be identified with degrees of confidence that vary in proportion to both the quality and the quantity of the evidence at our disposal. In either case, however, efforts have been made to summarize the etiologic, epidemiological, and pathological evidence in such a fashion that the diseases of classical antiquity can be correlated historically with the same diseases viewed in later terms.

Apoplexy

Apoplexy (Greek *apoplexia*) is sometimes also called paraplexia or paralysis. The name *apoplexia,* according to Caelius Aurelianus, is derived "from the fact that it involves a sudden collapse, as if from a deadly blow. It is a sudden seizure (*oppressio*), in general without fever, and it deprives the body of all sensation; it is always acute and never chronic."

The etiology of apoplexy was stated in different ways by the ancient medical authors. The earliest account is from the Hippocratic corpus: It is caused by winds or breaths (φυσας), "so, if copious breaths rush through the whole body, the whole patient is affected with apoplexy. If the breaths go away, the disease comes to an end; if they remain, the disease also remains." Centuries later, Celsus wrote that the relaxation of the sinews (*resolutio nervorum*) was a common disease everywhere. "It attacks at times the whole body, at times part of it. Ancient writers named the former, apoplexia, the latter, paralysis."

Elsewhere a humoralistic etiology was advanced: black bile (melancholy) by Hippocrates, or cold, vis-

cous phlegm by Paul of Aegina (see also Galen). Finally, a solidist etiology was proposed by the Methodist sect — for example, by Soranus, whose last work was translated into Latin by Caelius Aurelianus. The latter states that apoplexy is a disease caused by strictures (*passio stricturae*) of the tube and pore structure of the human body. Isidore of Seville suggests quite a different theory, but offers no evidence or source. In fact, Isidore's entire entry for apoplexy consists of one sentence: "Apoplexia is a sudden effusion of blood, by which those who die are suffocated."

In addition to the clinical relationship between apoplexy and paralysis, there is evidence of a more primitive distinction between apoplexy and temporary mental confusion (e.g., the state of being dumbfounded, astounded, speechless), which is translated as 'αποπλγκος and/or απυπλγκτικος in the nonmedical literature, such as that by Herodotus, Aristophanes, and Sophocles.

It is difficult to separate neatly the classical beliefs regarding the incidence and epidemiology of apoplexy because of the ignorance surrounding its etiology. A few brief passages, here and there, suggest, however, that its incidence in particular must have been a subject of some discussion. Thus, there are two Hippocratic aphorisms concerned with age incidence: The first contains a short list of complaints common to old men, including apoplexy. The meaning of *old* is specific in another: "Apoplexy occurs chiefly between the ages of forty and sixty." (See also Caelius Aurelianus, who notes that old women have special therapeutic problems.) Data on seasonal incidence are also scarce. Hippocrates simply stated that apoplexy was one of several diseases that frequently occurred in rainy weather. Caelius Aurelianus, however, thought it most prevalent at the end of autumn or in the winter.

With regard to the pathology of apoplexy, detailed, clinical descriptions are provided by Celsus, Caelius Aurelianus, Galen, and Paul of Aegina. Though their descriptions do not agree verbatim, we can summarize them by noting the major areas of consensus:

1. Sudden onset (with no or few antecedent indications)
2. Lack of fever
3. Feeble pulse and shallow respiration following the stroke
4. Lack of sensation
5. Impairment of muscular control, sometimes accompanied by tremors
6. Comatose state

If there is recovery, the victim may show evidence of mental impairment, especially in his or her speech and uncontrolled muscular action. This catalogue of signs was important to the physician not only for making a diagnosis but also for differentiating apoplexy from other diseases, especially epilepsy, lethargy, and some forms of paralysis.

Asthma

"The disease called orthopnoia," wrote Aretaeus, "is also called asthma because those who have paroxysms pant for breath (asthmainousi)." The Greek term asthma, used by Homer for a gasping, painful breathing, had acquired a distinct medical sense by the time of Hippocrates.

The two terms asthma and orthopnoia are not uncommon in ancient literature, but on the basis of the adjectival form, asthmatikos, a nonmedical usage (e.g., the labored panting of an athlete) may be suspected.

Like many diseases, the etiology of asthma was explained in humoralistic terms. "The cause," Aretaeus states, "is the coldness and moistness of the pneuma but the matter is moist, cold, and glutinous." Airborne pollen and dust do not seem to have been implicated in the sometimes sudden onset of an allergic reaction, the latter a concept not explicitly associated with asthma in classical texts. It may be significant, however, that Hippocrates notes that asthmatic attacks are frequent in the autumn.

Aretaeus's account of the symptoms, the best single description in classical antiquity, refers in unmistakable terms to the overt characteristics of asthma and emphasizes the dry wheezing, often unproductive cough, inability to sleep in a prone position, and labored efforts to breathe leading to gulping or gasping. He seems not to have recognized, however, the constriction of the lumen of the bronchi or the possibility of neurological or hereditary factors.

Bubonic Plague

In the large, sometimes uncritical literature in the history of bubonic plague, the earliest, unimpeachable reference to the plague in classical antiquity is that provided by Rufus of Ephesus. There are also a considerable number of Greco-Roman descriptions of and references to epidemics in our sense of the term (or, in Greek and Latin, λογος [whence our word plague] and pestis pestilentia). These were of various kinds, usually unidentifiable, with various degrees of morbidity and mortality, and not always chronologically or geographically positioned. The most famous were those of the Iliad, the "plague of Athens,"

and the "plague of Justinian." Many different communicable diseases have been proposed for these "epidemics" (a term that in Hippocrates' Epidemics does not always mean what we mean by an epidemic disease; see Deichgraber 1933). Likewise, many different diseases have been proposed for the less well known, but equally sporadic and frightening epidemics whose echoes frequently resound in classical texts, such as those of Karl Jax, Jürgen Grimm, and Jean-Marie André. Some of those epidemic diseases may have been bubonic plague but, save for the description by Rufus and the acknowledged existence of the plague of Justinian (sixth century A.D.), the evidence is inconclusive. The likelihood of bubonic plague cannot be dismissed totally, however, because there is good evidence, first, that the plague was endemic in the Near East in the preclassical period and, second, that the Greeks and Romans had frequent contact with the people of the Near East from the sixth century B.C. onward and could easily have contracted diseases thereby. It is, finally, almost certain that bubonic plague was not unknown in late antiquity, as Byzantine reports by Paul of Aegina and Arabic and early Western medieval reports testify.

It is, then, in the context of the later stages of Greco-Roman civilization that one must consider the passage from Rufus noted at the beginning of this section. Rufus of Ephesus, a highly regarded physician and medical writer, lived during the reign of the emperor Trajan (A.D. 98–117). He is known to have been active in Rome and to have spent some time in Egypt. A short passage referring to the buboes typical in a case of plague was preserved, presumably because of its unusual interest, by the later (fourth-century) Greek physician Oribasius in his chapter on buboes. Because of its historical importance, I have translated the passage from Rufus:

The buboes termed pestilential are the most fatal and the most acute, especially those that are seen in Libya, Egypt, and Syria, as reported by Dionysius the Kyrtos. Dioscorides and Poseidonius have studied especially the plague (λοιηος) which occurred in Libya in their time. They have said that [it was characterized by] high fever, pain, disturbance (συστασις) of the entire body and the formation of large buboes, hard and non-suppurating. They develop not only in the ordinary places but also in the groins and the neck. (Translated from Oribasius.)

It may be noted that buboes had been mentioned many centuries earlier by Hippocrates. Sometimes they meant glands, but in other cases they seemed to refer to the large lymphatic swellings associated

with the plague. Because Hippocrates does not as-
sign a name to the disease of which the buboes are
one of the most dramatic signs, it is difficult to de-
cide whether bubonic plague was known to him.

Before Oribasius, Aretaeus referred to pestilential
buboes of the liver, whereas Pliny the Elder referred
to a plant, *bubonium,* whose name derived from the
fact that it was considered especially beneficial for
swellings of the groin (*inguinum*). These bits and
pieces of information (and undoubtedly others exist),
especially when coupled with references to "pestilen-
tial times" by Marcus Aurelius and Aristides, sug-
gest that bubonic plague may have been implicated,
more often than we have recorded, in the numerous
outbreaks and epidemics, though not recognized as a
discrete clinical entity.

Cancer

The term *cancer* derives from the Latin *cancer,*
which in turn derives from the Greek καεκινοω both
originally meaning a crab. Other medical terms
used in classical antiquity derive from the same
root. These terms, however, do not necessarily mean
or refer to a neoplastic growth or malignant lesion.
There is some evidence, in fact, that ulcers and le-
sions associated with other diseases (e.g., erysipelas
and gangrene) were not always distinguished from
malignancies.

As a medical term, καεκινοω first appears in
Hippocrates but in contexts that only suggest what
is meant today by cancer. Later uses of the term by
Galen and his followers were similar to the medical
and clinical uses that prevailed up to the time of
Rudolph Virchow. In the same way, the more re-
stricted term *carcinoma* might have denoted a malig-
nant condition, especially when the condition termi-
nated fatally as, for example, in Hippocrates,
Caelius Aurelianus, and Cassius Felix. The most
extended account of cancer, next to Galen's, was that
of Celsus, who attempted to distinguish a variety of
swellings (tumors). He gave special names (e.g.,
atheroma, steatoma, and *therioma*) to some of these –
probably not the malignant ones. However, he also
described certain, more serious conditions, perhaps
complications of erysipelas and gangrene, and these
he likened to cancer. He reserved the term *carci-
noma* or *carcinode* for other tumors that, when they
did not appear to have been the result of another,
antecedent disease, may have been malignant.

The terms just noted and other Greco-Roman cog-
nates such as *cancroma* are not as common in the
medical literature as one might expect and are even
rarer in the nonmedical literature. Instead, there

developed an elaborate taxonomy, with correspond-
ing names, for a wide range of conditions that are
reproduced in English by the nonspecific, generic
term *swellings.* Celsus's distinctions were carried
further by Galen, who distinguished among a wide
range of diseases, localized morbid conditions, and
various dermatological complaints. But Galen intro-
duced one important improvement: He identified as
malignant only those ογκοι (tumor[s]) that most
closely resemble our concept of malignant neo-
plasms and called them κακογδγ.

The large amount of space devoted to recipes and
other therapeutic forms for "swellings" and abscesses
(e.g., by Cato, Paul of Aegina, Pliny, and Hippocrates)
strongly suggests that malignant, often fatal, condi-
tions were not uncommon, despite the lack of con-
sensus on signs and symptoms and the equally obvi-
ous lack of a standardized nomenclature. Slightly
more certain to have involved cancer is a series of in-
operable, incurable, or fatal conditions of specific
organs or bodily parts that were, more or less, amena-
ble to examination, such as the breast, testicles, nose,
and throat. It is even more problematic that
neoplastic growths of internal organs were recog-
nized, but perhaps it was to these that Hippocrates
was referring by the phrase κευπτοι καεχιωοι (hidden
cancers).

Reflecting the uncertainties in the diagnosis and
therapy of what Galen called "swellings contrary to
nature," their etiology was equally uncertain.
Galen, however, twice explicitly stated that black
bile was the cause of cancers. A hint of another, not
necessarily incompatible etiology is contained in
Celsus's statement that, whereas some ulcers arise
from an external cause, carcinomata and the like
"arise from within, from some part of the body which
has been corrupted."

Diphtheria

The term *diphtheria,* introduced by Pierre Bre-
tonneau to replace his earlier term *diphtheritis,* de-
rives from the Greek, literally "skin, hide," referring
to the characteristic tough, white pseudomembrane
of the trachea and other respiratory organs in ad-
vanced cases. There do not appear to be any classical
Greek or Latin terms to designate this once-dreaded
infectious disease. Aretaeus's terms (Egyptian and
Syriac ulcers) were not adopted by later writers.
Diphtheria seemingly was not always differentiated
from other infectious diseases, and it was not unam-
biguously described until many centuries later.

The two best accounts of diphtheria in classical
antiquity are those of Aretaeus and Aetius of

Amida. These two passages, supplemented by the more vague accounts of Hippocrates, described the principal signs and symptoms on the basis of which classical diagnoses were made before Friedrich Löffler's identification and isolation in 1884 of *Bacillus diphtheriae*, now *Corynebacterium diphtheriae*. The Hippocratic passages alluded to and a remotely possible reference by Soranus describe a condition that is not incompatible with diphtheria, but the absence of crucial data make a more positive identification impossible.

At any rate, these passages together provide a clinical picture similar to the early modern accounts of *angina maligna,* one of the many names in use before Bretonneau. Signs and symptoms as reported by Aretaeus and Aetius of Amida (Hirsch 1886) include the development of a phlegmatic, whitish film in the mouth and throat, rapidly spreading to the trachea, accompanied by a foul odor. The disease, often accompanied by fever, is rapidly fatal, especially among juveniles. Death is caused by suffocation, but weakness due to an aversion to food and drink may be a contributing factor. The voice is hoarse and strangely modulated; respiration is rapid but shallow; and liquids are sometimes passed out through the nose (due to a paralytic destruction of the soft palate, though not explicitly so stated by the classical authors).

As is well known, diphtheria epidemics have occurred, and both morbidity and mortality rates can be high, especially for children. For those reasons one would expect prima facie a larger number of classical references to diphtheria. There are perhaps two reasons for the paucity of data. First, diphtheria might have been confused with other diseases (e.g., aphthae, tonsilitis, candidasis). Second, the rapid course of fatal diphtheria did not permit the ancient physicians sufficient time to examine the patient with an eye on prognosis.

The source material at our disposal suggests that the etiology of diphtheria was somewhat uncertain. An overabundance of phlegm easily accounted for the development of the characteristic pseudomembrane. A further explanation is provided by Aretaeus's remark that the natural heat of young children is cooled by the rapid respiration and inspiration of cold air (apparently thus hastening the development of the phlegmatic pellicle). Finally, a dietetic cause is subjoined by Aretaeus: The thick and impure food and drink of the Egyptians lead to morbid changes, the so-called Egyptian ulcers.

Only the barest facts on incidence are available, but they highlight two important facts: Children,

especially infants, were highly susceptible, and the season of highest incidence was winter. There seems to be no evidence for a disproportionate sexual incidence.

Dysentery

The word *dysentery* (Latin *dysenteria*) derives from the Greek *dys* (bad) plus *enteria* (intestine), thereby indicating the system involved, though not, of course, the causative agent.

Although explicit references are not common, it is probable that dysentery was widespread in antiquity. Some evidence is provided by a series of four aphorisms in Hippocrates, as well as the explicit statement that dysentery was common in the summer and autumn. Elsewhere, in an attempt to establish the disease pattern and age incidence, it is written that men (beyond the age of young men, i.e., 30 years and older) commonly suffer from 11 diseases, 2 of which are chronic diarrhea and dysentery. This fits the pattern of men of military age and the conditions of crowding and lack of proper sanitation facilitating local outbreaks, if not small epidemics.

Various philosophical and medical theories were advanced to explain the sudden outbreak, its spread, and the distinctions, not always clear, between acute and chronic dysentery, on the one hand, and between dysentery and diarrhea, on the other. Roughly, there were two different kinds of etiologic proposals, each of which had its adherents, some of whom tried to combine the salient features of the two competing theories. Whether the humoral explanation came earlier is difficult to judge; at any rate, Hippocrates seems to have been the earliest exponent of the theory that one of the humors, in this case black bile, was the causative agent. Other writers (e.g., Plato, Timaeus, and Cassius Felix) selected other humors as the causative agent. The other theory, equally reasonable at that stage of medical inquiry, was that unconcocted or undigested food, not necessarily "bad" food, was the cause. This theory is represented by Aristotle and Aretaeus. At the end of the classical period, Paul of Aegina suggested that the mucus found in the feces indicated undigested food, although he opted for black bile as the principal cause. We may note here, before discussing the pathology of dysentery, that no evidence is available at present as to whether the dysentery of the classical writers was bacillary (shigellosis) or amebic.

The literature on the signs and symptoms of dysentery corroborate the belief that dysentery was both widespread and common. All authorities are in agreement that a compelling need to defecate, the fre-

quency of which is proportionate to severity, quickly becomes unproductive and that the production of well-formed stools, within 48 to 72 hours, changes to the production of watery stools. Such watery stools, from ones tinged reddish to ones highly colored with blood, were often thought to contain fleshlike shreds of undigested food (i.e., mucus or pus). In addition, the gripings in the lower abdomen, so ran the prevailing theory, led to typical straining – tenesmoi – that both physically evacuated the inadequately concocted food products and dehydrated and physically enervated the victims.

There was less agreement regarding other signs. Celsus, for example, asked whether the patient was always fevered, and Alexander of Tralles tried to determine the extent to which the liver was involved. Galen has left us the best account of the typical ulcerated lower intestine. Finally, Hippocrates seems to have regarded dysentery following an enlarged spleen (perhaps of malarial origin) as a favorable condition, doubtless with the thought in mind that a natural catharsis would help to reduce a swollen organ by removing impurities.

Erysipelas

Erysipelas is a direct transliteration of the Greek, literally "red skin," referring to its most obvious characteristic. It was usually termed ignis sacer (holy fire) in classical Latin, and the synonym is confirmed by Celsus and Cassius Felix. It is important to note that the erysipelas termed ignis sacer is distinct from ergotism, sometimes also called ignis sacer or St. Anthony's Fire.

Although noted several times by Hippocrates, erysipelas was not given much attention in classical medical writings and is very rare in nonmedical writings (but see Lucretius and possibly Virgil). It was considered to be serious, however, and an epidemic was reported by Hippocrates. Fatalities were reported by Hippocrates and Paul of Aegina. It is clear that the erysipelas of classical texts is not always restricted to the streptococcal infection known by that name today, for apparently sometimes it was confused with gangrene and herpes, as, for example, by Scribonius Largus.

Despite the relatively slight attention paid to the etiology and incidence of erysipelas by classical writers, there are reasons for believing that, in fact, it was far from rare. First, the disproportionately large amount of space devoted to a host of different therapeutic forms by Caelius Aurelianus, Scribonius, Pliny, and Oribasius strongly suggests it was not uncommon. Second, the prevalence of wounds, abra-

sions, and contusions must have provided easy access to the pathogens. Third, even without therapeutic intervention, many cases of self-limiting erysipelas ran their courses with little lasting trauma to the patient.

The symptoms of erysipelas are so clearly described by the classical medical writers as to leave little doubt about the accuracy of the identification. These include redness and swelling with a spreading painful lesion (Celsus), usually accompanied by fever (Hippocrates). In agreement with modern symptomatology, erysipelas was described on most of the more exposed portions of the body; specifically, it was noted as involving the face and the mucous membranes of the mouth and throat (Hippocrates), thus perhaps as being one of the causes of noninfantile aphthae. Celsus and Hippocrates noted appearance of erysipelas soon after the infliction of a wound, and Celsus made the distinction, though not with complete understanding, between idiopathic and traumatic erysipelas. It is more difficult to understand what is meant by erysipelas of specific, usually internal, organs, for example, uterus and lungs (Hippocrates) and brain (Paul of Aegina). A Hippocratic aphorism suggests that the phrase inward-turning erysipelas (regarded as a dangerous sign) is simply a way of expressing the fact that other, more serious symptoms accompanied the external, reddened areas.

The etiology of erysipelas was not altogether clear but, as was frequently the case with infectious diseases of rapid onset, a humoralistic explanation was advanced by Galen and Paul of Aegina.

Hippocrates noted that "early in the spring" was the season of highest incidence and that "those of about sixty years" were especially prone; however, his detailed case history in Epidemics describes the nonfatal case of an 11-year-old boy.

Malaria

In the opinion of most scholars, malaria was common in classical antiquity. Moreover, it seemed to be widespread geographically, as references to both local malarious and malaria-free regions indicate. Malaria, in fact, may have been endemic in some regions; if so, it undoubtedly colored the clinical findings of some chronically ill patients and may have been responsible for infant deaths not otherwise indicated. Less certain are the socioeconomic consequences of endemic malaria, although work efficiency must certainly have been impaired in malarious regions and among those who suffered from chronic malaria.

Despite the large literature on the history of ma-

laria and the innumerable surveys undertaken in conjunction with malaria eradication programs (in which patients were examined before or in the absence of chemotherapy, and hence were clinically analogous to patients of classical times), it is not easy to document the early history of malaria.

There are many reasons for our lack of certainty regarding malaria in classical antiquity, and since they are so intimately bound up with our interpretations of classical sources, it is worth listing some of them. This will help us to do what the ancient physicians tried to do, namely to distinguish malaria from a host of other diseases and pathological conditions.

First, until the late nineteenth century, there was no knowledge of the pathogenic organisms (the *Plasmodia*) involved. Thus, any diagnosis of malaria (or of one of the diseases with which it was often confused) depended, to a great extent, on the accurate recording of the signs and symptoms exhibited by a patient. Second, and perhaps as a function of its widespread distribution, malaria was often confused with other febrile conditions (e.g., phrenitis). On this matter, we have the explicit testimony of Galen's works, as well as smaller texts such as that of Alexander of Aphrodisias. Diocles and Crasistratus both wrote books entitled *On Fevers,* which have been lost. Third, and as a consequence of the first two points, the nomenclature was confused and inconsistent. Until the postclassical term, literally meaning "shivering fever," came into use, other terms were commonly employed. None of them were completely satisfactory because they had other conflicting definitions such as "nightmare" or the shivers that accompanied the disease. The term *febris* was too broad, and hence although the root meanings of fire, heat, and burning were applicable to malaria fever, they could and did apply to other febrile conditions; xαυσος, or *febris ardens,* also signified intense, burning heat, though, of course, there was no way of translating the subjective sensations of a feverish patient into thermometric terms. Other, more restricted terms existed, but they will be examined later. Fourth, the different types of *Plasmodium* infection, best exemplified by the well-known terms *tertian* and *quartan* malaria, were so well recognized that they were regarded as separate diseases; moreover, other diseases (e.g., phrenitis and lethargy), which may have had a malarial basis, were regarded as capable of passing or changing into other febrile conditions and hence confounded diagnosis, prognosis, and therapy alike.

These difficulties notwithstanding, a close reading of the chapters devoted to "fever" and so forth in the classical medical texts and a comparison of those texts with the numerous but scattered references to "fever" in the nonmedical texts leaves little doubt that malaria was indeed common and well known. The best evidence for this claim is provided by the conjunction of signs and symptoms that would be recognized as malarial today, in the absence of any chemotherapy. Principally, three signs, when associated with other data (e.g., cachexia or habitation in an area known to be "unhealthful," especially when situated near a marsh or estuary), established diagnoses until the advent of blood smears. First was splenomegaly. In routine physical examinations of the sort that Hippocrates advocated, palpation of the hypochondrium would often reveal an enlarged, tender spleen according to Celsus and Hippocrates. Second was the invariable sequence of chills, fever, and sweats, which was noted in many texts, among them those of Celsus, Pliny, and Hesychius. Third was the periodic nature of the disease, usually indicated in Latin by *accessia.* This is a more complex issue because of the nosological tendencies of medical writers who divided and classified fever into various forms: cottidian (daily); tertian (every third day; counting day of onset and day of crisis = every 48 hours); quartan (every fourth day; counting day of onset and day of crisis = every 72 hours). To these may be added the more puzzling quintans, septans, nonans, semitertians, and other mathematical, though not necessarily clinical, entities.

It was presumably through a long period of noting and recording the constellation of such signs, and patients' symptoms, that a "malarial constitution" was defined, according to Hippocrates. This, in turn, led to the establishment of the typical malaria cachexia and its common occurrence in classical Rome, as indicated by Martialis, Juvenal, Horace, and Livy.

The same wide range of opinion covering the differential diagnosis of malaria applies equally well to its etiology. There are hints of a very ancient belief in a supernatural origin. Sophocles, when describing an epidemic (of unknown origin) at Thebes, refers to a "fever-bringing god." This does not prove that malaria was the cause of the epidemic any more than the presence of a temple dedicated to the goddess or numen Febris in Rome (according to Cicero and Pliny) proves that malarial fevers could always be distinguished from other fevers.

In Hippocrates, the etiology of four types of fever was explained in humoralistic terms. Three of the fevers are clearly malarial: cottidian, tertian, and quartan. The first two of these were caused by various amounts of surplus yellow bile; quartan was

caused by a mixture of yellow and black bile. It was the "mixed humoral state" that was responsible for the longer cycle, which explained why quartan was more recalcitrant to therapy.

In addition to a humoralistic etiology, Galen wrote of a "feverish constitution" being due to a pestilential air, which could also be described as a "pestilential constitution." It was also observed, for example by Celsus, that fatigue and hot weather led to fever; elsewhere he states, however, that therapy is difficult because fever can have both evident and hidden causes.

Both medical and nonmedical writers (e.g., Hippocrates, Horace, and Juvenal) agreed that late summer and autumn were the most likely seasons to be characterized by fever – a vestige of which survived until recently in the phrase *estivoautumnal fever* for falciparum malaria.

V.3
Diseases of the Middle Ages

During the Middle Ages (roughly A.D. 500–1500),
Europe changed from an agrarian society composed
of relatively small and isolated communities to an
increasingly commercial and urban world, though
still predominantly agricultural. After centuries of
static or declining growth in late antiquity, the popu-
lation of Europe increased approximately threefold
between 800 and 1300. Generally, the history of medi-
eval diseases reflects these demographic and eco-
nomic facts. While the ancient diseases of pneumo-
nia, tuberculosis, and smallpox, and others including
typhoid, diphtheria, cholera, malaria, typhus, an-
thrax, scarlet fever, measles, epilepsy, trachoma,
gonorrehea, and amebiasis persisted throughout our
period, many diseases of Europeans during the early
Middle Ages were related to deficient diet.

Improved nutrition in the later Middle Ages led to
a relatively larger population. As Fernand Braudel
(1979) has emphasized, an increase in population
alters all aspects of life, bringing advantages but at
the same time threatening the existing standard of
living and hope of improving that standard. In addi-
tion, it can bring disease. Ironically, the improved
nutrition that made possible the growth of popula-
tion, towns, and trade in the Middle Ages in turn
created fertile opportunities for the contagious dis-
eases that ultimately changed the face of Europe.

Nutrition and Disease

A revolution in agricultural techniques in northern
Europe has been credited with this remarkable popu-
lation growth (e.g., White, Jr. 1962). Agrarian meth-
ods inherited from the Roman Empire were suitable
for the warm, dry lands of the Mediterranean and
Near East, but proved inadequate on the broad, fer-
tile plains of northern Europe. The old scratch plow
that required the double labor of cross-plowing to
turn the soil, plodding oxen, and two-field rotation

(half of the fields sown in the autumn to take advan-
tage of winter rains in the south, half left fallow to
restore fertility) were ultimately replaced by the
heavy plow, the horse, and a three-field rotation
system. A new plow, usually mounted on wheels and
heavy enough to require eight animals to pull it,
turned the soil so thoroughly that no cross-plowing
was required and produced long, narrow fields in-
stead of the square plots of the south. The moldboard
of the new plow, which could turn the turf in either
direction to assist drainage of the fields, was ideal
for the opening of alluvial bottomland, the richest
land of all. After the development of nailed horse-
shoes and a padded horse collar with harness at-
tached (the old oxen neckstrap tightened across the
jugular vein and windpipe of the horse), horses
gained greater speed and staying power, which not
only increased the amount of land a peasant could
farm but also the distance he could travel to reach
his outermost strips.

But horses eat more than oxen do and prefer oats,
which are planted in the spring; therefore, the wide-
spread use of the horse had to await the food sur-
pluses of the three-field rotation system. Spreading
outward from the Frankish lands between the Rhine
and the Seine, this system faced great practical ob-
stacles in the creation of the third field and was
firmly established only in the wake of the devasta-
tion caused by raids of Vikings and Magyar horse-
men in the ninth and tenth centuries. By approxi-
mately 1200, most of northern Europe had accepted
the three-field system, whereby one-third of arable
land was planted in spring to catch the abundant
summer rains, one-third was planted in autumn,
and one-third was left fallow. The system meant an
overall increase in production of 50 percent.

Before this revolution, the peasantry, which com-
prised 98 percent of the European population, had
subsisted on a high-carbohydrate diet ingested as
bread, porridge, and beer, whether derived from bar-
ley, as in some parts of the north, or from rye and
wheat. When a peasant's principal crop failed, he
and his family might well starve. Moreover, even
with optimal harvests, they very likely experienced
severe protein deprivation. The agricultural revolu-
tion brought them not only greater yields, but a
diversity of crops, including legumes and peas,
which served as a protection against famine and
provided more vegetable protein. These nutrients
were to be of far-reaching nutritional consequence,
for the peasant seems to have received little animal
protein in the early Middle Ages.

It is true that abundant meats – domestic and

game – as well as poultry and fish covered the tables of the rich. But the peasants are believed to have consumed what very little animal protein they received in the form of what was known, with unmistakable irony, as "white meat," that is, dairy products – milk, cheese, and eggs (Drummond and Wilbraham 1959). Peasants might own some livestock and poultry, which wandered freely in the village; however, early medieval animals were subject to the frequent hazards of disastrous epidemics, winter starvation, and sacrifice in time of famine, and consequently they could not be regarded as a dependable source of food (Drummond and Wilbraham 1959). Seemingly conflicting evidence has been obtained from excavations of several ports and other emporia of the ninth century (Dorestad, Holland; Southampton, England; and others) that reveals that not only prosperous merchants, but humble citizens with small houses and farm plots within the town, consumed a considerable amount of meat and seafood, judging by bones and shells found in pits (Hodges 1982, 1984). However, town dwellers, especially in coastline communities, were not representative of the great portion of the population that was tied to the land, and as a general rule, early medieval peasants can be assumed to have seldom eaten meat – usually what they could obtain by hunting or poaching on the manor lord's land (Drummond and Wilbraham 1959).

Hunting diminished as population increased and the forests yielded to the plow. Presumably, as the forest dwindled, poaching penalties became more severe, though the trapping of small animals must have remained common. Freshwater fish filled mill ponds, of which England had 5,624 in 1086 according to the Domesday Book, and ocean fish became far more available after the salting of herring was introduced in the thirteenth century or soon after. Rabbits spread northward slowly across northern Europe from Spain in the early Middle Ages, reaching England by 1186 at least (White 1976). Nevertheless, it was only after the agricultural revolution produced food surpluses that could sustain food livestock, as well as humans and horses, that animal protein became readily available. That this was the case by the early fourteenth century is evidenced by the fact that the church saw fit to urge abstinence from eating flesh on fast days, indicating that regular meat consumption must have become an ordinary practice (Bullough and Campbell 1980). In addition, protests against the enclosure movement of the sixteenth century, in which country people complained that they could no longer afford beef, mut-

ton, or veal, suggest that by then these meats had become the food of ordinary people (Drummond and Wilbraham 1959). Finally, the agricultural revolution brought surpluses in a variety of crops, so that there was less risk of starving when one crop failed. The result was better nutrition for all, which preserved the lives of those less fit, especially children.

Women are believed to have suffered more than men from the deficient diet of antiquity and the early Middle Ages. Many sources from the ancient world indicate that men outlived women, and an examination of French and Italian records from the ninth century shows that, whereas more female childern than male reached the age of 15, males nonetheless enjoyed a greater life expectancy than females (Herlihy 1975). Numerous explanations of this paradox have been offered, including the underreporting of women because they were living in concubinage and death in childbirth (for a survey of theories, see Siegfried 1986).

In the thirteenth and fourteenth centuries, however, writers begin to indicate a surplus of women. Rheims had an excess in 1422, Fribourg in 1444, and Nuremberg in 1449 (Herlihy 1975). Some scholars explain this reversal by the greater iron content of the average diet of the later Middle Ages that accompanied the greater consumption of meat and legumes. Until the onset of menstruation at 12 to 14 (the average age mentioned in ancient and medieval medical treatises; see Bullough and Campbell 1980), young girls need no more iron than boys, but after menarche, they require replacement iron of 1 to 2 milligrams per day.

In the early Middle Ages women probably received no more than 0.25 to 0.75 milligram and consequently must have become progressively iron deficient. Cooking in iron pots can increase iron intake, but pottery probably was in common use until the twelfth or thirteenth centuries. During pregnancy and lactation, a woman's iron requirements are considerably greater, rising to as much as 7.5 milligrams per day in late pregnancy. Severe anemia predisposed women to death from other causes – respiratory, coronary, or hemorrhagic – and by the third pregnancy, a woman's life must have been at severe risk (Bullough and Campbell 1980).

Unfortunately for historians, few medieval records exist to document protein or iron deficiency or the other numerous deficiency diseases recognized by modern science. Still, rickets, known since ancient times, can be assumed to have existed in regions where neither ample sunshine nor a diet containing substantial amounts of seafood or dairy products was

available. Ophthalmia, caused by vitamin A deficiency, would have been a problem wherever famine or severe poverty was found. Scurvy may be assumed to have been prevented by the inclusion of cabbage or other vegetables or fruits in the diet, though fruits were expensive, available only for a limited season, and widely regarded with suspicion (Drummond and Wilbraham 1959; Talbot 1967). Pellagra, however, was not a problem in Europe until maize, which is deficient in niacin, was brought from the New World in the sixteenth century and became the staple crop in some areas.

Although malnutrition or undernutrition can produce higher infection rates, history shows us that epidemics by no means regularly follow famines. It is true that in the process known to biologists as the synergism of infection, victims cease to eat well, even though they have greater metabolic needs and are exhausting their protein reserves in the fight against infection. But the host's immune system fails only when actual starvation exists. Indeed, chronic malnutrition may actually assist the host in withholding nutrients necessary for a microorganism, in the natural defense mechanism known as nutritional immunity, and many virulent infections appear without any synergism in victims of poor nutrition (Carmichael 1983).

Although not a deficiency disease, ergotism, called ignis sacer or St. Anthony's fire, is associated with such diseases because it attacked whole communities that had consumed rye grain infected with the ergot fungus. Because the fungus grows in damp conditions, contamination of the crop occurred most frequently after a severely cold winter (which reduced the resistance of the grain) and a rainy spring, or when rye had been planted in marshy land, such as land newly cultivated because of the pressures of population growth. Figuring prominently in the history of French epidemics in the Middle Ages, ergotism can be traced as far back as 857, with five outbreaks in the tenth century and several in each successive century. It occurred most frequently in the Loire and eastern French provinces. Its cause was not then recognized, and miraculous cures were claimed through the intercession of St. Anthony the Hermit, who was generally associated with ignis sacer. It was in his name that an order of hospitallers was founded at La Motte, in a mountainous region of France (inhabitants of alpine areas were particularly vulnerable to ergotism because of cool weather), which became a pilgrimage center for those who suffered from the disease (Talbot 1967). Victims — frequently children and teenagers, who,

because they were growing, ingested more ergot per unit of body weight – exhibited dramatic symptoms, writhing and screaming from burning pains in their limbs. In fact, a close correlation has been made between the growing of rye, cold and damp weather, and the persecution of what was regarded as witch-like behavior in sixteenth- and seventeenth-century England (Matossian 1983).

Infectious Disease

As the agricultural revolution progressed, it promoted population growth and a much greater population density – indeed, a density not known since the decline of Rome in the late empire. This density in turn became the new enemy of population growth in the West. The Near East had long been characterized by a relatively high density of population and urban centers, and consequently the peoples of the region had long been developing resistance to the disease generated in such dense populations. Thus, Europeans who came in contact with the old centers of civilization were at serious risk of developing infection.

Nonetheless, travel to these centers increased throughout the Middle Ages. Simple pilgrimages drew Europeans to the Holy Land as early as the fourth century. Wars of Christian reconquest in Sardinia, Spain, and Sicily reopened the Mediterranean Sea in the eleventh century, and from 1096 to 1271 Crusaders struck out for the Holy Land. Contact with the East stimulated a taste for its products, especially textiles, furs, and spices, and led to the establishment of permanent trade routes, with caravans regularly traveling as far as the Mongol Empire.

This trade contributed to the widespread growth of European cities and the birth of new towns. Overcrowding in poorly ventilated dwellings with thatched roofs and dirt floors, and infested with rats and fleas, provided fertile ground for the spread of communicable diseases inevitably brought in, often from afar.

The water supply in these urban areas was usually dependent on a river, which underwent seasonal variation in volume and was subject to contamination from sewage and refuse. Brewers, dyers, tanners, and other trades people dumped waste into waterways, as did butchers and fishmongers; in 1369 London butchers were ordered to stop polluting the Thames (Talbot 1967). Perhaps the greatest pollution was found in the streets: Household waste was thrown from windows, dead animals were left to decay where they fell, and the entire contents of stables were swept outside.

The absence of good personal hygiene also predis-

posed the populace to contagious disease. Although physicians prescribed steam, cold, or herb baths, and bathing had a role in rituals such as those performed upon induction into knighthood or on certain feast days (Talbot 1967), baths, partly because of limited water supplies, could not have been as common as they are today, even for the well-to-do. Urban dwellers were undoubtedly better served: Public baths were available in many towns, even for the less wealthy. Country people surely bathed less than town dwellers, and had few changes of clothing. Apparel, predominantly woolen in northern Europe, was relatively expensive and difficult to launder. For rich and poor alike, clothing and hair sheltered lice and fleas, according to medical treatises of the time (Talbot 1967). All of these conditions greatly assisted the spread of contagious diseases.

With population density at a critical level, the last few centuries of the Middle Ages saw the unique social, intellectual, economic, and demographic influence of four contagious diseases – plague, influenza, leprosy, and tuberculosis. The dramatic impact of the Black Death in 1347–50 inspired contemporary accounts as well as subsequent studies, now literally in the thousands. Leprosy has also been a favorite subject for historians. The study of influenza, however, has long suffered from problems of correct identification. And the presence and importance of medieval tuberculosis must be largely inferred.

Tuberculosis

The incidence of tuberculosis, an age-old malady, is believed to have increased greatly during the Middle Ages, although this is difficult to document. Although excavation of medieval graves has disclosed only a few skeletons showing tuberculosis of the bone, this tells us very little since the disease is known today to affect the bone in only 5 to 7 percent of untreated cases (Steinbock 1976; Manchester 1984).

Tuberculosis is a population-density-dependent illness, and the growth of towns may well have been accompanied by an increase in the disease. Relying on the assumption that a high death rate in the years from 20 to 40 is evidence of widespread tuberculosis, (historically it has ravaged this age group the most), investigators examining skeletons dating from the years 1000 to 1348 in Germany and other areas have concluded that an increase in the disease did indeed parallel urbanization (Russell 1985). Evidence for the importance of tuberculosis in the Middle Ages is provided by the ancient custom among French and English kings of attempting to cure victims of scrofula (tuberculosis of the cervical lymph nodes) by touching them. Called the king's evil or the royal disease, this form of tuberculosis was sufficiently widespread to have attracted the attention of the court. According to English records of the king's pence given as alms to the sick, Edward I touched 1,736 victims during 1289–90, 983 during 1299–1300, and 1,219 during 1303–4 (Bloch 1973). In part because of the natural remissions of scrofula (if, indeed, these cases were correctly diagnosed), which were thought to be effected by the God-given powered of the monarch, the practice persisted, in some form at least, into the nineteenth century in France.

No doubt, the design of medieval farm homes, in which cattle and humans were housed under the same roof, contributed to the spread of the bovine tuberculosis bacillus to humans, and thus spread of tuberculosis in Europe. Bovine tuberculosis existed in Po Valley dairy cattle before their introduction to northern Europe in the thirteenth century (Manchester 1984). Crowded conditions in the new towns also increased the diffusion of the disease, for it can spread by droplets produced by sneezing, coughing, and the like.

Tuberculosis is caused by *Mycobacterium tuberculosis*, which is of the same genus as *Mycobacterium leprae*, the causative agent of Hansen's disease, termed leprosy by commentators in the Middle Ages.

Exposure to tuberculosis confers an immunity to leprosy. Because tuberculosis was often transmitted to small children by human or cow milk, early immunity to both tuberculosis and leprosy might have been acquired by those who survived the first few years of life. One factor in the late medieval decline of leprosy may have been the concurrent increase in tuberculosis in the densely populated urban centers. Unfortunately, leprosy does not confer an immunity to tuberculosis (Manchester 1984).

Leprosy

Leprosy flourished in Europe during the twelfth and thirteenth centuries, afflicting as much as 1 percent of the populace, according to some authorities. Possibly brought to the West from India with the returning army of Alexander in 327–6 B.C., leprosy traveled across Europe with Roman colonization. Skeletons from fifth-, sixth-, and seventh-century England display clear evidence of lepromatous leprosy in the skull or limbs, with loss of phalanges. Anglo-Saxon England apparently did not segregate lepers, because the bones of victims have been found in general cemeteries (Manchester 1984), but a few lazar houses were established as early as the eleventh century. The

disease seems to have reached a high point in England during the first half of the thirteenth century, when 53 hospitals were constructed. In all, some 200 such institutions are known to have been established. By the fifteenth century no new ones had been built, and by the sixteenth century the disease had nearly disappeared from England.

The pattern in other European countries was similar. In the twelfth and thirteenth centuries almost every Italian town had a leper house outside its walls. France was said to have had 2,000 leprosaria in the thirteenth century. Medieval Denmark had 31, and in the cemetery of the leprosarium of St. Jorgens in Naestved, Denmark, 650 patients were buried between 1250 and 1550 (Møller-Christensen 1969).

The Third Lateran Council in 1179 directed that lepers be segregated from the rest of society, and that separate churches and burial places be provided for them. Great differences in the stringency of rules among communities existed, varying from clement care to the burning of live victims. Typically, a ceremony was conducted over a male leper in which he was declared to be "dead unto the world, but alive unto Christ." As the leper stood in a grave, a priest threw earth over him (Brody 1974). He, in fact, lived on, but he was dead in the eyes of the law, and his heirs inherited his possessions, though divorce was usually not permitted. Bishops or abbots endowed leprosaria with income from tithes, rents, and tolls; and in parts of Europe – northern Italy, for example – lepers were under civic control. A leper house usually lodged 6 to 12 people, but might be built for one victim alone. Such community efforts to prevent the spread of the disease were no doubt motivated by terror of the dire symptoms of leprosy, despite widespread ecclesiastical declarations that the illness was caused not by mere exposure to the disease but by divine punishment for lechery and other sins. Though the mechanism of contagion might be unclear, medieval Europe was ready to be empirical. Lepers were provided with cloaks and bells and ordered to keep their distance on penalty of death, and lazar houses were built downwind from towns.

Historians long believed that "leprosy" in the Middle Ages actually included a range of skin disorders, perhaps including syphilis. However, the excavation of medieval leper cemeteries, principally in Naestved, Denmark, has demonstrated that diagnosis by medieval doctors was actually conservative. Approximately 80 percent of the 650 skeletons at Naestved showed evidence of advanced lepromatous leprosy, whereas only a small percentage of modern

cases, even untreated, are known to involve bones. Therefore, it can be speculated that only those most severely affected by the disease were confined there (Møller-Christensen 1969). As John of Gaddesden advised in the fourteenth century, "No man is to be adjudged a leper and isolated from all his fellows until the appearance and shape of his face be destroyed" (as cited by Cholmeley 1912). This was a merciful criterion in view of the grief and penalties of banishment, but one that allowed the population to contract the disease from those with early or less apparent forms.

Medieval physicians had repeatedly observed that the blood of lepers was thick, greasy, or gritty (Bernard of Gordon 1496; Guy de Chauliac 1890; John of Gaddesden, cited in Cholmeley 1912). Recently, laboratory tests have substantiated these descriptions. Blood samples show two or three times normal platelet adhesiveness, among other qualities (Parvez et al. 1979; Ell 1984a). The age-old claims that lepers were unusually sexually active and that leprosy was sexually transmitted have been harder to explain. It has been demonstrated, first, that subclinical leprosy may become overt during pregnancy (Duncan et al. 1981), thereby giving the impression that the disease has sexual origin, and second that remissions of leprosy in men might heighten sensitivity to testosterone. In addition, confinement in a leper house could have released the sexual inhibitions of both sexes (Ell 1984a). Yet because of the similarities of the early stages of leprosy and syphilis, syphilis may in fact have been present in medieval Europe and mislabeled leprosy. Modern lepers show an unusually high incidence of syphilis, suggesting an unknown affinity (Murray 1982; Ell 1984a). V. Møller-Christensen (1969), however, found no skeletal evidence of syphilis in the 650 leprosy victims at Naestved.

Historians have long believed that the Black Death greatly diminished the incidence of leprosy during the second half of the fourteenth century, attacking the weakened victims in their leper houses, which were found virtually empty at the end of the plague. However, it has recently been recognized that leprosy was already in decline when the plague began. The immune defect in the lepromatous patient is specific; it is not a generalized immune deficiency until the disease becomes advanced. In many ways, leprosy represents a hyperimmune state (Ell 1987). Leprosaria were probably found empty because members of the religious orders serving as keepers suffered a high death rate (Biraben 1975; Russell 1985), and the lepers fled to find food, escape the plague, or run from

persecution as scapegoats. Alternatively, leprosy has been claimed to confer an immunity to plague, because leper houses consistently served meals very sparse in meat, whereas the plague bacillus requires a high serum iron level (Richards 1977; Ell 1984b, 1987). For all these reasons some medieval scourge other than plague may have hastened the end of leprosy. Tuberculosis, as noted earlier, confers an immunity to leprosy (only one leper with tuberculosis was found among the victims at Naestved; Møller-Christensen 1969), though leprosy does not confer immunity to tuberculosis (Manchester 1984). Thus, tuberculosis itself may have promoted the end of the leprosy epidemic in the late thirteenth and fourteenth centuries as tuberculosis increased among the new urban population.

Influenza

Believed in the Middle Ages to be a singularly English disease, "sweating sickness" (now widely accepted as influenza) first appeared in the very month in 1485 in which Richard III was defeated at Bosworth Field. Four other outbreaks – in 1508, 1517, 1528, and 1551 – occurred in the first half of the sixteenth century, before, according to the theory that prevailed until recent times, the disease vanished forever. After the eminent Tudor physician John Caius had treated victims in 1551, he described the disease as a sweat and fever with pains in the back, extremities, head, with "grief in the liver and the nigh stomacke," killing "some in one hour, many in two," but lasting only 24 hours if the patient survived (Caius 1912).

Even though an epidemic of fever and sweats was known to have devastated much of northern Europe in 1529 at approximately the same time as an English outbreak of the sweating sickness, no relationship between the two phenomena was seen at the time. In keeping with the prevailing doctrine of humoral pathology, which accounted for all disease as an imbalance of the four natural humors – blood, phlegm, black bile, and yellow bile – the English sweating sickness was believed to be drawn to a constitution predisposed by an excess of one of the humors and possibly by an immoderate life-style. The immediate cause was believed to be, in the words of Caius, "evel mists and exhalations drawn out of the grounde by the sune in the heate of the yeare." Explanations of the causation and character of the disease remained localist and miasmatic into the nineteenth century, when in 1844 German historian J. F. C. Hecker (1844) called it a "spirit of the mist" and said that epidemics were inevitable if

"rain be excessive . . . so that the ground is completely saturated, and the mists attract baneful exhalations out of the earth."

Even August Hirsch (1883) accepted the unique nature of the English sweating sickness, and not until the twentieth century were the five British epidemics recognized to be influenza, an illness known to be caused by an unstable microorganism having variable disease patterns.

Traditionally, the first influenza epidemic, as identified by Hirsch (1883), occurred in 1173 in Italy, Germany, and England, during which the monk Godefridus described an intolerable cough as a symptom. There were major bouts of influenza in France and Italy in 1323, when nearly all of the citizens of Florence fell ill with chills and fever, and again in 1387, when the disease was described as *ex influentia coelesti,* giving rise to the use in Italy of the term *una influenza.* When the disease struck Paris in 1411, one of the symptoms was a cough so severe that it caused women to abort. Influenza returned in 1414 to Italy and to Paris, where some 100,000 cases were claimed, and again in 1427. Following this, Hirsch (1883) described no more epidemics until the great 1510 outbreak, with general diffusion all over Europe, starting in Sicily in July and reaching northern Italy in August, France in September, and the Netherlands and Spain in October. But even as the visitations of influenza in Europe were increasing and the incidence of leprosy diminishing, a greater scourge than either was about to strike.

Bubonic Plague

Bubonic plague (Black Death or the Black Plague) was commonly known as the Great Mortality or the Great Pestilence. Probably in the majority of cases, certain symptoms were characterized as "black." In the words of Giovanni Boccaccio (1978), an eyewitness: "There appeared . . . certain swellings, either on the groin or under the armpits . . . of the bigness of a common apple . . . [or] an egg. From these . . . after awhile . . . the contagion began to change into black or livid blotches . . . in some large and sparse and in others small and thick-sown." Other sources describe small black blisters spread widely over the body, swollen glands and boils surrounded by black streaks, or the throat and tongue black and swollen with blood. But many victims experienced no "black" symptoms. As a consequence, many believe that the *black* in the name of the disease derives from a too-literal translation in sixteenth-century Scandinavia of a common fourteenth-century Latin

phrase, *atra mors* meaning "terrible death," as "black death."

In 542, during the reign of Justinian, bubonic plague was reported to have taken the lives of 25 percent of the population of the Roman Empire, in what has been called the first European epidemic. Though the exact nature of this outbreak has been debated, plague is now believed, on the basis of literary and cemetery evidence, to have spread across Europe, reaching the British Isles in 544 and returning there in 664 (when, significantly, the Venerable Bede described St. Cuthbert as having a tumor [or bubo] on the thigh) and again in 682 (Russell 1976). Probably, episodes of plague attacked Rome in 1167 and 1230, Florence in 1244, and Spain and southern France in 1320 and 1333. It was during the last outbreak that Roch of Languedoc, who was on a pilgrimage to Rome, contracted the disease, was cured, began to nurse plague victims, and subsequently became the patron saint of plague.

In 1331 civil war and plague struck Hopei, China, and both soon raged throughout that nation; chronicles report that two-thirds of the population perished. The disease moved west along the caravan routes through Tashkent, Astrakhan, and other cities of southern Russia, transmitted by rats and fleas perhaps lodged in the grain supplies of the caravans (for a discussion of caravan transportation, see McNeill 1976). It reached the Crimea in 1346, where Genoese merchants were being attacked in their fortified trading post of Caffa by a Mongol army. The attackers were suffering from plague, and before they withdrew they transmitted their affliction to the besieged town by catapulting corpses of victims over the walls.

Fleeing Caffa, the ships of the now-diseased Genoese were driven away from Messina, Sicily, and the disease was carried to North Africa and the western Mediterranean. Soon Corsica and Sardinia, Spain and southern Italy were affected, then all of Italy, Austria, Hungary, Yugoslavia, and Bavaria. Marseilles was the destination of one of the ships, and the disease quickly spread up the Rhone and then throughout France. By 1348 most of France and Switzerland were under siege by the plague, which soon reached the southern coast of England, Germany, Sweden, and Poland. The plague's assault on Russia was delayed until 1351, good evidence that the disease traveled by the international trade routes and not by river transport, or it might have reached Russia from the Crimea several years earlier.

Plague was transported by armies and ships, merchants, pilgrims, fair goers, transient laborers, and other human travelers. Traders hauling grain, fodder, forage, hides, furs, and bolts of cloth also transported rats, fleas, and other vermin. Pilgrimage routes and trade routes to fairs were natural paths of the disease, which first broke out in London at the time of the Bartholomew Fair. When Edward III began the construction of Windsor Castle in 1359, plague attacked the workforce (Shrewsbury 1970).

Plague is a millennia-old disease of wild rodents. In a cycle widely believed to be the method of transmission of the Black Death, rat fleas (*Xenopsylla cheopis*) carry the *Yersinia pestis* bacillus to the black or house rat, *Rattus rattus*. When the host rat dies, its fleas leave to find another living rat, but failing that, they may jump temporarily to less favored hosts, human beings, and by biting them transmit the disease.

In humans, plague has three major forms: bubonic, septicemic, and pneumonic. The first form results from an insect bite, with the bacillus moving through the lymphatic system to the nearest lymph node, frequently in the groin, where it forms a palpable swelling, the characteristic "bubo," from the Greek word for groin. Other possible sites for buboes are the armpits and the neck, depending on the location of the bite. In the septicemic form, the insect injects the bacillus directly into the bloodstream of the victim, where it multiplies quickly. Blood seeps from the mouth and the nose, and death results in a few hours. Septicemic plague is virtually always fatal. Nevertheless, the most menacing form is pneumonic plague. A modern outbreak in Manchuria in 1921, for example, was 100 percent lethal (McNeill 1976). Because the pneumonic form is a lung infection, it can be transferred directly from human to human by airborne sputum or by fomites (clothing and other articles contaminated by victims).

All three forms of the disease were found in the fourteenth-century pandemic, and judging by a study of 300 contemporary literary sources, the relative importance of the three types may have been 77 percent bubonic, 19 percent septicemic with secondary pneumonia, and 4 percent pneumonic (Ell 1980).

Because of the entrenched medieval belief in the humoral pathology inherited from the Greeks, which had not been seriously challenged in more than a thousand years, therapeutic measures were based on correction of the imbalance of humors. The imbalance might be precipitated by an immoderate intake of food or drink or by meteorological or astronomical phenomena. Because plague was of a short incubation period and therefore could readily be seen to be

transferred from person to person, the best etiologic explanation consistent with the traditional pathology was that corrupt air emanated from the ill person or a corpse, or even from someone still not ill but coming from a place of sickness. Standing only a few feet away from such a source might be enough to contract the disease. Belief in the vital role of air was so strong that the clergy of Avignon imagined that mountain dwellers had been immunized against the plague by their own pure air and so imported them as gravediggers in 1348. Unfortunately, they died of the infection as soon as they arrived (Biraben 1975).

Medieval physician and surgeon Guy de Chauliac (1890) wrote the most accurate and complete medical account of the 1348 plague epidemic of any contemporary observer. In it he described both the pneumonic and bubonic types of the disease, and may also have recognized the septicemic type with a reference of blood spitting. His first counsel was the traditional injunction *"Fuge cito, vade longe, rede tarde"* – "Flee quickly, go far, and come back slowly." But he also advised such surgical and medical measures as reducing blood volume by phlebotomy, purifying the air by fire and incense, and opening or cauterizing buboes. Most of the medical texts of the time echo the treatments Guy de Chauliac advocated. Surgical intervention, baths, and apothecary cures were recommended. Physicians visiting the sick were accompanied by boys carrying incense burners to purify the air, and all held before their noses a sponge soaked in vinegar and spices. When Philip VI of France ordered the Paris medical faculty to ascertain the cause of the disease, a confident report came back that the pestilence was caused by the conjunction of Saturn, Jupiter, and Mars, which had occurred at 1 P.M. on March 20, 1345 (Campbell 1931).

Those who could afford to, including physicians, fled the infected towns. Orvieto, for example, had to offer a doctor 100 livres per year to stay and treat the poor. The Catalonian Cortés fled Barcelona, and all the inhabitants of Agrigento, Sicily, ran away in 1347. Citizens of Marseilles burned the La Rousselle quarter to contain the plague (Biraben 1975). Perhaps because both cities forbade entry by travelers, Milan and Parma remained largely free of the disease during its first outbreak in 1347–50. In Milan early victims were also heartlessly walled up in their houses (Ziegler 1970; Ell 1984b). At Ragusa (now Dubrovnik, Yugoslavia), ships were isolated for 40 (*quaranta*) days, in a first effort at quarantine.

The first great outbreak of the Black Death was followed by three waves in the same century, in 1360,

1369, and 1375. It has been estimated that the death rate in Britain decreased with each successive wave, starting with 25 percent in 1348 and becoming 22.7 percent in 1360, 13.1 percent in 1369, and 12.7 percent in 1375. It is assumed that the disease lost its virulence at the same time that people's immunity increased (Russell 1948; Carpentier 1978).

Persistent questions about the Black Death perplex modern historians. Was bubonic plague the sole disease, or where there others? Why was no unusual black rat mortality mentioned by contemporary writers? Why is the black rat unknown today in Europe except in a few port cities? Was a sylvatic, or wild, home for the plague ever created in Europe – either at the time of the sixth-century eruption or in the fourteenth century? If so, what eradicated it? Modern sylvatic foci, in the southwestern United States and Russia, are almost impossible to eradicate (McNeill 1976).

It has been suggested that more than one disease was active during the fourteenth-century epidemics, with typhus, smallpox, and anthrax as candidates. Scholars have been puzzled by records of high infection rates during the winter months, since plague is a warm-weather disease. This and other contradictory factors support the case for anthrax, which is caused by a much hardier organism, is characterized by pustules with a jet-black center, often precipitates the voiding of black blood, and also has a pulmonary form (Twigg 1984).

Doubts about the classical explanation of plague transmission derive partly from the present-day absence of *R. rattus* in northern Europe, except in a few port cities. Moreover, no medieval record exists of the explosive black rat mortality that would have been expected. Finally, *R. rattus* is timid and not normally migratory (Shrewsbury 1970; Ell 1980).

As already mentioned, spring and summer are the seasons of ratborne plague in cities (infection occurs most commonly when both Fahrenheit temperature and humidity are between 68 and 80; Russell 1976), yet the Black Death occurred throughout the year. The explanation may lie in two possible forms of interhuman transmission: Respiratory infection, which produces pneumonic plague, would explain the winter occurrences, and transmission by the human flea, *Pulex irritans*, would account for the undoubted majority of bubonic cases (Ell 1980). *P. irritans*, which can transmit plague, would have needed no rat host and could have lodged in long, loose clothing, traveling from person to person. Lice, ticks, and bedbugs, which can also transmit plague, may have been vectors as well (Biraben 1975; Ell 1980).

As for the sylvatic foci in rodents, an alternative explanation would be that multiple human and animal reservoirs, based on complete and partial immunities, perhaps constantly shifting, propagated the plague bacillus without a sylvatic home. Plague immunity is known or suspected to be conferred by salmonella infections, *Yersinia enterocolitica,* tularemia, and typhus, as well as leprosy (Ell 1984b).

Explanations for the final disappearance of plague from Europe in the eighteenth century included speculations that the bacillus mutated to a less virulent form, that *R. rattus* was replaced by *Rattus norvegicus,* and that new practices of housing construction, shipping, personal hygiene, nutrition, and public health finally brought the disease to an end (for reviews of theories see Appleby 1980; Ell 1984b). In addition, the rats themselves may have become immune. Communities of immune rats are known to have existed in India in the twentieth century. The reason the rats did not become immune in northern Europe until the seventeenth century (and a few decades later in the south) may be that a certain high density of population would have been required for all remaining susceptible rats to be infected and finally killed (Appleby 1980).

Historians have long accepted a type of Malthusian theory to account for the appearance of plague in 1348. According to this theory, a too rapid population expansion led to the clearing of all arable land and crowding into already overpopulated cities. The populace then suffered a series of crop failures and famines when the weather turned unusually cold early in the fourteenth century. As rats fled empty granaries to find food in human dwellings, the human population, weakened by starvation, fell victim to a chance epidemic. Critics of this Malthusian position have objected that the weakest members of society were not eliminated by the plague; men between 20 and 40 died in larger proportion than women, children, the aged, or even lepers. The *Y. pestis* organism requires exogenous iron for growth and replication, and young men were the least iron-deficient group in the medieval population (Ell 1984b, 1987).

Believed to have left in its wake some 20 million dead in Europe in the four years from 1346 to 1350, the Black Death brought about critical social and ideological changes. Considering the medical world alone, we find that the public health tradition, inherited from the care of lepers, was strengthened – even though social efforts to clean streets, collect garbage, empty sewers, remove bodies, regulate the sale of food, and enforce quarantines of ships did little to stop the spread of plague. A new charitable impulse, encouraged by the religious revival after the plague, led to the building of hospitals, both religious and civic. New religious orders were devoted to the care of the sick. Owing to the heavy loss among scholars, physicians, and other educated men, Latin ceased to be the sole language of important texts, and medical as well as other books began to be written in the vernacular (Campbell 1931).

A widespread interest in disease prevention became current, and many works on diet, hygiene, proper clothing, and other topics of health care were published. Because surgeons had made heroic efforts to lance or cauterize buboes during the plague, the status of this profession was considerably enhanced, rising relative to that of physicians, too many of whom had fled. The growth of surgery as a discipline and desire to ascertain the causes of the pandemic led to an increased sanctioning of postmortem examinations, a practice that was to contribute directly to the growth of academic anatomic dissections in the following century.

Finally, humoral pathology suffered a serious blow – from which it would ultimately expire in centuries to come – because of its complete failure to palliate suffering and effect cures, not only for plague but for the other contagious illnesses of leprosy, tuberculosis, and influenza that ravaged the late Middle Ages.

V.4
Diseases of the Renaissance and Early Modern Europe

The Renaissance in European history was a time of political, intellectual, and cultural change that had its origins in Italy during the fourteenth century. Beginning roughly during the lifetime of the poet Francesco Petrarch, who died in 1374, literati began to look to classical Greece and Rome for models of human political behavior and stylistic models of discourse and artistic representation. This humanistic quest involved the energies of philosophers and artists throughout the fifteenth, sixteenth, and seventeen centuries, as Renaissance ideas spread northward. Though narrowly conceived in scholarly and artistic circles, the Renaissance matured in urban settings. Because this time period coincides with technological innovations and the subsequent exploration and conquest of new worlds, we are inclined to associate the issue of Renaissance diseases with both

the growth of cities and the age of European discovery. The period also frames the era of recurrent epidemics of bubonic plague in Europe.

Population growth in Europe was steady during the central, or "High," Middle Ages but did not lead to the growth of large metropolitan centers. Urbanization was earliest and most dramatic in the Mediterranean lands, where city cultures had also been the basis of ancient Roman hegemony. By the late thirteenth century, Florence and Venice, as successful commercial centers, had populations of more than 100,000. Rome, Milan, and Barcelona may have been equally large. Smaller urban areas of 50,000 to 80,000 individuals existed throughout northern Italy and Spain. These cities were roughly twice as large as the "urban" areas of England, including London. Uniformly dense, mixed urban and village networks were also characteristic of the Low Countries at the end of the Middle Ages, and the Seine valley could boast of at least one true city, Paris.

Outside the urban Mediterranean, the period of the Renaissance is better labeled the late Middle Ages. Most people lived in small villages and market towns, where goods, information, and epidemic disease passed through at a more leisurely rate. The British Isles, for example, had no town larger than 50,000 people until after 1600. But by the late sixteenth century, France, Germany, and England began to grow in population and in number of cities. The Thirty Years' War effectively eclipsed growth in Germanic Europe during the early seventeenth century. London and Paris, however, became the largest cities of Europe. By the eighteenth century, Scotland and Scandinavia began the processes of urbanization, commercialization, and protoindustrialization. A general improvement in health and longevity accompanied economic growth, even though the prevalence of infectious diseases remained high.

The "Black Death" epidemic of bubonic plague in 1348–50 caused up to 40 percent overall mortality in large cities, and as much as 60 percent mortality in smaller Italian cities such as Siena. Nevertheless, the greatest proportional destruction of the plague and subsequent periodic epidemics of disease in the fourteenth century seems to have fallen on villages and towns of western Europe, necessitating changes in landholding and land usage, and forcing individuals to migrate to cities in search of nonagricultural work. From 1350 to 1500, recovery was slow and uneven, but as early as the 1450s the great cities of Italy, Spain, and the Low Countries began to wrestle with the sanitary pressures brought about by new growth. These cities grew at the expense of the surrounding countryside, and market economies responded to this growth with the development of local industries, particularly in cloth, and with the development of trading networks that would facilitate further urban growth. During the sixteenth century, an impressive demographic recovery of rural populations seems to have fueled still more urban growth as more and more individuals migrated steadily, even relentlessly, to the cities from the countryside. Thus, even though struck by epidemics of plague, the populations of Venice, Florence, Milan, and Rome all exceeded pre-1348 levels. During the sixteenth century, Madrid expanded 10-fold in population while increasing only 4-fold in size, a dramatic example of the problems of crowding that the growth of Renaissance cities created.

In both Renaissance and early modern Europe, social and economic conditions help to identify and define the diseases then common. Naturally the disease experience of urban settlements differed significantly from that of rural town networks. City administrators were forced to deal with increasingly serious health threats, particularly with problems of refuse disposal and the provision of clean water, and of course with recurrent epidemic diseases.

At a time when at least one-third of all babies born died before their fifth birthdays, chronic infections mediated the lives of most adults, and two-thirds of rural residents did not survive to reproductive age, the acute crises of plague and other epidemics may not have been the most important diseases of the Renaissance. But they were certainly the most visible disease threats, and this shapes modern-day perceptions of the period as a dark age of plagues and other acute infections.

In early modern Europe the specter of famine loomed over the rural landscape. Although the adage "First famine, then fever" did not hold true for all periods of food shortage, periodic subsistence crises tended to provoke mortality crises. Normal annual mortality was as high as 3 percent of a population. But these crises generally carried away 6 to 10 percent of the population, and when very acute could claim as much as 30 to 40 percent. This short-run instability of mortality rates, what Michael Flinn (1981) has described as the demographic system of the ancien régime, was also nonuniform, so that neighboring towns could be affected quite differently during any given crisis. Across a community, the highest death rates occurred among those less than 10 years of age, with most deaths occurring within the first 2 years of life.

The basic problem, then, is to identify the cause or

causes of such high mortality. Famine, epidemics, or war could singly or in combination precipitate a mortality crisis, though infectious disease usually became the proximate cause of death. Yet rural populations often made up the losses quickly through reproduction, and years immediately before and after a period of crisis were times of lower than average mortality. Certainly it would seem that the most vulnerable members of a population were systematically pruned away during a mortality crisis, a classic Malthusian picture.

Plague

Beginning with the wave now called the Black Death, plague appeared in Europe at least once every generation between 1350 and 1720. During the late fourteenth century, smaller communities may have been disproportionately affected, for depopulation and deserted villages were uniform phenomena throughout Europe. Indeed, smaller centers may not have remained economically or demographically viable settlements after an episode of plague, leading to the reaggregation of people in villages, towns, and cities. By the fifteenth century, however, no matter how uniform the distribution of rodent vectors responsible for conveying plague to smaller human settlements and however sophisticated the development of trade networks to supply food to nonagricultural centers, the written records of plague recurrence suggest that the human plague epidemics were largely confined to urban areas. O. J. Benedictow (1987), however, has argued that a knowledge of the ecology and epidemiology of plague allows us to infer that there were heavy losses in the rural areas surrounding affected cities.

Bubonic plague epidemics were principally summer infections, no doubt augmented in severity by diarrheal diseases. Most surviving records of these epidemics suggest that overall mortality rates of 10 percent were common among the people who could not escape the city. Nevertheless, devastating population losses from plague epidemics, comparable to those from the Black Death, occurred in the sixteenth and seventeenth centuries in the heavily urbanized areas of north central Italy and Castille and may have led to the economic decline of the Mediterranean areas by the seventeenth century. During the seventeenth and eighteenth centuries, northern European countries witnessed the growth of cities and large towns, whereas Mediterranean centers slipped into a period of stagnation, probably because the epidemic waves of 1575–7, 1596, and 1630 were particularly severe in southern Europe.

Only during the fourteenth century do descriptions of plague note the loss of many principal citizens. After that period elites seem to have established effective patterns of flight. For those who did not flee, plague controls may have increased the risk of death, because both sufferers and their healthy contacts were isolated for weeks in pesthouses, temporary shacks, or, if they were lucky, their own homes. The maintenance of normal standards of hygiene and alimentation was difficult in such circumstances, and many undoubtedly died from less extraordinary causes than plague.

Whatever the individual causes of death in these mixed epidemics, for more than 300 years bubonic plague recurred in Europe at least every quarter-century. Then it disappeared during the late seventeenth and early eighteenth centuries, a phenomenon that has prompted two vexing, unsettled questions about diseases of the Renaissance and early modern Europe. First, why did plague disappear? Second, was its disappearance in any way responsible for the early phases of the modern rise of population? The first of these two questions has rather clearer options, if not firm answers. Some scholars argue that quarantine and other efforts to interrupt the spread of plague from town to town, region to region, or country to country effectively localized the outbreak of the plague. Admittedly these sanitary measures were designed to thwart a disease spread by human-to-human contact and did little to disturb rodent colonies that harbored the plague. But because rodents are commensal, rarely traveling far from human settlements, it is felt by some that the dispersal of plague ultimately depended on human actions. The proponents of this "quarantine-worked" model argue that humans inadvertently carried rodents and infected fleas in containers ranging from satchels to ships. This explanation has much to recommend it, but depends on the assumption that plague was always imported to Europe and that efforts to intercept and deter such importation ultimately succeeded even when quarantine stations were poorly maintained and were, at best, sieves straining out only gross contaminants.

Others argue that either climatic changes or changes in trade patterns led to the retreat of plague from Europe. The disease hit northern Europe for the last time in the 1660s and southern Europe (Marseilles and Provence only) in 1720. The interval between these last European plagues corresponds roughly to the "Maunder minimum" of sunspot activity and to the peak phases of the "little ice age." Insofar as global climate changes could have af-

fected rodent colonies in central Asia, where bubonic plague has a perennial home, the number of infected fleas and rodents reaching Europe could have declined independently of efforts to control plague. Alternatively, the fact that northern Europeans turned to an Atlantic-based trade, shifting markets away from the Mediterranean to colonies in the Western Hemisphere and to the Far East, may be related to the decline of plague first in Great Britain, Scandinavia, and the Low Countries. The plague was always conveyed east to west across the Mediterranean and principally by sea. The relatively later survival of plague in Italy and Spain, where plague surveillance and quarantines had long been used, adds some weight to these latter explanations.

Whether the retreat of plague had any measurable effect on subsequent population growth is more difficult to answer, for there is no easy way to frame a model showing what would have happened had plague continued its assaults. Urban population growth in northern Europe was well underway before the two great plagues of 1630 and 1665–6. Even if Benedictow is right in stating that bubonic plague epidemics claimed horrifying percentages, on the order of 40 to 85 percent, of both the urban and rural populations exposed, net European population growth was not reversed during the sixteenth and seventeenth centuries.

John Hatcher (1977) and others have claimed that the profound demographic depression of the late fourteenth and fifteenth centuries was due in part to the combination of plague with other lethal epidemics, often staggered in such a way that few children reached reproductive age. Nonetheless, the frequency of *recorded* epidemics of diseases other than plague increased during the later centuries, and yet did not bring on population stagnation, as may have been the case in the late Middle Ages.

Thus, the economic expansion of Europe, with some improvements in travel, trade, and communication and dramatic improvements in regional and interregional markets, seems to best account for the beginnning of the European mortality decline in early modern times. The Europeans found themselves increasingly insulated from local famines, periodic harvest shortfalls, and other crises that evoked great fear of accompanying plague and pestilence, and were gradually able to overcome the hemorrhagic demographic impact of recurrent epidemic plague. To understand how this could have happened, it is necessary to assess what other infections threatened human survival at this time and to ask whether improved nutrition because of regularly available food has a positive influence on human survival even in the presence of serious infectious diseases.

Other Epidemics

During the Renaissance period, influenza pandemics recurred frequently enough to be well described by the fifteenth century. At least three influenza epidemics were quite severe during the sixteenth century, those of 1510, 1557–8, and 1580. The last in particular resembled the devastating influenza of 1918, in that the first wave occurred in the summer and early fall, and morbidity and mortality were high among young adults. The periodic influenza in the seventeenth century has not been a subject of scholarly study, though the epidemics of 1627 and 1663 seem to have been quite lethal. In contrast, epidemics of the eighteenth century have received considerable attention. K. David Patterson (1986) points to two epidemic periods in particular, from 1729 to 1733 and from 1781 to 1782, that mirror sixteenth-century pandemic influenza, suggesting that worldwide distribution of this common infectious disease antedated advances in global transportation.

Virulent smallpox, by contrast, may have appeared in Renaissance Europe only in the mid-sixteenth century (Carmichael and Silverstein 1987). Before that time measles and smallpox were described as relatively mild infections of childhood, an observation resting on those of ninth- and tenth-century Muslim physicians, Rhazes and Avicenna. Unless many of the fourteenth- and fifteenth-century epidemics of plague were in fact mixed epidemics of plague and smallpox, with the latter masked by the horror of the plague, records of epidemics of smallpox were sparse before the 1560s and 1570s. More likely a milder strain of smallpox prevailed before virulent smallpox entered England in the seventeenth century. Smallpox has a much more prominent — if not preeminent – place among the diseases of the seventeenth and eighteenth centuries and will thus be discussed later in more detail.

The history of other infections transmitted by airborne droplets is a patchy one during the Renaissance. Diphtheria was certainly described well in epidemics of malignant sore throat, as was whooping cough, the earliest examples dating from the sixteenth-century epidemiologist Guillaume de Baillou. In Spain, accounts of epidemics of *garoffilo* appeared during the early seventeenth century, depicting what was presumably a considerable threat to young children. Yet diphtheria was confused with epidemics of streptococcal sore throat as late as the mid-nineteenth century.

The German physician Daniel Sennert is credited with having written the first unambiguous description of scarlet fever. Rheumatic fever, another manifestation of severe streptococcal infection, was described well by Baillou in the sixteenth century and by the English physician Thomas Sydenham in the seventeenth century. Epidemic typhus fever seems to have been a new disease in Renaissance and early modern Europe.

One of the great problems facing historians of Renaissance diseases is the difficulty of discerning the precise cause of an epidemic much before 1500. For example, the following account from a Parisian chronicler in 1414 suggests both whooping cough and influenza:

And it pleased God that a foul corrupt air should fall upon the world, an air which reduced more than a hundred thousand people in Paris to such a state that they could neither eat, drink, nor sleep. They had very sharp attacks of fever two or three times each day, especially whenever they ate anything. Everything seemed very bitter to them, very rotten and stinking, and all the time, where ever they were, they shook and trembled. Even worse, besides all this they lost all bodily strength so that no one who had this disease could bear to touch any part of his body, so wretchedly did he feel. It continued without stopping three weeks or more; it had begun in early March of the same year and was called the tac or herion. . . . As well as all the misery described above, people had with it such a fearful cough, cattarh, and hoarseness that nothing like a high mass could be sung anywhere in Paris. The cough was so much worse, night and day, than all the other evils that some men suffered permanent rupture of the genitals through it and some pregnant women gave birth prematurely because of this coughing, alone and without help, and died, mother and child, in great distress. When people began to get better they passed a lot of clotted blood through nose, mouth and below, which frightened them very much. Yet no one died of it. But it was with great difficulty that people managed to recover from it, even after the appetite came back it was still more than six weeks before they were really cured. No physician could say what this disease was. (Shirley 1968)

This vivid description is echoed by a brief mention of a contemporary catarrhal illness in the other urban areas of Europe, suggesting that the disease was influenza. The cough and low case fatality, however, indicate whooping cough (the chronicler is unlikely to have noted the deaths of babies). But if either whooping cough or influenza was a truly new disease in the early fifteenth century, then the implications for changing disease patterns in the later Renaissance would be considerable. It is more likely that the criteria for diagnosis and the medical theories governing the description of disease changed during the Renaissance, making difficult a retrospective assessment of what was new and different then.

In others words, evidence for the sudden appearance of many common diseases in the sixteenth and seventeenth centuries is somewhat artifactual – a "reporting phenomenon." During the Renaissance, physicians increasingly turned to models of contagion to explain (and, hence, control) the spread of plagues and pestilences, and were aided considerably by adoption of ontological theories of disease. That is, physicians crafted new medical definitions of diseases, which had long possessed common lay names, describing them as individual entities with unique and distinguishing characteristics. Though chronic "diseases," such as fevers, consumption, arthritis, gout, cancer, ulcers, and fistulae, were still best explained and treated only by a thorough understanding of the Galenic–Hippocratic humoral system that dominated medicine until the nineteenth century, medical accounts from the sixteenth century onward tended to identify acute health problems in terms of specific diseases. These new ways of looking at illness had a profound effect on the recognition and description of diseases known today. Moreover, the spread of medical information through the medium of print accelerated and normalized the understanding of many diseases as specific and individual.

In the sixteenth and seventeenth centuries, dozens of "new" diseases seemed to demand or defy medical explanation, which resulted in some of the earliest medical descriptions we possess for scurvy, rickets, typhus, syphilis, scarlet fever, the "English sweate" (whatever that was), and even anorexia nervosa. Thus, one of the fundamental problems for historical epidemiologists is determining which of these, if any, were indeed new or newly important during the period from 1400 to 1800. And by "newly important," we mean diseases that changed in incidence and prevalence in a society rather than those that became important to some groups within these societies. For example, was gout "important" to Renaissance and early modern elites because it became a noble form of suffering – in contrast, for example, to the ignominy of syphilis – or because meat consumption among the upper classes, together with a heavy consumption of dehydrating alcohol, increased the clinical expression of gout? In many cases we will never know the answer, and thus must make some assumptions based on those data that did not change over the reporting period while considering significant shifts in the criteria for definition and diagnosis. In this respect, much scholarly attention has been devoted to smallpox and

syphilis, which thus form two illustrative case studies of the problems involved in tracing the history of diseases of early modern Europe.

Smallpox and the Modern Rise of Population

Smallpox was long recognized as a contagious disease with a pustular rash. Distinctive clinical features, such as the simultaneous maturation of pustules (this distinguishes it from chickenpox) and the centripetal distribution of pustules over the body, were not noted. Oddly, the residual facial scarring among recovered variola major victims, was rarely mentioned. Nevertheless, by the early seventeenth century, smallpox was recognized by both lay and medical observers as a distinctive disease.

Even if many cases were missed because the victim was severely infected, or was very young, and died before the rash appeared, mortality records from England, Italy, Sweden, and elsewhere testify to the accelerating intensity of smallpox over the course of the seventeenth and eighteenth centuries. Epidemic years of smallpox in Italian cities of the eighteenth century could account for up to 30 percent of the annual mortality, and recurrences swept urban areas at least once a decade (Panta 1980). In London, the largest city of Europe by the eighteenth century, there were no gaps between major outbreaks of smallpox. Annual mortality in the metropolis averaged 10 percent of all deaths. Thus, there is much agreement that smallpox was one of the principal causes of morbidity and mortality after plague disappeared. The residual questions are: Why was smallpox increasing in incidence and prevalence, and what effect on population and other diseases did inoculation and vaccination against smallpox have? Finally, can the stepwise retreat of smallpox with the introduction of innovative therapies explain any part of the modern rise of population, which began in the eighteenth century?

The answers to these questions depend in part on the assumptions demographers and epidemiologists make about the principal causes of death in early modern cities. Many view cities as death traps, their highly unsanitary environments containing a rich variety of gastrointestinal pathogens that tipped the balance between births and deaths and necessitated in-migration to maintain populations. Nonrespiratory tuberculosis, water- and foodborne infections, and, to a somewhat more limited extent, midwinter respiratory infections complete the list of pathogens that plagued the cities. However, Allan Sharlin and Roger Finlay (1981; see also Sharlin 1978) have chal-

lenged this picture with an even broader equilibrium model, arguing that the reason the difference between deaths and births was quite large in the cities was that many adult migrants temporarily resided in the city, without marrying or contributing to the replenishment of the population. Thus, an excess of nonreproductive adults in the cities accounts for a good part of the difference between rural and urban mortality statistics.

William H. McNeill (1976) portrays cities as the frontlines of the human battle against microbes that entered these cities through commerce and migration. City residents were usually the first group to be hard hit by a novel infection, but over the long run city populations were, on the whole, immunized earlier in life to viral diseases, which produced lifelong immunity. Young adults migrating into the city from the countryside might add to the pool of individuals susceptible to common infections. Unhealthy-appearing, impoverished urban dwellers would better survive an epidemic of measles than a comparable group of strapping young adults from the provinces.

McNeill's view would make smallpox an excellent example of the long-term advantages, largely immunological, to city dwellers, and John Landers and Anastasia Mouzas (1988) have found robust empirical support for this view in the records of London mortality. Moreover, Landers (1987) has found the beginning of a decline in the summer peaks of deaths from gastrointestinal infections by the late seventeenth century. Thus, he doubts the view of an endogenously unhealthy city, with its citizens at the mercy of microbes. Moreover, with the immunity of survivors of exogenous killer diseases, such as smallpox, urban mortality changed significantly during the "long" eighteenth century, 1670–1830. Hidden in those changes, he believes, are the reasons for the initial modern rise of population.

In addition, A. J. Mercer (1985) argues that smallpox may have been uniquely important in a demographic sense not only because it killed a large number of young children, but because its survivors often succumbed to other infections, once "weakened" by smallpox. Although general crisis mortality, in city or countryside, cannot be linked to famine or to weather conditions, statistically it can, in the eighteenth century, be linked to epidemic waves of smallpox. Mercer is not willing to ascribe a determinant role to smallpox among the diseases of the eighteenth century, but he is convinced that vaccination, where adopted even halfway, contributed significantly to the survival of children to adulthood, accel-

erating population growth in the early nineteenth century.

Other scholars consider typhus and tuberculosis to have been as important as smallpox. There is once again an artifactual aspect to the high prevalence of typhus, for it was only during the eighteenth century that physicians first described its clinical and epidemiological features well and differentiated typhus from a miscellany of other fevers – nervous, biliary, inflammatory, continuous, hectic, and intermittent.

Most have accepted Hans Zinsser's (1935) argument in his celebrated *Rats, Lice and History* that epidemic typhus fever was a new disease in the late fifteenth century, brought to Spain and Italy during the battles against Turkish expansion in the Mediterranean. The dramatic urbanization of northern Europe (London grew from c. 400,000 in 1650 to more than 1 million by the early nineteenth century) accelerated crowding and poverty, optimal social conditions for the spread of typhus by body lice. Crowding and poverty also supported the transmission of respiratory tuberculosis, which many have argued was at a peak at about 1800.

It was during this era of earliest industrialization that population began to swell, and thus the model of the city as a death dispensary or as a provider of immunity may not be especially relevant. Indeed, Thomas McKeown (1976) has been the principal spokesperson for a view that credits improving nutrition rather than declining disease with that growth. According to McKeown, whether an individual survives a disease, be it an acute viral infection such as measles or a chronic infection such as tuberculosis, depends on the individual's state of nutrition. Yet this argument is based more on experiential data generated by physicians treating well-nourished and undernourished mothers and children than on laboratory studies of human nutrition and specific infectious diseases. With many diseases, there is little direct relationship between the outcome of infection and the prior nutritional state of the host. Yet the ability to outlast several serious infections does depend on steady access to food and, obviously, to protection from further health insults. In a few diseases, such as measles and tuberculosis, there is, moreover, a positive association between poor nutrition and severity of infection. Insofar as these two were among the most common diseases of the early modern period, nutritional security and the generally improved standards of living this implies may have permitted the survival of more children to reproductive age. When smallpox, the last great killer of little children, came under control, population growth was dramatic, even though exposure to multiple infections and specific medical measures did not change the features of disease experience for nineteenth-century Europeans.

At just the time McKeown finds general improvements in human nutrition, the appearance of widespread deficiency diseases marked further change in the European disease experience. The prevalence of scurvy increased, including that of "land scurvy" suffered by the most impoverished city dwellers. Pellagra was described first in the eighteenth century among the desperately poor farmers of northern Italy and Spain, who became dependent on American maize. Potato and squash cultivation eased the lives of many northern Europeans, helping them to avoid famine crises that had been common before the eighteenth century, but well into the nineteenth century the dependence on single crops or foodstuffs often gave the poor no relief from a miserable nutritional regimen. Thus, in many instances, the benefits of improvements in nutrition may have largely accrued to upper- and middle-class urban dwellers. It would seem that the disappearance first of plague – a relentless killer of young adults – and then smallpox permitted the survival of a greater number of reproductive adults, well nourished or not.

Chronic Infectious Diseases

The attention of demographers and others trying to explain the modern rise of population has seldom turned to the chronic infectious diseases. Thus, the steady silent killer, tuberculosis, and the flashy new infection of Renaissance Europe, syphilis, are seldom discussed in this context. Yet there exists a reciprocal relationship between copathogens, acute and chronic. For example, survivors of smallpox might have been weakened by this disease and thus succumbed to tuberculosis. Conversely, an underlying tuberculosis infection should have weakened the ability of individuals to fight off smallpox and other epidemic illnesses. A reduction in the morbidity of chronic infectious disease may play an important role in the decline of mortality from acute infectious disease. Thus, Stephen Kunitz (1983) has argued that the cause of the modern rise of population was stabilization of mortality from all causes.

Those historians, such as Alfred Crosby (1972), William McNeill (1976), Emmanuel Le Roy Ladurie (1981), Kenneth Kiple (1984), and others, who have taken very grand perspectives of the period from 1400 to 1800 have seen Europeans participating in a saga of unprecedented success because of their outward

migration and colonization. European population expanded externally far beyond the bounds of a modest modern rise of population. They unintentionally exported both chronic and acute infectious diseases, which had disastrous consequences for the native populations of the Western Hemisphere and Australasia. In return, Europeans brought back home only a few infections that caused serious concern.

Foremost among these may have been syphilis. Imported, at some time during the late fifteenth century, possibly with the Spanish colonization of the Americas, possibly with earlier Portuguese conquests in western Africa, syphilis suddenly appeared in the mid-1490s, uncharacteristically as a pustular rash, a large pox in contrast to the small pox. Within half a century, however, syphilitic patients suffered the same general pathology that untreated victims would in the twentieth century, including long, chronic bouts with ulcers and fistulae. The records of both the initial pandemic wave and individual cases of syphilis from 1550 to 1800 are intertwined with heightened moral concerns and fears of stigmatization, so that it is difficult to assess the prevalence of syphilis during this period. Police and public health officers of the nineteenth century took an aggressive interest in the control of syphilis, especially in the control of prostitution. They thereby generated our earliest numerical surveys of syphilis, comparable to earlier records of plague and smallpox.

Because of European contacts with Africa and the tropical world, mosquitoborne diseases also traversed Europe increasingly after 1500. Malaria may have increased in prevalence, partially from increased contact with Africans and partly from increased rice cultivation. A more alarming mosquitoborne disease, however, was yellow fever, epidemics of which increased in frequency through the seventeenth and eighteenth centuries and culminated in the catastrophic Barcelona outbreak of 1821. The eighteenth-century expansion of urban environments, especially of port cities and other trade centers, along with the construction of irrigation ditches for agriculture and canals for transport between markets, increased the number of breeding places for mosquitoes.

Finally, we should mention again tuberculosis, as John Bunyan called it in *Pilgrim's Progress,* "captain of all these men of death." Scourge of the wealthiest Renaissance families and a persistent problem in Renaissance Italian cities, tuberculosis followed the pulse of European urbanization, moving northward as cities appeared, to peak in the eighteenth century. Most city children were infected early in life, recovered, and lived a normal life span, then 40 to 55 years. The heaviest mortality from tuberculosis occurred in infancy, the heaviest morbidity probably in the middle adult years. A small percentage of older children died of pulmonary tuberculosis, chronic diarrhea, or any of the many varieties of extrapulmonary infection. A slightly larger percentage of the once-infected succumbed as young adults.

Thus far we have concentrated mainly on mortality. But the biography of Alexander Pope by Marjorie Nicholson and George Rousseau, *This Long Disease, My Life* (1968), provides a classic illustration of the process of chronic disease in individuals who escaped plague and the ravages of smallpox. Pope was struck by a tubercular infection that left him disabled. He labored to keep up his correspondence and wrote poetry between visits to the baths and visits from physicians. Throughout his life, he valiantly bore the great pain of travel by coach, a harrowing experience for a body as gnarled as his, bravely sampled the latest remedies, and occasionally confessed his trials to his numerous invalid friends: "I am grown so tender as not to be able to feel the air, or get out of a multitude of Wastcotes. I live like an Insect, in hope of reviving with the Spring." One of the last visitors to Pope's deathbed observed, "He dyed on Wednesday, about the Middle of the Night, without a Pang, or a Convulsion, unperceived of those that watched him, who imagined he was only in a sounder Sleep than ordinary."

One suspects that the gradual recession of both acute and chronic infectious diseases also went unperceived even among those who were watching. But the human costs of epidemic diseases as well as chronic infections lessened as people gained greater access to food, as well as more nutritional variety, and developed means of distancing their exposure to acute infectious diseases during the economic expansion of the eighteenth century.

V.5
Diseases and the European Mortality Decline, 1700–1900

In his study of world population published more than 50 years ago, A. M. Carr-Saunders (1936) observed that the population of western Europe had begun to increase by the early eighteenth century, if not earlier, as a result of a growing gap between births and deaths. The gap was accounted for primarily by the fact that mortality was declining whereas fertility was high and in some countries was even growing. Addressing the reasons for the decline in mortality, he, like others both before and since, classified the causes into several categories:

For the purposes of this discussion the conditions, of which note must be taken, may be classified into four groups, though the boundaries between them are indefinite and though there is much overlapping: (1) political, that is conditions in relation to the maintenance of external and internal order; (2) social, including the state of knowledge in relation to the production and use of food, and to the making and use of clothing; (3) sanitary, that is conditions relating to housing, drainage, and water-supply; (4) medical, including both the state of knowledge concerning the prevention and cure of disease and its application to the public at large.

Because Carr-Saunders was dealing with the period after 1700, he thought that the first category – social order – no longer applied because conditions in England and the rest of northwestern Europe were by that time comparatively stable and orderly. Thus, the other three categories were of most value in explaining the mortality decline in northwestern Europe in the eighteenth and nineteenth centuries. Under (2) he included the adoption of root crops, the improvement of gardening, and the use of cotton for clothing, which improved personal cleanliness. Under (3) he included the improvement of towns and their water supplies, the paving and cleaning of streets, and the substitution of brick for timber. Category (4) included increased scientific knowledge, practical applications even when the theory was not understood, a profession of practitioners (apothecaries in England), and the construction of hospitals (Carr-Saunders 1936). He did not attempt to determine which category was most significant.

He then pointed out that in the countries of southwestern Europe (excluding France) mortality did not begin to decline until the 1890s, probably as a result

of the late introduction of improvements in catego-
ries (2), (3), and (4). Finally, in eastern Europe the
course of mortality showed some resemblance to that
of southwestern Europe, but began to decline even
later, when the same three causal categories were
first introduced.

In general, writers before Carr-Saunders had
taken a similarly broad approach. After World War
II, however, the situation changed. In an article on a
century of international mortality trends, George
Stolnitz (1955) observed the following:

Increasing life chances are almost always explained by
reference to two broad categories of causes: rising levels of
living on the one hand (income, nutrition, housing, liter-
acy), and on the other technological advances (medical
science, public health, sanitation). The usual approach has
been to regard these sets of factors as more or less coordi-
nate, with little attempt to assess their relative impor-
tance. At the same time there has been considerable em-
phasis on their interdependence, a common observation
being that the developing and application of disease con-
trol techniques would have been very different in the
absence of widespread social change. Both of these views,
which evolved largely on the basis of Western mortality
experience, have also been traditional explanations of the
contrasting patterns found in other parts of the world.
Only recently has their adequacy been seriously ques-
tioned, mainly as a result of developments in Latin
America–Africa–Asia. The introduction of new disease-
control methods in this region, usually unaccompanied by
any important shifts in socio-economic conditions, has led
to drastic mortality declines in the last few years. It is
worth noting, therefore, that a similar causal process may
have been operative in the acceleration of Western survi-
vorship a good deal earlier.

The measurable reduction in mortality rates fol-
lowing the introduction of antibiotics and pesticides
led not only to revisionist views of the past accom-
plishments of medical technology. It led as well to a
major reshaping of the biomedical research and edu-
cation establishment in the United States in the
decades following World War II, at a time when the
United States had emerged as the dominant force in
scientific research in the West.

Both the intellectual and institutional changes
evoked a response from others with different ways of
explaining historical and contemporary disease pat-
terns. We may call theirs a "holistic" approach, for it
emphasized the significance of the social context,
economic forces, and modes of life, and placed less
weight on medical factors. For example, in 1955
Thomas McKeown and R. G. Brown wrote that the
medical interventions usually invoked to explain de-
clining mortality in eighteenth-century England

could not possibly have had the effect attributed to
them. In fact, some may have done more harm than
good, as R. Dubos (1959) also pointed out.

Others have argued that, at worst, hospitals and
dispensaries, inoculations for smallpox, and "man-
midwives" had no discernible effect and may have
been beneficial. McKeown (1976), in *The Modern
Rise of Population,* has suggested that improved nu-
trition in the eighteenth century initiated the de-
cline. Others have their favorite "first causes" as
well: J. Riley (1987) has suggested environmental
improvements, and W. H. McNeill (1976), among
others, has advanced the increasing genetic resis-
tance to infectious diseases of European populations.

It is likely that the mortality decline proceeded in
stages, with certain classes of diseases being reduced
in sequence (Omran 1971). The first to be reduced
were pandemic and epidemic diseases not responsive
to the nutritional status of the host. Next were dis-
eases that caused lifelong immunity after an infec-
tion. Last to decline were diseases that were either
identifiable nosological entities or clusters of signs
and symptoms (i.e., the so-called pneumonia-
diarrhea complex), all of which were made espe-
cially lethal by the malnourished state of the host.
Different conditions were causally associated with
the decline of each disease.

By the early 1700s the great pandemics of plague,
as well as subsistence crises, had receded from west-
ern Europe. As Carr-Saunders (1936) had suggested,
this was largely the result of the growing stability of
governments. More recently M. W. Flinn (1981) has
elaborated this point, suggesting that a number of
factors were responsible for the diminution of mortal-
ity from wars, famines, and plague. There was, he
suggests, a change in warfare: a shift to naval and
colonial wars, the development of a science of mili-
tary hygiene, greater discipline of armies, and in-
creasing isolation of armies from civilian populations
(all of which would have contributed to a decline in
typhus, among other causes of death). There was also
a diminution of subsistence crises, attributable to the
spread of new crops, the opening (in eastern Europe
especially) of new lands, improved transportation,
and more sophisticated "social administration" and
famine relief. There was, finally, a diminution of
plague in western Europe, which a number of observ-
ers have attributed to increasingly effective quaran-
tine procedures, for example, the Hapsburgs' *cordon
sanitaire* along the boundary of their empire with the
Ottoman Empire. All of these measures were a reflec-
tion of growing efficiency in the administration of
increasingly large states (Flinn 1981).

Thus, by 1700, the start of the period under consideration, a major transformation in mortality was well underway. The great waves of mortality were ebbing and, by the mid-eighteenth century, death rates were stabilizing – albeit at high levels. Not until about the turn of the nineteenth century, however, did they begin a definite decline.

These observations refer primarily to northwestern Europe. Eastern Europe and the Balkans, and to a lesser degree southern Europe, still suffered from high and fluctuating mortality rates, as can be seen in the devastating plague epidemic that afflicted Moscow in the 1770s (Alexander 1980). Indeed, it was in the eighteenth century that mortality in northwestern Europe began to diverge from that of the rest of Europe. These large regional differences will be dealt with first, followed by mortality in northwestern Europe.

It is beyond the limits of this essay to account for the rise of urban industrial societies in northwest Europe during the eighteenth century, and more rural, agricultural societies elsewhere. That both processes were somehow related is generally agreed, though precisely how is much less clear. Certainly as cities grow, they must draw on a hinterland of increasing size for agricultural produce. Just why rings of production within nations or across Europe (and the globe) acquired the characteristics they did in the eighteenth and nineteenth centuries is a subject of disagreement. Clearly, ease of transport and magnitude of demand are important variables (Dodgshon 1977).

Whatever the cause, it appears that in the eighteenth century agricultural production was differentiated across Europe such that the east central, eastern, and southern areas were devoted largely to the production of staples on large estates, worked by an impoverished peasantry. In contrast, agriculture in northwest Europe was characterized largely by mixed dairy and arable activities on farms of 20 to 50 hectares (Abel 1980), usually worked by individual families and servants.

Family organization and household size differed significantly among regions of Europe as well, again for reasons that are poorly understood. Northwest European family organization tended to be neolocal, and household size to be smaller than elsewhere in Europe, where households were large and complex in organization. In northwest Europe, too, marriage tended to occur at an older age than elsewhere, and it was not universal (Laslett 1983). Even to attempt to explain the genesis of these differences, or their association with differences in

agricultural patterns and industrial and urban development, is not appropriate here. It is sufficient to note simply that, even before industrialization occurred, northwestern Europe differed significantly from the rest of Europe with respect to land use, the organization of work, and household size and composition. However, it is also appropriate to suggest some of the ways in which these differences may contribute to an explanation of the differences in mortality rates and patterns across Europe in the eighteenth and nineteenth centuries after the recession of great pandemics. Indeed, distinctions remained even into the twentieth century.

It has been said that mortality stabilized in northwestern Europe during the eighteenth century as a result of growth of stable states, and that elsewhere rates tended to fluctuate widely as epidemics persisted into the nineteenth century. Nonetheless, even in the more peripheral regions of Europe, there seems to have been a diminution of pandemics and famines as compared with their occurrence in previous centuries. The diseases that remained were endemic. They included named diseases such as tuberculosis, typhoid, scarlet fever, measles, as well as various forms of pneumonia, enteric infections, and, in children, the so-called pneumonia–diarrhea complex. Even smallpox, which in the past had caused such fearsome epidemics, became in the course of the eighteenth century and even more in the nineteenth, increasingly a disease of children rather than of young adults, a result of both the growth and integration of populations and inoculation and vaccination. Most of these diseases were made more lethal by the malnourished state of the host, although smallpox seems to have been an exception.

There were several ways in which agricultural and household organization affected this constellation of airborne, foodborne, and waterborne diseases. For example, early marriage associated with early childbearing increased the risk of infant death. Large households were likely to be crowded, and density increased the risk of contracting airborne infections as well as the opportunity of spreading body lice (vectors of typhus) in particularly unsanitary conditions. Indeed, typhus continued to be common in the civilian populations of Russia and the Balkans well into the nineteenth century.

The pattern of agriculture that persisted in the peripheral regions of Europe throughout the nineteenth century – agricultural wage laborers or serfs working on large estates devoted to monocropping – required the exploitation of female labor. In addition to imposing physiological stress on women, it pre-

vented them from breast feeding for as long as might have been desirable. Moreover, the fact that dairying was not common probably meant that, when infants were weaned, they were put on a very modified adult diet rather than one that included a large amount of nonhuman milk. Under such circumstances, so-called weanling diarrhea was probably very common. Weanling diarrhea is a lethal syndrome in which a malnourished child develops diarrhea and in which diarrhea may precipitate malnutrition. Diarrhea may or may not be caused by malnutrition, but mal-nutrition increases the likelihood that an episode of diarrhea will be fatal.

Studies in Russia at the end of the nineteenth century showed that infant mortality increased dur-ing the summer, when mothers often worked long hours in the fields, generally leaving their children at home, where they could not be nursed. In addi-tion, the practice of using a pacifier rather than breast feeding increased the chances both of malnu-trition and of the acquisition of infections, since the pacifier was "a rag covering crumbled bread or rolls, wet dough, or milk kasha – a device ripe with bacte-ria, especially when combined with milk or, as was the custom, prechewed by an adult" (Frieden 1978). Medical reformers who attempted to change these practices frequently met resistance from people for whom domestic arrangements within an extended family reinforced traditional beliefs and child-rearing practices.

Germany provides another example of the associa-tion between peasant life on large estates and mor-tality. In eastern Prussia the growth of Junker es-tates devoted to grain monoculture gave rise to a peasant class that needed to exploit women in order to subsist, the result being, as in Russia, an inability to breast feed properly and a high rate of infant mortality. In western Prussia, by contrast, land re-forms in the early nineteenth century led to a wider distribution of peasant landownership, a greater va-riety of crops, and greater ownership of livestock by more people. Thus, spontaneous abortions and in-fant, perinatal, and maternal mortality were all lower in the West than in the East (Kunitz 1983).

Similar regional differences were observed in It-aly, where the south was distinguished from the north by a high proportion of latifundia and high crude mortality rates. Interestingly, however, in this case infant mortality did not differ from one region to another. No explanation for the lack of difference is available; rates all over Italy continued to be among the highest in Europe right to the present century. Indeed, in one particularly poor "latifondo"

region in Calabria, the crude mortality rate aver-aged about 50 per 1,000 in the latter part of the nineteenth century. In one commune of this area between 1861 and 1875, the average annual crude mortality rate had been about 60 per 1,000 and the infant mortality rate averaged about 500 per 1,000 live births. There was no natural increase in the population (Kunitz 1983).

There are no available data from nineteenth-century Spain that permit a distinction to be made between areas of latifundia and areas where peas-ants owned their own land. Similarly, nineteenth-century data from the Balkans are somewhat sparse. Crude mortality rates in Croatia were almost 40 per 1,000 between 1800 and 1870 and began to decline significantly only in the 1870s. Rates were lower in Slovenia, probably reflecting the greater influence of Austria. Data from Serbia are available from 1860, with rates ranging from 27 to 33 per 1,000 between 1860 and 1890 (Gelo 1982–3). It is likely that mortality stabilized gradually over the century as the Ottoman Empire instituted reforms modeled on those of Western governments, including efforts to control plague. The fact that it stabilized at high rates was undoubtedly due to continuing backward-ness, for throughout the area feudal or semifeudal relations persisted for much of the nineteenth cen-tury. In the Hapsburg lands, where servile obliga-tions were formally revoked in 1848, the state devel-oped semifeudal relationships between members of its bureaucracy and the peasantry, but in Bosnia-Herzegovina, under Hapsburg domination from 1878, and in Macedonia, feudalism persisted until 1918. In Serbia the state and money lenders were the chief forces dominating the peasantry (Kunitz 1983).

Turning now to a consideration of mortality pat-terns within northwestern Europe during the eigh-teenth and nineteenth centuries, we have already observed that mortality had stabilized and even be-gun to decline in the eighteenth century. This was primarily a rural phenomenon. Urban mortality re-mained high well into the nineteenth century, though a widely shared definition of *urban* is some-times difficult to arrive at.

The points made about the consequences for mor-tality rates of agricultural and household organiza-tion in the peripheral regions of Europe suggest, by way of contrast, why mortality in the rural parts of northwestern Europe declined more rapidly. House-holds were smaller and presumably less crowded; marriage and therefore childbirth occurred at later ages; dairying became increasingly common and

was practiced year round beginning in the eighteenth century; there seems to have been less exploitation of female labor; increasing emphasis was placed on breast feeding of infants and young children; and when weaning occurred, infants were likely to be given cows milk rather than a watered-down version of adult table foods. The result was lower rates of infant, child, and crude mortality in rural northwestern Europe than elsewhere.

In contrast, urban mortality in northwestern Europe throughout most of the nineteenth century was often as high as in the high-mortality countries of Europe; rates in some cities seem actually to have increased in the first part of the nineteenth century. The issue of whether urban mortality did in fact increase is bound up with the so-called standard of living debate (Woods and Woodward 1984). On one side are the "pessimists" – usually to the left of the political spectrum – who claim with Friedrich Engels that industrial development resulted in a deterioration of living conditions of the working class. On the other side are the "optimists," who claim that development made life better for all and that in some regions of Europe industrial development averted a subsistence crisis, so severe was rural poverty (Komlos 1985). As almost always happens, there is a middle position, whose advocates in this case claim that urban mortality did increase but that it was never as high as it had been in the seventeenth and eighteenth centuries, when epidemics could run amok (e.g., Armstrong 1981).

In both England and France, urban mortality seems to have begun to decline in the second half of the nineteenth century. The diseases that declined were spread in different ways: through the air (e.g., respiratory tuberculosis), food, or water (e.g., typhoid and gastroenteritis of all sorts). Many of them seem to be more lethal if the host is malnourished. Indeed, McKeown (1976) has argued that the decline in deaths from tuberculosis in England was the result of improved host resistance resulting from better nutrition, whereas the decline of foodborne and particularly waterborne diseases was the result of improvements in public health measures, such as protected water supplies and sewage disposal, which seem to have been introduced with increasing frequency in the second half of the nineteenth century. Some diseases such as scarlet fever may have decreased in virulence as a result of genetic shifts in the microorganism itself. Others, such as diphtheria, may have increased in virulence for the same reason. There seems little doubt that, in both urban and rural places, the incidence of smallpox declined dramatically throughout the century as a result of vaccination. And unquestionably the pneumonia-diarrhea complex of childhood declined significantly as well.

It will never be possible to apportion credit with total accuracy to the many preventive measures that contributed to the decline in urban mortality. Public health interventions, changing standards of individual behavior, and improved housing and diets presumably played more or less important roles. Efforts to sort through all of these factors will doubtless raise more questions.

For example, because it has proved difficult to get good direct measures of the standard of living in past times, individual stature, an ingenious indirect measure, has increasingly been relied on (Fogel, Engerman, and Trussell 1982). It is generally assumed that height is a good reflection of nutritional status. Thus, if better diets were responsible for the stabilization of or increase in life expectancy, there should have been an accompanying increase in stature. Unfortunately, the association is complicated by the fact that height also reflects the impact of disease, particularly gastrointestinal afflictions. Permanent stunting may not occur if the intervals between bouts of childhood sickness are sufficiently long that catch-up growth can take place. In developing countries this is often not the case, however, and it has been said that "infections are as important a cause of malnutrition as is the limited availability of food" (Martorell and Ho 1984).

The same may have been true in eighteenth- and nineteenth-century Europe. Thus, the findings regarding variations in height among European populations (Floud 1984), between urban and rural populations (Sandberg and Steckel 1987), and within populations over the course of 100 or 200 years (Fogel et al. 1982) are difficult to interpret if one wants to use them as a measure of the availability of food. This is important because an increase in height (which began in most western European countries in the nineteenth century) could be interpreted as a reflection of the increased availability of food or a reflection of declining sickness resulting from public health measures and from changes in personal behavior, or – what is more likely – both.

In England, at least, fluctuations in life expectancy diminished by the mid-eighteenth century, stabilized at relatively low levels, and then began to increase in the first decades of the nineteenth century. Height also began to increase in the early nineteenth century. Unfortunately, regional data on height are not yet available. But these observations

can be interpreted tentatively to mean that the stabilization of mortality was not caused by improved nutritional status and that, when both height and life expectancy began to increase in the nineteenth century, the effects could have been reciprocal: reduced sickness contributing to increased height, improved nutrition (partially reflected in increased height) making people less susceptible to the lethal effects of the most prevalent infectious diseases. In other words, height is a good measure of the standard of living, but it is difficult to determine whether more food or less disease was responsible for the height increase.

There are several points on which most observers seem to agree. First, the initial recession of pandemics seems to have been a result of the growth of nation-states. Second, specific curative measures applied by individual physicians to individual patients had little if any impact on mortality, regardless of the comfort or distress they may have caused patients and their families. Third, the recession of a variety of endemic diseases had a mix of causes: environmental cleansing and active public health interventions; changes in personal behavior (more frequent bathing, handwashing, the cessation of spitting in public, the covering of one's mouth and nose when sneezing and coughing); and improvements in living conditions. Fourth, urban mortality in western Europe increased for a generation or two in the early nineteenth century.

There are also significant areas of disagreement. One, the standard-of-living debate, has already been mentioned. Another, which has received less attention, is the degree to which individual behavior, as opposed to collective measures, affected mortality. McKeown (1976) has argued that, in developed nations, individual behavior is now more significant than environmental conditions in determining health status whereas in the past environmental conditions were more important than individual behavior. There is certainly disagreement with regard to the truth of this assertion. It has been argued, for example, that attitudes toward breast feeding and personal cleanliness had a measurable impact on mortality in the eighteenth and nineteenth centuries (Razzell 1974; Fildes 1986).

Another subject of disagreement has to do with the notion that European populations were selected for resistance to a wide variety of infectious diseases. Some claim that this was an important determinant of declining mortality, whereas others deny that it was. What is clear is that the European mortality decline was a momentous phenomenon, not simply for Europeans but for all peoples. Its causes were bound up with the very creation of the world as we now know it and will continue to be a topic of debate for as long as we disagree about why the world is as it is.

V.6
Diseases of Sub-Saharan Africa to 1860

Disease in Africa, as elsewhere, has been and continues to be intimately linked with the ways that human populations have fed themselves. Throughout most of the evolutionary journey of *Homo sapiens* on the African continent (again, as elsewhere), the species existed in small bands of hunter-gatherers with generally fewer than 100 members. As such, individuals were constantly on the move, seldom pausing in one place long enough to foul their water supplies or let their garbage and excrement pile up. They were, as a consequence, spared a host of water-borne parasites and insect disease vectors. Because hunter-gatherers did not have domesticated animals, they were also spared the incredible number of ailments that animals pass along to human masters. Moreover, their numbers were too small to support directly transmitted microparasitic diseases such as smallpox and measles. Finally, evidence suggests that hunter-gatherers were essentially free from the predominant noncommunicable diseases of today, such as cancer, heart-related diseases, and diabetes.

This does not mean that they enjoyed perfect health. They were tormented by a variety of arthritic conditions and suffered from accidents connected with hunting and warfare. Those living within the line of 40-inch rainfall would have been infected from time to time by the trypanosome, which is presumably a very ancient parasite of wild animals. When it is transmitted to humans and large animals by the tsetse fly, it causes often-deadly sleeping sickness. Indeed, as William McNeill points out, the disease probably set some limits on the territory in which early humans were able to hunt and gather. Those living close to the forest would also have been infected on occasion by arboviruses (carried by primates) such as dengue and yellow fever, and it would appear that vivax malaria was ubiquitous at some stage of human development in sub-Saharan Africa. *Plasmodium vivax* is thought to be the oldest of the malaria types that presumably were passed along to humans by their primate cousins. That this occurred quite some time ago is suggested by the fact that the blood of most (95 percent or more) black Africans and those of African descent scattered around the globe lack Duffy antigen, which makes them absolutely refractory to this malarial parasite. Indeed, vivax malaria has died out in Africa, presumably for a lack of hosts.

It is perhaps ironic that, by domesticating plants and animals in the first gigantic effort of humans to control their environment, they created a disease environment over which they had no control, one over which even today only a small measure of control has been gained. We will probably never know with certainty what prompted hunter-gatherers to become sedentary agriculturalists. A good guess, however (for Africa as elsewhere), is that the relatively disease-free environment contributed to population growth, that slowly a band of fewer than a hundred individuals became more than a hundred and divided, and that these bands grew too large and divided again, until at some point there were simply too many people for even the huge expanse of Africa to support in their hunting and gathering.

If this is true, then another factor was the expansion of the Sahara desert, which meant the shrinking of resources. The concept of sub-Saharan Africa is a relatively recent one. Some 50,000 years ago that desert was no desert at all, but rather a region covered by Mediterranean flora, and as late as 4,000 years ago farmers and pastoralists inhabited many regions that are dry and barren today. The effect of the desiccating desert was to split the continent into two subcontinents, cut off most intercourse between

the two, and leave the lower subcontinent in relative isolation from the rest of the world. The isolation of eastern Africa, which fronted on the Indian Ocean, was less severe than that of the West, where a hostile Atlantic Ocean formed still another barrier to the rest of the world.

They were Stone Age peoples who found themselves slowly pressed south by the expanding Sahara. At first they lived by harvesting the seeds of wild grasses on its fringes. Then, gradually, they learned how to sow those seeds, which, with repeated effort, would become domesticated sorghums and millets. To the south, on the edge of the forest, dwelled other Stone Age peoples, who fed themselves by trapping small animals and collecting the roots and fruits of the forest, which they also learned to domesticate. To the east, however, hunting and gathering continued, although some cattle were apparently herded in the northern regions.

It was in the south on the eve of the Iron Age, which is to say, the first millennium B.C., probably in the Congo basin, that there developed an agriculturally oriented people who would soon spread over much of sub-Saharan Africa. These were the Bantu. Their language, proto-Bantu, was not a language of hunters, but rather of farmers with words for domesticated animals and plants. It would seem, however, that at first they were not the cereal agriculturalists that most later became, but rather yam and palm oil cultivators who had discovered that these plants grew best in the wetness of cleared-forest areas. While the language was still in a formative stage, it incorporated words for ax and knife and iron and bellows. These agricultural people with a knowledge of ironworking made up the groups that began to expand southward and eastward from their nuclear area to absorb, conquer, and supplant other peoples until the Bantu culture (and agriculture) predominated in almost all of sub-Saharan Africa save for West Africa.

The latter region was, in the meantime, filling up as the expanding desert continued to nudge people, as well as the forest itself, farther and farther south, with the densest populations staying just to the north of the retreating forest. Many of these peoples were perhaps slower than the Bantu to become accomplished agriculturalists, but by the end of the first millennium A.D. most had done so. By this time the region had achieved a good deal of urbanization on the savannas of Sudan, Mali, northern Ghana, and Nigeria, and obviously a well-developed agricultural base was necessary to support the cities.

It is likely that this political consolidation on the savannas, coupled with the advent of the Iron Age, hastened the occupation of the West African forest. For one thing, the forest was a place of refuge from that consolidation, which was based to some extent on slavery, and from mounted slave hunters who were frustrated by the lack of mobility in the forest and whose horses were vulnerable to the tsetse fly and sleeping sickness in many forest areas. Another reason that people gravitated to the forest had to do with both the development of iron tools that were used to clear it and the efficient cultivation of newly imported Southeast Asian food plants such as the Asian and coco yams: These yams were considerably higher yielding than any African food plant and grew well in forest clearings.

Accompanying this conversion to sedentary agriculture for most sub-Saharan Africans were parasite proliferations. They came from herds of domestic animals in the north, they arrived via caravan across the desert as people from the northern subcontinent came to trade, and they developed internally. The hot, rainy, humid portions of Africa harbor a vast and nasty collection of disease-bearing insects, among them some 60 of the world's species of *Anopheles* mosquitoes. The creation of clearings and slash-and-burn agriculture made fine breeding places for many of them, including *Anopheles gambiae,* the most efficient vector for malaria. With stationary humans acting as reservoirs for the disease, human being to mosquito to human being malaria cycles began. Vivax malaria was in recession but was replaced by the new and much more deadly falciparum malaria, which forced populations to build genetic defenses against it, such as sickle trait, glucose-6-dehydrogenese deficiency, and thalassemia traits. In addition, the less lethal but nonetheless debilitating *Plasmodium malariae* became widespread, and genetic defenses notwithstanding, immunity acquired by suffering a few bouts of malaria and surviving them was doubtless the first line of defense.

With the development of sickle trait, however, African youngsters probably began to develop deadly sickle cell anemia. Although sickle-shaped cells somehow limit the extent of parasitization in the case of *Plasmodium falciparum,* that protection comes at a very dear price. When both parents of a child have the trait, the odds are 1 in 4 that the child will be born with sickle cell anemia. In the past, an afflicted child would most likely have died. Thus, in the more malaria-ridden regions of Africa, where the frequency of sickle trait reached 40 percent or

more, sickle-cell anemia must have been an important killer of the African young.

Permanent villages in and near the forest accumulated human junk, such as broken pottery, which encouraged the breeding of another disease vector, the *Aedes aegypti* mosquito. As the latter came to depend on closely packed human populations for blood meals, it began to spread yellow fever among them. Depending on location, villages were cursed with dracunculiasis (guinea worm infection), schistosomiasis, and filariasis (elephantiasis) including onchocerciasis (river blindness, craw craw), and loiasis (loa loa). Individuals now living in close proximity to one another in large numbers passed yaws and leprosy back and forth. Fouled water supplies supported endless rounds of typhoid fever and amebic and bacillary dysentery. In addition, the blood of the animals that were domesticated and lived cheek to jowl with their masters attracted the tsetse fly, which infected humans as well with sleeping sickness (sleepy distemper). They also attracted disease-bearing insects with their dung and passed along parasites like tapeworm, ascaris, and trichuris worms. These and other worms, such as the hookworm, became ubiquitous in towns and villages where fecal material was disposed of casually, if at all, and individuals went barefoot. Indeed, for reasons yet to be explained, West Africans, at least, had so much experience with hookworm infection that they developed a natural resistance to hookworm anemia.

If the forest offered protection from human predators, a price of that protection was frequently isolation: Self-sustaining village-states were remote from one another as well as from the larger world outside the forest. One consequence of this was the development of a rigid social structure that guaranteed the social stability so necessary for survival, but at the expense of innovation and change. Another likely consequence was frequently sufficient isolation from the disease pools of the outside world that when epidemics did strike they proved to be of exceptional virulence.

It is important to stress that the shift to sedentary agriculture among both cereal farmers and yam and palm oil cultivators was not an overnight phenomenon (and indeed, Africa today has hunter-gatherers). Rather, the shift was the result of a process in which expanding food supplies created expanding populations, which in turn sought new areas to bring under cultivation. However, as the diet narrowed from the variety of foodstuffs enjoyed by hunter-gatherers to

the single crop generally produced by sedentary agriculturalists, nutritional illnesses must have joined the list of new diseases in Africa. A diet that is essentially vegetable in nature and limited to a very few nutriments is low in iron, the vitamin B complex, and essential amino acids. In these circumstances it is the young, just weaned from the high-quality protein in breast milk to a vegetable pap, who suffer the most from protein–energy malnutrition with kwasiorkor and marasmus as its symptomatic poles. Animal milk would have prevented the disease, but as hinted at previously those within the line of 40-inch rainfall could not develop a dairying industry because of the blood-sucking tsetse fly, which seeks out large animals and infects them with African trypanosomiasis. This explains, in large part, the high frequency of lactose intolerance among those of West African descent. If they did not drink milk after infancy, there was no reason to maintain the lactose enzyme.

Most West Africans, in particular, were limited to raising a few animals such as goats, chickens, dogs, and perhaps a pig or two. But because these animals were slaughtered only on festive occasions, and because of taboos against drinking goats milk and eating eggs, animal protein figured very little in the diet. Moreover, African soils in the tropical belt are heavily acidic, nitrogen deficient, and leached by rains of their mineral content, especially calcium and phosphorus. As a result, crops that grow on them, as well as animals that graze on them, are protein and mineral deficient. That the West African diet was extraordinarily low in high-quality protein is suggested by the fact that slaves from Africa reaching the Caribbean Islands were significantly shorter than island-born counterparts, despite the miserable quality of the slave diet in the West Indies.

In addition to deficiency diseases, sedentary agriculture led to a reliance on crops that could and did fail because of insects, drought, and warfare. Thus, periodic famine, famine-related diseases, and starvation thinned populations that had swelled during good times, and this synergism became another unpleasant fact of African life. In short, in the switch from hunting and gathering to sedentary agriculture, Africans became what Thomas Malthus called a "forced population," meaning that although the population grew, this growth was managed only at a decreased level of subsistence for everybody.

Contact with Europeans and, through them, their American empires brought a second agricultural revolution to sub-Saharan Africa. Cassava (manioc),

maize, peanuts, and sweet potatoes, high-yielding plants imported from America, spread throughout Africa until they became much more important than indigenous crops and further stimulated population growth. Ironically, much of that growth was drained off to America via the slave trade. In addition to population growth, however, the new plants stimulated disease. It has been discovered that those Africans whose diets centered on maize very often suffered from pellagra, and those who consumed cassava were assaulted by beriberi. Also, given the vegetable nature of their diets coupled with the parasites that infected them, most sub-Saharan Africans were anemic. Moreover, the tell-tale spongy and bleeding gums of scurvy were not uncommon.

With the Europeans, and with more contact with the outer world, also came increased exposure to contagious diseases. The earliest European report of smallpox in sub-Saharan Africa dates from Angola in the 1620s, but the strong probability exists that it had been present there for several preceding centuries. In fact, August Hirsch pinpointed regions of central Africa along with India as the "native foci" of the disease, and others have also reported that smallpox was a very old disease on the African continent. This was very likely true of measles, chickenpox, and most other Eurasian diseases as well. Evidence for this assumption derives from the fact that, unlike the American Indians or the Pacific Islanders, sub-Saharan Africans did not die in wholesale fashion after contact with the Europeans. The Europeans, however, were extremely susceptible to African illnesses, especially to the African fevers – yellow fever and malaria. Indeed, white sailors on slaving vessels, and especially soldiers stationed in Africa, suffered such horrendous levels of mortality (in some instances soldiers died at a rate of 500 to 700 per 1,000 per annum) as to earn West Africa the sobriquet "the white man's grave." Thus, it was not until the advent of modern medicine that Europeans were able to colonize much of sub-Saharan Africa.

One Eurasian disease that was slow to make inroads in Africa was tuberculosis. There seems no doubt that whereas tuberculosis was a disease of many ancient civilizations and even prehistoric people in Europe, it was unknown in sub-Saharan Africa until the arrival of the Europeans. Because a long experience with this disease appears to confer some ability to resist it, and conversely, because it falls on "virgin-soil" peoples with considerable fury, one might have expected tuberculosis to have become a severe health problem in Africa long before it did in the nineteenth and twentieth centuries. In the

latter part of the nineteenth century, Hirsch pronounced the disease "very malignant" in sub-Saharan Africa. Yet eighteenth-century European observers saw little of it and called it rare.

It may be that the observers in question simply did not recognize the disease, because tuberculosis can have atypical symptoms. Certainly the isolation of many African groups and the relative lack of urban life probably also help to account for the phenomenon. Another possibility, however, deserves some attention.

Leprosy and tuberculosis are both caused by bacilli from the genus *Mycobacterium* and an inverse relationship between the two diseases has been noticed (e.g., where leprosy is prevalent, tuberculosis is not and vice versa). It is generally thought that, although tuberculosis protects against leprosy, the converse is not the case. Yet in Nigeria, in the heart of the leprosy belt, where it is assumed that the disease has been endemic for many centuries, tuberculosis was very slow to take hold. As late as 1936, for example, a British physician reported much leprosy in Nigeria, but made no mention of tuberculosis.

Bacillary pneumonia, like tuberculosis, was brought to Africa by the Europeans, and like tuberculosis it would prove to be of extraordinary virulence among the Africans, at least by the nineteenth century. Observers reported much lung disease around the Bight of Benin; the disease was viewed as one of the most serious to torment the people of Angola; and Hirsch reported pneumonia as "common" on most of the African West Coast and the East Coast as well.

Syphilis was also a late arrival in sub-Saharan Africa and, like tuberculosis, was slow to spread. But here we are on more solid ground in explaining its slow diffusion. The causative agents of both syphilis and yaws are of the same family (the two diseases may be only one illness with different symptoms and means of transmission) and thus provide cross-immunity. Because yaws was endemic to much of sub-Saharan Africa, it would seem that syphilis had much difficulty finding hosts – so much so that David Livingstone was convinced that "pure Africans" could not develop the disease. Earlier, Mungo Park, the great explorer of the Niger River at the turn of the nineteenth century, saw a great deal of yaws but no syphilis. In contrast, Father Giovanni Cavazzi, in his classic treatment of the diseases of the Congo and Angola, writes of the "mal Frances," called "bubas" by the Portuguese, as the most common disease of the region. Though incomplete, his description suggests syphilis racing through a virgin-soil

people, which may well have been the case, for the padre was describing people who had been in contact with Europeans longer than had most others. Yet the disease he reported could also have been leprosy, because until well into the twentieth century, physicians have had difficulty differentiating between syphilis and leprosy in Africa.

To the extent that they were successful in making this distinction, reporters indicate that the disease had apparently overcome the resistance of yaws to become common at least in the port cities of West and West Central Africa during the nineteenth century, although it remained rare in Mozambique until the early twentieth century. From the reports of Livingstone and Park, however, the disease was slow to spread inland.

Gonorrhea, the other major sexually transmitted disease of yesterday, was present much earlier in sub-Saharan Africa and probably had been acquired from the Arabs. Unlike syphilis, gonorrhea had no yawslike disease to hinder its spread and quickly became ubiquitous. The disease is usually not life threatening. But it may cause ophthalmia neonatorum, which along with onchocerciasis was probably responsible for much of the blindness reported among the African natives.

Other nonlethal ailments that tormented sub-Saharan Africans include still more eye ailments, which must have been caused by an absence of vitamin A, since night blindness was regularly seen. The skin complaints that seemed to plague almost everyone resulted from riboflavin deficiency as well as from pellagra, yaws, syphilis, onchocerciasis, and a variety of insect pests including the mites that produce scabies, which were widely reported. Ainhum, sometimes called the "dry gangrene of the little toe" by European observers, which involved the constriction and eventual loss of that digit, was another ailment reported with some frequency; and rheumatism and arthritis were rife across the continent. Finally, women and children often ate dirt and clay, presumably in response to mineral deficiencies.

By 1860, then, sub-Saharan Africans were being born into a world teeming with pathogens. Almost all of the major diseases of the rest of the world had been introduced, including cholera, which had already paid visits to East Africa in 1821, 1836–7, and 1858–9, to enrich a disease pool already brimming with tropical ailments that much of the rest of the world had been spared (cerebrospinal meningitis and plague were yet to arrive). The reasons for the abundance of tropical diseases – helminthic, viral, microbial, and protozoal – in sub-Saharan Africa are diverse. The existence of numerous populations of primates that could harbor diseases and pass them on to humans is obviously one. Another has to do with the high average temperatures and humidity that, along with lush vegetation, make tropical Africa a paradise for the myriad insects that are free from the seasonal controls of more temperate climates and thus can abuse humans on a year-round basis. The same, of course, is true of the many helminthic parasites that find the ecology of the African tropics ideal. As a result, Africans were seldom free of disease, and most likely suffered from more than one at the same time.

Moreover, those born into this world were not provided with much good nutrition to combat their illnesses, and in fact illness often worked synergistically with malnutrition. The chief sufferers of both the disease and nutritional environments were, of course, the young. Infants died at horrendous rates, as did children, and it is likely that 50 percent of those born in sub-Saharan Africa did not live until age 5. Yet such high infant and child mortality constitutes a powerful selective mechanism, and it seems clear that, in the face of sickness and malnutrition, Africans adapted to both in ways we know and in ways we have yet to discover.

V.7
Diseases of Sub-Saharan Africa since 1860

Africa was long characterized as the "dark continent," impenetrable, disease-ridden, and dangerous. To many Europeans, Africans personified degeneracy and suffering, and their environment seemed a hothouse of fever and affliction. Europeans had good reason to connect sub-Saharan Africa with disease. For centuries, their attempts to penetrate the coastal fringes of the continent had been effectively frustrated by diseases against which they had little or no resistance (Carlson 1984). In the early nineteenth century, Europeans arriving in West Africa suffered appalling mortality from disease (most often yellow fever and hyperendemic malaria) at rates of between 350 and 800 per 1,000 per annum (Curtin 1968), and the West African coast became known as the "white man's grave." With such mortality rates, it is no surprise that Europeans believed that Africa was more disease-ridden than other parts of the world.

In fact, many continue to believe that tropical Africa has a well-deserved reputation as a vast breeding ground and dispersal center for dozens of diseases and thus would subscribe to the recent assertion that "Africa is a sick continent, full of sick and . . . starving people" (Prins 1989). This view has been reinforced by scientific speculation concerning the appearance of so-called exotic new diseases like Ebola, Marburg, and Lassa fevers in the 1960s and 1970s (Westwood 1980; Vella 1985). The HIV viruses that cause the acquired immune deficiency syndrome (AIDS) are the most recent additions to this list.

Recent technological advances, especially in electron microscopy, coupled with the rapidly expanding specialties of molecular biology, genetics, and immunology, have given rise to an equally rapid expansion of virology. Scientists are now on the threshold of making important new discoveries that it is hoped will lead to cures for viral infections to equal those available for many bacterial, fungal, and parasitical infections. Unfortunately, however, the identification of Africa as the home of "exotic new diseases" has reinforced the widespread view of that continent as a major source of disease-causing germs.

Disease has been an important factor in the history of sub-Saharan Africa since 1860. Across the continent people have been under constant attack by endemic diseases in their struggle for survival, and epidemic diseases have decimated millions. In 21 countries, life expectancy today ranges from only about 44 to 56 years according to I. Timaeus (personal communication). In some countries, mortality rates have grown recently, and in most regions they remain high. Increases have occurred in Angola, Ethiopia, Mozambique, Niger, Nigeria, and Rwanda. In the first three there were 250 to 299 deaths per 1,000 live births, and in Gambia, Sierra Leone, Mali, and Malawi child mortality rates were more than 300 per 1,000 (United Nations 1987). The direct causes of this mortality in most developing countries are the following: diarrhea, malnutrition, malaria, measles, acute respiratory infections, tetanus, and other neonatal causes. Now AIDS reminds us of the potential havoc of an epidemic disease in Africa.

Nevertheless, other countries have experienced an appreciable decline in infant and child mortality in the past 20 years. In Kenya in the late 1950s, the child mortality rate (for children less than 5 years of age) was 265 deaths per 1,000 live births, whereas in 1989 it had declined to 150 per 1,000 (Blacker 1989). It must be made clear that in some regions of Africa there have been significant increases in population growth, whereas other regions such as Kivu in eastern Zaire have been densely populated for many decades. African demography is a rapidly expanding field of study among social scientists and members of the medical and scientific communities, and there is a continuing debate concerning the relationship between biomedical provision and morbidity and mortality rates in sub-Saharan Africa. Some observers contend that over the past century, medical provision has been the major factor in lower morbidity and mortality, whereas others believe that improved socioeconomic conditions, more than medical provision, have resulted in less illness and death among

Africans. Proponents of this view refer to the apparent paradoxical situation in some regions of the continent in which populations have increased in spite of the quite dramatic disintegration of health care delivery systems that were inherited from the colonial period. We shall probably have to await the twenty-first century for satisfactory explanations of the dynamics of African demography and its history.

An analysis of disease environments can be made in terms of both natural factors and socioeconomic considerations. Natural factors, crucial to proponents of the "determinist" school of disease causation, include such items as altitude, temperature, rainfall, humidity, and soil, as well as the proliferation of potential disease hosts and vectors like animals, birds, insects, and parasites. Epidemiologists describe three major disease patterns in sub-Saharan Africa roughly akin to the three main climatic zones: damp uplands, damp lowlands, and savanna regions with a long dry season. Damp uplands include the Kenyan highlands, southwestern Uganda, mountain slopes of eastern and western Africa (mounts Elgon and Kilimanjaro), and parts of Rwanda and Burundi. The much vaster damp lowlands include coastal West Africa and the massive Congo basin, which are the regions of Africa that most readily fit the popular notion of "the tropics." The third and most extensive climatic pattern is identified by a limited rainy season and a longer dry season. At one extreme in this climatic pattern is the Sahel, where the dry season dominates, but the pattern pertains to savanna regions as well (Bradley 1980).

Disease patterns vary immensely throughout these three zones, yet generalizations can be made. In the damp uplands, including the Kenya highlands, the southwestern tip of Uganda, parts of Rwanda and Burundi, and the southern Kivu district of eastern Zaire, population densities are high and the predominant infections are respiratory and diarrheal, both largely diseases of poverty and poor sanitation. In the damp lowlands with their prolific insect vectors, malaria dominates the disease pattern, with almost every person infected within the first year of life. Yaws, hookworm, the diarrheas, typhoid, infective hepatitis, and numerous viruses are also common. The third disease pattern, that of the savannas, is again dominated by malaria, with diarrheal diseases and waterborne diseases predominating. The latter include schistosomiasis and dracunculiasis (guinea worm), whereas another devastating disease, sleeping sickness, is especially prevalent along waterways, the haunt of many tsetse flies, which transmit the disease. Another important disease of this environment is cerebrospinal meningitis.

Analyses of disease patterns that focus more on the role of social, cultural, political, and economic factors emphasize the dynamic relationships that exist between humans and their total environment. This is the approach of those concerned with the "social production of health and disease" (Turshen 1984). Only rarely do analyses of disease patterns combine both the deterministic and the socioeconomic approaches and thus reveal the complex interrelations between natural and socioeconomic factors (Blacker 1989). John Ford's (1971) brilliant study of the tsetse problem is an example of a successful combining of the two.

Yet in the case of Africa, climate and geography are less important determinants of health than are the social, economic, and political factors. (The majority of sub-Saharan Africa is not the sweltering, humid tropics of popular imagination but is rather temperate savanna or forest.) Medicine has only a limited role in ameliorating the health of populations (McKeown 1979), and upon closer examination, it can usually be shown that the *root causes* of ill health are embedded in social and economic structures. Indeed, in much of sub-Saharan Africa, it is precisely because of social and economic upheaval that we have recently seen a rapid increase in morbidity and mortality, and medical services in some regions have deteriorated so seriously as to be nonexistent (Dodge and Wiebe 1985).

Overview of Disease in Africa Since 1860

Most of the written sources for the history of diseases in Africa since 1860 derive from Europeans, who had very specific interests in health. Their first concern was for their own health and that of fellow Europeans, whereas concern for the health of Africans was extended mainly to those people the Europeans needed as laborers or producers. It was clear from the outset that Africans were human capital. Medical opinion of the mid-nineteenth century set the pattern for most of the colonial period when it expounded the view that only blacks could labor in the tropical regions of Africa, and in this, science allegedly corroborated the imperialist view that the physical constitution of the African was different from that of the European.

Certainly it must have seemed so. Early European accounts describe the devastating morbidity and mortality they suffered, but we learn very little about the impact of disease on African populations apart from those employed as porters and soldiers.

Non-Eurocentric accounts of diseases and health conditions among African populations are rare for the earlier period, and those dating from World War II are also limited in number and scope. Nearly all Europeans in Africa – explorers, traders, missionaries, or colonials – were concerned primarily with the diseases that threatened their own health, and this must be borne in mind by anyone looking at early accounts of diseases of Africa.

Between 1860 and 1885 European exploration and trade along with coasts of Africa increased and finally culminated in the full expression of foreign imperialism with formal colonization; by 1920 most of equatorial, eastern, and central Africa had been taken over by Europeans. The result for much of the region was a series of catastrophes in the form of wars of conquest and the initial consolidation of colonial rule. The primary motive for colonization was economic exploitation of natural resources and human populations. In their rush for profit, Europeans often employed roughshod, even brutal, methods that greatly affected disease patterns.

Some African societies, like those located along the west coast of the continent, had long been in contact with outsiders and thus did not seem to be as immediately affected by new pathogens and other stresses as were populations in eastern and central Africa, which had been more isolated. For many societies of eastern, central, and southern Africa, however, the period 1890–1920 was so traumatic as to have been described as a time of tumultuous "ecological disaster" (Ford 1971; Kjekshus 1977). New diseases were spread to nonimmune populations, and previously endemic diseases became epidemic. It is clear that the great epidemics of human sleeping sickness throughout the Congo basin beginning in the late nineteenth century, which in Uganda produced an estimated 300,000 deaths between 1901 and 1905, were a result of violent disruptions to those regions. In fact, the history of sleeping sickness illustrates well the effects of upheavals in large parts of sub-Saharan Africa around the turn of the century. Increased stresses accompanied by reduced nutritional and immune status led to greatly increased morbidity and mortality for millions of Africans.

During the four decades between 1920 and 1960, colonial rule and economic exploitation of the land and people were refined and greatly extended. Ever-increasing numbers of Africans were drawn, often unwillingly, into colonial economies as laborers and tax payers. Others were forced into an "informal" economy earning cash as prostitutes or petty traders and by providing other services. Highly mobile and most often poorly nourished, these Africans often attracted the attention of colonial authorities, who considered them an important source of disease, especially venereal disease. Military leaders commonly complained about the threat to public health posed by prostitutes and female "camp followers."

In all colonies, there was constant fear among European colonizers that the new "detribalized" individuals gravitating toward the new urban centers were spreading disease, which in turn contributed to the development of powerful stereotypic images of Africans. Technologically inferior, Africans were thought to be less "civilized" (Comaroff and Comaroff 1991), and because civilization was equated with hygiene, many believed that Africans were by nature unhygienic. Consequently, all colonies by the early decades of the twentieth century had implemented a public health policy of racial segregation in order to protect the health of whites (Spitzer 1968; Swanson 1977).

By 1940 many African societies had been literally "restructured" as a result of the need to meet the increasing demands of European industries and markets. Throughout the continent, millions of Africans were forced to migrate annually to labor in unsafe and unsanitary conditions in mines, on plantations, and in public works projects such as road and rail building. In addition to the more apparent effects of heavy labor in harsh conditions on African health were those that attended the proletarianization and urbanization of millions of Africans across the continent. This had the important effect of disrupting and often destroying African forms of social organization, which also had an adverse effect on the health of Africans.

Migrant laborers, who were usually malnourished, poorly clothed, crowded into miserable dwellings, and overworked, were victims of a wide range of infectious and contagious diseases. Similarly, men and women left behind in the rural sector were burdened with the crushing labor of agricultural production, which was required by the colonial administrators to feed the migrant labor force as well as the rapidly expanding urban populations. The result was that nutrition declined everywhere in Africa, and given the complex interaction of disease and malnutrition we can guess the result.

Large parts of sub-Saharan Africa experience a "hungry" season, which takes place after the long dry season, just as the rains start and food stores are low or depleted. This period is the point in the agricultural calendar when intense labor is required, but it is also the time when people are ill. Recent

studies have revealed that it is at the end of the dry season when measles and pneumonia deaths peak for a combination of reasons. Among them are lower standards of child care because mothers have to labor in the fields and suppressed immune responses exacerbated by malnutrition, both of which must have played a major role in disease incidence during the colonial period. Other contributing factors were the widespread colonial practice of implementing cash crop economies, which were often based on monoculture. In Ghana, for example, where cocoa production formed the basis of the colonial economy, when prices were high, staple food production fell off and people suffered accordingly.

The two world wars compounded the burden of colonial labor and production for African populations. The wars were also periods of nutritional deprivation for millions of people. Thousands of men were recruited into military service, and disease and death were rife. Mass recruitment programs during the First World War revealed the poor state of African health to colonial authorities, and as a consequence plans were launched to provide medical services to the masses. The emphasis remained, however, on the curative as opposed to the preventive approach.

Since the 1960s, when most African colonies gained political independence, there has been a considerable increase in population throughout much of the subcontinent. This is a subject that in the last part of the twentieth century has become the focus of much study and debate and that in all likelihood will have to wait the next century for an in-depth explanation. While population has increased in many regions, in many African states economic decay has been accompanied by a reduction in the immune and nutritional status of large segments of the population. An important cause has been protracted wars of independence such as those in Angola, Mozambique, Zimbabwe, and Namibia and civil wars such as those in Nigeria, Sudan, and Uganda. These political upheavals have caused the widespread destruction of human lives, a decline in agricultural production, the disruption of civil society, and the creation of hundreds of thousands of displaced persons and refugees. Closely related to the political upheavals have been a series of droughts, famines, and epidemics that have further increased the toll on human life. If current World Health Organization projections are even only partially correct, mortality from AIDS in sub-Saharan Africa can be expected to devastate parts of the continent, where it threatens to strike down young adults in their productive and reproductive prime.

A number of accounts of the overall health of Africans since 1860 have stressed the point that biomedicine and improved public health were the most valuable legacies of the colonial powers. Certainly there were some notable successes starting in the 1920s with the introduction of the sulfa drugs. Yaws, a widespread endemic disease, responded almost miraculously to sulfonamides; Africans by the thousands eagerly sought injections, and in many regions yaws was almost eradicated. Similarly, sleeping sickness, endemic throughout much of eastern, central, and western Africa, was by the 1950s and 1960s under control as a result of sometimes enormous campaigns aimed at this one disease. In the Belgian Congo and French Equatorial Africa, the systematic examination and medication of the entire population was the goal, and at the same time all affected colonies practiced some degree of mass removal and resettlement of populations thought to be at risk of infection.

Yet even where biomedical solutions have proved effective, the serious problem of their costs remains. Large-scale medical campaigns launched against single diseases like those aimed at sleeping sickness, yaws, malaria, and more recently smallpox are called "vertical" campaigns and are expensive. More general, or "horizontal," health programs address a broad spectrum of public health issues such as control of endemic and epidemic diseases, infant and mother care, vaccinations, and primary health clinics and are usually far more cost effective in their use of personnel, infrastructure, and supplies. Unfortunately, throughout much of the colonial period in sub-Saharan Africa, medical services tended to be more vertical than horizontal. The huge and costly campaigns launched against single diseases absorbed scarce resources and drew money away from other crucial areas of health provision. For Africans, closely related to this problem of health economics is another: Most pharmaceutical companies have been and remain reluctant to invest heavily in the research and development of medicines for diseases that afflict mainly impoverished, often rural populations in underdeveloped regions of the world. Since the late 1800s, the combination of vertical medical campaigns and the reluctance of pharmaceutical companies to invest in research has had profoundly adverse affects on the health of millions of sub-Saharan Africans.

Nonetheless, by the time of their independence in the 1960s the health of many African populations was considerably better than that of preceding generations. Vaccination campaigns in many countries

had become routine. In some regions, more often urban centers, public health programs had imposed a degree of control over malaria. Maternal and child health programs were also well established in many colonies. Large-scale employers such as mines and plantations had expressed some concern for the well-being of their labor forces, and in some regions working conditions were improved. Mortality and morbidity rates were lower than ever, and major epidemics occurred far less frequently than before.

Departing colonial administrations took credit for these improvements, which were seen as stemming from the ameliorating effects of those medical services that, as we noted, many believed to be the most valuable colonial legacy. In other words, it was believed that the incidence of disease had been decreased through the beneficial effects of Western biomedical staff, infrastructure, and techniques. At that time few would have credited improvements in the standard of living of many millions of Africans for the decreased incidence. Yet as Thomas McKeown has argued convincingly, it was improved socioeconomic conditions, rather than medical therapies, that accounted for the overall improvements in the health of Western populations. Doubtless this also played a substantial if not well-recognized role in ameliorating the health of Africans as well.

Science and Disease in Africa

The last quarter of the nineteenth century was an exciting chapter in the history of science and medicine. It was also the period when much of sub-Saharan Africa was formally colonized by Europeans and, indeed, the two phenomena were not unrelated. By the late nineteenth century, important developments in the areas of scientific, statistical, and epidemiological thought had combined with the development of specificity in disease etiologies and therapies to enable Europeans to penetrate and permanently settle the interior regions of the continent.

Late Victorians had great confidence that Cartesian science and new, rapidly evolving technology would provide humans with the means to reshape their environment to suit themselves. In fact, medical advances seemed to be elegant proof of this ability to overcome the dangers of the environment. During the 1854 expedition along the Niger, for example, the successful prophylactic use of quinine demonstrated that it was at last possible for Europeans to survive the onslaughts of malaria. Then around the turn of the century, new concepts of what constituted disease rapidly evolved, as did the role of the new expert health professionals – both develop-

ments having serious implications for the new African colonies.

Most important in the new science was the role of the laboratory, which became the real battlefield on which questions of life and death would be settled. Laboratories could be mobile, as they were soon to be in the new specialty of tropical medicine. Between 1860 and 1900, Joseph Lister, Louis Pasteur, and Robert Koch transformed forever our understanding of the relationships of humans and their disease-causing pathogens. The new sciences gave specificity to diseases whose etiologies could now be ascertained. With more concrete understanding of the pathology of a specific disease and knowledge of its particular cause, the pathogen or germ, scientists could think in terms of equally specific therapies (e.g., Paul Ehrlich's "magic bullet").

There was an unfortunate consequence, however, for these exciting developments prompted scientists involved in tropical health in Africa to cast aside most of the earlier theories of disease causation. Earlier ideas concerning the influences of environment on health, a view that stressed the relationships between humans and their environment, were overshadowed by the empiricism of the new laboratory science with its method of verifiable experiment. Thus, budding theories of the "social construction of diseases" were, by the turn of the century, almost entirely superseded by powerful theories of the "biological determinism of disease." The latter approach would dominate most medical and public health thinking throughout the colonial period.

The Disease Environment

In addition, Africans had their own tropical illnesses: malaria, blackwater fever, yellow fever, trypanosomiasis (sleeping sickness), filariases, leishmaniasis (*kala-azar*), schistosomiasis (bilharziasis), onchocerciasis (river blindness), leprosy, yaws, guinea worm, helminthiasis, relapsing fever (louse- and tickborne), and tropical ulcer. A number of these are caused by parasites that are transmitted to humans by insects. Because both the parasites and the insects require very specific conditions of temperature and moisture and because many of the other diseases are water-borne, the emphasis on "tropical" is understandable. Also understandably, diseases that had such complex and fascinating etiologies and that required the combined expertise of zoologists, protozoologists, epidemiologists, chemists, and biologists overwhelmingly attracted the attention of early investigators in Africa. Unfortunately, other important causes of morbidity and mortality, such as respiratory diseases,

childhood diseases, and malnutrition, were not given research priority. "Tropical" diseases were mistakenly conceptualized as distinct from other communicable diseases. In this way, tropical medicine evolved as a specialty outside of mainstream medicine.

By the mid-nineteenth century, tropical Africans were afflicted by most of the diseases of the temperate Old World, such as brucellosis (Malta fever), undulant fever, cerebrospinal meningitis, cholera, diphtheria, influenza, measles, plague, pneumonia, poliomyelitis, smallpox, tuberculosis, typhoid fever (enteric fever), typhus and other rickettsial infections, venereal diseases, and whooping cough. The causes of 50 to 90 percent of illness and death among the poor in the underdeveloped world, including Africa, fall into two main groups: nutritional deficiencies and communicable diseases (Sanders 1985). The major causes of adult mortality are infectious and parasitic diseases, acute respiratory infections, cardiovascular disease, and accidents and violence. Most childhood mortality is caused by a limited number of infectious diseases: diarrheal diseases, acute respiratory infections, malaria, measles, and neonatal tetanus (I. Timaeus, personal communication). Moreover, there is evidence that in recent years the incidence of noninfectious and degenerative diseases is increasing.

What constitutes a disease environment and what causes it to change? Every human community coexists with specific microorganisms that contribute to the disease environment of the group. Many diseases represent the failure of one organism, in this case human beings, to cope successfully with competing organisms, in this case microorganisms, in the ceaseless struggle for survival. A disease environment contains many elements: humans, animals, various other forms of flora and fauna, microorganisms, climate, and geographic features. Many disease environments are often located close to one another, and these undergo frequent and sometimes rapid change. For instance, after a period of interaction with a stable human population, disease-causing pathogens can adapt and produce new strains in response to the immune defenses produced by that population. In recent decades this has been demonstrated in parts of the world by the appearance of new strains of chloroquinine-resistant *Plasmodium falciparum,* the cause of the most deadly of the malarial diseases.

Conversely, human host communities develop immunity to endemic diseases. In other words, humans who survive the diseases of their environment often acquire some resistance to further infection. Epidemics of disease occasionally flare up when nonimmune members of the community are exposed to pathogens or when newcomers in large enough numbers reach a disease environment containing pathogens against which they have no immune protection. Poor hygiene resulting from ignorance of disease causation coupled with the widespread lack of safe water supplies and sewage disposal also profoundly affect a society's disease environment.

As stated previously, disease environments are affected by both natural and sociocultural factors. A natural factor of much importance in Africa is the proliferation of insects, many of which serve as vectors of disease-causing pathogens. Another factor is climate, which can be a major determinant of those diseases that have specific requirements of temperature, humidity, or aridity. An equally important factor encompasses the sociocultural practices of communities. For instance, ritual practices may bring humans into regular and intimate contact with certain features of the physical environment that results in contact with disease-causing pathogens. Shrines hidden deep in forested regions may bring humans into contact with pathogen-bearing insects such as the tsetse fly and anopheles mosquito. In addition, agricultural practices, such as the cultivation of certain crops close to homesteads, often bring humans into contact with pathogens. And changes in crops or techniques often provide new ecological niches in which disease-bearing pathogens flourish. An example of this is the introduction by a British colonial officer of a new variety of hedge, the lantana, from India into Uganda in the 1940s. The lantana flourished in its new environment, gradually spreading northward toward the southern Sudan. Unfortunately, it provided an excellent habitat for a species of tsetse fly, *Glossina pallidipes,* which in turn introduced new strains of trypanosomes, the cause of human sleeping sickness.

Perhaps the most important factors in disease environments are water supply and human excreta. Waterborne diseases include typhoid fever, poliomyelitis, infectious hepatitis, cholera, schistosomiasis, dracunculiasis, and leishmaniasis. Water supplies and sewage disposal are complex subjects of much concern to health planners in the late twentieth century. But during much of the nineteenth century these two vitally important areas of public health were given very little serious attention and even less investment. Indeed, despite John Snow's brilliant 1849 analysis of the epidemiology of cholera in London when he revealed that a water pump was responsible for the spread of the disease, the supply of safe water and the disposal of sewage remained for more

than a century conceptually separate from the concerns of medicine with its focus on cure.

Rather, clean water supplies and sanitary sewage disposal, as means of disease prevention, were, until very recently, solely the concern of the engineer. Thus, a major source of much human disease was neglected by medical people. The colonial legacy included very little in the way of safe/water supplies and effective sewage disposal systems, except in a few of the urban areas where the Europeans themselves resided. And Africans are suffering the effects to the present day.

Last but hardly least among the African "pathogenic factors" is protein–energy malnutrition, for the excessive mortality of African children under 5 years of age is due largely to the synergism between protein–energy malnutrition and infectious and parasitic diseases. Until fairly recently, nutrition has been largely ignored in relation to morbidity, yet it is a vitally important key to understanding the widespread perception of Africa as a "disease-ridden" continent.

Earlier theories of epidemiology held that exposure to new pathogens was sufficient cause for epidemic outbreaks, and much emphasis was laid on the increased interactions of African populations, witnessed by Europeans from the mid-nineteenth century on, as an explanation for apparently increased rates of morbidity and mortality. More recently, however, it has been argued that more than mere exposure is needed to explain why humans fall ill and why epidemics flare. Thomas McKeown (1979) argued convincingly that, for almost the whole of human existence, disease and early death have resulted from basic deficiencies or from hazards related to them and that the role of nutrition is of paramount importance.

Thus, medical services, specific remedies, and the increasingly complex technology of biomedicine may not provide the best solutions to African health problems; rather, the total ecology of health and disease may be a more fruitful area of study for future health planners.

V.8
Diseases of the Pre-Columbian Americas

Although the antiquity of the earliest colonists in the Americas remains a controversial subject, human presence is well established by the close of the Pleistocene, approximately 10,000 B.P. (before the present) (Bryan 1978, 1986; Shutler 1983; Fagan 1987). Kill sites and habitation areas, in conjunction with lithic tools and a few human remains, provide convincing evidence for the presence of highly mobile, small groups whose subsistence was based on hunting and gathering of naturally available "wild" resources.

The health of these most ancient American populations, poorly documented owing to a paucity of human remains (Hrdlicka 1907, 1912; Stewart 1946, 1973; Young 1988), can best be inferred by analogy with recent hunting and gathering peoples. In making inferences we must keep in mind that such groups today tend to occupy marginal environments, unlike the often resource-rich ecosystems that attracted early human populations. If we use contemporary hunter-gatherers for our model, then parasitic infections, infections for which insects and animals serve as the primary vectors or intermediate hosts, and traumatic episodes would have been among the primary sources of ill health among the earliest Americans (Dunn 1968; Truswell and Hansen 1976; Howell 1979; Lee 1979; Cohen 1989). Degenerative diseases, neoplasms, and epidemic diseases would have been extremely rare, as would have been chronic undernutrition. Seasonal periods of nutritional stress would, however, have been expected. Thus, health status would have reflected the exceptionally close relationship between hunter-gatherers and their environment.

We must be careful, however, not to overgeneralize and thus simplify our picture of hunter-gatherer adaptations, which were undoubtedly complex and rich with the knowledge gained through intimate acquaintance with the landscape (Cohen 1989). Given the wide variety of settings available for human occupation in the Americas, ranging from stark Arctic polar environments to lush tropical forests, we should anticipate that human cultural and biological adaptions ranged widely within the context of changing cultural systems and environmental regimes. The quality of life, as measured by health status, would have depended on the nature of these interactions as well as those among the human groups themselves.

Beginning with the earliest colonists – the Americans who entered this continent before the end of the Pleistocene – we find a rich fabric of evolving relationships between people and their natural and cultural environments that held strong implications for both health and the history of disease. Although certain groups maintained life-styles without plant and animal domestication (or management) throughout their history, the Americas also saw the development of complex civilizations. The Maya, the Aztec, the Inca, and – on a smaller scale – the eastern North American agriculturalists, known to archeologists as Mississippian peoples, all developed cities where thousands of people lived together in permanent settlements. Problems of health, sanitation, and nutrition common to such large agglomerations of humans throughout the world emerged in each of these situations.

Although animal husbandry never assumed the importance that it did in the Old World, the dog was one of several domesticated New World animals, along with the turkey, the Muscovy duck, the guinea pig, the alpaca, and the llama (Crosby 1972). These animals, living close to humans, could have served as vectors or intermediate hosts of disease. Similarly, the nutritional adequacy of ancient diets depended on these as well as wild animal resources.

Inedible, but economically important plants, such as cotton and tobacco, along with many comestibles including maize, manioc, squash, beans, cocoa, sunflower, potatoes, chiles, chenoa, and tomatoes, were domesticated (Crosby 1972). These crops attracted the attention of Europeans and are presently part of Western cuisine (Crosby 1972, 1986). Other indigenous plants were also cultivated prehistorically, with some being truly domesticated, that is, showing distinctive morphological changes due to human intervention or growing beyond their natural range. In eastern North America, for example, a group of cultivated indigenous plants, termed the eastern horticultural complex, included sumpweed (*Iva annua*), goosefoot (*Chenopodium berlandieri*), knotweed (*Polygonum erectum*), and little barley (*Phalaris carolin-*

iana), as well as sunflower (*Heliantus annuus*) and various cucurbits (Asch and Asch 1985; Smith 1987). In that nutritional adequacy is closely linked to health status, these components of ancient diets must also be mapped when one is investigating paleopathological conditions.

This review of health conditions in the pre-Columbian Americas focuses primarily on the evidence gained through the study of skeletal material. Mummified remains, a very rich data source, are unfortunately found only in a few settings favoring soft-tissue preservation, especially the arid North American Southwest and coastal Peru and Ecuador. Dry caves, such as those of the Mammoth Cave system in North America, also yield mummified human remains, but only in small numbers (Watson 1974). Other sources of information concerning disease and medical treatments, such as the Mochica and Mexican figures, and various pictographs will not be considered here. These renderings are notoriously ambiguous, frequently charged with symbolic meanings that relate to ritual life rather than accurate representations of maladies and deformities.

Figures V. 8.1 and V. 8.2 present model chronologies for eastern North America and coastal Peru and Ecuador, two regions frequently referenced in the following text. The chronological basis for Figure

V. 8.1 follows J. Buikstra (1988); Figure V. 8.2 is based on the sequences presented in R. Keatinge (1988) and B. Fagan (1972). Sites discussed in this text are placed appropriately on these time lines. This brief chronological review is developed in order to establish a broad time scale against which to display disease patterning. In general, North American materials are emphasized, given that the majority of the relevant literature is based on North American collections.

We first focus on trephination, distinctly South American and an enormously successful form of ancient surgery. Following this we consider the expression of two forms of trauma in human skeletal materials, fractures and osteoarthritis. A discussion of fractures and true degenerative joint disease centers on North American materials, as does a consideration of rheumatoid arthritis in adults. Brief mention, however, is made of an example of juvenile rheumatoid arthritis that was recovered from a c. 1000 B.P. Peruvian grave. The subsequent discussion of two forms of infectious pathology, treponematosis and tuberculosis, ranges widely across the hemisphere, as does the description of techniques for inferring diet from bones and teeth. We close with a consideration of parameters used to estimate population health, dealing primarily with North American

skeletal samples that chronicle the development and intensification of maize agriculture.

Trephination (Trepanation)

Trephination, one of the earliest surgical procedures involving the skull, was first reported in prehistoric skeletal remains during the nineteenth century (Squier 1877; Rytel 1956; Lisowski 1967; Steinbock 1976; Ortner and Putschar 1981). E. Squier's early description of trephination in Peruvian remains led to the recognition that this procedure was frequently practiced in pre-Columbian South America (Stewart 1958; Steinbock 1976). The success rate of this surgery, which exceeded 50 percent in the South American examples (Stewart 1958), is particularly significant for the history of medicine. It far exceeded recovery predictions for individuals subjected to brain surgery in eighteenth- and nineteenth-century Europe, where death was the expected result (Schröder 1957, cited in Lisowski 1967).

The removal of a segment of skull without injuring the underlying meninges and brain is an exceedingly delicate operation. Commonly practiced in South America during the millennium between 1500 and 2500 B.P., trephination encompassed several distinctive techniques with various results. One of the most extensive descriptions is that of M. Meyer (1979), who reports 10 different types of surgical method in his study of 374 trephined crania from Peru. Most common were the scraping and grooving procedures (Figure V. 8.3, after Lisowski 1967), which had been performed on more than 61 percent of this sample. Meyer (1979) attributes the popularity of the scraping technique to its high success rate (85 percent). Given that the key problem in surgery of this type is the removal of bone without penetrating the dura, the finer control afforded by the scraping technique rendered it maximally effective (Ortner and Putschar 1981).

The overall recovery frequency reported by Meyer (1979) is 61.9 percent, which compares quite favorably with the rate of 62.5 percent reported by J. Tello (1913) in a sample of 400 Peruvian skulls. Meyer also reports similar figures for researchers dealing with smaller series. Thus, fewer than half of these ancient Peruvian patients died as a result of skull surgery.

Various motives have been attributed to those who performed trephination, ranging from the utilitarian to the spiritual. Meyer (1979) observed cranial pathology, due either to infection or to trauma, in association with 42.0 percent of his trephined sample. As he notes, the rate would undoubtedly have been higher, given the fact that either the operation itself or subsequent healing would have obliterated symptoms visible at the time of surgery. He also reports that fractures were more commonly, but by no means exclusively, associated with men in his sample, with infection appearing more frequently in

trephined women. There tended to be a larger number of healed trephinations among men than among women, which contributes to Meyer's observation that relatively few young men appear in his trephined sample. He attributes "ritual practice" to this pattern, but male survival rates must also be considered.

Meyer also suggests, on the basis of observation of stains and osteoporotic pitting in the trephined region, that Peruvian surgeons used antiseptics. Unlike earlier observations by T. Stewart (1958) on a less extensive series, Meyer's (1979) observations revealed that most trephinations in his sample occurred on the parietal bone. The left side of the skull was more commonly trephined than the right, which may reflect the agonistic origins of many cranial fractures.

Contemporary examples of trephination using primitive technology include the African cases cited by E. Margetts (1967) and Bolivian examples reported by K. Oakley and colleagues (1959). The African techniques were similar to prehistoric methods, whereas in Bolivia a young man was operated on with "a rusty nail and a stone" (as cited in Meyer 1979). The African operations were quite successful; in one instance of multiple trephinations, for example, the subject continued to live a "normal" life. Clearly, ancient peoples had discovered a surgical strategy that was remarkably successful, even in the absence of modern antibiotics.

Fractures

Evidence of healed fractures has been reported for numerous skeletal series throughout the Americas. Few workers, however, have attempted to develop a biobehavioral model for interpreting etiology, through either a rigorous diachronic approach or the development of an epidemiological viewpoint. Exceptional perspectives have been developed by R. Steinbock (1976), who surveys temporally sequential North America samples, and by C. Lovejoy and K. Heiple (1981) in an intensive investigation of the Libben site (900–1200 B.P.).

Using the individual as the basis for comparison, Steinbock reports postcranial fracture frequencies for 12 skeletal series from North America (V.8.1). The highest fracture frequency occurred in Middle and Late Archaic populations – those considered to be hunters and gatherers. Given our previous model derived from ethnographically documented groups, this observation is not unexpected. As an aside, G. Steele (personal communication) noted that the only pathological condition in a survey of Paleo-

Indian remains that pre-dates 8500 B.P. is a healed fracture in the right eighth rib of a skeleton from the Pelican Rapids site, Minnesota.

As noted by Steinbock (1976), and emphasized by Lovejoy and Heiple (1981), Steinbock's frequencies may be unreasonably low, due to his method of reporting. Steinbock's use of the individual as the unit for analysis led him to include incomplete remains whose missing elements might have presented healed fractures. Also, as pointed out by this author (1981a), Middle Archaic cemetery samples can be segregated by health status. Thus, archeological recovery may have emphasized those areas where individuals with fractures were more likely to be buried.

Lovejoy and Heiple (1981), basing their analysis on the Late Woodland Libben site of northern Ohio, report that each individual within this series had a 45 percent chance of fracturing a major limb long bone. The clavicle was most frequently broken, with the humerus showing the fewest healed fractures. The rather high rate of forearm fractures is attributed to falls rather than to conflict owing to the low prevalence ($n = 2$) of classic "parry fractures." That only two cranial fractures were observed in the series also supports this conclusion. Although these data have undoubtedly been affected by the ease of reduction for each of the elements surveyed, it is very clear that the Libben series represents a sample for which there is little evidence of conflict.

After developing a years-at-risk analysis, Lovejoy and Heiple (1981) concluded that there were two

periods within the Libben life span in which the risk of fracture was greatest: 10 to 25 years years and 45 plus years. Youthful activity and senescence undoubtedly explain this pattern.

A contrasting picture is presented by the Norris Farms No. 36 sample described by G. Milner, V. Smith, and E. Anderson (1991). Slightly more recent than the Libben sample, this Oneota series is derived from a late prehistoric population that lived near major Mississippian settlements. Healed fractures within the Norris Farms No. 36 series include many in the trunk and upper limb, with the skull also heavily involved. In addition, 33 individuals, approximately 12.5 percent (33/264), show evidence of mutilation, including scalping, decapitation and postcranial dismemberment, actual injuries, such as projectile points in bone and spiral fractures, or both forms of damage to bone. Many of these skeletons, as well as 10 others for a total of 43, exhibit carnivore gnawing that is thought to have occurred after death but before the recovery of the body for burial in the village cemetery. Those who were older than 15 years at the time of death are evenly divided between men (18) and women (18). This represents about 33 percent of the total male subset of the population and 29 percent of the female subset. The male proportion is not unexpected in tribal-level societies; however, the female frequency is extremely high, suggesting the presence of intensive raiding and social conflict.

The contrasting patterns presented by the Libben and Norris Farms No. 36 series underscore the impact that life-style and living conditions can have on the expression of trauma in prehistoric remains. Just as there appears to be no typical late prehistoric pattern, it would be foolhardy to generalize concerning any other temporal or chronological unit without contextual data.

Arthritis

As pointed out by D. Ortner and G. Theobald in their examination of the diseases of prehistory in the West in this volume, a great many conditions can lead to inflammation of the joints. In the Americas, most diagnostic attention has been paid to articular changes that may be characteristic of tuberculosis, treponematosis, rheumatoid arthritis, and osteoarthritis due to mechanical stress. Our current knowledge of the first two conditions is discussed in the relevant sections of this essay. Here we will focus on recent studies of osteoarthritis (degenerative joint disease) and rheumatoid arthritis.

Daily activities produce stresses that over time promote degeneration of joint surfaces in the human skeleton. Thus, the "wear and tear" of ancient lifestyles can be read through an analysis of the porosity, eburnation, and lipping characteristic of arthritic joints. One of the most careful studies of extensive degenerative joint changes is that of Ortner (1968), who details the patterning discovered in Alaskan Eskimo and Peruvian skeletons. Ortner's work is reminiscent of the methods pioneered by J. Angel (1966) and T. Stewart (1932). Stewart's careful investigation of intraindividual patterning established the standard of comparison of vertebral osteophytosis, whereas Angel's creative inferences concerning behavior (e.g., atlatl [spear or dart throwing stick] elbow) are oft-cited attempts to link individual activities to bone pathology.

R. Jurmain (1977) has compared arthritic patterns characterizing the Alaskan Eskimo shoulder, elbow, knee, and hip with those of Pueblo Indians and modern skeletons. Jurmain emphasizes the multifactorial nature of osteoarthritis, although he believes that functional stress is of paramount importance.

After an extensive survey of degenerative joint disease among the Native Point Sadlerimiut Eskimo from Southampton Island, Canada, C. Merbs (1969, 1983) identified distinctive male and female activity patterns that yielded arthritic change. Typical male activities that produced upper-limb arthritis included harpoon throwing and kayak paddling. Female skeletons bore evidence of activities related to the processing of skins.

Following the recording strategy developed by Ortner (1968) and Merbs (1969), J. Tainter (1980) observed distinctive arthritic patterning across status groups of Middle Woodland men from Illinois. He interpreted these patterns to mean that the day-to-day activities differed significantly across socially defined segments of Hopewell communities.

A more recent study (Pickering 1984) has extended Tainter's earlier synchronic investigation to an analysis of diachronic changes associated with the development of maize agriculture. Also embedded in this work is an attempt to isolate patterns in the male upper limb that were associated with the documented shift in hunting technology between the spear, characteristic of Middle Woodland groups, and the bow and arrow, used by Late Woodland and Mississippian populations.

Although an altered hunting technology was indeed documented within west-central Illinois during the period in question, no significant difference in symmetry, timing of onset, patterning, or degree of arthritic expression in the upper limb was discov-

ered in the male subsample. The arthritic costs of agricultural intensification are clearly written, however, in age-corrected severity scores for the female upper back. The demands of repetitive food production activities associated with maize agriculture and larger family size are implicated in the apparent differences in degenerative joint disease.

In provocative new work based on observations in two large prehistoric North American skeletal populations, B. Rothschild and colleagues argue that rheumatoid arthritis "is a New World disease that subsequently spread to the Old World" (Rothschild, Woods, and Turner 1987; Rothschild, Turner, and DeLuca 1988; Woods and Rothschild 1988). Their conclusions are based on the form and distribution of erosive lesions in several series of skeletons, including the Libben Late Woodland sample (900–1200 B.P.) and Archaic skeletons from Alabama that are at least 5,000 years old (Rothschild et al. 1987, 1988; Woods and Rothschild 1988). A convincing case of juvenile rheumatoid arthritis in an adolescent from the Tiwanaku period (c. 1100 B.P.) in Peru has also been described (Buikstra 1991).

Treponematosis

Evidence of inflammatory response, usually appearing as symmetric periostitic expressions on the surfaces of the limb long bones, is common in North American skeletal series. South American materials are said to present similar symptoms (Williams 1932; Goff 1967). At times accompanied by evidence of osteomyelitic changes, as well as occasional stellate scarring of the external table of the skull, these lesions are the basis of a long-standing controversy concerning the possible New World origin of venereal syphilis (e.g., Jones 1876; Whitney 1883; Williams 1932; Goldstein 1957; Bullen 1972; Cook 1976; Brothwell 1981). Theoretical articles by medical historians enrich this literature (e.g., Cockburn 1963; Hudson 1965; Hackett 1967; Crosby 1969, 1972).

The cause of these lesions, which are characteristic of many cemetery samples from throughout eastern North America, has been a matter of debate for more than a century. In 1876 J. Jones argued that the "erosions" he observed in burials from stone box graves and mounds in Tennessee and Kentucky were syphilitic, a conclusion cautiously supported by W. F. Whitney (1883), curator of the Warren Anatomical Museum of the Harvard Medical School, a decade later. Such notables as the anatomist R. Virchow have disputed this conclusion, thus fueling an argument that continues today (Jarcho 1966).

The nature of the debate has changed, however. Today few would disagree with the notion that the skeletal lesions presented by these prehistoric remains resemble most closely the constellation of related diseases collectively known as the treponematoses. Included within this group are venereal syphilis, yaws, and endemic syphilis. In her rigorous consideration of clinical and epidemiological patterning from recent medical literature, D. Cook (1976) argues compellingly that either nonvenereal syphilis or yaws is the best modern model for the observed prehistoric pathology. Her thesis is based on the high prevalence of lesions observed in American prehistoric series, the age-accumulative patterning of incidence, and the total absence of dental changes diagnostic of congenital syphilis, such as Hutchinson's incisors or mulberry molars.

Yet it is clear that, in isolated examples, venereal transmission of this disease occurred. The most convincing cases are two prehistoric burials that include both adults and juveniles with the stigmata of venereal syphilis. In one of these, a mulberry molar was found in juvenile remains in a burial site that also included adult skeletons having treponemal long-bone lesions (Clabeaux Geise 1988). A second example is represented by the remains of a prehistoric achondroplastic dwarf recovered from a Middle Woodland burial mound in Illinois (Charles, Leigh, and Buikstra 1988; Burgess 1988). This adult woman, whose left lower limb is heavily remodeled, died in childbirth. Her fetus presents evidence of periostitic changes, as well as dwarfing. Although the data are scant, they suggest that at least some prehistoric American women acquired treponemal infections as adults, presumably through sexual intercourse. The infection thus acquired would have been in an acute stage during the childbearing years, which would have facilitated transplacental infection (Grin 1956; Powell 1988).

The most recent overview of theoretical and empirical arguments concerning the origin of venereal syphilis is that of B. Baker and G. Armelagos (1988). After extensively reviewing current evidence, these authors conclude that pre-Columbian American skeletal materials reflect a treponematosis that spread to the Old World through nonvenereal contact. European social and environmental conditions favored the development of venereal transmission, and thus originated the "French disease."

Doubtless the question of treponematosis and the development of venereal forms will remain controversial for some time. Eagerly awaited is further skeletal evidence from Europe, as well as the devel-

opment of an immunological technique that will make it possible to identify treponemal antigens in ancient materials (Baker and Armelagos 1988).

Even though there is little evidence for venereal transmission of treponematosis in pre-Columbian American skeletons, it is important to underscore the presence on this continent of a chronic treponemal disease that affected a significant number of individuals. Beginning in childhood and progressing throughout life, inflammations produced by the illness doubtless created a considerable health burden for prehistoric peoples of the Americas.

Tuberculosis

A form of pathology distinctly different from the treponematosis syndrome also affected prehistoric peoples from North and South America (Allison, Mendoza, and Pezzia 1973; Buikstra 1981b). Expressed most commonly as erosive spinal lesions, less frequently affecting joint surfaces of the limb long bones, this disease is found in North American populations postdating 1100 B.P. The Chilean materials reported by M. Allison and colleagues (1981) predate the North American examples by over a millennium. Pulmonary involvement is reported for three individuals from the Caserones site (c. 1660 B.P.), as well as an isolated case of Potts's disease dating to c. 2110 B.P.

Epidemiological patterning considered with lesion location suggests that the most closely analogous modern disease is tuberculosis rather than blastomycosis, a fungal infection. Both blastomycosis and tuberculosis present similar skeletal lesions, but their expected age-specific mortality patterns differ. Young adults are disproportionately represented among those dying with clinically documented bone tuberculosis, whereas blastomycosis tends to present an age-accumulative profile. The age-specific disease pattern observed in large series, including those from west-central Illinois, resembles tuberculosis more closely than blastomycosis (Buikstra and Cook 1981; Buikstra 1991).

The tuberculosis diagnosis developed from modern clinical literature does not, however, provide a perfect diagnostic fit for our prehistoric example. Through simulation analysis, J. McGrath (1986) has modeled the course of a tuberculosislike disease in Middle Woodland, Late Woodland, and Mississippian populations from west-central Illinois. She concludes that a disease resembling modern tuberculosis would have rendered our prehistoric peoples extinct or would have itself ceased to exist. Thus, either our estimates of group size and interaction frequency are misspecified, or the modern tuberculosis model is not fully transferable to prehistoric contexts. The important role of effective population size in the spread of disease is emphasized in McGrath's conclusions, underscoring the importance of relatively brief periods of contact involving a large number of individuals. Thus, the role of socially important economic and religious collective activities that encourage population aggregation – however brief – must be considered in explaining patterns of disease spread and maintenance in prehistoric groups.

Diet

Although paleobotanic and paleofaunal residues are the most accurate indicators of resources available to prehistoric peoples, estimates of ancient diets are best derived from the actual physical remains of the consumers. Dental health, for example, can assist in dietary determinations. Caries rates in adults are widely recognized as an indication of maize in the diet of native North Americans (Cohen and Armelagos 1984; Powell 1985). One must postulate such an association with care, however, because it appears that an intake of high-carbohydrate seeds from the eastern horticultural complex can also lead to an elevated frequency of caries (Rose, Marks, and Tieszen 1990). Circular caries in Late Woodland juvenile dentitions have been used by Cook and Buikstra (1979) to argue for a significant proportion of carbohydrates in the weaning diet, most likely a disadvantageous circumstance.

More sensitive to dietary differences, however, are the chemical constituents of the skeleton. The composition of both the mineral and the organic phases of bone is to some degree influenced by diet. Trace elements, such as stable strontium and barium, are carried from the soil to an herbivore's bones through plant consumption. Because both strontium and barium tend to concentrate in osseous rather than soft tissue, primary and secondary carnivores receive relatively little dietary strontium. Thus, within a region, the relative herbivory of an omnivorous species such as *Homo sapiens* can be estimated. Zinc tends to concentrate in flesh and is thus a dietary marker for animal protein consumption.

The strontium content of bones has been used by M. Schoeninger (1979) in her investigation of status clusters of graves from the Chalcatzingo site, Morelos, Mexico. Her careful argument concludes that diet varied by status group at this prehistoric Meso-American site dating from 2900 to 3100 B.P.

Zinc and strontium have been used to investigate dietary differences within and between Middle and

Late Woodland groups in west-central Illinois (Lambert, Spzunar, and Buikstra 1979; Buikstra et al. 1989). Although other elements such as vanadium co-vary with diet and would thus be desirable dietary markers, most are subject to postdepositional enrichment or depletion (diagenesis) and are thus contextual signatures rather than dietary signals. Focused on intrasite variation, the earliest Illinois studies examined patterning across status groups in Middle Woodland mounds and sought gender-related differences within Middle and Late Woodland samples. The nonrandom distribution of trace elements across burial groups in Hopewell mounds suggests the presence of status-related dietary habits within Middle Woodland communities. Although no gender differences were observable in Middle Woodland data, bones of Late Woodland men contained significantly more zinc and less strontium than those of women. This may reflect either a true gender-based dietary difference or the increased metabolic demands that Late Woodland women faced owing to closer birth spacing (Buikstra et al. 1987).

Diachronic study of Illinois Middle and Late Woodland samples indicates that, although zinc values do not vary chronologically, strontium levels do decrease during Late Woodland times. This decrease may seem enigmatic, given the development of maize agriculture during this period. Maize, however, is relatively poor in elements, and thus the observed pattern is expected. The values for zinc suggest that the proportion of animal protein in the diet did not vary significantly across Woodland groups. Similar patterning has been reported for a temporally sequential series of skeletal samples from Ontario (Katzenberg and Schwarcz 1986; Katzenberg 1988).

A second form of chemical study has focused on the collagen fraction of bone. The results of studies based on stable carbon isotope ratios derived from bone collagen make it possible to predict the presence of maize in diets with a precision far beyond estimates based on the paleobotanic record or dental health. Maize, a tropical grass, fixes carbon through the Hatch–Slack, or C_4 pathway. This contrasts with the usual pattern for temperate-climate vegetation in which the common pathway is Calvin, or C_3. As partial differential carbon-13 values – the standard transformation used in such studies – become more positive, the presence of maize in the diet is more likely. Values derived from human collagen that are more positive than −20 or −21 are considered evidence of C_4 plant consumption.

The association of maize agriculture with Missis-

sippian cultures is well known. Debate has centered, however, on the degree to which the timing of maize intensification was directly associated with the development of Mississippian lifeways and the relative importance of maize to Mississippian peoples. The carbon isotope technique has provided a means of resolving these and related issues concerning agricultural intensification in the eastern United States. This significant methodological advance, developed only within the past 10 years, has facilitated the resolution of century-old arguments about the role of corn in North American prehistory.

Partial differential carbon-13 values from across eastern North America clearly document the fact that maize consumption predates the Mississippian period (Lynott et al. 1986; Buikstra et al. 1988). In the central Mississippi valley, these values suggest a rather gradual increase during the terminal phases of Late Woodland, including a highly variable period of experimentation. Values stabilize during Mississippian times, indicating that corn was a significant component of the diet for the late prehistoric peoples. Of special interest is the fact that corn consumption was apparently higher in the "farmstead" communities of the lower and central Illinois valley than it was at the major ceremonial center of Cahokia during the early, expansive phase of the Mississippian period (Buikstra and Milner 1988). Also significant is the fact that the partial differential carbon-13 values from Illinois never reach the extremely positive figures (−7.8 to −8.0 o/oo) that characterize the Mississippian peoples of the Ohio Valley and the Nashville Basin of Tennessee. These very positive values are currently a source of debate, with suggested causal factors ranging from true dietary contrasts to varietal differences in corn (Buikstra et al. 1988). Certain of these late prehistoric populations present evidence of severe ill health (Cassidy 1984; Eisenberg 1986). The degree to which nutritional deficiencies are implicated remains a point of controversy (Buikstra et al. 1988).

Ratios of nitrogen-15 to nitrogen-14 have been used to identify the presence of legumes in prehistoric diets, as well as to distinguish between marine and terrestrial resource utilization (DeNiro, Schoeninger, and Tauber 1983; Schoeninger and DeNiro 1984; DeNiro 1987). A bivariate plot of partial differential carbon-13 and nitrogen-15 values enables the researcher to distinguish the effects of marine enrichment from those of maize utilization. Diets composed of marine resources derived from coral-reef habitats appear to present an anomalous pattern (Schoeninger et al. 1983; Keegan and DeNiro 1988).

At present, most studies of coastal series using both carbon and nitrogen ratios are limited to small samples. Expanded applications of these promising techniques are anticipated.

Nonspecific Indicators of Stress

Within the past two decades there has been an explosion of interest in applying the so-called nonspecific indicators of stress to questions of community health. These indicators range from those that apparently mark episodes of acute stress and recovery, such as Harris lines and dental defects, to those that are associated with chronic mal- or undernutrition. Each type of change has been observed to be associated with disadvantaged health status in modern clinical examples, with predisposing factors including nutritional inadequacy, infectious disease, and even severe emotional episodes. Working with ancient materials, the observer cannot precisely determine the cause of a specific condition, but instead assumes that a sample with more evidence of nonspecific stress is less advantaged than one with fewer indicators of poor health. The popularity of this approach has been influenced by an emphasis on population biology in physical anthropology, as well as by archaeological interest in human ecology (Buikstra and Cook 1980; Cohen and Armelagos 1984).

Harris lines, observed as radiopaque lines perpendicular to the cortex of limb long bones, result from episodic stress. Because the lines, which can also be visualized as disks in the affected diaphyses, can remodel, they are less satisfactory indicators of poor health than are dental defects that include both hypoplastic bands and microdefects such as Wilson's bands (Rose, Condon, and Goodman 1985). Even so, Harris lines have proved useful in documenting the presence of annual periods of growth arrest, which appear to be characteristic of archaic peoples in Illinois, Kentucky, and California (McHenry 1968; Buikstra 1981a; Cassidy 1984). Such repetitive patterning is not characteristic of sedentary groups, whose storage facilities may have buffered them from seasonal stress.

A number of North American studies have focused on the biological costs and benefits of increased dependence on maize agriculture. As noted at the beginning of this essay, maize cultivation represented a late prehistoric intensification of a trend in plant utilization begun many centuries before. Estimates of relative maize dependence suggest that maize comprised a very significant part of the diet for certain late prehistoric peoples, including the Fort Ancient Late Mississippian communities of Ohio and Kentucky.

These studies have employed various markers of health status, including stature attainment rates in juveniles, adult stature, sexual dimorphism, cortical thickness, demographic patterning, and porotic hyperostosis, as well as the Harris lines and dental defects mentioned previously (Lallo 1973; Lallo, Armelagos, and Rose 1978; Rose, Armelagos, and Lallo 1978; Cook 1979, 1981, 1984; Lallo, Rose, and Armelagos 1980; Buikstra 1984; Cassidy 1984; Goodman et al. 1984; Larsen 1984; Perzigian, Tench, and Braun 1984; Goodman and Armelagos 1985). In general, it is assumed that populations with disadvantaged health status will exhibit slower growth, depressed adult stature, less sexual dimorphism, reduced cortical thickness, elevated death rates, and increased frequencies of porotic hyperostosis when compared with closely related groups in advantaged situations. In this context, it should be noted that the cranial porosities termed porotic hyperostosis and cribra orbitalia are usually considered to be evidence for nutritional anemias in the New World. No convincing arguments have been made for the existence of anemias of genetic origin, such as sickle-cell anemia and thalassemia, in the prehistoric Americas.

The regional studies cited earlier generally support the notion that a certain health risk was associated with the development of maize agriculture. Late Woodland agriculturalists in West-Central Illinois, for example, present evidence of disadvantaged health status in juveniles, including such features as depressed growth curves, elevated weaning age, elevated death rates, and decreased cortical thickness (in juveniles). However, as Cook (1984) pointed out, the more recent and increasingly maize-dependent Mississippian peoples in the same region show less evidence of nonspecific stress. Their only liability appears to have been a tuberculosislike pathology (Buikstra and Cook 1981), a density-dependent disease, which is most closely linked to effective population size and only indirectly reflects subsistence base.

A. Goodman and co-workers (1984; see also Lallo 1973; Lallo et al. 1978, 1980; Rose et al. 1978; Goodman and Armelagos 1985) report deteriorating health for Mississippian peoples from Dickson Mounds, located in the central Illinois River valley. It is clear, however, that the shift to maize intensification in this region does not correlate tightly with the periods of extreme ill health (Buikstra and Milner 1988). The residential sites associated with Dickson Mounds are fortified during the Mississippian period, which suggests that socially mediated stresses may

have been at least as important as diet in explaining the health status of the skeletal sample excavated from the Dickson Mounds cemeteries.

Farther to the east, there is evidence of extreme maize dependence among late prehistoric populations from Ohio, Kentucky, and Tennessee (Broida 1983, 1984; Buikstra et al. 1988). Disadvantaged health status is clear for many of these same groups (Cassidy 1984; Eisenberg 1986). In fact, the population profile for the Averbuch site (Eisenberg 1986) is consistent with the presence of disease epidemics (Buikstra et al. 1988). Thus, however probable it is that Western diseases caused severe depopulation during protohistoric times (Ramenofsky 1987), there is also convincing evidence for severe ill health in at least some American native populations that clearly predates Columbian contact.

Summary

This essay has presented an overview of recent research on ancient disease in the Americas. Materials from North America and the west coast of South America have been emphasized, as they have been in studies of pathology. Our survey highlights the success of ancient Peruvian surgeons, and as well illustrates the frequency of healed fractures and osteoarthritis in North American materials. North American remains also dominate the recent investigations of nonspecific indicators of population health, as they do studies of bone chemistry designed to reveal the approximate content of ancient diets. Recent studies emphasizing the biological costs and benefits of maize agriculture, as summarized in this essay, illustrate synergism between diet and health status, as well as the importance of cultural and environmental contexts in explaining disease in the past.

Several of the subjects addressed here are a source of debate in the 1990s. The antiquity of rheumatoid arthritis in the New World has received recent attention, as has the long-standing question of venereal syphilis and its origins. In the 1950s the prevailing opinion was that no tuberculosislike pathology existed in the prehistoric New World (Morse 1961), a view that has been reversed. Even so, the conditions under which this tuberculosislike pathology developed remain obscure and controversial.

As noted by Buikstra and Cook (1980) in their review of paleopathology in the Americas, there has been increased emphasis on the study of ancient disease since 1970. Frequent collaboration between medical and social scientists, with input from chemists, is producing remarkable new insights concern-

ing the quality of life of peoples who left few clues other than their tissues. This productive trend is vital to the full appreciation of America's unwritten past, as it is to research concerning the history of disease.

V.9
Diseases of the Americas, 1492–1700

During the first 200 years of European exploration and settlement of the Americas, native populations experienced catastrophic die-offs from the introduction of acute infectious diseases. Pinpointing which parasites were responsible for this decimation is not a simple matter. European knowledge of the infectious disease process was primitive in the sixteenth and seventeenth centuries, with the result that conquerors, settlers, and clergy were ill-prepared to describe the illnesses they witnessed. Statements that simply describe the death experience of native peoples are the most common. In the Roanoke documents of 1588, for instance, T. Hariot described native death from disease, but he attributed the outbreaks to witchcraft:

There was no towne where he had any subtile devise practiced against us, we leaving it unpunished or not revenged (because we sought by all meanes possible to win them by gentlenesse) but that within a fewe dayes after our departure from every such town, the people began to die very fast, and many in short space, in some townes about twentie, in some fourtie, and in one sixe score, which in trueth was very many in respect to their nombers. This happened in no place that we could learne, but where we had bene, where they used a practice against us, and after such a time. The disease, also strange, that

they neither knew what is was, not how to cure it. (Hariot 1973)

The quality of disease descriptions in the Americas greatly improved during the eighteenth century. A description of the frequency of colds among the Natchez stands in stark contrast to Hariot's sixteenth-century description of disease:

Colds, which are very common in winter, likewise destroy great numbers of natives. In that season they keep fires in their huts day and night; and as there is no other opening but the door, the air within the hut is kept excessively warm without any free circulation; so that when they have occasion to go out, the cold seizes them, and the consequences are almost always fatal. (Le Page du Pratz 1975)

Because of epidemiological advances, it is easier for historical epidemiologists to reconstruct disease etiology in the Americas from the eighteenth century to the present. Unfortunately, focusing epidemiological reconstructions on later centuries to the exclusion of the sixteenth and seventeenth centuries is comparable to measuring the destruction of a hurricane that strikes the Gulf Coast by its effect in St. Paul, Minnesota. As has been stressed (Burnet and White 1972), the earliest epidemics among virgin-soil populations are the most severe.

Although new pathogens, such as cholera (Benenson 1976a), reached America's shores in later centuries, they operated at reduced scales, affecting only those who had survived a microbial war of 200 years. Thus, this essay attempts to reconstruct the group of diseases that spread to the Americas between A.D. 1492 and 1700. Although multicellular organisms, including round- and pinworms, undoubtedly reached the Americas during the sixteenth and seventeenth centuries, this discussion focuses largely on unicellular or subcellular organisms, viruses, bacteria, and protozoa, that are defined as acute and infectious and that periodically erupt as epidemics.

Disease Source Material

Whether explicitly stated or not, the identification of parasites responsible for past epidemics is always indirect. The truth of this statement is dramatized by the 1918 influenza pandemic that killed millions of people in less than a year and a half (Jordan 1927). Despite early-twentieth-century advances in public health, microbiology, and immunology, an understanding of the variations of the influenza viruses was not attained until the 1970s (Mackenzie 1980; Stuart-Harris 1981). In 1918 and 1919 suggestions regarding the source of the disease ranged

from Pheiffer's bacillus to swine influenza (Crosby 1976).

At least four methods are employed to reconstruct disease agents in historical epidemics: (1) evolutionary theory; (2) disease loads in nonimmune populations; (3) historical documents; and (4) skeletal biology. Typically, researchers rely on one or, at the most, two of these methods. To determine the strengths and weaknesses of any epidemiological reconstruction, the assumptions of each method must be evaluated.

Parasite Evolution and Ecology

Darwinian evolution is the theoretical framework for explaining the differential persistence of variation. Variation and natural selection are the principles that account for this persistence. Variation arises through such processes as mutation and genetic drift. Mechanisms of selection determine which variations persist or become extinct (Lewontin 1974; Levins and Lewontin 1985).

In the disease drama, individual variation between parasites and hosts determines, in part, which parasites become fixed in the disease load of the population. Parasites are predators seeking to maximize their reproductive fitness by colonizing hosts (Burnet and White 1972; Youmans, Paterson, and Sommers 1980). Not all predators are successful. Those that are take over cell machinery; cells then produce parasites at the expense of host cells.

The host's defenses, including skin, cilia, mucous membranes, and antibodies or immunoglobins, are the primary selective agents working to repel parasites. If the host's defense mechanisms are successful, there will be no predatory invasion. If they are not, illness and death of the host may ensue.

Besides explaining the relationship between predator and prey, Darwinian principles focus attention on how and why the relationship changes through time. If the parasite is specific in its reproductive requirements and kills the host before a new generation of parasites is released, the parasite faces death. A more successful strategy for the parasite is to inhibit or neutralize host defenses without causing the death of the host. As suggested by the European experience with epidemic or venereal syphilis (C. J. Hackett 1963; Hudson 1968; Crosby 1972), over time a kind of symbiosis evolves in which the host works for the parasite, but both host and parasite survive.

The pattern from initial virulence to relative quiescence has implications for the reconstruction of past infections. Quite simply, as I have stated elsewhere

(Ramenofsky 1987), present diseases cannot be accepted as analogs for diseases of antiquity. New parasites have become fixed by human populations; older parasites have evolved less destructive adaptive strategies; still other parasites, most likely unidentifiable, have died out. Although present processes of infection and transmission may be comparable to those of the past, the present human disease load does not mirror the past.

Epidemiologists with an interest in understanding past diseases are well aware of this problem of analogs. To overcome it, they have focused on reconstructing the human ecological settings most conducive to the fixing and persistence of human infectious parasites (Cockburn 1963, 1971; Black 1966, 1980; Fenner 1971, 1980). Immunology, population size and density, and population mobility are the key variables considered in this approach.

Most of the diseases considered in this essay have one trait in common: Recovery from the infection confers long-term or permanent immunity. Because of this protection, parasites require a continual pool of susceptible hosts to survive.

Large nucleated populations, such as those of cities, meet the criterion for such a pool. As documented archeologically, nucleated populations of any magnitude did not become a consistent feature of the human landscape until after the evolution of agricultural systems. Cities developed shortly thereafter, having a temporal depth in western Asia of approximately 5,000 years (Wenke 1984). Although it is likely that acute, infectious parasites periodically colonized individuals or populations before 5000 B.P., natural selection fixed these parasites only when population density passed a threshold necessary for parasitic survival. Even after 5000 B.P., the distribution of acute infections probably was uneven across Asia and Europe simply because population distribution was uneven.

Smaller nucleated populations that are sedentary or consist of those who practice a mobile settlement strategy are likely to be infected by other types of parasites. The list of potential parasites varies, depending on the degree of mobility, the presence or absence of herd animals or pets, and the size of the population. Both F. Fenner (1980) and F. L. Black (1980) think chronic or latent infections, including chickenpox (*Varicella zoster*) and *Herpes simplex*, are probable candidates for persistence in small populations. Zoonotic infections, including yellow fever (arbovirus) and tetanus (*Clostridium tetani*), that are transferred from animal reservoirs to humans by accidents of proximity are also likely.

On a global scale, these abstract treatments suggest that a variable set of diseases have infected human populations through time. Small mobile or sedentary populations are expected to have chronic or latent microbial flora. As population size or density of movement between populations increases, human groups are subject to acute infectious parasites that periodically erupt as epidemics. To determine whether these expectations hold on a local scale requires the use of other data sets.

In summary, Darwinism is crucial for any discussion of historical epidemics. Variability and selection explain the evolution and differential persistence of human diseases under differing environmental conditions. These simple principles account for the extinction of older diseases and the sudden onset of new ones. Ecological factors, including population distribution, nature of settlement, and immunology, are useful for stipulating the global distribution of chronic and acute infections.

Although important, Darwinian theory is also subject to limitations. Because of evolutionary changes in hosts and parasites, present diseases cannot be accepted as analogs for past diseases. In addition, theory, by definition, is ideational. Without testing ideas against the complexity of empirical variability, ideas about how evolution, persistence, or extinction occurred are empty.

Infectious Diseases in Population Isolates

The second method of reconstructing historical epidemics is to study the effects of introduced acute infections on living population isolates. Because of population size, distribution, or geography, these isolates, or virgin-soil populations, do not maintain acute infections endemically. These infections must be introduced from external sources. The temporal lapse between introductions of the same parasite coupled with the immunological responses of previously infected individuals determine whether the foreign parasite will have a minimal or maximal effect. Whereas temporal isolation of one year may be sufficient to cause an epidemic of the common cold (Burnet and White 1972), a six- to eight-year lapse may be necessary to cause a smallpox epidemic (Pitkanen and Eriksson 1984).

There are two approaches to the study of acute infectious outbreaks in nonimmune populations. During an epidemic, surveillance teams may continuously monitor the appearance of new victims and the recovery or death of older victims (e.g., Paul and Freeze 1933; Nagler, Van Rooyen, and Sturdy 1949; Christensen et al. 1953a,b; Peart and Nagler

1954; Phillip et al. 1959; Monrath et al. 1980; Brenneman, Silimperi, and Ward 1987; Gerber et al. 1989). Alternatively, antibody reactions can be measured in sputum or serological samples (Black and Rosen 1962; Adels and Gajdusek 1963; Brown, Gajdusek, and Morris 1966; Black et al. 1970; Brown and Gajdusek 1970; Neel et al. 1970).

Although both attack and mortality rates can be determined from disease notifications, the accuracy of the rates varies according to the severity of the outbreaks, the rapidity of spread, and the number of surveillance teams. In severe disease episodes, it is likely that both morbidity and mortality are greatly underestimated (Crosby 1976).

Because of immunological memory, antibody testing can be done at any time. Consequently, an entire population can be surveyed for the presence of measles antibody 15 years after the epidemic. Unfortunately, the resulting trends apply only to the survivors. Without independent evidence (e.g., death certificates, disease notifications), trends in mortality cannot be measured.

In addition to incomplete reporting, contemporary studies of epidemics in virgin-soil populations are subject to the problem of analogs. Although it is tempting to use modern morbidity and mortality data to account for what might have occurred 500 years ago, such an approach is erroneous for two reasons. First, as previously described, less deadly symbioses between parasites and hosts evolve through time. Second, where present, medical intervention will curtail the course of a disease outbreak. Because of these factors, contemporary responses of virgin-soil populations to acute infectious parasites are likely to be rather pale reflections of sixteenth- or seventeenth-century disease events.

Despite these limitations, knowledge of contemporary epidemics is crucial for understanding the infectious process. As demonstrated by the accidental introductions of measles to southern Greenlanders in 1951, stochastic contacts between infected and susceptible individuals still occur (Christensen et al. 1953a,b). In addition, these contemporary studies detail the complex interactions between the health of the hosts and primary and secondary invasions. Between 1942 and 1943 in the Yukon, a small band of Tlingit experienced six epidemics, including measles, malaria, whooping cough, diarrhea, and meningitis. With each episode, the health of the population deteriorated, allowing for the invasion of other parasites (Marchand 1943).

In summary, contemporary studies of the infectious process and disease loads of nonimmune populations are useful guides to understanding epidemic conditions in the past. These studies document the ease with which infectious parasites spread and the trauma that follows in the wake of epidemics. Rather than single epidemic events, it is likely that native Americans in the sixteenth and seventeenth centuries experienced waves of infections. The deterioration of health following an initial disease event established conditions appropriate for the invasion of other, allochthenous and autochthenous, parasites.

Historical Descriptions of Epidemics

Consulting historical documents is the third method of reconstructing past epidemics. Although lumped within a single heading, these sources vary from casual references to disease outbreaks to detailed descriptions of a single epidemic. Finding these documents demands great investments of time. Rarely are medical data indexed or otherwise distinguished in archives. Consequently, researchers may search assiduously through primary documents before coming across a single description of a disease event.

Descriptions of epidemics among native Americans during the Columbian period are subject to three sources of error. First, because contacts during the period were irregular, descriptions of any sort, including references to disease, are also irregular. Consequently, the first reference to a disease event may not mark the onset of introduced parasites. As late as 1800 contact between Europeans and native groups of the North American plains was still irregular. When Meriwether Lewis and William Clark visited the Upper Missouri tribes, the Mandan described a smallpox epidemic that had occurred 20 years earlier (Thwaites 1904).

Second, as discussed previously, the crudeness of European knowledge during the Columbian period affected the nature of early disease descriptions. For one thing, it is likely that observers failed to record many outbreaks. Moreover, a lack of familiarity with the people being described made it difficult for even the most conscientious explorers to estimate the number of deaths that diseases wrought. The Gentleman of Elvas (Bourne 1904), for instance, simply described the abandonment of villages visited by the expedition of Hernando DeSoto. Similarly, Daniel Gookin (1806) described an epidemic event from hearsay evidence that had decimated native groups of New England seven or eight years before the English established New Plymouth.

Third, there is confusion over disease names. Because Europeans were writing about native disease experiences, knowledge of what was known in Eu-

rope is crucial for understanding this ambiguity. C. Creighton's (1894) sourcebook on epidemics in Britain continues to be one of the finest and most readily available compendiums of evolving medical knowledge.

Before 1743, influenza was frequently confused with other agues or catarral fevers. Diphtheria was not defined as a separate illness until the eighteenth century. Before that time, it was lumped with scarletina or the purples. Because measles and smallpox both produced rashes, the two terms were used interchangeably until 1593. By 1629, however, when the Bills of Mortality were established, smallpox and measles were consistently differentiated. Smallpox was noted as "flox or smallpox."

Because smallpox, measles, influenza, and diphtheria are acute and infectious, they all could have been introduced to the Americas at the time of first contact. Whether they were requires careful reading of documents informed by contemporary epidemiological knowledge. Historical documents by themselves are of marginal utility. The confusion over names, which they reflect, coupled with medical naïveté and unfamiliarity with the populations being described by observers, has led one microbiologist to state that documentary evidence "provides, at best, an accumulation of suppositions, since most accounts give insufficient details of symptoms or of epidemiological patterns for us to impute an aetiological agent" (Mackenzie 1980).

Despite these limitations, historical descriptions are crucial sources of information and must be integrated into any disease reconstruction. Documents not only highlight the presence of some infectious parasite, but force the historical epidemiologist to investigate what and why the disease event occurred.

Burial Populations

Irregularity of initial contact and the limitations of medical knowledge among observers during the Columbian period have been recognized as sources of error for some time. To compensate for these problems, other types of data have been deployed in reconstructing historical epidemics. Human skeletal remains are of some importance here (Milner 1980; Blakely 1989). G. R. Milner (1980) has argued that the analysis of mortuary populations from the earliest period of contact is of central importance in unraveling the timing and magnitude of aboriginal population loss from introduced infectious diseases.

Skeletal populations are employed in two ways. Analysis of the age–sex structure of a population can suggest whether its demographic profile reflects

an epidemic episode (Blakely 1989; Blakely and Detweiler-Blakely 1989). Moreover, the frequency and type of skeletal pathologies can provide information on the presence, absence, and, perhaps, type of acute infectious agent (Steinbock 1976).

The use of reconstructed demographic profiles to infer past epidemics requires two assumptions, however. First, the mortuary population represents a single temporal interval comparable to an epidemic interval. Second, the burial sample is representative of those who lived. Both assumptions are difficult to support archeologically.

Although archeologists are skilled in controlling for time, the temporal resolution obtainable from the archeological record is rarely comparable to a single epidemic event. Only in unique depositional settings, such as the Tathum burial mound in west Florida (Mitchem 1989; Hutchinson 1990), does the weight of evidence suggest that the burial population represents an epidemic episode. Mortuary settings that incorporate 50 to 100 years are far more common.

Even if the temporal dimension is controlled for, the problem of the representativeness of the burial sample remains. Skeletal populations are typically biased samples of those who lived. Some age–sex classes are underrepresented; others may be overrepresented (Buikstra and Cook 1980). Controlling for these biases is challenging, especially under epidemic conditions. As suggested by historical descriptions and rarity of burial populations during the Columbian period (Ramenofsky 1987), native populations may have ceased interment in some areas. This practice raises serious questions about the nature of available burial samples: Do they represent the victims or survivors of epidemics? Without controlling for sampling biases, accurate reconstruction of demographic profiles from cemetery data is, at best, difficult.

As with skeletal analyses, the investigation of osteological evidence of epidemic mortality has serious shortcomings. First, not all acute infections are expressed osteologically. In illnesses such as venereal syphilis, or tuberculosis, bone cells become involved only when the disease has progressed to a severe stage. If the individual dies before that point, the disease will not be reflected osteologically.

Second, bone cells have limited ways of responding to infectious agents: tissue loss, tissue gain, both loss and gain, or abnormal morphology (Ortner and Putschar 1981). The remodeling may be variously expressed, but different causative agents can result in the same osteological expression (Steinbock 1976;

Ortner and Putschar 1981). Although osteological remodeling may suggest the presence of an acute infection, stipulating the causative agent responsible for the remodeling is frequently impossible. Even in those rare instances where a specific acute infectious parasite is implicated as causing osteological remodeling (Jackes 1983), it is unlikely that the individual died from the infection. The process of osteological remodeling is of longer duration than the illness.

Because of inherent difficulties in isolating causative agents, bioarcheologists have begun to consider nonspecific stress indicators, especially osteomylitis and periostitus (Detweiler-Blakely 1989). If the health of native populations deteriorated after contact, the frequency or intensity of stress responses should have increased. To determine whether the suggested association holds requires the analysis of burial populations through time. Even if such a series were available and the appropriate pattern were documented, the cause or causes of the stress responses would remain elusive (Buikstra and Cook 1980). Periosteal responses, for instance, can be caused by anemia, treponemal infections, scurvy, trauma, or osteomylitis (Ortner and Putschar 1981).

In summary, inadequate control of the temporal dimension, biases present in cemetery populations, and nonspecific skeletal responses to disease limit the utility of skeletal populations as primary sources of data for reconstructing epidemic mortality in the Americas during the Columbian period. As a secondary resource, these investigations may provide information unobtainable through other sets of data.

The reconstruction of past epidemics is challenging because it is elusive. Instead of a single infallible method, historical epidemiologists must employ a suite of methods. Results of one investigation can then be weighed against those obtained from other inquiries. Even then, we can never be certain whether smallpox or malaria was the biggest killer of native Americans in the sixteenth century. At the same time, the integration of evidence from Darwinian theory, contemporary disease investigations of nonimmune populations, historical documents, and skeletal analyses can suggest the magnitude of the parasitic invasion that faced native peoples during the earliest centuries of European contact.

Allochthonous Parasites in the Americas

Previous Syntheses

Some researchers have investigated the introduction of specific diseases to the Americas in general

Table V.9.1. *Diseases suggested to have been introduced to the Americas*

Disease	Crosby (1972)	Crosby (1986)	Dobyns (1983)	Ramenofsky (1987)
Chickenpox		X		X
Dengue fever		X

Bubonic plague			X	X
Malaria			X	X
Typhus			X	X
Yellow fever		X	X	X
Total	3	11	12	14

(e.g., Stearn and Stearn 1945), whereas others have studied the introduction of all diseases to a specific region (e.g., Cook 1982). Few have attempted a comprehensive treatment of the introduction of all diseases to both continents. Table V.9.1 summarizes the conclusions of three scholars regarding the introduction of acute infectious agents to the Americas.

It will be noted that none of the lists includes epidemic (venereal) syphilis or tuberculosis. The omission of these two major diseases should not be interpreted as supporting the notion that either disease originated in the Americas. Controversies over their origins are extensive (regarding syphilis: Crosby 1972; Ramenofsky 1987; Baker and Armelagos 1988; regarding tuberculosis: Black 1980; Clark et al. 1987; Ramenofsky 1987). Until this question is resolved, these diseases cannot be considered to be either allochthonous or autochthonous to the New World.

There are some disagreements about specific introductions that stem from the temporal or intellectual focus of the work. In 1972 A. Crosby considered only sixteenth-century introductions. In 1986 he adopted a much larger temporal framework; his suggested introductions reflect that change. Although in 1983 H. Dobyns described more introduced infections than those listed in Table V.9.1, the summary is limited to those diseases that arrived during the

sixteenth and seventeenth centuries. My own list (1987) is also limited to the first two centuries of European contact.

In developing that list, I weighed evidence from all sources described previously. Although my total was greater than either Crosby's or Dobyns's, several diseases were excluded; other diseases were included. Cholera was excluded because according to current opinion (Creighton 1894; Benenson 1976a) it spread to the Americas in the eighteenth century. Diphtheria was excluded because of the ambiguity of the name (Creighton 1894).

Typhoid (enteric) fever was excluded for several reasons. Although native populations of the Americas certainly suffered from diarrheal infections in the postcontact period, the question becomes whether these infections were new and whether *Salmonella typhi* caused some of the infections. The first question cannot be answered; the second can be addressed indirectly. The disease was not isolated from typhus or other nonspecific childhood fevers until the nineteenth century (Creighton 1894; Overturf and Underman 1981). In addition, although rare, typhoid fever can take a chronic form and can spread to humans from nonhuman reservoirs including turtles (Youmans et al. 1980). The combination of a chronic state and the indisputable presence of turtles in precontact America suggested that *S. typhi* could have been present in the Americas before 1492.

The diseases that I listed as introductions, but not treated by Crosby or Dobyns, include anthrax, rubella, and pneumonia. Anthrax is typically a relatively minor infection in humans. Domestic stock, cattle, sheep, horses, and goats are the primary source of the infection; humans become ill through accidents of proximity (Whiteford 1979). In those areas, such as the Southwest or the pampas of South America, where domestic stock were part of the cultural baggage of European colonists, anthrax could have been a source of infection.

Rubella was added to the list for two reasons. First, although a relatively mild disease in adults, it can seriously affect the reproductive fitness of a population. If a woman develops German measles during the first trimester of pregnancy, the fetus may be born with major congenital defects, including cataracts, heart disease, microcephaly, and mental retardation (Top 1976). Second, although rubella was confused with measles and smallpox until the eighteenth century, the presence of measles and smallpox in America during the sixteenth and seventeenth centuries suggested that rubella could have been introduced at the same time.

The bacterial pneumonias are caused by a group of unrelated organisms. Some of these (*Streptococcus pneumoniae*) are part of the normal flora of the human upper respiratory tract. Thus, some causative agents of severe lung infections in humans had to have been present in the Americas before European contact. In contrast, contemporary studies (Brenneman et al. 1987) suggest that some native American populations are at higher risk from other agents of pneumonia (*Hemophilis influenzae*). This elevated risk may indicate that not all causative bacteria of pneumonia were present before Europeans arrived in the Americas. Moreover, because pneumonias are major secondary invaders that follow such viral infections as measles and influenza, and because both measles and smallpox were allochthonous to the Americas, it is likely that at least some types of lung infection spread to the Americas with Europeans. As health deteriorated from viral infections, bacterial agents could invade and cause death.

Although both Dobyns and I view epidemic typhus as an Old World introduction to the Americas, H. Zinsser (1947) thought that it predated European contact. The vector of typhus is the human body louse. The current worldwide distribution of people means that epidemic typhus is also worldwide (Wisseman 1976). Although it is likely that body lice predated Europeans in the Americas, I think it unlikely that typhus-infected lice were present. The disease thrives under conditions of intense crowding, poor sanitation, and social or economic upheaval associated with war. Despite the archeological evidence of warfare in the Americas, the distribution of human populations was inappropriate for fixing epidemic typhus as part of the disease load of native populations. Dense concentrations of people were simply too rare.

In summary, a minimum of 11 and a maximum of 14 viral, bacterial, or protozoal diseases are suggested in Table V.9.1 as having diffused to the Americas during the first two centuries of European contact. There is unanimous agreement on five disease introductions (influenza, measles, smallpox, scarlet fever, and yellow fever). I have increased the total introductions from 11 to 14 by adding anthrax, rubella, and pneumonia.

Current Synthesis

After reexamining the evidence for and against the introduction of diseases listed in Table V.9.1, I have removed one disease. Chickenpox is omitted from Table V.9.2 because it is present in small nucleated populations that lack antibodies for acute, infectious

Table V.9.2. *Viral, bacterial, and protozoal agents introduced to the Americas*

Mode of transmission	Viral	Bacterial	Protozoal
Direct	Influenza	Pneumonia	
	Measles	Scarlet fever	
	Mumps	Pertussis	
	Rubella		
	Smallpox		
Zoonotic	Yellow Fever	Anthrax	Malaria
		Bubonic plague	
		Typhus	

microbes (Black 1980). In addition, *Varicella zoster* can follow a chronic course, expressing itself as chickenpox in children and as shingles in adults (Brunell 1976).

Table V.9.2 lists viral, bacterial, and protozoal agents, characterized by two modes of transmission. Eight of the 13 viruses (influenza, measles, mumps, rubella, smallpox) and bacteria (pneumonia, scarlet fever, pertussis) colonize humans only and are transmitted by them only. Of the remaining 5 diseases, yellow fever is viral; anthrax, plague, and typhus are bacterial; and malaria is protozoal. All 5 of these agents are classified as zoonoses, meaning that the primary reservoir is a nonhuman, invertebrate or vertebrate species (except in rare cases, e.g., pneumonic plague [Benenson 1976b]).

Previously discussed difficulties of reconstructing past epidemics by a single method have direct implications for the current synthesis. I will not attempt to reconstruct the precise date or port of entry of each disease introduction. My goal is to build general expectations about the postcontact spatial persistence of parasites, and to accomplish this I will use data on transmission cycles, evolution, ecology, and history.

For those viruses and bacteria that colonize and reproduce only in humans, density of human populations, regularity of communication, and incubation period of the parasite determined the size of spatial epidemic waves. As population density decreased or communication became irregular relative to the incubation period of the parasite, the parasite died out. Whether a second introduction of the same parasite caused another epidemic outbreak varied according to the number of reproductively active survivors and time. Although individuals who escaped infection during the first disease event could be subsequently infected at any time, the size of the susceptible pool

determined whether any new outbreak would be local or regional in scale (Bartlett 1956; Black 1966; Cockburn 1971).

Recently, the 1520 introduction of smallpox to the Americas has been a subject of some interest. It is a classic example of disease transmission and spatial diffusion. On the basis of information drawn from historical documents, Dobyns (1983) has argued that the virus became the initial New World pandemic, spreading as far south as Chile and as far north as the Canadian border. The Caribbean islands were the initial focus of infection in 1518. The virus was then carried to Mexico by a crew member of Panfilo de Narvaez's expedition. The large size and extreme density of aboriginal populations in the valley of Mexico encouraged the rapid dissemination of the virus.

The question of spatial diffusion beyond the valley of Mexico has been investigated by historians and archeologists. Noble Cook (1981), historian, has not found evidence of spatial diffusion into the Peruvian Empire. A second introduction of smallpox to Panama in 1524 did, however, spread down the Andean chain (Cook 1982). Using climatic data to explain the persistence of smallpox, S. Upham (1986) argued that the smallpox epidemic did spread to southwestern groups. Other archeologists (Ramenofsky 1987; Campbell 1989) have relied on archeological indicators of population change and time. Although generally supportive of an early-sixteenth-century introduction of the parasite to North America, the archeological evidence of catastrophic population loss was ambiguous. Evidence of a sixteenth-century disease introduction was not documented in central New York or the Middle Missouri (Ramenofsky 1987). S. Campbell (1989) documented a large population decline in the Chief Joseph Reservoir during the early sixteenth century. I discovered a comparable population decline in the Lower Mississippi valley between 1540 and 1600. The magnitude and rapidity of the loss argued in favor of some acute, infectious parasite. Neither the 1520 nor the 1524 smallpox epidemic could be implicated directly.

In summary, for directly transmitted viruses and bacteria, the distribution of susceptible populations, communication systems, and incubation periods of the parasite determined whether local disease events became regional or multiregional. Even with detailed historical records, it is difficult to define the spatial extent of a specific parasite. Although the scale of resolution currently obtainable from regional archeological data bases may be sufficient for concluding that acute infectious microbes caused ca-

tastrophic die-offs, current knowledge is simply insufficient for stipulating whether one or another epidemic event was causal.

Transmission cycles of zoonotic infections are fundamentally different from infections transmitted solely between humans. Because vertebrate or invertebrate species other than humans are the primary reservoir of the parasite, niche requirements of the reservoir and microbe determined the postcontact spatial pattern across the American continents. Humans became infected through accidental interactions with the reservoir and causative agent. The following focuses on those aspects of reservoir or microbial niches pertinent to reconstructing the postcontact spatial patterning of these infections.

Temperature severely curtails the distribution of yellow fever. The viral disease is transmitted to humans or other nonhuman primates by several mosquito vectors, including *Aedes* and *Haemagogus* (Taylor 1951). The optimal temperature for incubation of the arbovirus and the transmission ability of the vectors is approximately 30°C (Whitman 1951). At temperatures less than 24°C *Haemagogus,* for instance, cannot transmit the disease, and the incubation period of the virus lengthens. In addition, the vectors have preferred breeding habitats. *Aedes aegypti* breeds in clay-bottomed containers; other species of *Aedes* and *Haemagogus* prefer breeding in trees of climax rain forests (Carter 1931).

Like yellow fever, malaria is a vectorborne disease that is transmitted to humans by numerous species of *Anopheles*. The temperature limitations and elevational preferences of these species vary greatly. Whereas *Anopheles maculipennis* can reproduce in cold pools along lake margins at elevations greater than 4,000 feet in the western United States, *Anopheles quadramaculatis* prefers breeding in swampy nonbrackish pools or bayous typified by the Lower Mississippi valley (Hackett 1941; Watson and Hewitt 1941). In addition, the body temperature of the vector affects the reproductive potential of the protozoans. *Plasmodium vivax* and *Plasmodium malariae* will not develop in anophelines if the body temperature is less than 15°C; *Plasmodium falciparum* requires an anopheline body temperature of greater than 18°C for reproduction (Zulueta 1980).

Epidemic typhus is an acute infectious disease for both vector and human populations. The human body louse, *Pediculus humanus,* is the vector; the causative agent is a bacterium, *Rickettsia prowazekii*. After ingesting the agent, the typhus-infected louse dies within 7 to 10 days. When the louse feeds on human blood, the rickettsial agent is transmitted to humans (Zinsser 1947; Wisseman 1976).

Plague and anthrax are bacterial infections transmitted to humans from nonhuman mammalian reservoirs. The distribution of the reservoir largely determines the distribution of the disease. Wild rodent populations in wooded or desert areas are the true reservoir of the plague bacterium: In these settings, the disease is endemic (Meyer 1963; Benenson 1976b). In urban areas, the causative agent, *Yersinia pestis,* is transmitted to humans through a secondary vector, the rat flea, *Xenopsylla cheopis*. The proximity of humans to rats and their fleas creates a tertiary focus of the disease.

As previously mentioned, anthrax is a bacterial disease of domestic ungulates. The causative agent, *Bacillus anthracis,* is transmitted to humans through the ingestion of contaminated meat or milk products, contact with infected animals, or the inhalation of viable airborne spores (Brachman 1976; Whiteford 1979).

Because not all New World habitats were appropriate for the reproduction of reservoirs, vectors, and parasites, it is likely that zoonotic infections were more limited spatially than were directly transmitted viruses and bacteria. Yellow fever became fixed in tropical climates; malaria survived between 60° north latitude and 40° south latitude (Watson and Hewitt 1941); epidemic typhus survived where human groups were concentrated; herds of domestic ungulates became the focus of anthrax; bubonic plague was fixed as a disease of ports. As rats migrated away from ports, plague also migrated.

The variability in reproductive requirements and, therefore, transmission cycles of parasites has implications for the postcontact spatial patterning in the Americas. Because all native populations were virgin soil, the accidental introduction of any parasite could decimate a single population aggregate. Whether the parasite diffused spatially and acquired an endemic status in the rich American environment depended on a number of factors.

The probability of fade-outs of directly transmitted viruses and bacteria varied according to stochastic contacts between infected and susceptible hosts, the overall distribution of population, and the time separating introductions of the same parasite. As just described, the spatial pattern of zoonoses depended on reproduction requirements of reservoirs, vectors, and parasites. Certainly by the seventeenth century, natural selection had fixed the spatial variability of all introduced parasites. Like threads joining patches of a quilt, communication mechanisms

linked sources of infection to potential recipients. Each epidemic wave further reduced survivors of previous disease outbreaks.

Conclusions

As demonstrated by this synthesis, simple questions are frequently the most difficult to answer. Determining which diseases were allochthonous in the Americas before A.D. 1700 requires the expertise of numerous disciplines, including the study of evolution, ecology, microbiology, history, archeology, and geography. The integration of diverse and sometimes contradictory sets of information provides a means of evaluating past and present assumptions and of suggesting future directions. Although skeptical of the possibility of reconstructing the exact number of introductions, or dates and places of entry during the Columbian period, I support serious interdisciplinary efforts aimed at establishing the nature of the parasitic environment that confronted native populations during the sixteenth and seventeenth centuries. I hope that this preliminary synthesis will promote such efforts.

V.10
Diseases and Mortality in the Americas since 1700

It has been clear to virtually every observer of demographic patterns in the Americas that the differences between Anglo and Latin America are traceable to the differences between the nations that colonized each region, as well as to the characteristics of the indigenous populations of each region. The settlement of North America by the British was a commercial venture, the numerous settlements reflecting the economic and religious diversity of the English Reformation and the growing economic complexity of Britain itself. By contrast, "in Spanish America, the diverse conditions of an entire continent had to find expression in the same set of standard institutions" (Lang 1975).

Moreover, by the sixteenth century the Iberian Peninsula was becoming "underdeveloped" in contrast to the countries of northwestern Europe, including England. Like eastern Europe, it was characterized by large estates worked by a servile peasantry. This pattern was replicated in the Americas, where the Spanish encountered an extensive indigenous agricultural population with whom they established a semifeudal relationship. There was no such indigenous population in the north, and the British either pushed aside or killed those they did encounter. As a result, socioeconomic and settlement patterns differed. With the exception of the southeast, family-owned and -operated farms became the dominant pattern in English America. In most of Latin America, haciendas and plantations became the dominant pattern. In the areas where an extensive agricultural society was conquered, Indians provided the servile labor force. Elsewhere, primarily in the Caribbean islands and in what became Brazil, slaves imported from Africa provided the servile labor force on plantations originally devoted to sugar growing. Only in the southeastern part of English America were there plantations worked by slaves.

Upon achieving independence, these two former colonial regions continued to develop in entirely different ways. The former Iberian colonies remained producers of raw materials for export (Stein and Stein 1970), whereas within a century the former English colony became one of the leading manufacturing nations in the world. It is beyond the bounds of this chapter to offer an explanation for these differences save to suggest the following: (1) In the new Latin American nations there persisted local land-owning elites with an interest in perpetuating the former colonial system, complete with its dependence on a servile, illiterate population for the extraction of staples and raw materials. (2) The settlers in English America came from a society "which generally treated literacy, toleration, individual rights, economic liberty, saving and investment as inseparable elements of the process of change and growth" (Stein and Stein 1970).

Latin America

Not all Iberian settlement in the Americas took place in areas in which Indians or black slaves formed a servile labor force. Grassland sections of what became Argentina, Uruguay, and southern Brazil were without a sedentary indigenous agricultural population and did not attract extensive European immigration until the latter part of the nineteenth and the twentieth centuries. The areas in which there were sedentary agricultural populations attracted the most attention and as a result suffered devastating pandemics. The magnitude of the result-

ing population collapse is a matter of debate, but that it was catastrophic is beyond question. Though crisis mortality caused by pandemics and famines receded over the three centuries following first European contact, mortality remained high enough that there was essentially no population growth during the eighteenth century (McGovern-Bowen 1983). Indeed, significant growth did not begin until the early decades of the nineteenth century (McEvedy and Jones 1978). The increase resulted partially from the importation of African slaves (particularly to Brazil and the Caribbean) and European immigration from Mediterranean countries (particularly to Brazil and Argentina) and partly from changes in mortality patterns.

Data on mortality are sparse until about the mid-nineteenth century. Some scattered estimates of crude mortality rates from the early years of the century are as follows: between 21.2 and 28.9 per 1,000 in São Paulo, Brazil, during the years 1777–1836; between 36 and 46 per 1,000 in Havana between 1801 and 1830; 44 per 1,000 in the town of San Pedro in Guatemala in 1810–16 (the most valid of several estimates from a series of neighboring towns); and probably never fewer than 30 to 35 per 1,000 in Mexico City at any time until the mid-nineteenth century. In São Paulo at the end of the eighteenth century, infant mortality is estimated to have been 288 per 1,000 live births and life expectancy at birth about 38 years (Kunitz 1986).

Judging by population estimates and scattered estimates of mortality as well as fertility, it was in the first half of the nineteenth century that births began to outnumber deaths with sufficient consistency for population to begin to grow. This presumed stabilization of mortality, albeit at a high level, coincides with the period when independence was achieved by most Latin American nations. The two are not unrelated, for the result of independence was that the monopoly on trade long held by Spain and Portugal was broken, and the new nations began to trade openly with the industrial nations, particularly England. Moreover, relative social stability characterized most of the new nations during the nineteenth century. "In sum, in Latin America the colonial heritages reinforced by external and internal factors produced economic growth without appreciable sociopolitical change during the nineteenth century" (Stein and Stein 1970). Thus, political and social stability and economic improvements – still within a neocolonial context characterized by an illiterate and servile labor force working on plantations and haciendas producing raw materials for export –

seem to have resulted in a stabilization of mortality at levels that were high but nonetheless low enough for population to grow.

It appears that among the most important identifiable endemic diseases or syndromes were the following: the pneumonia–diarrhea complex of infancy and childhood, the severity of which is exacerbated by protein–energy malnutrition; in some regions malaria; and tuberculosis, which was widespread. Among black troops serving in British West Indian regiments in the West Indies, for instance, the average annual death rate from tuberculosis was 6 per 1,000 in the 1860s, 8.5 in the 1870s, 5 in the 1880s, 3 in the 1890s, and less than 1 in the 1900s. Diseases of the respiratory tract, including tuberculosis, were the leading cause of death. Over the same period black deaths from malaria ranged between 1 and 2.5 per 1,000 per year (Curtin 1987). Life table estimates are available from the middle of the nineteenth century for all of Latin America, except Argentina, Uruguay, and Cuba. From 1860 to 1900, life expectancy at birth increased from 24.4 to 27.2 years. These average figures mask differences among countries. The Dominican Republic, Guatemala, and Nicaragua had a lower life expectancy in 1900 than Brazil, Chile, Colombia, Costa Rica, Mexico, and Panama had had in 1860 (Kunitz 1986). Diversity within some of the large nations, such as Mexico, was probably every bit as great as it was among nations.

The differences in mortality among nations, as well as in the rate at which it declined in the latter half of the nineteenth century and the first several decades of the present century, were primarily reflections of their economic development. These in turn were a reflection of the degree to which countries were dependent on a servile labor force or had, like Argentina and Uruguay, attracted a large European population. Starting in the 1930s, however, the rapidity with which mortality declined increased substantially, particularly in the high-mortality countries, and the rate at which improvement occurred became essentially the same among all of them. Eduardo Arriaga and Kingsley Davis (1969) attribute this to the widespread availability of public health programs that were imported from the industrial nations beginning at about this time or somewhat earlier. This interpretation is supported by the observation that among Latin American nations with the lowest crude mortality rates at the turn of the twentieth century were Cuba and Panama, both places in which the U.S. government had important interests and in which major public health activities had been established (Kunitz 1986).

Thus, crisis mortality seems to have been reduced by the development of relatively stable societies with a slowly improving standard of living. But because living conditions did not improve dramatically due to the neocolonial structure of most of these nations, mortality rates remained high. Dramatic improvements began to occur in the twentieth century when public health measures were introduced. These measures were aimed primarily at controlling the vectors of the most lethal and most prevalent infectious diseases, most notably perhaps malaria and yellow fever (Mandle 1970; Soper 1970; Giglioli 1972), and were not especially concerned with changing either the living conditions or the socioeconomic status of the bulk of the population. Thus, up to a point, technical interventions could play the same role in reducing mortality that economic and social development played in western Europe and North America. The question remains, where is that point? In other words, at what point can technical interventions no longer take the place of socioeconomic development?

Mortality continued to decline after World War II, although to the present there has been a strong positive association between life expectancy and per capita gross national product, along with adult literacy, and an inverse relationship with the proportion of the labor force involved in agriculture. These ecological data as well as individual-level studies (Kunitz 1986) suggest that in much of Latin America, the relationships persist between agricultural production for the international market, low levels of economic development, and high mortality.

Between 1950–5 and 1980–5 there were substantial increases in life expectancy in most Latin American nations, the rate of improvement being inversely associated with the life expectancy in 1950–5, which is to say, the greater the life expectancy at the beginning of the period, the less was the proportionate increase over the following 30 years (PAHO 1986). The reason for this seems to be that populations with greater life expectancy to begin with were those in the economically more developed nations, in which a relatively large proportion of deaths were due to noninfectious diseases. Low life expectancy was associated with high death rates, particularly at young ages, for those infectious diseases most responsive to public health interventions. Thus, the diminution in the rate at which life expectancy has improved over the past two decades has been associated with a shift in the proportionate contribution to mortality of infectious and noninfectious diseases. Noninfectious diseases are accounting for an increasing share of mortality, and they have continued to be less responsive

to public health and medical measures than the infectious diseases (Arriaga 1981).

It appears that what differentiates the contemporary mortality experience of most Latin American nations is mortality rates among infants and young children rather than rates and patterns at older ages. That is to say, mortality at all ages beyond about age 5 is due primarily to violence, accidents, and noninfectious diseases such as cancers and cardiovascular diseases. It is the magnitude of the contribution of infectious diseases to deaths among children during the first 5 years of life that accounts for most of the international differences, and these rates are highest in the poorest countries. The explanation that has been offered for these observations by the United Nations (1982) is as follows:

The departure of Latin American countries from the European experience is related to a disequilibrium between improvements in socio-economic conditions and health interventions. While the latter may have a significant influence on adult mortality in the complete absence of the former, the connexions between one and the other are more subtle at the beginning of life. The longer the population is exposed to health interventions in the absence or under conditions of precarious improvements in standards of living the greater will be the disparity between child and adult mortality.

This is so, it is argued by some, because neither therapy (including oral rehydration) nor public health measures are likely to have a profound impact on infant and child mortality caused by the interaction of malnutrition, pneumonia, and diarrhea in the absence of significant economic development. Others disagree, claiming that, rather than economic development, relatively simple interventions such as equitable distribution of food, increased literacy, and a few simple primary health care measures are all that are required (Halstead, Walsh, and Warren 1985). How easily achieved even such "minor" measures are is a question that will undoubtedly engender debate.

In either case, to the degree that reductions in infant and child mortality are dependent on increased spending for health and social services, as well as on improving standards of living, the current economic crisis and international indebtedness may make such improvements difficult to achieve. The evidence for an association between international indebtedness and a diminution in the rate of improvement of life expectancy has been suggestive but not overwhelmingly persuasive, however, largely because changes in domestic policies may mitigate the

worst effects of the economic crisis, at least in the short term (Musgrove 1987).

Thus, there are two observations about contemporary mortality changes in Latin America that, though not necessarily at odds with each other, place emphasis on different elements of the process. One emphasizes that continuing improvements in life expectancy will result from continuing socioeconomic improvements, which will have their most profound impact on the health of infants and children. The other suggests that the pattern of causes of death now reflects the overwhelming significance of human-made and noninfectious conditions among adults and that behavioral change at the individual level is likely to contribute most to further significant declines in the future (Litvak et al. 1987).

North America

The indigenous peoples of North America suffered as catastrophic a population decline as did those in what became Latin America. As already suggested, the North American Indians did not live in the same sort of extensive agricultural societies as existed to the south, nor did the new settlers come from a society like those of the Iberian Peninsula. Settlement patterns therefore tended to differ, with family-owned and -operated farms predominating in most of the region except the southeast.

Endemic diseases such as dysentery and malaria, and epidemic diseases such as measles, smallpox, and yellow fever, were prevalent throughout the colonial period, but their severity seems to have differed substantially from North to South. Life expectancy was lower in Maryland than in New England in the seventeenth century, for example, and crude mortality rates were higher and epidemic diseases more severe in the South than the North throughout the eighteenth and nineteenth centuries.

In the eighteenth century, crude death rates in New England ranged from 6 to 20 per 1,000 population, depending on the location of a given community as well as its age structure (Meindl and Swedlund 1977; Dobson 1987). In French Canada during the eighteenth century, the crude mortality rate varied from 23 to 39 per 1,000, again probably depending on the changing age structure of the population (Henripen 1954).

In the early nineteenth century, crude mortality rates varied widely as well. In northern U.S. cities they tended to be in the range of 18 to 25 per 1,000, increasing as one moved south to 80 or 90 per 1,000 in such cities as Savannah and New Orleans (Dobson 1987). Though there is some disagreement, evidence now exists that mortality rates increased in the course of the first half of the nineteenth century (Meindl and Swedlund 1977; Kunitz 1984; Fogel 1986). This coincided with the first great wave of Irish immigration to the United States, and it is likely that the new settlers were poorer than their predecessors, lived in more squalid circumstances, and spread new diseases to the rest of the population while suffering disproportionately from diseases themselves. Nonetheless, in the North at least, mortality rates remained remarkably low.

Though mortality crises seem not to have been frequent in New England during the colonial period, regular epidemics of measles and smallpox did sweep the population. They seem to have diminished by the end of the period as both diseases increasingly afflicted children, a sign that the population was becoming sufficiently large to convert the diseases into endemic diseases (Kunitz 1984). In general, however, the curve of mortality from year to year retained the jagged, saw-toothed shape characteristic of the presence of epidemics (Omran 1975), although these were never of sufficient magnitude or frequency to keep populations from growing.

Mortality began to decline after the Civil War, though whether this occurred in the 1870s or 1880s is still a matter of disagreement (Kunitz 1984). Robert Higgs (1973) has estimated that the crude mortality rate declined from between 23 and 29 per 1,000 in the 1870s to 15 to 17 per 1,000 in the 1910s in urban areas; and from 21 to 23 per 1,000 to 14 to 15 per 1,000 in rural areas over the same period. These rates are roughly comparable to those observed among Catholics in Canada in the 1860s: 20.9 per 1,000 (Kalbach and McVey 1971). Among the most important of the identifiable syndromes and diseases were the pneumonia–diarrhea complex of infancy and childhood and tuberculosis. Both afflicted Amerindians, blacks, and immigrants more than native-born whites, and both declined in the late nineteenth and twentieth centuries.

Yet even at their zenith in the middle decades of the nineteenth century, mortality rates in North America were low compared with the rates in most of Latin America half a century later, with the exceptions noted previously: Uruguay and Argentina, with no indigenous Indian populations and a high proportion of European settlers, and Cuba and Panama, which both benefited and suffered from the presence of the U.S. army (Sanchez-Albornoz 1974).

The significance of the decline in mortality from midcentury onward is enhanced by the fact that these were the very years during which masses of

immigrants from poverty-stricken regions of eastern and southern Europe flocked to the United States and Canada. Although, in general, immigrants had higher mortality rates than native-born people, they tended to have lower mortality rates than were observed in their countries of origin (Kunitz 1984).

The very low mortality observed during the colonial period is explicable in terms of the dispersed nature of settlement and the fact, supported by data on heights, that the population tended to be well nourished. With the exception of blacks brought as slaves to work on plantations in the South, there was not a large servile class such as existed in much of Latin America. The increase in mortality that seems to have occurred after the colonial period has been attributed to the influx of a large and impoverished immigrant population living in unsanitary and rapidly growing cities.

What, then, explains the decline in mortality after the Civil War, when an even larger influx of immigrants every bit as poor as those who had preceded them flooded the cities? It seems likely that the sources of the change were the remarkable productivity of the industrializing U.S. economy and the reform movements that resulted in sanitary improvements in many cities, as well as in small towns and villages (Levison, Hastings and Harrison 1981).

There were, of course, differences in the mortality rates of different cities. By the end of the nineteenth century, these were attributable largely to differences in deaths of infants and young children caused by endemic conditions such as the pneumonia-diarrhea complex. Variations in death rates among cities were explainable by differences in socioeconomic measures, except among southern cities, in which the proportion of blacks living in extreme poverty was an important variable (Crimmins and Condran 1983).

In the course of the eighteenth and nineteenth centuries, then, there was a shift from epidemics afflicting people of all ages to endemic infectious diseases afflicting primarily infants and children. The change occurred earlier in the North than the South, although by the 1920s and 1930s, malaria was in decline south of the Mason–Dixon line. In the course of the twentieth century, the pneumonia–diarrhea complex continued to decline as economic conditions continued to improve, literacy increased, and public health measures were strengthened. By the 1930s tuberculosis and other infectious diseases caused fewer deaths than cardiovascular diseases and cancer. This change was unrelated to medical therapy, for until the late 1930s such therapy had no discernible effect on mortality (Omran 1977). At that time, however, first sulfonamides and then antibiotics were introduced. The result was a small but measurable impact on mortality rates. In the last seven years of the pre-chemotherapy era (1930–7) the age-adjusted mortality rate declined an average of 4.28 deaths per 100,000 population per year. From 1937 through 1954, when antibiotics became widely available, the age-adjusted rate declined on average 19.4 deaths per 100,000 population. From 1955 through 1968 the decline all but ceased, averaging 2.1 deaths per 100,000 population per year. At the time many people argued that the decline had ceased because infectious diseases had ceased to be a significant cause of death, and the noninfectious and human-made causes of death were refractory to any intervention. It will be recalled that the same explanation was given for the diminution in the mortality decline in Latin America. Beginning in the late 1960s, however, the decline resumed. From 1968 to 1978 the average annual decline was 11.8 deaths per 100,000 population, and this decline has continued to persist (McDermott 1981).

The decline in mortality since the late 1960s has been accompanied by a shift to later and later ages at death, a pattern sufficiently unusual that some observers have claimed it represents a new and previously undescribed stage of epidemiological history (Olshansky and Ault 1986). The debates generated have been about several issues. First, what has caused the decline in mortality since the late 1960s: medical care, changes in behavior, or environmental changes? There is no doubt that early, widespread, and vigorous treatment of hypertension has had a measurable impact on the prevalence of that condition. Presumably that is reflected in a decreasing number of deaths from cardiovascular disease. There have also been changes in smoking patterns, the consumption of meat, and the degree to which people exercise.

Second, is survival to older and older ages accompanied by improvements in morbidity and level of function? On one hand are those who argue that there is a finite life span of about 85 years; that more and more people are living that long in a healthy state; and that they will then die of "natural causes" without lingering illnesses. This has been called the "rectangularization" of the mortality and morbidity curves (Fries and Crapo 1981). On the other hand are those who argue that 85 does not seem to be the upper limit to the human life span; that the survival of more and more people to older and older ages will be accompanied by a disproportionate increase in disability and morbidity; and that the presence of lingering chronic

conditions will impose an enormous cost on the health care system (Schneider and Brody 1983).

Finally, what causes of death have been responsible for most of the decline in mortality at older ages? Although cardiovascular conditions are generally implicated, sorting out causes among chronically ill people with multiple health problems is often difficult.

Conclusions

Whether one is considering mortality in highly developed or less developed countries, similar questions frequently emerge: To what degree have public health and therapeutic interventions made a difference? To what degree has economic development been responsible for increasing life expectancy? And to what degree are changes in individual behavior important?

It is generally agreed that in the developed countries development itself has been responsible for most of the change. In contrast, much of the improvement in mortality in less developed countries is said to have been caused by imported public health measures, especially those that could be widely and inexpensively applied in the absence of fundamental changes in the socioeconomic characteristics of the population itself.

More evident disagreement surrounds the question of what is required to reduce mortality further in less developed countries: relatively modest technical assistance from abroad and a domestic policy of literacy and equitable food availability or major socioeconomic change. In developed countries, disagreement has to do with the degree to which individual behavioral changes, on one hand, and environmental changes, on the other, have been important, as well as what will be the future role of biomedical research and health care in addressing the health care problems of the very old. The questions are fraught with political implications and the answers are by no means obvious.

V.11
Diseases of the Islamic World

The advent of Islamic culture is well defined by the life of the founder of Islam, Muhammad (c. 570 to 632). Shortly after his death, Muslim Arabs began a series of dramatic conquests of the Middle East and North Africa, so that by A.D. 750 their hegemony stretched from Andalusia (southern Spain) to the Sind (modern Pakistan). Islam was gradually established as the predominant religion in these areas, and Arabic became the preeminent language in most of them. In the later Middle Ages, Islam spread appreciably in sub-Saharan Africa, Turkey, eastern Europe, the Indian subcontinent, and Southeast Asia; the only areas in which it retreated were the Iberian Peninsula and eastern Europe.

Most of our information about disease has been derived from literary sources, including Muslim hagiography and medical texts. The former are biased toward urban conditions, although the majority of the population lived in the countryside at a subsistence level and often at the mercy of nomadic depredations. The medical works have the serious disadvantage of being largely nonclinical and highly derivative of classical medical texts, and the anecdotes of renowned physicians are frequently apocryphal. Yet major features of a "pathological tableau" do emerge, in which illness is inextricably tied to poverty as both cause and effect. Blindness is conspicuous, particularly in Egypt; the result of a number of diseases, blindness seems to have afflicted a large percentage of the population, and the blind were traditionally employed as Koran reciters in mosques. Deafness was often congenital, and mutism was associated with nervous disorders. Paralysis, epilepsy, and mental disorders are frequently described in the medical and nonmedical texts, which include surviving magical incantations and prayers directed against demonic possession.

Among internal maladies, digestive and excretory complaints are commonly referred to; the descriptions suggest dysentery, internal parasites, typhoid-paratyphoid, and cancer. In Moghul India, cholera and dysentery were clearly the major diseases from the sixteenth century; Asiatic cholera does not appear to have afflicted the Middle East until the early nineteenth century. Schistosomiasis (bilharzia) has been present in Egypt since pharaonic times, but it attracted no special interest in the medieval period. Dropsy and elephantiasis are often mentioned in the medical texts. Along with these conditions are observations of muscular problems, fatigue, and general malaise; the last-named might be attributed to malaria, but its endemic and chronic forms were not always recognized as a specific illness and were accepted as a natural state of health.

Some of the most common complaints were dermatological disorders, which are particularly difficult to distinguish in the historical sources but appear to have aroused considerable apprehension. Skin ulceration, infections, and bleeding disorders appear to have been due to nutritional deficiencies. There is also some evidence of an endemic, nonvenereal form of syphilis in the rural population. More certain are the existence and recognition of smallpox and measles. In the tenth century, Rhazes (al-Razi), who was atypical of Muslim medical writers in giving detailed clinical descriptions of diseases, was the first to provide a complete description of the symptoms of both diseases and their treatment.

Plague (*tā'ūn*), leprosy, and syphilis are given special attention here. They seriously endangered personal and public life, and consequently illustrate

well Muslim cultural responses to life-threatening diseases. These three diseases were also generally distinguishable in the past because of their distinctive symptoms and, therefore, are amenable to historical investigation.

Plague

There have been three major plague pandemics in recorded history: the plague of Justinian in the mid-sixth century, the Black Death in the mid-fourteenth century, and the Bombay plague in the late nineteenth century. Apart from the high mortality rates and the social dislocation caused by these pandemics, each initiated a long series of plague epidemics with significant cumulative effects.

Before the Arab conquests in the seventh century, plague had recurred cyclically in the Near East following the plague of Justinian, but it apparently had little effect on the Arabian Peninsula, where environmental conditions for plague were unfavorable. In 638–9, however, a plague epidemic struck the Arab army after its conquest of Syria and it spread to Iraq; the disease killed many soldiers of the conquering army as well as the native population. During the Umayyad caliphate (661–749), plague reappeared a number of times in Syria, Iraq, Egypt, and North Africa. Inexplicably, however, the disease disappeared after 749 and did not reappear again until 913, when it struck Baghdad. There were occasional outbreaks of "pestilence" until the fourteenth century, but they cannot be clearly identified as plague because of the imprecision of the Arabic sources and the lack of any distinct epidemic pattern.

In 1347 plague dramatically reappeared in the Middle East, being carried overland from central Asia to the Crimea in 1346. From the Black Sea region, it was transported by Italian merchants to Constantinople and from there to the major Mediterranean ports. Egypt was infected by the autumn of 1347 and Syria by the following spring. In addition, the plague spread inland; the central Middle East may have been infected from southern Russia as well. There is, incidentally, no evidence for the theory that the pandemic was transmitted from India via the Persian Gulf and the Red Sea to the Middle East and Mediterranean littoral. In 1348–9 plague attacked Arabia for the first time and infected Mecca. This pandemic was the same one that struck medieval Europe and is known familiarly as the "Black Death." From all indications, the effects of the Black Death in Muslim lands were as devastating as they were in Europe.

In both regions the Black Death also established a cycle of plague recurrences, but the reappearances in the Middle East (roughly about every nine years) were far more damaging because of the nature of the epidemics and their persistence. In the Near East, recurrences until the end of the fifteenth century included pneumonic plague (the form of plague that is most infectious and almost always fatal) as well as the other two forms, bubonic and septicemic; all three forms had been present in the Black Death. The result of these plague recurrences was clearly a sustained decline in population in the late fourteenth and fifteenth centuries. This decrease in population was the essential phenomenon of the social and economic life of Egypt and Syria in the later Middle Ages.

There is little evidence for pneumonic plague in Europe after the Black Death, except in isolated Russian epidemics. The recurrent epidemics in the Near East were frequent and lasted until the end of the nineteenth century, whereas epidemics of plague disappeared from most parts of Europe in the seventeenth century. Generally, the Middle East was at the crossroads of a number of endemic foci of plague, which accounts for the numerous and seemingly chaotic occurrences of the disease since the Black Death. By land and sea, the movements of men and their cargoes promiscuously carried the disease over the entire region, giving the appearance of endemicity throughout the Middle East. The endemic foci, however, that were the generators of recurrent plague before the twentieth century in the Middle East appear to have been the following: central Asia, western Arabia (Assîr), western Asia with its center in Kurdistan, central Africa, and northwestern India.

Plague was a well-recognized disease in Muslim society after its first appearances in early Islamic history. Drawing on classical Greek medical works, physicians adequately described the disease, and although it had not been discussed by Hippocrates and Galen, they interpreted it according to humoral theory, attributing it to a pestilential miasma. Not until the Black Death, however, do we have relatively accurate medical observations of plague and historically reliable accounts in the Arabic sources, which are primarily plague treatises and chronicles.

Three of the treatises at the time of the Black Death in Andalusia were mainly medical works. Comparable medical tracts devoted to plague do not seem to have been written in the Middle East, but it was discussed in most of the standard medical compendia written both before and after the Black Death. Following the Black Death, Muslim scholars in the Middle East composed treatises of a largely

legal nature that interpreted the disease according to the pious traditions of the Prophet, instructed the reader on proper conduct during an epidemic, and gave some peripheral medical advice. In addition, these works usually ended with a chronology of plague occurrences from early Islam until the writer's own time. These treatises virtually form a genre of religiolegal literature, inspired by the constant reappearances of plague from the time of the Black Death until the end of the nineteenth century.

The treatises are obviously important for their chronicling of plague epidemics but also for the evidence they provide of an ongoing concern of a religious elite that was split on the issue of the religious tenets regarding plague, some arguing for them and some against them. The tenets in question were the following: Plague is a mercy and a source of martyrdom for the faithful Muslim and a punishment for the infidel; a Muslim should neither enter nor flee a plague-stricken region; and plague is noncontagious.

There must have been serious doubts about the soundness of these precepts. The treatises are repetitive concerning this conflict between martyrdom and health, although they often supply original observations of the symptomatology of contemporary plague epidemics. In one respect, the series of tracts show an increasing interest in pseudomedical or magical methods of plague prevention and treatment. It would be hazardous, however, to conclude that this is evidence for the decline of medical practice in the Islamic world, because the discussion of magical practices may indicate merely a greater recognition by legal scholars of common folk practices, which had always existed side by side with professional medical practices. In any event, the treatises explain to a great extent the Muslim attitudes toward plague.

The historical chronicles are relatively abundant for the Black Death and the recurrences of plague during the latter half of the Mamluk period in Egypt and Syria (1250–1517), although we have only one complete eyewitness account of the Black Death itself. These chronicles diminish sharply in quality and quantity in the last half of the fifteenth century, and we are no longer supplied with the kind of specific descriptions of epidemics that enable us to determine with a fair degree of accuracy the duration and nature of the various epidemics.

From the late fifteenth century, the Arabic sources can be supplemented by information from European observers, including merchants and pilgrims, physicians and diplomats, whose reports increase in number with an increasing Western involvement in the Muslim world. The subject of plague in that world alone inspired a large European literature, especially among physicians, who gave conflicting interpretations and advocated conflicting prophylaxes. By and large, this literature is surprisingly uninformative despite some interesting accounts, such as those of the English physicians Alexander Russell and his brother Patrick Russell on plague in Aleppo in the mid-eighteenth century.

The immediate and long-term consequences of plague epidemics are difficult to judge, but in the cities of Egypt and Syria at the time of the Black Death and later plague recurrences, no serious breakdown of urban life was noted, although there were certainly disruptions in food supplies. The organization of large processions, funerals, and burials would suggest the maintenance, if not a heightening, of public order. There is evidence that, despite religious proscription, people did flee from infected regions – both to and from the cities – which doubtless aggravated the situation, because they would often have carried the disease to unaffected areas while exposing themselves to other illnesses and to starvation.

In the Egyptian countryside, by contrast, considerable evidence exists of depopulation through either death or flight from the land, and thus the most disruptive, long-term effect of plague epidemics appears to have been the changes that were wrought in rural areas. Reduced cultivation led to a decrease in the amount of food available for the cities, which depended on surplus rural production, as well as in tax revenues. The first consequence was less important than the second because (based on evidence suggesting that there was no long-term price inflation for agricultural products in Egypt in the aftermath of the Black Death) reduced agricultural production was apparently feeding a diminishing population. The government's attempts to maintain tax revenues, however, were disastrous because a larger share of taxes was imposed on a smaller rural population, which in turn encouraged peasant indebtedness and flight to the cities. Symptomatic of the social and economic plight caused by plague epidemics in Egypt was the virtual disappearance of Christian monasticism, which had begun in Egypt and thrived there for more than a millennium.

Leprosy

Unlike plague, leprosy (Hansen's disease) was often a disfiguring, lifelong disease, and it posed very different social problems. Leprosy appears to have existed in the Middle East from the early Christian Era. The earliest proof of the presence of leprosy in

the Middle East has been found in the bone lesions of two skeletons from Aswân (Egypt) that date from about A.D. 500. Therefore, there can be little doubt that genuine leprosy was present from the early Islamic period and that physicians had sufficient opportunity to observe it. Practically every Arabic medical writer discussed leprosy to some degree. The pathology and therapeutics of the disease in these accounts are largely consistent with earlier Greek medical texts. The Arabic medical works said that leprosy was both contagious and hereditary; yet it was not viewed as fiercely contagious, and those sources lack any element of moral censorship of the diseased. Moreover, the medical texts did not recommend flight from lepers or their isolation from the community.

The Arabic terminology for leprosy was created on the basis of its symptomatology. Yet aside from the distinctive signs of advanced lepromatous leprosy, these terms were not restricted to leprosy and were applied to other skin disorders as well. No clinical case descriptions of leprosy have survived in the medieval Arabic medical literature that might clarify the terminology. (The best clinical description in the medieval Near East is, curiously, the early-thirteenth-century description by William, bishop of Tyre, of the condition of Baldwin IV, king of the Latin Kingdom of Jerusalem. This description contains incontrovertible evidence of the anesthetic symptoms of leprosy.) The difficulty is certainly due to the numerous forms that leprosy can take, particularly in its early stages, and its mimicry of other skin diseases.

The Arabs in pre-Islamic Arabia were afflicted by leprosy, along with a large number of other communicable diseases. Leprosy is mentioned by the famous Arabic poets of the period. The Koran mentions in two places the healing of lepers by Jesus. More important for Muslims were the pious traditions of the Prophet concerning the disease, which were in contradiction to the medical texts. For example, the best known of these traditions is the statement that a Muslim should flee from the leper as he would flee from the lion. Similarly, another familiar tradition asserts that a healthy person should not associate with lepers for a prolonged period and should keep a spear's distance from them. The two traditions are prescriptions for social behavior and appear to deal with both moral and medical difficulties posed by the leper. The traditions may have strengthened the desire of those who wished to avoid individuals who were conspicuously afflicted by the disease because it was morally as well as physically offensive.

Atypically, leprosy was believed by some to be a punishment by God for immorality and thus was sometimes invoked as a curse for immoral behavior. But there were also traditions of the Prophet that recommended supplication to God for relief from leprosy, for the matter should not be left entirely to fate. Medically, both traditions seem to express an implicit belief in contagion, which is incompatible with the predominant Muslim view of noncontagion. The pious legend of the Prophet advising flight from the leper is, in fact, preceded by a complete denial of contagion in the canonical collection of such traditions by al-Bukhari, which was made in the ninth century. Certainly those who argued in favor of noncontagion would have been able to make a good case, because leprosy is only moderately contagious and some people are not susceptible to it at all.

The legal status of the leper was directly related to the pious traditions. Leprosy is not discussed in the Arabic legal texts as a separate subject, but it is treated as a disability within such broad areas as marriage, divorce, inheritance, guardianship, and interdiction of one's legal capacity. Because leprosy was considered a moral illness, the leper was limited in his legal rights and obligations – along with minors, the bankrupt, the insane, and slaves. In fact, the leper's status seems to have been particularly close to that of the insane in legal matters, especially with regard to marriage and divorce: A marriage could be dissolved by either person because of the disease. In Maliki law, a man in an advanced state of leprosy was to be prevented from cohabiting with his slave wives and even more so with his free wives. In addition, whereas Maliki law allowed an automatic guarantee of three days against any "faults" in a slave, that guarantee was extended to one year in the case of leprosy. Moreover, the development of the disease could be cause for his or her manumission.

The differing religiolegal traditions served as the bases for various interpretations of leprosy, and underlie a wide spectrum of behavior by and toward the leper, from total freedom of action to segregation in leprosaria. The range of popular responses to the leper is reflected in the early Arabic literature that deals with the disease and other skin irregularities. The famous Arab prose writer al-Jahiz, in the ninth century, collected poetry and narrative accounts on this subject. One of his works is devoted to physical infirmities and personal idiosyncrasies. His objective was to show that they did not hinder an individual from being a fully active member of the Muslim community or bar him from important offices. Al-Jahiz

maintained that such ailments were not social stigmas but were what could be called signs of divine blessing or favor. The afflicted were spiritually compensated by God, and special merit was to be attached to their lives. He also cited numerous references to leprosy in early Arabic poetry and mentioned those poets who were themselves leprous.

Nonetheless, there are indications of discrimination against lepers. According to a late-medieval Egyptian handbook for urban market inspectors, they were not supposed to allow people suffering from leprosy to visit the baths. Lepers were also excluded from employment in endowment works. Such discrimination shows that the theological proscription of contagion might have had very little practical effect.

Leprosy certainly existed throughout the Islamic world in the medieval period, but there is no way of determining its extent. Individual cases of leprosy are occasionally mentioned in the historical literature. The most important political figure in early Islam who was afflicted by leprosy was Abd al-Aziz ibn Marwan, an early governor of Egypt who died in 704. It is reported that he suffered from "lion sickness," that is, leprosy. He was given many medications for the ailment, but they were ineffective. Therefore, his physicians advised him to move to Hulwân because of its sulfurous springs, and he built his residence there. Hot springs were a popular treatment for skin disorders in the medieval period and especially for leprosy. It is known, for example, that the Jews commonly sought healing for leprosy in the hot springs and salubrious air of Tiberias.

Shortly after the time of Abd al-Aziz, the caliph al-Walid I conferred a number of benefits on the people of Damascus, the capital, in 707. The chronicles say that "he awarded the lepers and said: 'Do not beg from the people.' And he awarded every invalid a servant and every blind man a leader." As he did with the invalids and the blind, the caliph apparently made provisions for the lepers. The passage seems to imply that he had the lepers separated from the rest of the population. Al-Walid's unusual act is traditionally considered by Arab historians to be the institution of the first hospital in Islam. One may well imagine that the caliph created a hospice for the afflicted in the city, comparable to Byzantine practice. The later well-known hospitals of the Abbasid period appear to have treated lepers and those with other chronic ailments in special quarters.

Still, lepers commonly begged in the streets of the medieval cities, despite the pious endowments on their behalf and laws against mendicancy. Though many must have been genuinely leprous, it was not unusual for men and women to feign the disease by intentional disfigurement in order to receive public charity. Deception of the opposite kind was also common in the slave market, where (despite guarantees) a buyer had to be on his guard against the concealment of leprous sores on the bodies of slaves. Moreover, during the late Middle Ages, the reappearances of plague must have destroyed a large number of lepers because debility increased their vulnerability to other infections.

In the Islamic West, leprosaria were established and special quarters were designated for lepers. The quarters seem generally to have been located outside the walls of many Muslim cities, often in conjunction with leper cemeteries. In Anatolia the Ottomans built leper houses as well as hospitals. A leper asylum was built at Edirne in the time of Murad II, the first half of the fifteenth century, and functioned for almost two centuries. In 1514 the sultan Selim I established a leprosarium near Istanbul and in 1530 Sulayman II built one in Scutari, and both survived until modern times. Lepers and leprosaria were increasingly noticed by Western travelers, and their accounts add to our knowledge about the plight of the diseased. There is, however, no reliable observation of true leprosy by these travelers in the Middle East during the medieval and early modern periods, except for the report of leprosy in Egypt by Prosper Alpin in the late sixteenth century. The disease seems to have been as common in the countryside as in the cities, and leprosy, syphilis, and elephantiasis are all reported to have occurred frequently in Egyptian villages in the nineteenth century.

Syphilis

Syphilis presents us with a new disease, or what was believed to be a new disease when it first appeared in Muslim societies, beginning in the late fifteenth century. Syphilis and other European diseases were introduced into the Middle East in the early modern period by Europeans, who also brought their own methods of treatment. Western medicine was disseminated by missionaries and merchants, travelers, and consular doctors. Before the era of translating Western medical textbooks into oriental languages, the extent of the transmission of Western medicine can be gauged, in some degree, by the recommendation by native physicians of Western treatments for the new Western diseases.

In the early sixteenth century, whooping cough and syphilis were reported, for example, by the Persian Baha ad-Dawla. In one of his works he de-

scribes, in considerable detail, "the Armenian sore" that had spread from Europe to Constantinople and Arabia. Reportedly, syphilis had appeared in 1498 in Azerbaijan, and then in Iraq and Persia. Because of some symptomatic similarities with smallpox, it was known as "European pox" or "little fire." It was also confused with anthrax or ignis persicus. Baha ad-Dawla observed the rash, sore throat, and neural involvement of the disease. He recommended purges, venesection, and appropriate foods and drugs, and he referred to European physicians, whom he did not mention by name. He recommended a salve known as the "European pox medicine," which he believed could restore health if properly employed. Baha ad-Dawla did not say what the salve contained, but he mentioned a few lines later that mercury could be given in an electuary. Another of his recipes and one of the European physicians also contained mercury.

According to Leo Africanus, who wrote in the first half of the sixteenth century, syphilis was brought to North Africa by Jews driven out of Spain, and it spread rapidly among the Berber population. In Fez "the first to be contaminated were regarded as lepers, driven from their homes, and obliged to live with the lepers." The first mention of the appearance of syphilis in Egypt was made by Ibn Iyas in his contemporary chronicle of Egypt for the year 1497–8. Among the unhappy events of that year, an evil known as "the French pox had appeared among the people . . . the doctors were powerless in the face of this disease that had never appeared in Egypt before the beginning of this century; countless people died of it."

Naturally, the indigenous physicians took cognizance of the new disease, and it is discussed in the medical textbook of Dawud ibn Umar al-Antaki, who wrote in the later sixteenth century and was perhaps the last great Arabic medical author in the Greek tradition. His textbook displays an intriguing mixture of hallowed Greco-Arabic medicine and the first indications of exposure to European learning, even in matters as small as the Western names for the months of the year.

More important, al-Antaki gives the earliest medical description of syphilis in Egypt in his chapter on carbuncles. He says that syphilis was popularly called "the blessed" in Egypt as a way of avoiding a mental association with the disease and contamination. As for treatment:

If one mixes mercury with frankincense, resin, wax, and oil and uses it as an ointment and if the patient is covered

warmly for a week and eats proper and unsalted food, he recovers after suffering gangrene of the mouth, salivation, and tumefaction of the throat. If he becomes cold, he will feel pain in the joints. The ointment should be used three times a week. It is a well-known treatment in the hospital of Cairo. Sometimes one begins by applying the ointment to the extremities and the neck and only after a purge.

Interestingly, al-Antaki provides the entire mercury treatment for syphilis in his textbook as it was practiced in Europe until the eighteenth century.

The broader context in which al-Antaki worked is presented by Prosper Alpin in his description of medical practices in sixteenth-century Egypt. His account, first published in 1591, is surely one of the earliest studies of non-European medicine, and Alpin himself well represents the means whereby Western medicine most effectively reached Egypt. He was an Italian physician-botanist; in 1580 he became physician to the Venetian consul in Cairo, where he spent three and a half years. Alpin did not confine himself to the closed European community in Cairo. He sought the widest possible contacts with Egyptians of all classes and religions. He treated their illnesses in collaboration with Egyptian doctors, and profited from the experience of these native physicians. Alpin watched them operate, observed their instruments, and talked at length with them since they shared the same Galenic tradition; he often criticized their knowledge of Galen but admired their empirical knowledge, which he believed went back to ancient Egyptian practice. He remarked particularly on the indigence and malnutrition of the poor and their medications. The habits of the ordinary people and the women's remedies drew his attention, so that he returned to Italy with a large number of recipes for dishes, medicaments, clysters, and refreshments, including coffee. Alpin also observed the widespread and dangerous use of bloodletting as a panacea for all ills, as well as the common resort to baths for their therapeutic effects and the employment of numerous drugs and medications. These methods had been adopted, according to Alpin, for the new Western diseases, especially syphilis.

In the long term, the appearance of these new diseases, in addition to periodic reappearances of plague, and the measures taken against these diseases by all the foreign European communities helped to diminish traditional Muslim opposition to the notion of contagion. Thus, in the seventeenth century, Evliya Chelebi, a renowned Turkish traveler, described the contagion of syphilis in Cairo quite matter-of-factly. The seventeenth century also witnessed clear evidence of the new age of European

medicine, when Ibn Sallum, physician to the midcentury Ottoman sultan Mehmet IV, wrote his medical textbook. In this work Ibn Sallum not only described the new illnesses – for example, chlorosis, syphilis, scurvy, and Polish plait (plica polonica) – but an altogether new system of medicine, namely the "chemical medicine of Paracelsus." Although the Paracelsian system was erroneous and Ibn Sallum's influence may have been slight, the work clearly marks the advent of European medicine in the Middle East. With the introduction of Western-style medical schools in Cairo and Istanbul in the second quarter of the nineteenth century, the ascendancy of Western medicine was assured. All of this, however, was to the detriment of many traditional values and native forms of healing.

PART VI

The History of Human Disease in Asia

VI.1
Diseases of Antiquity
in China

Only because of a great movement in China that has been going on for about 70 years have we been able to review the records of diseases in ancient China and publish them in a Western language. This movement has been closely allied with a revaluation of the practice of traditional Chinese medicine by those who have taken a special training in it. Many valuable works have been written in Chinese on the history of Chinese medical art and science. So far, however, all this material has remained practically unassimilated by sinologists and other Western students of Chinese culture. Thus, for example, most of the dictionary definitions in common use are quite out of date. Among the works that we have used in preparing the present contribution is the brilliant monograph of Yü Yün-hsiu on ancient nosology, or what might be called *pathognostics* – the recognition and classification of individual disease entities. Western historians of medicine should be aware that the treatise of Wu Lien-te and Wang Chi-min (K. C. Wong and Wu Lien-teh 1932) on Chinese medicine (nearly always the only one they know) may be described as the very small exposed piece of an iceberg, 90 percent of which is "below the surface" (i.e., in the Chinese language and therefore inaccessible to most historians of medicine). Since about the mid-1950s, the study of Chinese medicine has been revitalized; a great number of rare medical books from ancient and medieval times have been republished in photographic form, and some ancient texts have been reproduced in the modern colloquial (*pai-hua*) style, "translated" as it were from the ancient (*ku-wen*) style, either abridged or complete. For this reason, we feel no need to apologize for departing from former translations and identifications. Limitations of space in the present work will prevent us from providing extensive documentation for our statements, but the reader can consult our more expansive work, *Science and Civilisation in China*, Volume 6 (Needham et al. 1954).

Overview
There are three sources of information concerning diseases prevalent among the people of ancient China during the 1½ millennia before the beginning of the present era: These include (1) the oracle-bone

writings of the second half of the second millennium B.C.; (2) epigraphical (especially sphragistic) evidence in the form of seals and other objects found in tombs during the first millennium B.C.; and (3) texts of the various classical writings ranging from the *Shu Ching* and the *Shih Ching* not long after 1000 B.C.; to the first of the great dynastic histories, the *Shih Chi,* completed in 90 B.C.; to the great medical classic, the *Nei Ching,* which took its present form probably about the first century B.C. This material provides, all told, a quite astonishing wealth of technical terminology. Although its analysis is not yet complete, it still provides a firm basis for our conclusions as to the diseases known during this period. The imprecise definitions of some of the terms present perhaps the greatest difficulty, but in fact they are much clearer than one might anticipate before undertaking such an investigation. Moreover, the great continuity of Chinese civilization should not be ignored. Almost unique among the cultures, China possesses continuous traditions of interpretation in this field, directly linking the "sorcerer-physicians" of the second millennium B.C. with the profoundly learned and enlightened medical exponents of the Ming dynasty (sixteenth century A.D.).

It would be possible to organize our material in several ways: purely chronologically, listing texts and their content; or purely nosologically, listing diseases and the terminology relating to them. Both of these approaches would, however, produce extremely dull reading, and therefore we shall adopt a combination of approaches. Moreover, we can provide only a limited number of examples. We propose to bring the story down to the end of the first century B.C., but in so doing we intend to utilize the *Nei Ching* only in part; we cannot mention all the diseases that are described in that fundamental medical classic. It will be convenient also to consider diseases in the light of the macrocosm–microcosm theories current in early Chinese medicine. The physicians of the Chou period, which lasted most of the first millennium B.C., were extremely conscious of the relation of diseases to geography, to the prevailing climate, and to the seasonal changes of the year. They therefore very markedly shared the Hippocratic conception of "airs, waters and places."

Oracle-Bone and Bronze Inscriptions
The oldest form of Chinese writing is that found on the scapulae and tortoise-shells used for divination in the Shang Kingdom (fifteenth to eleventh centuries B.C.). From this was derived the scripts found on bronze vessels recovered from tombs of the Chou

g h

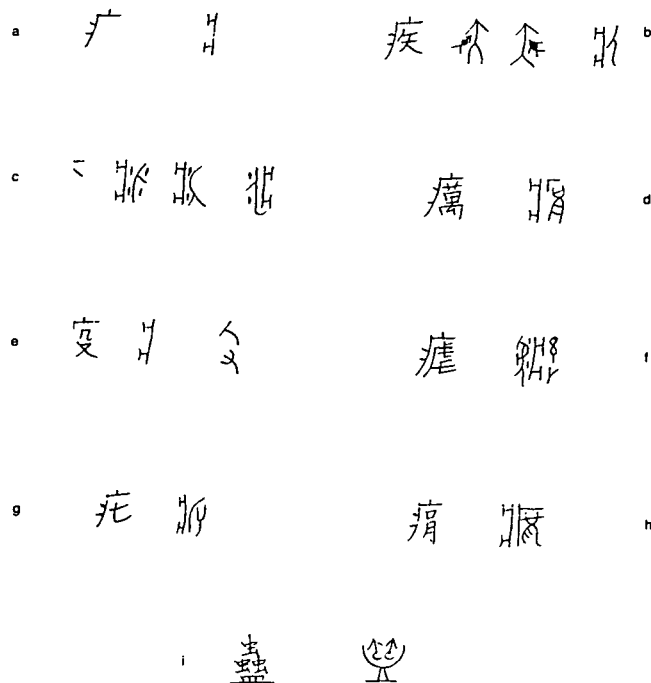
i


Figure VI.1.1. Oracle-bone and bronze terms specifying disease entities: (a) *ni* – sickness (radical); a bed. (b) *chi* – epidemic disease; a man with arrows of disease attacking him, or lying on a bed. (c) *chieh* – "itching scabies-like epidemic"; a man with spots of rash lying on a bed. (d) *li*[1] – epidemic fever; man, bed, and scorpion. (e) *i* – epidemic fever; bed, and hand holding stick; the patient belabored by the disease. (f) *nio* – fever (later more specifically malarial); man, bed, and spots, with other pictographic components of unknown significance. (g) *pi* – thin scabs or lesions on the head; bed, and unknown pictographic components. (h) *yuan* – arthritic pains; bed, and other pictographic components of unclear significance. (i) *ku* – poison or disease; insects or worms within a vessel. (From Yü 1953.)

period (first eight centuries of the first millennium B.C.). Chinese writing was stylized into approximately its modern form after the first unification of the empire under the Chhin dynasty in the third century B.C.

The radical *ni*, under which the great majority of diseases were later classified, is revealed by the oracle bones to have been the pictogram of a bed (Figure VI.1.1a). Of the 20 or more medical terms that are found on bronze inscriptions, some four of these are clearly recognizable already on the oracle bones. For example, *chi*, which subsequently invariably meant "epidemic disease in general," shows a man alone or lying on a bed with the arrow of the disease shooting into him (Figure VI.1.1b). The word *chieh*, in great use afterward to designate an "itching scabieslike epidemic" (i.e., infectious fever preceded by rash),

shows again a man lying on a bed, but the spots are actually indicated (Figure VI.1.1c). *Li*[1] also means an epidemic fever, and in this case the oracle-bone form seems to show a scorpion (for that is the meaning of the phonetic in this case) occupying the bed alone, with little remaining of the patient; or, perhaps the maggotlike object is the patient, and the scorpion is represented by the little numeral "1" (Figure VI.1.1d). Another term for epidemic disease, *i*, combines the disease radical with a phonetic that is a pictogram of a hand holding a stick (Figure VI.1.1e). This, however, has been found only on bronzes. The last of these oracle-bone terms is the word *nio*, which combines the disease radical with pictograms for tiger and hand; the drawing in Figure VI.1.1f is complex, and the significance of it is not clear. In later ages, this word came to be confined to fevers of malarial type, but in ancient times it was used to indicate all kinds of fevers.

Among the bronze forms we find the word *pi* (Figure VI.1.1g), which means "thin scabs" or "lesions on the head," suggesting eczema and lichen or alopecia or psoriasis, for which there were other words used later on. On the bronze we also find *yuan* (Figure VI.1.1h), which signified arthritic pains in the joints.

The medical content of the oracle bones is, of course, far from exhausted by mere consideration of the few technical terms that had been developed at that early time. Many inscriptions show that illnesses were defined without relying on technical terms. From these we know that there were diseases of the special sense-organs such as eyes and ears; dental problems; speech defects; abdominal diseases; dysuria; diseases of the extremities, including beriberilike syndromes; and pregnancy abnormalities and diseases of women and children. We also know of epidemic diseases coming at a particular time of year and causing death. All these they mention without recourse to a technical phraseology. There is one other oracle-bone term of great interest, however, and that is the poison or disease *ku* (Figure VI.1.1i): This pictogram indicates insects or worms within a vessel. Although we know that in later ages *ku* did indicate particular poisons prepared artificially by humans, there is also reason to think that it referred to a particular disease. This has been identified by Fan Hsing-chun and others as schistosomiasis, partly because the term *ku* occurs so often in combination with the term *chang* (*ku*[1] *chang*, *ku*[2] *chang*) and hence indicates without any doubt edematous conditions of various kinds – in particular, ascites. And the *Nei Ching* describes similar

syndromes; certainly in schistosomiasis the liver and spleen become enlarged, and ascites occurs when the disease is chronic.

Seals of Excavated Tombs

Another valuable source of information about the diseases of the late Chou period (the Warring States period, i.e., the fifth to third centuries B.C.) is the seals that have been discovered in excavated tombs. These are important also because they demonstrate an early development of specialization in medical practice. Thus, for example, we have the seal of physician Wang, who specialized in speech defects (*yin*); physician Chang, who claimed to be able to cure external lesions (*yang*); physician Kao, who specialized in the care of ulcers (*yung*); physician Kuo, who dealt with edematous conditions (*tso*), very likely beriberi; physician Thu, who specialized in removing nasal polypi (*hsi*); and physician Chao, who was expert in psychological diseases (*yü*[1]). These are only a few examples taken from those that Chhen Chih has collected. From the Warring States period also there are a large number of records written with ink on strips of wood or bamboo, but these have not so far yielded much of medical interest. Medical material on this medium indeed exists, but it derives largely from the army records of the later Han dynasty (first and second centuries A.D.), which is later than the period we are discussing here.

Classical Writings

Diseases and the Seasons

Yüeh Ling. The *Yüeh Ling* (Monthly Ordinances) is admittedly an ancient text, but opinions differ as to its date; some would put it as late as the third century B.C., when it was incorporated in the *Lü Shih Chhun Chhiu,* or also later in the *Li Chi;* but internal astronomical evidence tends to place it earlier (seventh to fifth centuries B.C.). In the course of its description of the activities proper to the different seasons, information is given about what is likely to occur if the weather is entirely unseasonable. Thus if autumn or summer weather comes in the spring, or autumn weather in the summer, or spring weather in the winter, there will be great epidemics (*ta i, ping i, chi i, yang yü i*). In one of these cases the word *li*[1] is used; here it is taken as standing for another word, *li*[2], and not for *lai,* which it often could do later on, for *lai* specifically refers to leprosy. As we shall see later in this chapter, the first indication of leprosy occurred just about the sixth century B.C. Now *chieh* refers to one of the evils of spring weather

coming in winter; although from early times this meant scabies, it must be translated here as an "itching, scabieslike epidemic." Under any winter conditions, exanthematic typhus is perhaps to be suspected, but the descriptions of *chieh* also sometimes include convulsions, with arched back, and speechless "lockjaw," so that the word sometimes may have been used for tetanus. We shall suggest immediately below a more satisfactory meaning for it.

The *Yüeh Ling* text has other interesting features: It says, for example, that if cool spring weather comes in what would normally be a very hot summer, there will be much *feng kho* (i.e., tonsillitis, bronchitis, pneumonia, etc.). It also says that if hot summer weather comes in autumn, there will be many cases of fever (*nio chi*). This is the word later appropriated to malarial fevers, but in the ancient times of which we are now speaking, it was simply associated with rapid alterations of shivering cold and hot fever. The text also says that if the hot rainy season continues into the autumn, there will be many cases of *chhou chih* (i.e., diseases involving sneezing, such as colds and catarrhs with some fever). The last part of the text says that if spring weather occurs in the last month of winter, there will be many problems of pregnancy, especially miscarriages and stillbirths (*thai yao to shang*). A possible explanation for this association might be shocks to the body caused by going out without sufficient clothing.

Another feature of this particular kind of unseasonableness was described as a high incidence of *kü*[3] *ping. Kü*[3] *ping* – literally, "obstinate diseases" or "enfeebling diseases" (*fei*) – might be described as those in which the patient is enfeebled and cannot easily help him- or herself; such "handicapped" people were not considered fit to participate in social affairs. The *Kuliang chuan,* one of the three great commentaries on the *Chhun Chhiu* (Spring and Autumn Annals) of the State of Lu (722–481 B.C.), defines four forms of handicap that prevented social competency: (1) *thu,* a skin disease of the scalp; (2) *miao,* an eye defect, possibly ankyloblepharon or Horner's syndrome but more probably trachoma; (3) *po,* lameness, often congenital; and (4) *lu,* meaning "hunchback" or "a person with arthritic limbs," the descriptions also covering rickets in advanced form, and osteomalacia. We shall mention this again.

Texts of the centuries just subsequent to the *Yüeh Ling* (if we may regard it as of the late seventh century B.C.) began to differentiate clearly between tertian and quartan malaria, the former being generally

termed *hsien* or *tien* and the latter *kai* or *chiai*. There is considerable reason, however, for believing that at some of these periods *chiai nio* was a joint expression used for a disease of slow development ending in hemoptysis, which we can identify as tuberculosis.

Chou Li. Another interesting description of the seasonal incidence of disease occurs in the *Chou Li* (Record of Institutions of the Chou Dynasty). Although much of the material in this book may well date from the Chou period, its compilation must undoubtedly be considered a work of the early Han (second century B.C.). It gives a detailed account of what the people of that time considered the ideal democratic organization of the state. Here in Chapter 2 we read as follows:

Each of the four seasons has its characteristic epidemics (*li¹ chi*). In spring there comes feverish aches and headaches (*hsiao shou chi*); in summer there are "itching scabies-like epidemics" (*yang chieh chi*); in autumn there are malarial and other fevers (*nio han chi*); in winter there are respiratory diseases (*sou shang chhi chi*).

How is one to interpret these technical terms? No doubt the feverish aches and headaches of the spring refer to influenza, catarrhs, and so forth, but the "itching, scabieslike epidemics" of the summer were certainly far more serious. In the light of the passage that we have just studied in the *Yüeh Ling*, it would seem that cerebrospinal fever (meningococcal meningitis, spotted fever) may have been one of the important components of these epidemics, for the course of the disease links together severe rash, fever, and convulsions. Here epidemic encephalitis is less likely, though it certainly occurred widely in North China down to our own times, and one must also leave a place for scarlet fever and other less important infectious diseases. In the autumn, apart from malaria, one would naturally also think of dysentery of both kinds and gastroenteritis (enteric fever caused by *Salmonella*, etc.) as constituting the meaning of the words *nio han chi* (i.e., epidemics caused by a cold, internal or external). The winter picture almost certainly involved pneumonia, acute and chronic bronchitis, and similar pulmonary afflictions. This is obviously indicated by the words used, which suggest the rising of the *pneuma* into the region of the lungs, with coughing and difficulty in breathing. Among the epidemics of summer and autumn, one would obviously also want to leave a place for typhoid-type diseases and perhaps staphylococcal bacteremia, though tuberculosis would hardly have been classified as an epidemic. The word that later would be universally used to denote diarrhea and dysentery, *li³*, does not seem to occur much in texts of this date earlier than the *Nei Ching* itself.

Diseases and "Airs, Waters, and Places"

In the *Lü Shih Chhun Chhiu*, Chapter 12, we read as follows:

In places where there is too much "light" (*chhing*, clear) water, disease of the scalp (*thu*; alopecia, ringworm, psoriasis, etc.) and goitre (*ying*) are commonly found. In places where there is too much "heavy" (*chung*, turbid) water, people suffering from swellings and oedematous ulcers of the lower leg (*thung¹*) are commonly found and there are many seriously affected who are unable to walk at all (*pi*). Where sweet (*kan*) water abounds, men and women will be health[y] and handsome. Where acrid (*hsin*) water abounds there will be many skin lesions, such as abscesses (*chü*) and smaller boils (*tso*); where bitter (*khu*) water abounds there will be many people with bent bones (*wang yü*).

These technical terms are of much interest. The scalp diseases (*thu*) we have already encountered, but this is the first time that we have seen goiter, for which the term *ying* is characteristic and indubitable. In the next sentence the term *thung¹* (more correctly written in medical usage *thung²*) associated with *pi*, which means lame in both feet, and bedridden, strongly suggests beriberi, indeed the wet form. This term occurs again in a much older text, in one of the poems in the *Shih Ching* (approximately eighth century B.C.) where it is associated with another word, *wei*, both meaning ulceration of the lower leg. The commentators of the Book of Odes describe it as a disease of swampy places, where, no doubt, the vitamin in the stored grain was destroyed by moulds. The word *wang* resembles that for edema in general (*chung*), which is to be distinguished from the terms for ulcers: *yung* if edematous and unbroken; and *chü* if open, much worse and generally fatal. The probable identification of beriberi in the *Shih Ching* as well as in the *Lü Shih Chhun Chhiu* is accepted by Hu Hou-hsüan and Chhen Pang-hsien, who indeed find evidence of it as far back as the oracle bones themselves, but there only with reference to disease of the feet. It is pleasant to hear of one place at least where people were healthy and handsome, but immediately afterwards we learn of places where *chü* were plentiful; *chü* means carbuncles, furuncles, and perhaps also cancer, whereas *tso* refers to smaller skin lesions such as acne. Rickets and osteomalacia are certainly to be recognized in the last sentence. The bronze script form of *wang* is a pictogram of a person with a

crooked back, and many famous people of antiquity are said to have been deformed in this way, even the great Duke of Chou himself. *Yü²* undoubtedly means hunchback; it occurs in the expression *yÿu² lu,* which we find in Chapter 7 of the *Huai Nan Tzu* book (approximately 120 B.C.). There Tzu-Chhiu at 54 years of age "had an illness which left his body deformed. He was so bent that his coccyx was higher than his head and his sternum was so lowered that his chin was bent below the level of his spleen." There can be no doubt that rickets and osteomalacia were widespread in ancient China. There are a number of other valuable texts of the "airs, waters, and places" type, such as those found in the *Huai Nan Tzu* book (Chapter 4) and in the *Nei Ching, Su Wen* itself (Chapter 12).

Shih Ching

Nosological data in the *Shih Ching* (Book of Odes, about eighth century B.C.) have been analyzed in detail by Yü Yün-hsiu, but there is a special difficulty here because these ancient folksongs naturally took advantage of poetic license and it is sometimes difficult to determine whether the disease terms are being used in their proper medical sense; some of them may have been used to indicate malaise or depression in general. Nevertheless, *shou chi* (feverish headaches), *shu* (enlarged neck glands, perhaps goiter, tuberculosis, or Hodgkin's disease) and *meng, sou* (various forms of blindness) are all of interest. Nosological data derived from the *Tso Chuan,* the greatest of the three commentaries on the *Chhun Chhiu* already mentioned, are more reliable and also much more abundant. More than 55 consultations or descriptions of diseases occur in these celebrated annals. Perhaps the most important is the consultation dated 540 B.C. which the Prince of Chin had with an eminent physician, Ho, who had been sent to him by the Prince of Chhin. Physician Ho, as part of his bedside discourse, included a short lecture on the fundamental principles of medicine that enables us now to gain great insight into the earliest beginnings of the science in China. Especially important is his division of all disease into six classes derived from excess of one or other of six fundamental, almost meteorological, *pneumata (chhi).* Excess of Yin, he says, causes *han chi;* excess of Yang, *je chi;* excess of wind, *mo chi;* excess of rain, *fu chi;* excess of twilight influence, *huo chi;* and excess of the brightness of day, *hsin chi.* The first four of these are subsumed in the *Nei Ching* classification under *je ping,* diseases involving fever; the fifth implies psychological disease;

and the sixth, cardiac disease. The classification into six divisions is of extreme importance, because it shows how ancient Chinese medical science was independent of the theories of the Naturalists, who classified all natural phenomena into five groups associated with the Five Elements. Chinese medicine never entirely lost its 6-fold classification; but that is a long story, which cannot be told here. Physician Ho diagnosed the illness of the Prince of Chin as *ku¹,* by which he did not mean the artificial poison nor, so far as we can see, schistosomiasis, but rather some kind of physical exhaustion and melancholia arising from excessive commerce with the women of his inner compartments.

Tso Chuan

There is something of interest in every one of the medical passages of the *Tso Chuan.* For example, in 638 B.C. a deformed (*wang*) sorceress, doubtless suffering from rickets or osteomalacia, was to be burnt as a remedy for drought, but a skeptical statesman, Tsang Wen-chung, intervened and said that other means would be much more efficient, so this method was not used. Two years later, we hear of Chhung Erh, the son of Prince Hsien of Chin State, who suffered from *phien hsieh* (i.e., his ribs were so distorted and deformed as almost to meet in front of the sternum). Moved by scientific curiosity perhaps, the Prince of Tshao succeeded in getting a view of him while in the bathhouse. In an episode of 584 B.C., a certain country was described as dangerous for giving people a disease named *o,* although in this particular case the disease endemic there seems to have been beriberi, because there is talk of edematous leg swellings and waterlogged feet (*chui*). We encounter the same term again (*o ping*) in the *Lun Yü,* the discourses of Confucius, dating from about a century later. One of his disciples, Po Niu, suffered from *o ping,* and the universal interpretation of all the commentators since that time has been that this disease was leprosy. We do not find the term *lai* at such an early date, but there seems no reason to reject so old and continuous a tradition that this was the first mention of leprosy in Chinese literature.

Another case relating to the date 569 B.C. was death by heart disease (*hsin chi, hsin ping*); it happened to a general, Tzu-Chung (Kung tzu Ying-chhi of Chhu), who was greatly distressed after a military failure, and we may regard it as angina pectoris brought on by anxiety. Soon afterward, the term *shan* came into use to denote this disease, the symptoms and psychosomatic nature of which are so characteristic. We find this word in the *Nei Ching,* used

instead of the term just mentioned for the parallel *hsin thung* of the *Shan Hai Ching,* an ancient geographical text that belongs to the middle of the Chou period. In 565 B.C., the *Tso Chuan* notes another case of *fei chi,* some kind of chronic disability that prevented the normal life of a minister's son. Hydrophobia is also fairly clearly indicated in an entry connected with 555 B.C., where a mad dog (*chi kou* or *hsia kou*) entered into the house of Hua Chhen, a minister of Sung State. The word *khuang* was used indiscriminately for the mad dog itself and for the disease that it caused. Toward the end of the *Tso Chuan* we have a story dated 497 B.C., in the latter part of the life of Confucius, which includes the famous remark that "only he who has thrice broken his arm can make a good leech."

Shan Hai Ching

We have already mentioned the *Shan Hai Ching.* This is a strange book, full of legendary material, which reached its present form probably about the second century B.C., but which contains much far older material. Many legendary and mythological elements pervade its descriptions of the mountains and forests of the Chinese culture area, the spirits proper to be worshiped by travelers in any particular region, and also the peculiar plants and animals and their virtues. More than 30 herbs, beasts, and stones are recommended to ward off various diseases, and this is where the nosological interest comes in. Many terms we have already met with, such as epidemic fevers (*i, li*[1]), epidemics with rash (*chieh*), edematous swellings (*chung*), goiter (*ying*), rodent ulcers (*chü*), and eye defects, probably trachoma (*mi*). *Ku*[1] disease is also mentioned. *Yu*[1] we have not encountered previously; it means both swellings in the neck and also torticollis or palsy. If equivalent to *yu*[2] or *chan,* the commentators interpret it as paralysis agitans or senile tremor, but it may also refer to an affliction called *yu*[3] *chui.* This consists not only of large swollen lymph glands or the parotitis of mumps, but also small, wartlike tumors on the head, neck, and extremities which recall verruca, the multiple warts produced by a rickettsia. Another of the disease terms met with in the *Shan Hai Ching* is *chia,* which undoubtedly refers to a massive infestation with intestinal worms (ascariasis or oxyuriasis). This brings us to the great period of Han case-histories, and so to the work of Shunyü I.

Han Period: Shunyü I

During the Warring States, Chhin, and early Han periods, there were two great schools of medicine:

The earliest grew up in the western state of Chhin; the other was located in the eastern seaboard state of Chhi. From Chhin came the physician Huan, whose attendance on the Prince of Chin in 580 B.C. long remained famous; the physician Ho, already mentioned as examining another Prince of Chin 40 years later, also came from there. More celebrated than either of them was Pien Chhio, about whom there is much to be said, but as the records concerning him do not give us very much in the field of disease nomenclature, we mention him only in passing. But Shunyü I is a different persona entirely. Born in 216 B.C. in Chhi, he studied under Kungsun Kuang and Yang Chhing, practicing medicine successfully from about 180 B.C. on. In 167 B.C., he was accused of some crime and taken to court, but he was acquitted after the supplication of his youngest daughter. As he had been attending on the Prince and lords of Chhi, he was summoned to answer an inquiry from the imperial court some time between 164 and 154 B.C., then released again, and he continued in practice until his death about 145 B.C. It is owing to this perquisition by the imperial authority that we possess today the records of some 25 detailed case histories which Shunyü I reported. For every one we have the name of the patient, the circumstances in which the disease was contracted, the details of the attendance of Shunyü I, the treatment that he prescribed, the explanations that he gave of his diagnostic reasoning, in which the pulse played a very prominent part, and finally the ultimate result. We also have the answers that Shunyü I gave to eight general questions, answers that throw a flood of light upon the general conditions of medical education and practice in the second century B.C. R. F. Bridgman (1955), who had given us a pioneer study of Shunyü I and his times, has concluded that the general level of Chinese medicine thus revealed was in no way inferior to that of the contemporary Greeks, and in this judgment we concur. For the present purpose the point is that the clinical descriptions are so detailed that we can see exactly what Shunyü I meant by his own technical terminology.

Let us first look at some of the less severe cases that Shunyü I was able to cure – or at least relieve for a time. In a child, *chhi ko ping* was clearly difficulty in breathing, probably influenza or catarrh, perhaps acute laryngitis; some fever is implicit in the explanation. In a palace superintendent, *yung shan* was evidently vesical schistosomiasis, accompanied by hematuria, urinary retention, vesicular calculi, perhaps prostatorrhea. Other similar cases, however, were too far gone to recover – for example,

a police chief who seems to have had bladder cancer accompanied by intestinal obstruction due to heavy ascaris infestation (*chia*). The Chief Eunuch of the Palace of Chhi fell into a river and got very cold and wet, so his *je ping* due to *han* was surely bronchitis or pneumonia; Shunyü I gave antipyretic drugs and pulled him through. Then the Queen Mother of Chhi had *feng tan*, which is clearly interpretable as acute cystitis, probably connected with nephritis. She had hematuria, but she got better under Shunyü's treatment. An old nurse of the princely family had *je chüeh*, with hot and swollen feet; this may have been gout accompanied by chronic alcoholism, or possibly simply a traumatic infection of the extremities. *Chhiu chih* was clearly dental caries, and one of the grand prefects of Chhi had it. One of the concubines of the Prince of Tzu-chhuan had a difficult childbirth; Shunyü I gave nitrate and obtained the rejection of postpartum blood clots. A young courtier had *shen pi* – traumatic lumbago or muscular strain caused by trying to lift a heavy stone, together with dysuria, perhaps caused by compression of the hypogastric plexus; he also got better. By means of a vermifuge prepared from the gingko tree, a girl was cured of an intense *Enterobius* infestation (oxyuriasis). Here the description is particularly precise because the term used was *jao chia*, and already by this time there were several other terms (*hui, chiao, pa,* etc.) for other types of intestinal parasites. Another case of *pi* was that of a young prince who had acute lobar pneumonia but recovered.

One of the more striking features of Shunyü I's practice was the way in which he was able to give a long-term diagnosis. For example, on one occasion he was asked to give a general health checkup of the serving maids of the Prince of Northern Chhi, and among these he found one who was certainly not ill but in his opinion was going to be. She was, he said, suffering from *shang phi,* and this must have been tuberculosis because it ended in a sudden and fatal hemoptysis some 6 months later. No one would believe that Shunyü I was right in saying that she was ill, but events confirmed his opinion. On another occasion he was alarmed by the appearance of a slave of the client of the Prime Minister of Chhi, who again, in his view, had a *shang phi chhi,* although the man himself did not feel particularly ill. Shunyü I said that he would not last through the following spring, and he did not. Here the clinical description suggests hepatic cirrhosis, almost certainly of parasitic origin, caused by liver flukes (hepatic distomiasis); jaundice was apparent, and the case might also have been one of acute yellow atrophy of the liver.

One of the most extraordinary cases reported by Shunyü I was that of another royal physician, by name Sui. He must have been interested in Taoist arts, for he had himself prepared elixirs from the "five mineral substances," and when Shunyü I saw him he was suffering from *chung je,* apparently in this case a pulmonary abscess, presumably brought on by arsenical or mercury poisoning. Shunyü I warned him that it would be hard to avoid a fatal result, and in fact some months later the abscess burst through under the clavicle, and Sui died. Another man had what Shunyü I described as *ping khu tho feng* (i.e., some progressive paralysis), possibly disseminated sclerosis or possibly progressive muscular dystrophy.

More rapidly fatal in termination were other cases. A palace chamberlain had a peritoneal abscess, perhaps a perforating ulcer (*chü,* leading to *chung je*); perhaps the perforation was due to heavy ascarid infestation. Another man died of *fei hsiao tan* with delirious fever (*han je*). This would have been acute hepatic cirrhosis, probably caused by liver and blood flukes. In this case, the royal physician of Chhi had diagnosed and treated it quite wrongly. It is curious that up to this time we have not found the characteristic term for cholera (*ho luan*), but it seems that Shunyü I may well have had a case of it among his records, for a minister of the Lord of Yang-hsü died of "penetrating pneuma" (*tung feng*), the description of which suggests total failure of digestion, intense diarrhea, possibly due to enteric fever, perhaps to cholera. The word *shan* appears again in a combination *mu shan,* where it clearly refers to an aortic aneurism that caused the death of a general. The last case we shall mention was that of a Court Gentleman of Chhi who had a fall from his horse onto stones; the resulting traumatic abdominal contusion followed by intestinal perforation of a gut probably already weakened by parasitic infestations of one sort or another was termed *fei shang,* that is, injury not to the lung but to the tract (*ching*) of the lung. This brings us to the last subject that we can touch upon here, namely the medical system of the *Nei Ching*.

The *Nei Ching*

The *Nei Ching* was, we think, approximately already in its present form by the first century B.C. The full title under which it is commonly known is the *Huang Ti Nei Ching* (The Yellow Emperor's Manual of Esoteric Medicine), consisting of two parts, the *Su Wen* (Pure Questions and Answers) and the *Ling Shu* (Spiritual Pivot). This was the recension that came

from the editorship of Wang Ping in the Thang dynasty, but it is probable that this was not the recension that the Han people had. Another one, known as the *Huang Ti Nei Ching, Thai Su,* which was edited 100 years or so earlier than Wang Ping, by Yang Shang-shan in the Sui period, and which has only come to light in very recent times, may be considered nearer the original text of the Han. The *Nei Ching* system of diagnosis classified disease symptoms into six groups in accordance with their relation to the six (n.b., not five) tracts (*ching*) which were pursued by the pneuma (*chhi*) as it coursed through and around the body. Three of these tracts were allotted to Yang (Thai-Yang, Yang-Ming, Shao-Yang) and three to Yin (Thai-Yin, Shao-Yin, and Chüeh-Yin). Each of them was considered to preside over a "day," one of six "days" – actually stages – following the first appearance of the feverish illness. In this way, differential diagnosis was achieved and appropriate treatment decided upon. These tracts were essentially similar to the tracts of the acupuncture specialists, though the acupuncture tracts were composed of two 6-fold systems, one relating to the hands and the other to the feet, and crossing each other like the cardinal (*ching*) and decumane (*lo*) streets of a city laid out in rectangular grid arrangement. Moreover, by the time of the *Nei Ching* the physicians had achieved full recognition of the fact that diseases could arise from purely internal as well as purely external causes; the ancient "meteorological" system explained by physician Ho had therefore been developed into a more sophisticated 6-fold series, namely *feng, shu, shih, han, sao, huo.* As external factors, they could be translated as wind, humid heat, damp, cold, aridity, and dry heat; but as internal causes we could name them blast (cf. van Helmont's *blas*), fotive *chhi,* humid *chhi,* algid *chhi,* exsiccant *chhi,* and exudative *chhi.* It is interesting to notice the partial parallelism with the Aristotelian–Galenic qualities, which were part of a quite different, 4-fold, system.

In the brief remaining space of this contribution, it would be impossible for us even to sketch the etiologic and diagnostic system of the *Nei Ching,* but it is fair to say that the system provided an elaborate classificatory framework into which the results of keen clinical observation could be fitted. A rather comprehensive theory of medicine, both diagnostic and therapeutic, was now available. Interpreting a whole millennium of clinical tradition, the physicians of the former Han dynasty were able to combine into one science the influences of external factors on health, the abnormal functioning of internal organs whether by excess or by defect, and

the manifestation and interrelationship of symptoms; using the concepts of Yin Yang (the two fundamental forces in the universe), Wu Hsing (the five elements), Pa Kang (the eight diagnostic principles), and Ching Lo (the circulatory system of the *chhi*). The five elements had not been part of the most ancient Chinese medical speculations; they derived from another school, that of the Naturalists (Yin–Yang chia) whose greatest exponent and systematizer had been Tsou Yen (c. 350–270 B.C.) Five-element theory (a lengthy discussion of which can be found in *Science and Civilisation in China,* Volume 2 [Needham et al. 1954]) was so influential and so widespread in all the nonmedical sciences and protosciences of ancient (and medieval) China that the physicians could not remain unaffected by it, but in incorporating it into their theoretical disciplines they added a sixth unit or entity to conform with their 6-fold categories. Thus there were five Yin viscera (liver, heart, spleen, lungs, and urinogenital organs) and five Yang viscera (gallbladder, stomach, larger and small intestines, and bladder) recognized by all schools. To these the physicians added a further entity in each category, the *hsin pao lo* (pericardial function) and the *san chiao* (three coctive regions); and the particular interest of this lies in the fact that these additions represented physiological operations rather than morphologically identifiable structures. The six "viscera" could thus correspond readily with the six *chhi,* the six tracts, and so on. It must not be supposed that the state of Chinese medicine at the time of the *Nei Ching* synthesis was destined to remain unchanged through the following nearly two millennia of autochthonous practice; on the contrary, there were great developments, many elaborations, and a proliferation of diverging schools. However, if we are to think of any presentation of Chinese medicine as classical, this is what deserves the name.

The ancient Chinese physicians were extremely conscious of the temperature-regulating and -perceiving systems of the human body, so that although they had no means of measuring temperature accurately, the observation of subjective chill or fever, together with algophobia or algophilia, was extremely important for them. By this time also the study of the pulse and its modifications had advanced to a highly developed state.

All fevers were placed in a category of *shanghan* diseases and termed diseases of temperature (*je ping*). Every sign that is still examined today (pain, perspiration, nausea, etc.), short of the results of modern physicochemical texts, was studied by them

and meant something to them. For example *fu man*, or abdominal fullness, was an important sign. This could mean edema (*chung*). The *Nei Ching* actually says that "fluid passing into the skin and tissues by overflow from above and below the diaphragm forms oedema." It could also mean ascites occurring in liver cirrhosis, heart failure, and especially schistosomiasis, undoubtedly so common in ancient China. *Fu man* was also accompanied by the excretion of watery feces with undigested food (*shih i*) found in gastroenteritis, cholera, and the like. *Fu man* was also called *fu chang* and *tien*. This latter word is a good example of a word that can be pronounced in two ways; pronounced *tien*, it meant abdominal distension; but pronounced *chen*, it meant various forms of madness and, in the *binome chen hsien*, epilepsy. It is clear from the clinical description that from Han times onward the terms *lao feng* and *lao chung* referred to tuberculosis. The term *feng* by itself always had the connotation of convulsion or paralysis; it might be regarded as a violent *pneuma*, in distinction from the mild *pneuma* (*chhi*), which was part of the physiology of the normal body. Other forms of *chung feng*, therefore, were hemiplegia (*phien khu*) and cerebral hemorrhage giving full apoplexy (*fi*). Among the fevers (*wen ping*) we now find fairly clear descriptions of diphtheria, as *she pen lan* (lesions at the root of the tongue), doubtless complicated by streptococcal infections. Diphtheria is also clearly denoted by *meng chü*, "fierce ulcer" (of the throat). Hepatic cirrhosis caused by liver and blood flukes was now called *kan je ping;* tuberculosis, *phi je ping;* pneumonia, *fei je ping*.

It does not always follow that the organs referred to in descriptions (in the three preceding cases: liver, spleen, and lungs, respectively) were those to which we might refer the diseases today. Rather these were the organs concerned with the six tracts already spoken of, each one of which was connected with an organ. Of the malarial types of fever (*chiai nio*) we have already spoken. The terminology now continued with little change, but one disease, *tan nio*, may be identified with relapsing fever caused by *Borrelia* spirochetes as Sung Ta-jen has suggested.

One last word on diabetes. Polyuria was recognized as the sign of a special disease in the *Nei Ching*, where it is called *fei hsiao*. Han ideas about this illustrate the principle of successive involvement or shifting (*i*) when some pathological influence spreads from organ to organ in the body. Thus in *fei hsiao* the cold *chhi* in the heart passes over into the lungs and the patient excretes twice as much as what he drinks. Though the characteristic name for diabetes (*hsiao kho, hsiao chung*) had not been developed by the end of this period, there can be little doubt that diabetes was here in question. The sweetness of the urine was discovered a good deal later, indeed in the seventh century A.D.

The fact that mummification was not practiced in ancient Chinese civilization has no doubt militated against the acquisition of a mass of concrete evidence concerning many of the diseases from which people suffered in those times, such as has been developed for ancient Egypt. As far as we know, almost nothing has been done on the pathological anatomy of the skeletons that have been excavated from ancient tombs in China, whether in the Neolithic or in the Chou, Chhin, and Han periods. Since there must be a mass of skeletal material in the Chinese museums, it may be that this task could still be accomplished with valuable results by Chinese archeological pathologists. However, the study of the written records of ancient China, from the middle of the first millennium B.C. down to the beginning of our era, shows that they have preserved a veritable mass of information concerning the diseases prevalent in those times, and although the study of human remains themselves may bring precious confirmation of what the writings reveal, it may well be that on balance the written records, when fully analyzed, will present a broader picture than the study of the skeletal remains themselves alone could ever give us.

VI.2
Diseases of the Premodern Period in China

Old Diseases

It is very difficult to trace precisely the historical development of particular epidemic diseases in China. First, traditional Chinese medical terminology is based on a system hardly translatable into modern Western terms. Second, not only the concepts of disease, but the diseases themselves have changed, so much so that it is impossible to determine whether an ancient classical term meant the same thing when used in premodern texts, or to find the exact modern counterpart of a disease discussed in old texts.

Only during the second half of the nineteenth century did diseases in China begin to be scrutinized by Western medical practitioners, and as late as the early twentieth century, it was difficult to construct a complete picture because "there were classes of disease that were rarely brought for treatment to modern doctors" (Polunin 1976).

One principal feature of the traditional Chinese medical system (a system that achieved classical form by the second century) that makes it difficult to identify individual epidemic diseases in premodern China is the ancient categorization of both epidemic and endemic diseases along with other afflictions into a large group labeled *shanghan* ("affection by cold," although today it is the modern term for typhoid fever). Ge Hong, one of China's most impor-

tant early medical thinkers, specified in the early fourth century A.D. that the *Shanghan* diseases included not only those caused by winter cold but also those caused by spring warmth and by seasonal *liqi* (epidemic "breath"). However, he conceded that differences among the origins of the three types of diseases were slight and they should therefore be grouped into a single category. This ambiguous conception of epidemic "fevers" as part of a more general category of "cold fevers," despite some minor modifications, remained relatively unshaken in Chinese medical thought until the seventeenth century (late Ming and early Qing dynasties).

Widespread epidemics during the late Ming dynasty (Dunstan 1975) induced certain medical thinkers to reject the entire *shanghan* theory because most of the diseases they were called on to treat were found not to be caused by winter cold. The most representative of these pioneer thinkers was Wu Youxing, a seventeenth-century native of the epidemic-stricken eastern Jiangsu region. His work *Treatise on Warmth Epidemic Disease,* written in 1642, put forward the theory that seasonal epidemics were caused by deviant *qi* ("ether") in the atmosphere (Dunstan 1975). The "warm factor" was now favored over the "cold factor" as cause for the disease. Even diseases such as smallpox that had traditionally been considered manifestations of the body's internal "fire" or "poison" were now grouped with communicable diseases caused by external *qi.*

Even this important development in understanding the etiology of epidemic diseases in premodern China does not help us understand all diseases in this period in Western terms. Insufficient descriptions of the symptoms of diseases in medical texts as well as in local gazettes and dynastic histories where most of the information on epidemics can be found constitute the main obstacle to such understanding. Moreover, China's vast size implies regional differences in disease history that are still grossly unappreciated. At the present stage of research, with the exception of a few diseases that are easily identifiable, the best guesses as to the identity of most remain highly hypothetical.

Old and New Diseases
The sixteenth century can be considered a watershed in China's disease history. With the coming of European traders to China's southeast coast and the intensification of international commercial activities in South and Southeast Asia, China entered the world community and a few new epidemic illnesses entered China. Scarlet fever, cholera, diphtheria,

and syphilis are the more important ones to be added to the reservoir of older diseases that had been ravaging China for centuries. Among the latter were smallpox, pulmonary diseases, malarial-types of fevers, other febrile illnesses, dysentery, and possibly plague. However, the social and demographic impact of the new diseases on China after the sixteenth century is a field largely unexplored despite its important historical implications.

Smallpox is one of the oldest diseases known to China. An early sixth-century medical work claimed that the malady (then called *luchuang,* "barbarian boils") was introduced around A.D. 495 during a war with the "barbarians" in northern China (Fan 1953; Hopkins 1983). Little is known of the development of smallpox thereafter, until the late eleventh century (Northern Song period) when treatises on the disease written by pediatricians first appeared.

That pediatricians wrote of smallpox suggests that by this time it had developed into a childhood illness among the Chinese population (Leung 1987b). The technique of variolation using human pox was first practiced in the lower Yangtze region not later than the second half of the sixteenth century, and vaccination became popular in the early nineteenth century, when Jennerian vaccination techniques were introduced through Canton. Yet, despite the early practice of variolation, smallpox was rampant in China, especially in the north (the Manchus and the Mongolians were the most vulnerable, and two of the Manchu emperors died of the disease) where variolation was much less practiced than in the south (Leung 1987b).

Malarial-types of fevers (*nue* or *zhang*) first appeared in medical texts in the seventh century, when the economy of the subtropical regions south of the Qinling Mountains became of great importance to the northern central government. From the twelfth century on, after northern China was occupied by the Jurchens and the Song government fled to the south, specialized medical books on malarial fevers and other subtropical diseases believed to be caused by the "miasma" (*zhangqi*) of these regions appeared in increasing number (Fan 1986). Some scholars believe that temperatures during the Tang period (A.D. 618–907) were probably higher than those of today, which suggests that the northern limits of diseases associated with the southern climates (malaria, schistosomiasis, and dengue fever) were further north than they are today (Twitchett 1979). The number of victims of these diseases was therefore likely to be larger than previously thought. In fact, malaria was still a major killer in South and South-east China during the early twentieth century (Chen 1982).

The history of plague in China is a controversial subject. Some believed that it arrived in China in the early seventh century (Twitchett 1979), whereas others date the first appearance in the 1130s in Canton (Fan 1986). Yet both of these views are based at least in part on simple descriptions of symptoms (appearance of *he,* "nodes"; or *houbi,* "congestion of the throat"), which is far from conclusive evidence. By tracing the development of plague epidemics in the Roman Orient, and in Iraq and Iran from the mid-sixth century to the late eighth century, D. Twitchett (1979) has argued that at least some of the epidemics that struck China from the seventh and eighth centuries were those of bubonic plague. By contrast, those who feel that plague burst out as devastating epidemics only in the early thirteenth or fourteenth century (McNeill 1976; Fan 1986) suggest a possible relationship to the European Black Death of the same period.

Unfortunately, there is no direct evidence to support either of the above hypotheses. Even as late as the seventeenth century, when China was again struck by a series of epidemics, it is impossible to prove that these were outbreaks of plague (Dunstan 1975). The first epidemic in China, which we have substantial reason to believe was plague, was that first striking Yunnan in 1792. It then spread to the southeastern provinces of Guangdong and Guangxi, up the Chinese coastline to Fujian and to the northern part of China (Benedict 1988). But it was only in the late nineteenth century that medical works on the "rat epidemic" (*shuyi*) began to be published (Fan 1986).

In addition to the epidemic diseases discussed above, several endemic ailments were likely to be equally devastating. Among these were pulmonary diseases (probably pneumonia and tuberculosis), dysentery, various fevers (the *shanghan* category of fevers), which probably included typhoid fever, typhus, and possibly meningitis, cerebrospinal fever, influenzas, and the like. Most popular almanacs and family encyclopedias of the Ming–Qing period that contained chapters on common illnesses and their treatment mentioned dysentery, the *shanghan* diseases, and coughs. Skin diseases, *huoluan* (prostrating fever with diarrhea), beriberi, and *nue* (malarial-type fever) were also frequently discussed (Leung 1987a).

Perhaps some notion of the relative importance of these endemic diseases, especially in southern China, can be gleaned from surveys done in Taiwan

during the Japanese occupation period (1895–1945). The disease that caused the highest mortality in Taiwan from 1899 to 1916 was malaria. In 1902, it accounted for 17.59 percent of mortality among the native Taiwanese, causing 4.62 deaths per 1,000. Malaria was followed by dysentery and enteritis until 1917, after which "pneumonia" became the region's biggest killer (4.42 deaths per 1,000 in 1935). Next in importance was dysentery (2.55 deaths per 1,000 in 1935), whereas other contagious diseases including parasitic ailments accounted for 1.5 deaths per 1,000 in 1935 (Chen 1982).

That pulmonary diseases and dysentery persisted as the major fatal diseases among southern Chinese from the premodern period to the early twentieth century seems obvious. The secondary place that Ming–Qing almanacs accorded to the malarial-type fevers, despite the fact that malaria was the principal killer in nineteenth-century Taiwan, can be explained by the fact that few, if any, of these almanacs were written by authors from subtropical and frontier regions. It is also possible that malaria was confused with some of the *shanghan* diseases in almanacs.

Parasitic diseases, which ranked third on the list of high-mortality diseases in Taiwan in the 1930s and 1940s, were rarely mentioned in the almanacs. But their importance was emphasized by Western scientists who came to China in the early twentieth century. Thus G. F. Winfield claimed that feces-borne diseases caused about 25 percent of all deaths in China, especially among peasants in the rice and silk regions of the south (Winfield 1948).

Syphilis was one of the first "new diseases" that reached China. It was probably first introduced to Guangdong through Portuguese traders in the early sixteenth century, as a 1502 medical work recorded that syphilis was called the "boils of Guangdong" (*guangchuang*) or "plum boils" by the people of the lower Yangtze region. The disease was already much discussed in sixteenth- and seventeenth-century medical texts, some of which clearly stated that it was transmitted through sexual intercourse (B. Chen 1981; Fan 1986). Along with gonorrhea, syphilis probably accounted for 2 to 5 percent of all Chinese deaths in the 1930s (Winfield 1948).

Cholera probably arrived after syphilis. The modern term for the disease – *huoluan* – was in the past a name for any disease that caused sudden and drastic vomiting and diarrhea. Reliable records date the first real cholera epidemics in China from the 1820s. Like syphilis it also was first introduced in Guangdong and spread from there along the south-eastern coast up to Fujian and Taiwan. It usually struck in the months of August and September.

Some scholars suspect that an epidemic in 1564, which had reportedly killed "10 million people," may have been cholera. But regardless of the possibility of cholera's presence at an earlier date, there is no question about the devastating effects of cholera in nineteenth-century and early twentieth-century China, especially in crowded urban centers (B. Chen 1981; S. Chen 1981; Fan 1986).

Scarlet fever and diphtheria came to China in the early and late eighteenth century, respectively. Scarlet fever was epidemic in the lower Yangtze region in the 1730s during the winter–spring transition and was then called "rotten-throat fever" (*lanhousha*). The contemporary epidemiologist Ye Gui (1665–1745) noticed that the illness struck all age groups and that the victims were covered with dense red spots and had red sore throats. The disease seemed to be more devastating in the north. In the Peking area of the 1930s, the estimated mortality of scarlet fever was 80 per 100,000 (S. Chen 1981).

Diphtheria was confused with scarlet fever when it first reached China in the late eighteenth century. It became widespread and epidemic in the decades of the 1820s through the 1850s, spreading from the lower Yangtze region to southwestern China and to the northeastern regions before it reached the northwest in the late nineteenth century. The first medical work on diphtheria (then called "white-throat disease," *baihoulong* or *baichanhou*) was also published in the mid-nineteenth century (Fan 1986).

It is difficult to estimate quantitatively the mortality caused by the new diseases. Their older counterparts seemed to remain on the top of the list of high-mortality diseases into the early twentieth century. However, as scarlet fever was the tenth leading cause of mortality in the Peking area between 1926 and 1932 (S. Chen 1981), and as syphilis (with gonorrhea) accounted for 2 to 5 percent of all deaths in China, their roles cannot be underestimated. Perhaps the reason why the impact of cholera and diphtheria epidemics in the premodern period was not quantified was that the former was too seasonal and the latter basically a childhood disease.

According to local gazetteers of the southern provinces, epidemics usually struck during the spring–summer and the summer–autumn transitions. This seasonability of disease prevalence was confirmed by the 1909 Foochow Missionary Hospital Report, which recorded 2,004 patients treated in May, 1,943 in June, and 1,850 in October – equaling about one third of the 17,456 patients treated during the entire

year (Kinnear 1909). Dysentery was generally the biggest killer in the summer, whereas cholera did its most important damage in October.

Unlike Japan whose isolation from the important world trade routes kept major diseases away from its shores during premodern times (Jannetta 1987), China was always exposed to epidemic disease. Trade through the old silk route, war with the northern "barbarians," travel to and from India and Indochina – all brought the "old" diseases to China, whereas the coming of the Europeans by sea from the sixteenth century onward brought a few "new" ones.

The low mortality rate resulting from diseases in premodern Japan preceded a period of low fertility, all of which shaped Japan's demographic development (Jannetta 1987). Comparison with Japan in turn raises the question of the extent to which epidemic diseases in China may have been an important factor in its population growth. For example, did China ever experience something similar to the Black Death, which struck Europe in the fourteenth and fifteenth centuries, or the smallpox epidemics that paralyzed the Amerindian communities in the sixteenth century?

Population and Disease

Questions such as those above have always intrigued historians of China because the Chinese population has experienced mysterious declines that were *possibly* caused by widespread epidemics. One such decline of population occurred in north China in the late seventh century, whereas another was a decline in the lower Yangtze region during the ninth century. Other examples are the drastic depopulation of north China during the Mongol dynasty in the fourteenth century, and the decline during the Ming–Qing transition in the mid-seventeenth century (Cartier and Will 1971; Zhou 1983; Wu 1988). Indeed, despite the nature of Chinese sources that do not permit any precise demographic reconstruction, it is generally conceded that China's population in the tenth century remained very much the same as it had been nine centuries earlier. A significant growth, however, took place during the three centuries following the tenth century and in the early thirteenth century, when the population was estimated to have reached an unprecedented high of between 100 million and 120 million people (Cartier and Will 1971). Yet the fourteenth century was one of demographic disaster. Ho Ping-ti estimates the population level at the end of the fourteenth century to have been around 65 million, although it exceeded

130 million by the turn of the following century and soared to 150 million by 1600 (Ho 1959). Another drastic decline seems to have occurred in the mid-seventeenth century, which may have reduced the population to 83 million in 1651 (Wu 1988). Momentum was regained during the eighteenth century by the end of which the population had tripled, reaching 313.2 million in 1795. By comparison, China's population in 1686 was ony 101.7 million.

Scholars have attributed some of these drastic population declines to epidemics. Twitchett (1979), for example, argues that epidemics had some effect upon demographic trends in the seventh, eighth, and ninth centuries, and might have been one major reason for population stagnation before the tenth century. It is also tempting to attribute the mysterious but real decline of population in north China during the fourteenth century to plague, as does William McNeill (1976). Some scholars would go even further by hypothesizing that plague was ravaging northern China as early as the thirteenth century. The beginning of the century saw a series of epidemics in Hebei and Shanxi, and then an epidemic struck Kaifeng (Henan) in 1232, reportedly killing nearly 1 million people within 50 or 60 days (Fan 1986).

Moving to the late Ming period, of the sixteenth and seventeenth centuries, H. Dunstan's (1975) preliminary survey of epidemics suggests that these catastrophes also had long-term effects on population growth and that the prosperity of the ensuing early and middle Qing dynasty was the result of an easing of pressure on land resources brought about by huge die-offs from disease, as well as from war and famine around the middle of the seventeenth century.

Yet the question of the impact of disease on China's population remains controversial because of different interpretations of demographic sources (Cartier and Will 1971; Bielenstein 1975; Wang 1988). Also remaining is the question of how regional differences in population development can be related to local epidemics. Natural catastrophes like epidemics or famines were usually local rather than widespread occurrences and of smaller magnitude and shorter duration than impressionistic accounts have led many to believe. In fact, it could be argued that they were unlikely to have had long-term demographic impact (Watkins and Menken 1985).

Thus, it is perhaps most reasonable to see the presence or absence of epidemic disease in China as just one of the determining factors in long-term population growth. The unprecedented upsurge in popula-

tion during the Song period (eleventh to thirteenth centuries) is generally believed to be closely related to a series of revolutionary changes in agriculture in the more developed southern regions, especially with rice growing. The period witnessed the introduction of early-ripening rice as well as improvements in irrigation and other agricultural technologies all of which greatly increased land productivity (Ho 1959, 1969; Bray 1984). The next upsurge in population, however, was from the eighteenth century onward, a period in which there was no comparable technological revolution. Could the "stagnation" between the two upsurges be explained by differing mortality rates in which infectious diseases had a role?

Stagnations in "preindustrialized" populations occurred when high or moderately high fertility rates were balanced by similarly high mortality rates resulting from uncertain food supplies and unavoidable diseases. It is generally agreed that in Asia, where marriage was early and nearly universal, fertility was higher than in preindustrialized western and northern Europe, where women married late and forced celibacy was more common (Coale 1986). Therefore, a stagnation in population development in China can best be explained by high "normal" mortality rates.

Subsistence crises were always a constant threat to the Chinese, which, by causing undernutrition (if not death from starvation), reduced their resistance to disease. The prevalence of dysenteries, *shanghan* (discussed earlier), and respiratory diseases might be an indication of general dietary deficiencies (Polunin 1976). Certainly, beriberi, which was often discussed in the family encyclopedias, could cause death directly or indirectly by leaving the individual less able to resist diseases, whereas infantile beriberi has proven to be a major killer of nursing infants in thiamine-deficient populations.

In addition, parasitic diseases probably killed millions of peasants because the use of human feces as fertilizer was a universal practice for centuries. Flooded rice fields were also breeding grounds of mosquitoes – the carriers of malaria and other infections. In addition to malnutrition and agricultural practices, poor hygienic conditions, especially in some of the southern provinces and frontier regions, must also have been an important factor in encouraging insect-borne diseases like malaria and plague. Other important factors that could account for high morbidity rates, especially in urban centers in the late Ming period, were the absence of sewage and water control, and the inflow of masses of vagrants

from poorer areas to the centers who were most likely carriers of contagious diseases (Liang 1986; Leung 1987a).

Thus, with fertility rates already high, the demographic upsurge of the eighteenth century is best explained by a remarkable decline in mortality. At least the initial stage of the upsurge can be explained in terms of mortality decline, although subsequent increases in populations were likely to have been generated largely by the internal dynamics of an already huge population. The industrialization of the period was neither important nor modern enough to cause a significant rise in tuberculosis.

Ann Jannetta (1987) suggests that the practice of infanticide and abortion in Tokugawa Japan was a sign of attempts to control fertility because of an already slowly declining mortality. This may also have been the cause in China, for it was the case from the late seventeenth century onward that foundling homes were widely established, possibly reflecting increasing infanticide and child abandonment. Interestingly, the only precursor to this movement was in the thirteenth century when China experienced its first population boom (Leung 1985).

Decline in Chinese Mortality

Why then did mortality decline? Ho Ping-ti's (1959, 1978) findings on the introduction of new crops from the Americas during the sixteenth century provide us with one of the more persuasive answers. These easy-to-grow crops – for example, sweet and white potatoes and maize – may well have substantially stabilized food supplies for the poor in less fertile and mountainous regions. D. H. Perkins (1969), however, suggests that changing cropping patterns and rising traditional capital inputs increased crop yields per acre. Either way an improved food supply was certain to have reduced the chances of starvation for the people and consequently their susceptibility to various diseases.

Some would argue that long-term climatological evolution was the main factor: the post–fifteenth-century population growth, its decline in the mid-seventeenth century, as well as the explosion in the eighteenth century, all corresponded to climate changes of the time (Eastman 1988). Here even the changes in food production and the disease factor can be considered as affected by the climate.

Another important factor that should be considered is that in its earliest stages, a mortality decline is the result of lowered mortality rates for the young. This was the case in modern Europe and in Japanese-occupied Taiwan (Chen 1982; Riley 1986).

The health of the mother is an important variable in infant mortality, whereas better resistance to childhood diseases typically explains a reduced mortality in children over one year of age. Surely mother's education and infant mortality are directly related; however, the relationship is impossible to verify in this period. In addition, the lowering of mortality in children in modern Europe and early twentieth-century Taiwan was closely linked to the improvement in general hygiene (Chen 1982; Riley 1986). Unfortunately, it would be mere speculation to say anything about the improvement in the hygienic conditions (especially the provision of clean water for drinking, washing, and bathing) in premodern China at this stage, and in any event, there must have been enormous regional differences.

However, the early practice of variolation against smallpox is a possible factor in explaining the decline in Chinese mortality. An eighteenth-century smallpox specialist, for example, claimed that over 80 percent of the children of wealthy families in China had been inoculated (Leung 1987b). On the other hand, the majority of children were not inoculated, and clearly, no single factor is likely to serve as an explanation. Avenues of research that may prove fruitful in examining the question of reduced infant and child mortality include changing concepts of pregnancy, childbirth, and infancy (Leung 1984; Furth 1987); the attitudes behind the nationwide establishment of foundling homes; improved hygiene and immunization; and traditional diet therapy based on the humoral dimensions, and the whole folk nutritional science built largely on empirical observation (Anderson 1988).

If we are uncertain of the positive effects of new developments in agriculture, new crops, or variolation on reducing mortality, we can at least be confident that diseases no longer hindered long-term population growth, and that the contribution of disease to the mortality rate was no longer as great as it had been in the past, despite the introduction of some new diseases from the sixteenth century onward. Improved therapy and medication may have played a limited role in reducing the importance of disease, as, for example, the increasing use of herbal-based drugs (before the introduction of quinine in the eighteenth century) to fight malaria instead of the more dangerous arsenicals used in the Ming–Qing period (Miyasita 1979). But like variolation, the effects of herbal-based drugs, probably only used by small sections of the population, are difficult to estimate.

Certain institutional changes may have had some indirect effects on mortality rates. The Song state in the twelfth and thirteenth centuries took responsibility for providing medical help to the poor through public pharmacies. The Mongol dynasty continued this tradition by creating a nationwide system of "medical schools" to train local doctors. Yet, the tradition began to decline in the late fourteenth century, and by the late sixteenth century such institutions had largely disappeared. To some extent, this void was filled by local philanthropists who took responsibility for providing regular medical help to the needy from the seventeenth century on. They organized charitable dispensaries that provided the local people with medical care and medicines, and sometimes decent burials for the dead. These public but nonstate medical organizations could be found in many urban centers in the eighteenth and nineteenth centuries (Leung 1987a), and the free or very cheap medical treatment offered must have provided at least a minimum of necessary care to the urban poor. Moreover, the burying of dead bodies collected from the streets also helped to upgrade the sanitary conditions of these urban centers. According to an 1860 report by the American Presbyterian missionary in Shanghai, John Kerr, the local charitable dispensary, which was staffed by eight or nine Chinese physicians, was visited daily by 300 to 500 individuals "of all classes" (Kerr 1861).

After weighing the many changes that together brought about the mortality decline in China, we find it probable that an improved supply of food, which strengthened the nutritional status of the general population, was the most important factor from the late seventeenth century onward. The spread of variolation and an increasingly denser network of charitable dispensaries in the same period may also have contributed to a reduction in mortality, especially in southern China. Improved hygiene and child care practices were also probably important factors in bringing about what seems to have been a decline in infant mortality rates, but this has yet to be demonstrated.

Chinese Medicine

Discussion of some prominent features of Chinese medicine and the traditional reaction of the people toward disease will help us understand the Chinese system and allow us to gauge its relative effectiveness from the modern point of view. Quarantine, which was a common practice in Europe from the fifteenth century onward, was never widely practiced in China. There were, however, instances of isolation of individuals for certain diseases such as smallpox and especially leprosy.

Apparently, lepers were put into "lazaretto"-type hospices as early as the Qin dynasty (221–207 B.C.), and examples of such institutions are also found in sixth-century sources (Xie 1983). Unfortunately, there is no systematic documentation relating to hospices, and there is only sporadic mention of them in later sources. In the mid-nineteenth century, for example, we know that leper hospices existed in eastern Guangdong, where interned lepers were allowed to marry only among themselves. Moreover, their offspring were freed only after the third generation, when the genetic "poison" was believed to be exhausted (Liang 1982). In the same period, leper hospices were also organized by overseas Chinese communities in Batavia (Yang 1842).

As for smallpox-quarantine measures, there is at least one instance on record. In 1645, when the Manchus had just conquered Peking, they decreed that all smallpox victims and their families be banished 40 *li* (about 3 miles) from the city wall. The policy was still in force in 1655 (Hopkins 1983; Leung 1987a). Yet, as noted above, these were exceptional instances, and it is difficult to understand the Chinese lack of interest in quarantine (Leung 1987a). Ethics, however, probably had something to do with it. Moralists like Zhu Xi of the twelfth century, for example, condemned the "abandoning" of one's relatives and friends who fell victim to contagious diseases. Rather, one should risk infection by remaining behind to care for the sick, and there existed some conviction that moral power thus manifested would somehow keep the epidemic spirit away (*Huizhoufu zhi* 1502). On the other hand, the concept that diseases were caused by broad environmental influences – ether or vital energy (*qi*), wind (*feng*), fire or heat (*huo*), and water (Xie 1983) – would also seem to have discouraged quarantine measures.

Chinese medicine as a body of knowledge to fight disease never developed into a "science" as it did in Europe from the seventeenth century onward. For the scholar, medicine was a respectable field of study linked to philosophy, although the practicing physician was not accorded a high social status (Hymes 1987; Leung 1987a). Medical skills were transmitted within families and not by government-authorized institutions. The Imperial Academy of Medicine (*tai-yiyuan*) trained doctors only for government service and for the imperial family, and had no obligation to standardize medical knowledge or control the medical profession. Under such circumstances, medicine had a tendency to become "democratized," because all educated people had access to medical literature.

Popular Ming–Qing almanacs and encyclopedias must also have reinforced this trend (Leung 1987a).

As in premodern Europe, peddler-doctors, self-trained midwives, women-pharmacists and other "heterodox" healers flourished especially in the countryside. Women and children were often treated by female healers exclusively (Leung 1987a). In 1759, a book on the principles and practices of peddler-doctors, *A Collection of Proper Methods* (*Chuanya*), was published by the scholar-pharmaceutist Zhao Xuemin. The work was based on his interviews with a peddler-doctor and reveals a long tradition of popular healing that relied heavily on acupuncture, purging either through *ding* (provoked vomiting) or *chuan* (provoked diarrhea), and other methods (*jie*) that aimed at stopping symptoms instantly. Yet healers who practiced these "violent" methods were the lowest stratum in a system that emphasized memorization of abstract theories from the medical classics, subtle diagnosis, and a long and respectable family tradition of medical practice.

More often than not during epidemics, state financial aid was used for buying coffins to bury the dead (Leung 1987a), and people, high and low alike, commonly resorted to rituals and shamanistic practices when illness struck. Indeed, healing by charms and amulets (*zhuyou ke*), which had its roots in antiquity, was part of the curriculum of the Imperial Academy of Medicine since Tang times. Diseases and especially epidemic diseases were firmly believed to be caused by unpacified ghosts and spirits of the locality; thus rituals were essential in disease avoidance (*Huangchao jingshi wenbian* 1897). Individuals afflicted by illness were likely to ask help from various deities, or to correct moral faults that were believed to be the source of the physical corruption (Leung 1987a).

Such fatalistic attitudes toward illness and lack of total confidence in medicine should not be cause for surprise. To a certain extent, this behavior is still prevalent among the Chinese populace today.

VI.3
Diseases of the Modern Period in China

Overview

Modern China, with a 1985 population of 1.04 billion (*World Development Report* 1987), is by far the most populous country on earth, though its surface area of 9.56 million square kilometers ranks it third in size (behind the former Soviet Union and Canada). Ninety-five percent of the population live on less than 50 percent of the total area, primarily along the great river systems of the east and southeast, and only 22 percent of those in the population are classified as urban residents. The climate covers a broad range of patterns, extending from the hot, humid, and wet provinces in the south and southeast to those provinces in the north and northwest, which are for the most part dry and subject to hot summers and cold winters. By 1985 China's per capita gross national product in current dollars was estimated at U.S. $310 (*World Development Report* 1987). Approximately 33 percent of the gross domestic product was derived from agriculture, down from about 39 percent in 1965. An estimated 74 percent of the labor force was in agriculture, 14 percent in industry, and 12 percent in services in 1980 (*World Development Report* 1987).

China's population growth has slowed dramatically. In 1956, Ma Yin-chu, China's well-known economic expert, urged the government to introduce population control, and to slow down population growth. But China's leader, Mao Zedong (Mao Tsetung) rejected this advice vehemently. In 1965, however, the slogan was *"yige bushao, liangge zhenghao, sange duole"* ("One [child] is not too few, two [children] are just right, three are many"). By 1972, population control was justified by eugenic arguments: "quality instead of quantity." The slogan was (and still continues) *shaosheng yousheng* ("few births but superior births"; or "few lives but superior lives"). A policy announced in 1978 was designed to achieve a stable population at the 1.13 billion level by the year 2000, and in 1979 the one-child policy was introduced. From 1965 to 1980, the annual population growth rate averaged 2.2 percent; and from 1980 to 1985, 1.2 percent. Owing to a slower rate of decline in the birth rate it is now estimated that China's population may stabilize at 1.6 billion by around the middle of the twenty-first century.

By 1985, life expectancy at birth was estimated to reach 69 years, and infant mortality had dropped to about 35 per 1,000 according to the World Bank (1987). In specific regions, however, the rates were quite different. In the *People's Daily* of April 26, 1989, the government admits that in about 300 of the poorer regions infant mortality averages 100 per 1,000. UNICEF estimates infant mortality rates at 190 per 1,000 for Tibet.

Despite a large number of small nationality groups who speak many different languages, China has a relatively homogeneous population. Approximately 93 percent of the population are Han, or ethnic Chinese. Most of China's peoples speak one of the two major spoken languages, which, though quite different, share the same written characters.

Patterns of Disease

China has been witness to one of the most rapid and profound changes in health patterns that has ever occurred in recorded history. This chapter gives primary consideration to the disease patterns present in China in the 1980s; however, to place current events in context, one must start with a brief description of the social, economic, and health situations that prevailed in 1949, the year the People's Republic was proclaimed.

Midcentury China emerged from yet another of what must seem to the Chinese a near endless cycle of natural and human-made disasters, in this case, more than two decades of foreign invasion, occupation, and civil war. The country was completely exhausted. The World Bank estimated that in 1950 the Chinese population was 603 million; the birth rate, 42 per 1,000; the death rate, 33.5; the infant mortality rate, 252; and life expectancy at birth, 32 years (*World Development Report* 1987). With a very low per capita income and an extremely limited health-care system, the predominant diseases were those associated with malnutrition and communicable disease.

China's disease patterns have changed so rapidly since the 1950s that it is helpful to compare the present situation with that estimated, by much less complete statistics, at around the time of the declaration of the People's Republic in 1949. The first two

sections look at the causes of mortality and morbidity, with a brief consideration of regional variations, and the last section looks at selected causes of disease, especially those that are unusually prevalent in China. Unless otherwise indicated, disease-specific data are from the 1984 World Bank report entitled *China: The Health Sector*. This source, as well as the 1986 publication *Public Health in the People's Republic of China*, relies primarily on official Ministry of Public Health data sources, which are still subject to numerous limitations in both coverage and quality despite many improvements since the 1950s. The reader will therefore need to interpret the reported findings with caution.

Figure VI.3.1. Mortality rates for the urban population of Shanghai, 1949–83. (From *Public Health in the People's Republic of China* (1986), p. 86.)

Mortality

Good historical data on mortality for all of China are not available. Figure VI.3.1, based on data from the urban population of Shanghai, China's largest city, dramatically depicts the shift from mortality due largely to communicable disease, to a situation in which cardiovascular disease and malignant tumors predominate. The 10 leading causes of death in selected cities in 1957 and in both urban and rural areas in 1984 are listed in Table VI.3.1. The top three causes of death in 1957, all communicable diseases, accounted for 32.3 percent of all deaths, whereas by 1984 they amounted to less than 10 percent. By 1984 the top three causes – heart disease, cancer, and stroke – accounted for 64.9 percent of urban deaths and 54.9 percent of those in rural areas. Collectively, the top 10 causes accounted for almost 90 percent of all deaths in 1984, as compared with only two-thirds of those in 1957.

Wide interprovincial variations exist in the death rates due to the top three causes (see Table VI.3.2). Although these are likely explained in part by reporting errors and age differences, they are probably

Guangxi Aut. Region	–[b]	Respiratory (79)	TB (57)

[a]The numbers in parentheses refer to the death rate per 100,000.
[b]The classification of causes of death in Guangxi differs from that in other regions; the leading cause of death in Guangxi in 1985 was "aging and feebleness," and the deaths attributed to this cause were omitted from the source table.
Source: Based on data in *Public Health in the People's Republic of China* (1986), table 3, p. 94.

also due to regional differences in environmental, nutritional, and other factors. Heart disease death rates are highest in the northern provinces, ranging from a high of 188 per 100,000 population in Jilin Province down to 73 in Shandong. Cancer rates are highest in the east, ranging from 122 in Jiangsu to 57 in Guangdong.

Morbidity
Communicable diseases reported for 1985 are given in Table VI.3.3. Though these estimates, especially for the less serious illnesses, are likely very much underreported, they do give some notion of the relative frequency with which the various conditions are reported to the authorities.

Table VI.3.3. *Communicable diseases in China, 1985*

	Number of cases	Number of deaths
Cholera	6	2
Cerebrospinal fever	654	7
Diphtheria	1,423	184
Dysentery	3,280,596	2,352
Encephalitis B	29,065	2,433
Epidemic hemorrhagic fever	103,778	3,111
Forest tick-borne encephalitis	270	15
Influenza	3,407,383	361
Leishmaniasis	145	1
Leptospirosis	26,632	544
Malaria	563,400	44
Measles	418,159	2,654

Plague	6	1
Poliomyelitis	1,537	95
Scarlet fever	61,591	17
Tsutsugamushi disease	1,695	6
Typhoid and paratyphoid fever	86,482	251
Viral hepatitis	794,269	2,313

Source: Excerpted from *Public Health in the People's Republic of China* (1986), table 13, p. 218.

No national data exist on causes of morbidity or reasons for seeking health care, but a 1981 study of 737 households in Shanghai County (Parker et al. 1982) provides some indication of what illness patterns may be like. On the basis of a 2-week recall it was estimated that area residents annually averaged 6.0 days of restricted activity, 2.4 days in bed, 7.6 days lost from work, and 2.6 days lost from school. There were 44 hospitalizations per 1,000 respondents per year, and every 2 weeks there were 156 morbidity conditions, 49 cases of acute disability, and 187 primary care visits. In a survey of 3,122 people, 499 ill persons experienced 487 conditions. The percentages reporting the five leading conditions were as follows: respiratory, 27.3; gastrointestinal, 14.4; cardiovascular, 13.3; musculoskeletal, 7.8; and nervous system, 5.1.

Communicable Diseases

Parasitic Diseases

Ancylostomiasis and Ascariasis. Estimates of the 1945–59 period suggest that up to 100 million people in China have had intestinal infestation with parasites causing ancylostomiasis (the hookworm) or ascariasis (the roundworm). Ancylostomiasis remains prevalent in 14 southern provinces, and ascariasis is widespread in most of China. Improved environmental sanitation and night soil management have reduced the prevalence of both parasites, but the limited information available indicates that both remain a public health concern.

Filariasis. In the 1950s, filariasis, transmitted by a mosquito vector, was said to have affected between 20 million and 30 million people. By 1958, more than 700,000 patients had been treated, and the Patriotic Health Movement led to major improvement of environmental sanitation in many localities and to widespread extermination of mosquitoes. Shandong Province, with a population of 75 million, had eradicated the disease by 1983, and by 1985 about 76 percent of China's endemic areas were essentially disease free. In the mid-1980s filariasis was prevalent in 864 counties and cities in 14 provinces, autonomous regions, and municipalities. Slightly over half of the jurisdictions were endemic with Bancroftian filariasis, about one-fourth were endemic with Malayan filariasis, and the rest had mixed infections.

Leishmaniasis (Kala-Azar). A 1951 survey showed the area of China endemic for visceral leishmaniasis to be entirely north of the Yangtze River, covering 1.2 million square kilometers. Prevalence was 1 to 5 per 1,000, with an estimated 530,000 cases, most of whom were children. Destruction of dogs and treatment of human cases with a specially produced antimony drug played a major role in decreasing transmission. Reduction in incidence may also have resulted from a decline in the sandfly vector due to insecticide spraying for both sandflies and malarial mosquitoes. Since 1958, kala-azar outbreaks have become sporadic, with fewer than 100 cases reported every year.

Malaria. Prior to 1949, malaria incidence in China was estimated at more than 30,000,000 new cases annually (5 per 100 people), with 300,000 deaths (a 1 percent case-fatality rate). Seventy percent of China's counties were endemic for malaria in the early 1950s. Surveys in 1957 reported 70 percent prevalence among children in Guangdong and 48 percent in counties in Yunnan. Vigorous efforts to control mosquito breeding sites – consisting of environmental management, mass chemoprophylaxis during the transmission period, and mass treatment – caused disease rates to fall rapidly in the 1950s.

Since 1974, the five provinces of Jiangsu, Shandong, Henan, Anhui, and Hubei, which together account for about 80 percent of the national total of malaria cases and which represent the main tertian malaria areas, have worked jointly to bring the disease under control. In 1985, the number of new cases in the five provinces was 350,000, compared to the 14 million cases recorded in 1973 before the joint prevention and control measures were taken. Overall, approximately one third of China's population is now living in malaria-free areas, another third in areas with minimum risk, and the remaining third in endemic areas. The 563,400 cases reported for all of China in 1985 represent an incidence of approximately 5 per 10,000 population, close to the goal of under 1 per 10,000 by the year 2000.

Schistosomiasis. Schistosomiasis japonica, the form of the disease found in China, is prevalent in the provinces of Shanghai, Jiangsu, Zhejiang, Anhui, Fujian, Guangdong, Guangxi, Hunan, Hubei, Yunnan, Sichuan, and Jiangxi. It is carried by snails and is endemic in three types of environments: water courses, hilly regions, and lakes and marshlands. Water courses account for 8 percent of the endemic areas and 33 percent of the patients; comparable values are 10 and 26 percent for hilly regions, and 82 and 41 percent for the lake and marshlands areas.

Control efforts have been deployed on a large scale. In December 1955, China set up prevention and control stations in epidemic areas, and by 1958, 197 stations were staffed by more than 1,200 medical teams and 17,000 specialized personnel (Chien 1958). By 1985, there were only 371 endemic counties with a total of 11.6 million cases and 14,000 square kilometers of snail-infested areas. During the early stage of the nationwide prevention and control program, infestation rates typically ranged from 20 to 30 percent and in some areas reached 40 percent. Of those affected, about 40 percent were symptomatic and about 5 percent evidenced advanced illness. Cattle and other domestic animals were also seriously afflicted by the disease.

The elimination of snails has been a key objective of the program through such measures as draining marshlands, digging new ditches and filling up old ones, changing paddies into dry crops, tractor ploughing, field rolling, building snail trenches, and killing snails by chemical methods. The construction of dikes and the use of chemicals have proved very effective along the banks of the Yangtze River in Jiangsu Province.

Efforts to reduce the source of infection have included early detection and treatment of patients at all stages of the disease, with emphasis on those who handle diseased animals. People in snail-infested areas are encouraged to wear protective gear and take prophylactic medicines when coming into contact with water. Measures are also taken to ensure the safe collection and use of feces, and to encourage the use of safe water supplies.

By the end of 1985, schistosomiasis was declared officially eradicated in Shanghai and Guangdong, while Fujian, Jiangsu, and Guangxi have virtually eradicated the disease with more than 98 percent of the endemic areas cleared of snails and over 90 percent of the known patients cured. Among the 371 endemic counties and cities, 110 have been declared eradicated and 161 have almost eradicated the disease. In the remaining 100 counties and cities, more than 50 percent of the townships and about two-thirds of the villages have eradicated or almost eradicated the disease. Accomplishments by 1985 included the following: 95 percent of the 11.6 million patients were treated; 77 percent of the infested area was cleared of snails; and 92 percent of the 1.2 million head of afflicted cattle were treated or disposed of.

Despite these gains, concerns are being expressed by Chinese and foreign schistosomiasis experts about the future. UNICEF's Situation Analysis for China of 1989 estimated that schistosomiasis was still present in 12 provinces with a combined population of 50,000,000 and that the total of old cases approached 1,000,000 to which several thousand new cases were added annually (UNICEF 1989). The schistosomiasis control problem seems to have shifted over the decades from that of devising methods to control a major endemic parasitic disease to that of identifying the few lightly infected individuals in a sea of negatives, and ensuring that past gains are maintained without backsliding (Basch 1986).

Nonparasitic Diseases

Acquired Immune Deficiency Syndrome (AIDS). As of August 1989, China had reported only 22 human immunodeficiency virus (HIV)-infected individuals and three cases of AIDS. All were foreigners except for four Chinese who were infected through contaminated blood products (*China Daily*, Sept. 7, 1989). The first indigenous case acquired through homosexual contact with a foreigner was reported in late 1989 (*China Daily*, Nov. 2, 1989). Persons from areas of

high endemicity who wish to extend their visa stay beyond a limited period of time are required to have a test for HIV antibodies performed in China, and must leave China immediately if the test is positive. By December 1990 (*China Daily,* Dec. 31, 1990), China had identified a total of 446 HIV-positive cases, since it started monitoring the epidemic in 1985, including 68 persons "from overseas."

Cholera. Cholera was said to be "virtually eliminated" by 1960 (Lampton 1977), and in 1985 only six cases and two fatalities were reported. More recent data from the Ministry of Public Health suggest that the disease is again of some importance, perhaps in part owing to better reporting. In 1989, the Ministry of Public Health reported that cholera still threatens residents of Hainan, Zhejiang, and Guandong provinces, a part of suburban Shanghai, and Guangxi Zhuang Autonomous Region. In 1988 more than 3,000 cholera cases were reported, but cases dropped to about 1,000 by the end of 1989 (*China Daily* 1989).

Dengue. The first recognized dengue epidemic since 1949 occurred in Guangdong Province between June and September 1978, with an estimated 20,000 cases affecting persons of all ages. Approximately 25 percent had hemorrhagic manifestations. Because the usual vector, the *Aedes aegypti* mosquito, is thought to be absent from this area of China, suspicion has focused on the *Aedes albopictus.* Epidemiologists who investigated this epidemic assumed that refugees from Vietnam (estimated to exceed 200,000) imported the virus. Another dengue outbreak occurred on Hainan Island in 1980, and sporadic cases continued until 1982. Transmitted by the *A. aegypti* mosquito, the epidemic resulted in a peak morbidity rate of 2,146 per 10,000 and caused 64 deaths (Qiu Fu-xi and Zhao Zhi-guo 1988). Dengue has been added to the list of officially notifiable diseases, and no cases were reported in 1985.

Epidemic Hemorrhagic Fever. Epidemic hemorrhagic fever was first found in Heilongjiang province in the 1930s and then in the construction sites of the northeast China forest zones and the Baoji-Chengdu Railway. The disease became more common in later years as the population increased in endemic areas as a result of water conservation, land reclamation, and other construction projects.

China has three types of epidemic foci: house mouse, field mouse, and the "mixed type." Gamasid and Trombiculid mites may also carry the virus. Measures directed primarily at reducing mouse populations have been found to be effective in controlling the disease. Early diagnosis, rest, and hospital care in order to reduce the incidence of coma and renal failure have lowered the case fatality rate to about 3.2 percent in 1984 (*Public Health in the PRC* 1986).

Influenza. Influenza is the most frequently reported disease in China. Surveillance has been under way since 1968, yielding an epidemic pattern in south China that peaks in the summer and early fall, and an epidemic pattern in north China that peaks in the winter. As China's population ages and grows more vulnerable to influenza because of other serious chronic diseases, influenza will become more important as an immediate cause of death. An extensive immunization campaign has been carried out in recent years, resulting in a reduction from 8 million cases in 1975 to about 500,000 in 1980 and 1981. An unknown part of this decline may simply reflect the cyclic nature of the disease.

Japanese B Encephalitis. Japanese B encephalitis is a mosquito-transmitted viral disease seen throughout much of East Asia and is thought to be present in all of China except Tibet and Xinjiang. The case-fatality rate in 1949 was estimated at about 30 percent, and large epidemics were frequently seen near Shanghai, where the annual incidence was over 50 per 100,000. Since 1965 the incidence in the Shanghai area has been only 2 to 3 per 100,000. Mosquito vector control and vaccination of children have been priorities. Human cases peak at 4 to 5 years of age. About 100,000 cases are reported annually in China.

Leprosy. Leprosy has been present in China for more than 1,000 years. High prevalence areas are in southeast and southwest China; low prevalence areas are in the northeast and north. The official estimate for prevalence in China in 1951 was 1.2 million, although some international estimates placed the prevalence as high as 3 million.

Since the 1950s about 500,000 cases have been found, and more than 400,000 have been successfully treated. Methods used included specialized training for health personnel, prevention and control networks, early diagnosis and treatment, and infection control. In Shandong, the average annual incidence declined from 5.1 in the late 1950s to 0.14 per 100,000 in the early 1980s; the prevalence declined from 91 in 1950 to 2.3 per 100,000 in 1984. In 1958, 17,535 villages reported leprosy cases, this number dropping to only 1,500 villages by 1984.

Current estimates suggest a total of 100,000 to 200,000 patients and a prevalence of less than 20 per 100,000. China has recently embarked on a campaign to eliminate most leprosy by the year 2000 through intensified efforts of education, research, and early diagnosis and treatment (*Pubic Health in the PRC* 1986).

Measles. In 1950 the measles case-fatality rate was 6.5 percent, declining to 1.7 percent in 1956 with improved nutrition. When mass vaccination began in 1969, the incidence was estimated at about 3,000 per 100,000, but it now has dropped to below 20 per 100,000 for most big cities. The 1989 Ministry of Public Health epidemiologic report gave a time series estimate of 2.4 million cases in 1978, and 418,000, 199,000, 105,000, and 96,000 cases in 1985 through 1988, respectively. During the years 1986–8, the proportion of infants under 1 year immunized for measles rose steadily from 63 percent to 78 and 95 percent. The total annual reported deaths from measles since 1985 has been less than 1,000.

Neonatal Tetanus. Although data for pre-1949 are unavailable, it is likely that neonatal tetanus accounted for as much as 20 percent of infant mortality, a percentage similar to that reported in the early 1980s in rural Thailand. Maternal and child health services in China now monitor more than 90 percent of deliveries in most provinces, and neonatal tetanus is now said to be a rarity. Sample surveys have detected neonatal tetanus in some of the more remote counties, with an average death rate of approximately 3 per 1,000, ranging from 0.3 to over 13. By using very fragmentary data from various sources, UNICEF has estimated that there are perhaps 10,000 neonatal tetanus deaths per year, or a rate of about 0.5 per 1,000 live births.

Plague. The earliest known outbreak of plague in China was in Lu'an County, Shanxi Province in 1644 (*Public Health in the PRC* 1986). A well-documented massive outbreak of pneumonic plague occurred in 1911 in Manchuria. This epidemic, in which 60,000 people were affected, led to the first international medical conference in China and to the establishment of the Manchurian Plague Preventive Service. The failure of traditional Chinese medicine to control the outbreak (practitioners of traditional medicine experienced a 50 percent case-fatality rate) and the success of Western methods (a case fatality rate of 2 percent) were important factors in the rise of Western medicine in China (Bowers 1972).

During the early phase of the antiplague campaign, the state encouraged and subsidized rat-killing drives by agricultural collectives along with programs to reduce other potential host animals. Measures were also taken to destroy the ecological environment of major hosts in the course of planting trees or in carrying out farmland improvement and water conservation projects. As a result, rodent plague has been virtually eliminated from most heretofore endemic foci, and the ground squirrel, marmot, and other host populations have been sharply reduced.

By the end of the 1950s, the annual incidence of plague in China had declined to about 30 per 100,000, and by the end of the following decade it was under 12. The number of counties reporting plague cases annually ranged from 26 to 61 in 1950–4, 6 to 15 in 1955–60, and 0 to 8 after 1961 (*Public Health in the PRC* 1986). There were only 6 cases of plague in 1985, and the case fatality rate in recent years has been less than 8 percent.

Poliomyelitis. Prior to 1955, epidemics of poliomyelitis were common in China. In 1959 in Nanning the incidence was 151 per 100,000, and incomplete statistics for 17 administrative jurisdictions showed an overall incidence of 5 per 100,000. There were polio epidemics early in the Cultural Revolution (1968–70), during which all immunizations were said to have been neglected. The generation of those 10 to 20 years old at that time was most affected. As a result of a vigorous live-vaccine immunization campaign, the incidence had declined to around 0.5 to 0.75 per 100,000 by the mid-1980s. About 3,600 polio cases were reported from January to September 1989 – up substantially from the approximately 700 cases during the previous year (*China Daily* 1989).

Smallpox. The incidence of smallpox may have been as high as 200 per 100,000 population before 1949. A massive immunization campaign was started, and by 1953 over 50 percent of China's then 600 million population had been vaccinated. The last cases, in Tibet and Yunnan, were seen in 1960 (Kung 1953).

Trachoma. Trachoma, an infectious eye disease that can cause blindness, was a major public health problem in China. Half of the population was estimated to have been affected in the mid-1950s, and in some areas the prevalence may have reached 90 percent. Trachoma was estimated to have caused 45 percent of the visual impairment and between 25

and 40 percent of the blindness in China. Although the current prevalence is unknown, trachoma is no longer a public health problem. Education against towel sharing ("one person one towel, running water for washing face") had been very important as a control mechanism.

Tuberculosis. Tuberculosis was a leading cause of death in China in the late 1940s, with a death rate of 200 per 100,000 and a morbidity rate of 5,000 per 100,000 in major cities. At that time there were only 13 prevention and control institutions and five small prevention and control stations in the country, and only 7,500 people in all of China received bacillus Calmette-Guérin (BCG) vaccine as immunization between 1937 and 1949 (*Public Health in the PRC* 1986).

Government control efforts resulted in the creation of a tuberculosis prevention and control network to find, register, and treat patients at the earliest disease stage possible. In addition, BCG immunization campaigns were launched, with emphasis on newborns and on the reinoculation of primary school students. The BCG immunization campaign began in 1950, and by 1979 an estimated 500 million immunizations had been given. A sample survey in the latter year indicated that prevalence had been reduced to 717 per 100,000, with sputum-positive cases averaging only 187 per 100,000.

Since 1984, the Ministry of Public Health has promoted the creation of tuberculosis prevention and control in existing antiepidemic stations. By the end of 1985, 1,686 such institutions had been established at the county level, and there were 117 tuberculosis hospitals throughout the country. A sample survey of nine provinces and cities in 1984 found a prevalence of less than 500 per 100,000. The incidence remains high, however, in remote areas and those inhabited by minority nationalities (*Public Health in the PRC* 1986).

Typhoid and Paratyphoid Fevers. National data on typhoid and paratyphoid fevers were not available until recently. In 1975, Shanghai registered an estimated 600 cases of typhoid fever (Lampton 1977), and in 1985 there were an estimated 86,000 cases of typhoid and paratyphoid nationwide.

Venereal Disease. In the early 1950s, the prevalence of venereal disease in China was estimated at 3 to 5 percent in the cities, and as high as 10 percent among those who lived in the frontier areas (Lampton 1977). Extraordinary efforts were mounted to combat these diseases and were reported to have successfully "eradicated" them in China by the mid-1960s.

Patients with venereal disease, however, began to be seen again in 1984, and by 1988 "tens of thousands" of such cases had been reported. Preliminary reports from the country's 16 venereal disease inspection stations for the first 9 months of 1989 showed a 61 percent rise in new VD patients over the 1988 figure, bringing the cumulative total for the period to more than 220,000 (*China Daily* 1989). The highest incidence has been in coastal areas, such as Guangdong, Guangxi, and Fujian provinces, though cases have also been reported in Beijing, Shanghai, Tienjin, Harbin, and Xinjiang. More than 70 percent of the patients are male, and the most common diseases are gonorrhea, syphilis, and condyloma. According to the head of a national venereal disease prevention committee, the renewed spread "arises from the reemergence of prostitutes, the increased activities of 'sex gangs,' as well as changing attitudes toward sex on the part of some young people seeking sexual freedom" (*Beijing Review* 1988). In response, the State Council has issued a "strict ban" on prostitution; sex education courses have been widely introduced in middle schools; courses on venereal disease are being reintroduced at medical colleges; a national center for prevention and treatment of venereal disease has been established; and monitoring and treatment stations have been set up around the country.

Viral Hepatitis. Since the 1950s hepatitis has been increasing in many countries. In China, outbreaks have occurred in the northeast and north, with fluctuation in the incidence. In 1979–80 an extensive nationwide survey of the disease was conducted covering 277,186 people in 88 large, medium-sized, and small cities and 121 rural counties. Positive seroreactivity to anti-HBV averaged 71.4 percent and to hepatitis B surface antigen (HBsAg), 88 percent. Infection appeared predominantly in two peak age groups, those under 10 and those between 30 and 40 years; rates for males were higher than for females. HBsAg seropositivity was higher in family groups and did not seem to be particularly correlated with occupation (*Public Health in the PRC* 1986).

Viral hepatitis research became a priority under the sixth five-year plan (1981–5), with particular emphasis directed toward development of a low-cost vaccine and on the improvement of prevention and control measures. Research and development of a hepatitis B hemogenetic vaccine began in 1978 and was completed in 1983. Confirmatory tests in 1985

showed that the vaccine was safe and effective, and mass production is planned.

Responsibility for hepatitis prevention and control is vested in the sanitation and antiepidemic stations at all administrative levels. Stations collect and analyze morbidity data, conduct epidemiologic studies, and provide assistance to medical units, to patients' families, and to organizations on such matters as patient isolation, sterilization, food and water management, environmental sanitation, and personal hygiene. They also provide regular medical examinations to food industry and nursery personnel.

Strengthened hygienic legislation, standards, and administrative guidelines have also contributed to a reduction in the spread of both hepatitis A and B. For example, many hospitals have set up hepatitis wards to prevent hepatitis B from spreading. Special attention has been given to screening blood donors and to the strict management of blood products. Most health facilities now use disposable needles and syringes and have tightened the control and disposal methods of blood stained water and objects.

Chronic Diseases

Chronic diseases now account for almost two-thirds of all mortality in China and are expected to become even more significant in the future, owing to an aging population and to changing environmental and life-style factors. This section considers briefly the three main chronic disease categories: heart disease, stroke, and cancer.

Heart Disease. Heart disease is now the leading cause of death in China. Among the deaths from heart disease the causes are, in declining order of frequency, hypertensive heart disease, cor pulmonale, rheumatic heart disease, and coronary heart disease. The importance of coronary heart disease is, however, increasing rapidly.

Hypertension's contribution to stroke and renal disease as well as to hypertensive heart disease probably makes this condition the largest single risk factor for death in China. Based on age-specific hypertension rates observed in a 1979 national hypertension sample survey, by 2010 China could have more than 110 million cases of hypertension. With rising incomes, however, and a probable parallel rise in age-specific rates, this may be a low estimate.

Cor pulmonale, manifested by right ventricular hypertrophy and decreased output, appears to be linked to the high prevalence of chronic obstructive lung disease (COLD). This condition is most often the end result of pneumoconiosis secondary to air pollution from factories, transport, home cooking over open stoves, and, with increasing frequency, cigarette smoking. Although national statistics are still inadequate to distinguish between cor pulmonale and COLD, data from the Disease Surveillance Point (DSP) system covering a population of about 10 million will soon be able to provide better estimates of the magnitude of these and other health problems. COLD morbidity has been estimated at 20 times COLD mortality and appears to affect rural residents substantially more than those in urban areas.

Rheumatic heart disease has accounted for a major portion of heart disease morbidity and mortality in the past, but today, with the widespread use of antibiotics, its significance is on the decline. In 1986, an estimated 50,000 deaths resulted from this disease, with perhaps some 1 million infected.

Coronary heart disease, the main form of heart disease in the industrialized countries, is in fourth place in China but is expected to gain rapidly in importance as a result of the delayed effects of richer diets and more cigarette smoking. In four urban districts of Beijing, for example, the coronary heart disease death rate doubled from 71 per 100,000 in 1958 (10.8 percent of all deaths), to 141 per 100,000 in 1979 (25 percent of all deaths).

Cerebrovascular Disease. More commonly known as stroke, cerebrovascular disease is most often a complication of hypertension and is currently the third leading cause of death in China. In the same four urban districts of Beijing mentioned above, stroke was responsible for 152 deaths per 100,000 population in 1979 (27.3 percent of all deaths), as compared to 107 per 100,000 in 1958. The ratio of stroke to coronary heart disease mortality (a relatively small part of all heart disease mortality) in China is about 4:1 as compared with about 1:3 in the United States, though this is expected to change rapidly as the effects of dietary and smoking habits come to be fully manifest.

Cancer. Cancer has become one of China's top three causes of death. According to 1986 Disease Surveillance Point mortality data, the five leading cancers in men were, in rank order, lung, stomach, liver, esophagus, and colorectal, while for women cervix cancer replaced colorectal in fifth place. Those who live in urban areas have a 50 percent higher cancer mortality rate than do rural residents, and men are about 50 percent more at risk than are women, regardless of location. When compared with

the results of a retrospective survey of all deaths in mainland China for the years 1973–5, these data suggest that overall cancer mortality rates are rising, lung cancer is gaining in relative importance, and esophageal cancer may be declining.

Three examples from the 1973–5 survey illustrate the wide regional variations that can be observed in cancer mortality according to site, variations that have recently been mapped by the government's National Cancer Control Office. Nasopharyngeal cancer is virtually limited to south China, with the highest incidence in Guangdong Province, from which it decreases in concentric bands. Mortality due to cancer of the esophagus varies more than sixfold across China's counties, with higher prevalence locations often separated by long distances. Liver cancer tends to be concentrated in coastal plains in the southeast.

The diverse patterns in the geographic distribution of cancer have led to epidemiological research on selected cancers (see, e.g., Armstrong 1982). With 60 percent of all fatal cancers originating in the upper alimentary tract, particular attention has been given to the role of diet and food hygiene. Cancer epidemiology has also focused on trend analysis. Through such studies it has been found that whereas the incidence of stomach cancer in China has been decreasing in recent years, that of lung cancer has increased rapidly. This latter trend had been especially pronounced in urban areas and is presumably associated with rising levels of smoking, as shown by studies such as that by Y. T. Gao and colleagues (1988). High lung cancer rates have also been found in rural areas subject to serious problems of indoor air pollution (Chapman, Mumford, and Harris 1988).

Chinese authorities have recently begun to address the public health hazards of smoking. Surveys have found that some 69 percent of Chinese men and 7 percent of women above the age of 20 smoke, and, although the rate for women is still low, this is likely to increase rapidly in the future. Antismoking measures – including education, cigarette price increases, limits on tobacco production, and banning of smoking in certain locations – have not had much effect thus far. Rather, cigarette production increased 9-fold between 1949 and 1980. Chinese cigarettes have about double the world average of tar, and now with the government deriving significant revenues from the sale of cigarettes, and the sudden increase in the importation of foreign brands, the potential for a rapid increase in tobacco consumption is great indeed.

Occupational Diseases

The safety of the workplace has received increasing attention since the first industrial health organization was established in 1950. By 1985 there were more than 170 such organizations and industrial health sections at more than 3,300 sanitation and antiepidemic stations, and about 25,000 persons were employed in this field. Starting with the promulgation of regulations on the control of silicon dust at the workplace in 1956, health authorities have extended industrial health regulations until by 1985 there were 122 industrial health standards and 16 standards for diagnosing occupational diseases. The decline in the incidence of silicosis documents both what has been accomplished and what remains to be done. According to a recent study of silicosis in 26,603 dust-exposed workers at seven mines and industrial plants, the 8-year cumulative incidence of silicosis declined from 36.1 percent among workers employed before 1950 to 1.5 percent for those employed after 1960 (Lou and Zhou 1989). During the same period, the cumulative incidence of tuberculosis decreased from 54.7 to 16.7 percent, and the silicosis case-fatality rate declined from 53.9 to 18.3 percent. The average age at the detection of silicosis increased from 41.3 to 52.7 years from the 1950s to the 1970s, while the average survival times of silicosis patients increased from 2.0 to 12.2 years.

Nutritional Diseases

Endemic Fluorine Poisoning.   Endemic fluorine poisoning is a chronic disease caused by an excess in intake of fluorine. On the basis of epidemiological surveys, it is currently estimated that in all areas of endemicity there are some 21 million people suffering from fluoride-caused mottled enamel and 1 million from bone disease caused by fluorine poisoning (*Public Health in the PRC* 1986). Efforts to control the disease include the use of rainwater, along with wells and other low-fluorine water sources, for drinking purposes, and treating water supplies to reduce the fluorine content. The provision of fluorine-free drinking water became one of China's projects in a 10-year world program for attaining a safe drinking-water supply and environmental hygiene.

Endemic Goiter and Endemic Cretinism.   Endemic goiter is caused by lack of iodine in the diet. Surveys suggest that about 35,000,000 people in China suffered from endemic goiter and another 250,000 from endemic cretinism. However, over the past three decades more than 2,500 monitoring stations have

been set up to supervise the production, marketing, and use of iodized salt. By 1985 this salt was available to about 85 percent of the counties in the endemic areas, and as a result of these and other measures, over 22,000,000 endemic goiter patients have been successfully treated. The average incidence of the disease has been reduced to under 4 percent, and few patients with endemic cretinism are now found (*Public Health in the PRC* 1986).

Kaschin–Beck Disease.   This disease is a chronic degenerative osteoarthropathy of unknown cause. The major pathological changes include degenerative necrosis of leg and arm joints and of epiphyseal plate cartilage. The earliest written record of the disease was made in 1934, but it is believed to have existed in China for a long time.

Surveys conducted since the early 1950s show that Kaschin–Beck disease prevails in a wide area from the northeast to the southwest, covering 287 counties and cities in 15 provinces, autonomous regions, and municipalities. It is estimated that 1.6 million people suffer from the disease, 65 percent of whom are youths and teenagers. Disease incidence fluctuates substantially, and a rainy autumn usually results in an increased incidence the next year. There are three views as to the etiology of Kaschin–Beck disease: poisonous organic matter in water, the fusarium tox in grain, and excessive or insufficient trace elements in water, soil, and grain (*Public Health in the PRC* 1986).

Several methods have been used to prevent and treat Kaschin–Beck disease. One includes the use of deep wells, alternate water sources, or water treatment with active carbon and magnesium sulfate to improve its quality. A study done in Fusong County of Jilin Province from 1972 to 1977 showed that disease incidence for people drinking water diverted from nearby springs was 1.2 percent, as compared with 13.5 percent for those who continued to drink from old sources (*Public Health in the PRC* 1986).

Another method is to provide grain from non-affected areas to people in affected areas. Meanwhile, efforts are made to prevent grain in storage from becoming mildewed. A 7-year study in Shuangyashan City which compared two areas using the same water sources found no new cases in an area where outside grain was available. By contrast, the incidence continued to rise in the area using indigenous grain (*Public Health in the PRC* 1986).

More recent studies have demonstrated a relationship between selenium intake and Kaschin–Beck disease. Between 1974 and 1976, Gansu Province

used sodium selenite and vitamin E to treat 224 children suffering from the early-stage Kaschin–Beck disease. In areas where the disease is present, the lower the ambient selenium levels, the greater the prevalence. From 1981 to 1985, Shaanxi Province experimented with use of seleniumized table salt to prevent the disease. Measures to increase selenium intake, now used among more than 8 million people, are considered a major approach to the prevention of Kaschin–Beck disease (*Public Health in the PRC* 1986).

Keshan Disease.   Keshan disease is a myocardial disease found in a long, narrow strip of land covering 309 counties from northeast to southwest China. The disease is sudden in onset and often acute, with a high case-fatality rate of around 20 percent. Housewives and teenagers are at particular risk. Keshan disease has been endemic in China for about 100 years, and a 1935 outbreak of the disease in Keshan County, Heilongjiang Province, led to its name. Endemic areas have been found to have low selenium levels in the water, earth, grain, and vegetables, and residents suffer from a deficiency of selenium. Considerable success in reducing disease incidence has been achieved with oral sodium selenite, but selenium deficiency may not be the only cause.

Effective measures to prevent and control Keshan disease include keeping homes warm, dry, and free of smoke, ensuring safe drinking water, improved eating habits, early diagnosis, and treatment. The principal treatment methods are intravenous injection of high doses of vitamin C and blood expanders; oral selenite is used to prevent acute and subacute Keshan disease. There have been no widespread outbreaks of the disease for 15 years. In 1985, only 374 cases of acute and subacute Keshan disease were found, with 92 deaths, the lowest rates ever. The number of chronic patients has decreased from 220,000 in the early 1970s to 76,500 by the mid-1980s. A total of 4.1 million people now take oral selenite, contributing to the falling incidence (*Public Health of the PRC* 1986).

Summary
China has undergone a remarkably rapid epidemiological transition over the past 40 years, from a preponderance of deaths due to communicable disease to a preponderance of deaths due to chronic disease. As China looks ahead to the twenty-first century, with its reduced birth rate and longer life expectancy, it faces the prospect of ever higher percentages of older people. According to World Bank

estimates, by 2025 China could have 185 million people aged 65 and over or about 12 percent of its projected 1.5 billion population, and the burden of chronic disease will be great. With the 2025 per capita gross national product unlikely to exceed U.S. $2,000, China will find it very difficult to provide the high technology, institution-based care for chronic disease that has become the dominant pattern in industrialized countries. Innovative and inexpensive methods for the prevention of and care for chronic illnesses, for providing continuing patient care, and for maintaining past gains in the control of communicable disease, are therefore even more important in China than in the economically developed countries. These challenges will be all the greater as China undergoes major social, economic, and political changes that have reduced its ability to mobilize mass patriotic campaigns and to provide organized rural health care.

VI.4
Diseases of Antiquity in Japan

Our knowledge about diseases in the prehistoric era of Japan is extremely limited because not much paleopathological research has been done thus far. For the little information we have about the occurrence of diseases during the early historic period we have to rely on a small number of literary sources. One general assumption, however, may be made from the geographic situation of the Japanese islands: Prior to more extensive contact with the Asian continent, Japan may have been free from regular epidemics of certain contagious diseases such as smallpox and plague.

The most important sources on the early history of Japan are the *Kojiki* (The Ancient Chronicle), completed in A.D. 712, and the *Nihonshoki* (The Chronicles of Japan), completed in A.D. 720. Both these chronicles include references to diseases that af-

fected individuals, as well as to epidemics. The *Kojiki* informs us that there "raged many plagues" at the time of Emperor Sujin, who was supposed to be the first Emperor and to have reigned around the end of the third century A.D. The *Nihonshoki* confirms that "plagues spread out everywhere in Japan." These epidemics may have been caused by climatic irregularities at that period; one passage in this source states: "Because the winter and the summer exchanged their places and the cold and heat occurred in irregular order, the plagues spread and the people suffered." Considering the influence of these climatic changes on the crops, one may speculate that these epidemics were famine-related dysenteries. A passage in the *Nihonshoki* describes the symptoms of a princess at the court who had fallen ill, by stating that she "lost her hair and became very thin" – symptoms suggestive of high fever and dehydration that might accompany such forms of dysentery. On the other hand, it would appear unlikely that famine would have reached the immediate environment of the emperor. Hence, with so little information a diagnosis can hardly be made with any degree of probability.

Undoubtedly, poor sanitation and a lack of hygiene must have been responsible for epidemics of dysentery; these were recorded as *ribyō* or *kakuran*. The epidemic recorded for the year 861 was identified as *sekiri,* possibly meaning bacillary dysentery. From the first mention of this illness onward, it appears to have reappeared frequently. One of the representations on the *Yamai-no-Sōshi* (Scrolls of Disease) made during the twelfth century, at the end of the Heian Era, carries a caption stating that a woman "has a sharp pain in the bowels, vomits water, has diarrhea and stumbles around to create a strange spectacle"; these symptoms suggest bacillary dysentery.

Diaries written by members of the gentry of the same period refer to the occurrence of malaria. The *Anopheles* mosquito, the host of various types of plasmodia, seems to have been present in Japan at all times. Malaria was called either *okori* or *warawa-yami,* the latter meaning high fever and chills. Another name, also found in the scrolls, was *gyaku-shitsu*: According to this source, illness was characterized by fever and chills that recurred throughout an individual's life.

Tuberculosis, especially pulmonary tuberculosis, may also have been present in ancient Japan. Possible references to pulmonary tuberculosis are contained in certain passages in the *Genji-Monogatari* and in the *Makura-no-Sōshi,* the two greatest literary works of ancient Japan. In these passages, persons are said to "suffer from the chest." The *Ishinpō,* a collection of excerpts from Chinese medical books, compiled by the Japanese scholar Tamba Yasuyori in 984, records a disease called *denshi-byō*. The symptoms of this illness were similar to those of tuberculosis.

The *Ishinpō* also lists nine helminthic parasites, among which the tapeworm, roundworm, and pinworm can be identified; in ancient Japan all three were called *suhaku.* With the understanding that the Japanese compiler of this book selected subjects from Chinese medical literature that were applicable to the situation in Japan at the end of the first millennium, it seems safe to assume the existence of a wide array of parasitosis there as well. Another text of the period describes a woman suffering from *suhaku,* who was pale and had dropsical swellings. A physician drew from her body a white worm, 12 to 14 meters in length.

Although there are some indications of the existence of lice in ancient Japan, there is no proof for the occurrence of exanthematous typhus. Nor is there any source prior to the nineteenth century suggesting an outbreak of the bubonic plague, a disease that raged in China for decades around the turn of the eighth to the ninth century.

Beriberi, a disease caused by thiamine deficiency and often associated with cultures that relied on rice as staple food, was endemic in Japan. It was called, alternatively, *kakke, kakubyō,* or *ashinoke,* the latter meaning "illness of the legs." The oldest record of beriberi in Japan refers to the son of the Emperor Shōmu, who died of this disease in A.D. 744, at the age of 17 years. The *Ishinpō,* compiled one and a half centuries later, contains a detailed description of the symptoms, such as pain, paralysis of the legs, anasarca, and palpitations.

In A.D. 733, Yamanoueno Okura, the famous poet of the *Manyōshu* (the oldest existing anthology of poetry), died at the age of 74. According to his poem he had suffered from a disease for 10 years that caused him considerable discomfort: "The hands and feet do not move, every joint aches, the body is like a heavy stone and walking is difficult." Hattori Toshirō (1945) has concluded that this disease was rheumatoid arthritis. Others believe that arthritis deformans is a more likely possibility. Both conditions must have tormented ancient Japanese, whereas neuralgia of the hands and feet must have been quite common because of agricultural labor.

The oldest Japanese statutory law, the *Yōro-ryō,* enacted in 718, classified diseases of laborers and

military men into three grades, ranging from severe to relatively mild. Among the most severe of diseases was leprosy. In this text it is described as follows: "The intestines are eaten by worms, the eyebrows fall down, the nose is out of shape, the voice changes, the body bends over, and it is contagious." Leprosy was called *rai* or *rei* or else *tenkei-byō,* which means literally "disease of heavenly punishment." Although lepers were regarded as untouchables and had to be strictly separated from the healthy population, a Buddhist legend has it that Empress Kōmyō (701–60), while cleaning pus from a leper's body, discovered that the man was Buddha.

As in all premodern societies, skin diseases, particularly inflammatory afflictions, were known among the Japanese. The *Ishinpō* includes chapters on afflictions that can be identified as scabies, pustular and other forms of suppurative dermatitis, carbuncles, scrofula, felon, and erysipelas. Some sources indicate that gonorrhea and soft chancre occurred in ancient Japan, under the names *rinshitsu, bendoku,* and *genkan.* However, these terms appear in medical books only from the fifteenth century onward. Similarly, syphilis is encountered for the first time during this period. Japanese pirates apparently brought the bacterium into the islands from European ports in China.

Among the diseases of the nervous system, we have an illustration of cerebral apoplexy in the *Yami-no-Sōshi.* Not unfrequently, diaries and literary works describe instances of mental disorders that can be identified as schizophrenia, or other neurological conditions such as epilepsy.

A well-documented and typical case of diabetes mellitus may be found in the medical history of Fujiwara no Michinaga, a very powerful nobleman of the Heian Era. In 1016, at the age of 62 years, he began suffering from thirst, weakness, and emaciation. His disease was diagnosed as *insui-byō.* As the illness advanced, he suffered from carbuncles, developed cataracts, and finally died from a myocardial infarction. As a matter of fact, this disease was hereditary in this branch of the Fujiwara family: Michinaga's elder brother, his uncle, and his nephew all died of diabetes at fairly young ages.

The relative isolation of Japan long protected it from the great epidemics, such as smallpox, plague, and influenza, which raged in other areas of Asia. This isolation was, however, as William McNeill (1976) has pointed out, a "mixed blessing." As Buddhism flourished, and contacts with Korea and China increased, diseases that were endemic in these countries began to strike the dense and immu-

nologically defenseless population of the Japanese archipelago. Smallpox, most probably originating from India, reached China in the wake of Indian Buddhist missionaries via the Silk Road. It was first described by a Daoist, Ge Hong, in his *Zhou-hou beiji fang.* The first record of a smallpox epidemic in China appeared in the Jianwu Era (around A.D. 495), when it was called *hu-dou,* "barbarian pox." It spread to Korea, and eventually reached Japan with the first Buddhist missionaries, arriving there in 552. In the same year a series of epidemics started ravaging the country and continued periodically until 582. There is no proof as to whether the disease was smallpox in every instance; measles or influenza could have been similarly devastating. Since the relationship between the opening of the country and the arrival of these diseases was apparently understood, there is little wonder that opinions about the question of whether Buddhism should or should not be introduced to Japan divided society and the influential feudal families.

VI.5
Diseases of the Premodern Period in Japan

The role of disease in Japanese history is a topic that has attracted the interest of Western historians only recently. The strongest stimulus for the study of disease and its effects on Japan's premodern society was the publication of a new edition of Fujikawa Yū's classic *Nihon shippei shi* in 1969 with a foreword by Matsuda Michio (*A History of Disease in Japan*, originally published in 1912). Along with his *History of Japanese Medicine* (*Nihon igaku shi*, 1904), *A History of Disease in Japan* provided historians with a detailed list of many of the epidemics that ravaged the Japanese population in the premodern era, including original sources of information and a diagnosis of many diseases in terms of Western medicine. Hattori Toshirō supplemented and updated Fujikawa's work in the postwar era with a series of books on Japanese medicine from the eighth through the sixteenth century.

William McNeill also kindled interest with *Plagues and Peoples* (1976), a book that fit the disease history of East Asia into the context of world history. Both William Wayne Farris (1985) and Ann Bowman Jannetta (1987) have investigated pestilence in premodern Japan in detail, but the field is still relatively undeveloped, as compared to work on Western history. The influence of the *Annales* school of France on Japanese scholars, which began in the late 1970s, may draw more scholars into work on disease, especially for the well-reported but unstudied period between 1300 and 1600.

Data for the study of disease in Japan present both opportunities and frustrations. The quantity of information on disease, especially epidemic afflictions, is better than for most other civilizations, including possibly western Europe. The reason for this is that the Japanese imported the Chinese practice of reporting diseases among the common people around 700. Many of these reports were included in court chronicles in abbreviated form. The custom of reporting epidemics suffered, however, as the links between the provinces and the capital waned after 900, and many outbreaks of pestilence undoubtedly went unnoticed by the aristocrats at court who did the recording of disease. Moreover, even when the reporting system was operating at its best, the sources often do not provide important facts such as the nature of the

disease, the regions afflicted, or levels of mortality inflicted. In addition, local records that would enhance our knowledge of diseases that prevailed are largely lacking before 1100, and the job of ferreting through village and town documents for signs of pestilence after 1100 has yet to be attempted.

About the time that the Japanese government borrowed the Chinese custom of recording outbreaks of pestilence, it also borrowed their medical theory. The description, diagnosis, and treatment of disease in premodern Japan almost always derive from Chinese texts. Buddhist scriptures from India also influenced how disease and medicine were perceived in early Japan. It is unclear how much the Japanese knew about disease and its treatment before Chinese and Indian influences. Some medical practices reported during early epidemics may well derive from native roots, as during the Great Smallpox Epidemic of 735–7 (Farris 1985). For the most part, however, the native Japanese view of disease was that it was demonic possession to be exorcised by shamans and witch doctors.

It is important to distinguish between infectious diseases, which can create epidemics, and other afflictions, which, to use McNeill's terminology (1976), form the "background noise" to history. Japanese sources provide information on a wide variety of diseases, especially when they attacked a statesman, artist, or priest. However, it is often difficult to classify the illness in Western terms. For this reason, the focus of this essay will be chiefly on epidemic outbreaks, with occasional reference to identifiable, noninfectious ailments.

The relationship between disease and Japan's geography is significant in two respects. First, Japan presents a good case of "island epidemiology" (McNeill 1976). Because of its comparative isolation, Japan remained relatively free of epidemic outbreaks as long as communication with the continent was infrequent. Consequently, the populations grew dense. However, once an infectious disease was introduced to the archipelago, it ravaged those dense populations that had had virtually no opportunity to develop resistance to it. Thus, immunities were built up only slowly in a process that took centuries.

Second, because of Japan's mountainous terrain, one cannot always assume that an epidemic reached the entire Japanese populace at once. Severe outbreaks undoubtedly afflicted isolated villages and regions even in the Edo period (1600–1868). Certainly, more study of the important relationship between Japan's topography and transportation routes and disease transmission is needed.

The history of epidemics in Japan until 1600 (when Japan banned travel and trade with most nations) falls into four periods: (1) from earliest times to 700, when little is known about disease; (2) 700–1050, an age of severe epidemics; (3) 1050–1260, a transitional stage when some killer diseases of the past became endemic in the population; and (4) 1260–1600, a time of lessening disease influence despite the introduction of some new ailments from the West.

Pre–A.D. 700

The record of disease in Japan's prehistory is a matter of guesswork. In the earliest times, the Paleolithic (150,000 B.C. to 10,000 B.C.) and Neolithic (10,000 B.C. to 200 B.C.) periods, population was too sparse to sustain many afflictions. Evidence indicates that there was a Malthusian crisis in the late Neolithic epoch, about 1000 B.C., but archaeologists have not been able to discern any signs of infectious diseases in the skeletons of Neolithic peoples (Kitō 1983). The bronze and iron ages (200 B.C. to A.D. 300), when rice agriculture was imported from the Asian mainland, would seen to have been an age of great population increase and therefore of potential disease outbreak as well. However, again the archaeological record gives no indication of illnesses in those few skeletons that remain. Similarly, there is little evidence on disease for the era from 300 to 500.

700–1050

Most scholars of Japan agree that the historical age begins with the sixth century, and hard evidence of disease in the region also originates with this time. Japan's first court history, *The Chronicles of Japan*, records that in 552 many were stricken with disease. It is no accident that this epidemic occurred at the same time that the gifts of a statue of the Buddha along with sutras arrived at the Japanese court from Korea (Aston 1972). Disease doubtless also arrived with the carriers, although the court blamed the outbreak on the introduction of a foreign religion and destroyed the gifts.

In 585, the court again banned the worship of the Buddha, and this time chroniclers noted that many people were afflicted with sores. *The Chronicles of Japan* states that those attacked by the sores were "as if they were burnt," a condition suggesting fever. According to Hattori Toshirō (1943), the 585 epidemic was the first outbreak of smallpox in Japanese history, although it should be noted that some sources from later centuries record that the 585 epidemic was measles.

The 552 and 585 (*not* 587, as some have reported) outbreaks are the only signs of pestilence between 500 and the end of the seventh century. There are two ways to interpret the absence of data on disease for this epoch. First, the sixth and seventh centuries may have been relatively disease-free, in which case the era must have seen a population boom – a boom that would have coincided with the introduction of Chinese institutions into Japan. A second and more likely answer is that the chroniclers simply did not record epidemics. Sources from the period 500 to 700 are notoriously scarce and inaccurate. Moreover, during these two centuries Japan sent 11 embassies to China, received 7 from China, and had about 80 exchanges with Korea (Farris 1985). Given these contacts with the outside world, it is therefore conceivable that disease was an important feature of Japanese demographic history for the era 500 to 700.

Beginning in 698, it definitely was. Historical sources disclose an alarming number of epidemic outbreaks. There are 34 epidemics for the eighth century, 35 for the ninth century, 26 for the tenth century (despite a marked decline in the number of records), and 24 for the eleventh century, 16 of which occur between the year 1000 and 1052 (*SZKT* 1933 and 1966; Hattori 1945; Tsuchida 1965; Fujikawa 1969; and Farris 1985).

Because of this spate of pestilential outbreaks, the period from about 700 to about 1050 stands out as Japan's age of plagues. Records suggest that the diseases were imported from the Asian mainland as the Japanese traveled to China and Korea to learn of superior continental political and cultural systems and to trade. Disease became a major influence on Japanese society, shaping tax structure, local government, land tenure, labor, technology, religion, literature, education, and many other aspects of life. Certainly, the epidemics in these centuries held back economic development of the islands. On the other hand, by undergoing such trauma early in their history, the Japanese people built immunities at a relatively early date and thus escaped the onslaught of diseases that came to the civilizations of the Incas, Aztecs, and others with Western contact in the sixteenth century.

Unfortunately, historical documents do not often reveal the nature of the diseases in question. Historians can identify only five of them: smallpox, measles, influenza, mumps, and dysentery. In addition, McNeill (1976) has suggested that plague may have found its way to Japan in 808, and his argument has a great deal to recommend it. Plague was then afflicting the Mediterranean and the Middle East, and

Arabic traders and sailors frequented Chinese, Korean, and Japanese ports. Denis Twitchett (1979) has shown that China received many diseases from the West via the Silk Route. The presence of plague in Japan would also go a long way in explaining several severe epidemics that have yet to be identified. Yet because there is no description of symptoms by the Japanese sources, the existence of plague in Japan during this period remains in doubt.

Smallpox

The most deadly killer among the five diseases that are known to have assaulted early Japan was smallpox (*mogasa*, "funeral pox"). Epidemics of the pestilence are listed for the years 735–7, 790, 812–14, 853, 915, 947, 974, 993–5, 1020, and 1036 (compiled from data in *SZKT* 1933; Hattori 1955; Fujikawa 1969; Farris 1985). During this era, especially in the eighth and ninth centuries, smallpox was primarily a killer of adults. According to Jannetta (1987), smallpox had become endemic in the population by 1100 or even earlier, but the basis for this belief is not clear.

The best example of a smallpox, and indeed of any epidemic in this period, is the Great Smallpox Epidemic of 735–7, the earliest well-reported smallpox epidemic in world history (Farris 1985). It began in northern Kyushu, transported there by a Korean fisherman. The foreign port of Dazaifu was the first to feel the effects of the disease, a sure sign that the affliction was imported. Kyushu suffered throughout the summer and fall of 735, and the disease raged again in 736. Just as the epidemic was burning itself out in western Japan, a group of official emissaries to Korea passing through northern Kyushu encountered the ailment and carried it to the capital and eastern Japan. The epidemic assaulted all levels of Japanese society, killing peasant and aristocrat alike. One record reads that "in recent times, there has been nothing like this" (Farris 1985).

Two remarkable records survive that describe the symptoms and treatment of smallpox. The disease began as a fever, with the patient suffering in bed for from 3 to 6 days. Blotches then began to appear, and the limbs and internal organs became fevered. After the fever diminished and the blotches started to disappear, diarrhea became common. Patients also suffered from coughs, vomiting, nosebleeds, and the regurgitation of blood.

The prescribed remedies are as fascinating as the descriptions of the symptoms. Government doctors trained in Chinese, Indian, and native medicine advocated a variety of palliatives, including wrapping the patient in warm covers, drinking rice gruel, eating boiled scallions to stop the diarrhea, and forcing patients with no appetite to eat. Medicines were seen as of little use against the disease. After the illness, those who recovered were admonished not to eat raw fish or fresh fruit or vegetables, drink water, take a bath, have sex, or walk in the wind or rain. Doctors also advocated mixing flour from red beans and the white of an egg, and applying the mixture to the skin to eliminate the pox. Bathing in a woman's menstrual flow or wrapping a baby in a menstrual cloth to wipe out the blotches; and applying honey, powdered silkworm cocoons, white lead, or powdered falcon feathers and lard was also suggested.

Tax records extant from the time of the epidemic provide a glimpse of the mortality inflicted by the Great Smallpox Epidemic of 735–7. In the year 737 alone, the province of Izumi near the capital lost 44 percent of its adult populace, while Bungo in northern Kyushu and Suruga in eastern Japan sustained death rates of about 30 percent. The average mortality for all known areas was about 25 percent in 737 alone. Population depletion for the 3 years probably amounted to between 25 and 35 percent, making the Great Smallpox Epidemic of 735–7 comparable in its death toll to the European Black Death of the fourteenth century.

Disastrous as it may have been, one great outbreak of pestilence would not have halted demographic growth for long. But harsh epidemics continued to follow on its heels. In 790, smallpox struck again, borne from Chinese ports and afflicting those aged 30 or less. The historical record is fragmentary and difficult to read for the epidemic of 812–14, but it seems likely that the dread killer entered Japan via its foreign port in northern Kyushu as early as 807 and spread across the archipelago to the east. According to the records, "almost half" of the population died. In 853, the disease seems to have focused on the capital, Heian (modern Kyoto), but the epidemic also spread to the countryside.

The disease, however, still seems to have been primarily an ailment of adults. In 925, for example, the Emperor Daigo contracted smallpox at the age of 41. The smallpox outbreak of 993–5 was particularly severe. In 993, the Emperor Ichijō was a victim at the age of 15, but the disease was probably not yet endemic, as smallpox appeared in Kyushu the next spring, suggesting a foreign source. The disease was so bad in the capital that 70 officials of the fifth court rank or higher died; the roads were littered with corpses serving as food for dogs and vultures. In

1020 smallpox returned to Kyushu again, possibly reaching Japan with one of the continental invaders the year before. A diary states that those aged 28 and under were especially afflicted (Tsuchida 1965; Farris 1985).

Measles

The second killer disease that attacked the Japanese populace in the era between 700 and 1050 was measles (*akamogasa,* "red pox"). Two epidemics are known, in 998 and 1025, although it is not clear that Japanese doctors were always able to distinguish between measles and smallpox in this early age. Nonetheless, *A Tale of Flowering Fortunes,* a chronicle of the tenth and eleventh centuries, clearly differentiates the 998 affliction from smallpox, stating that the disease caused a "heavy rash of bright red spots" (McCullough and McCullough 1980). The pestilence began in the early summer in the capital, where the wives of high officials were the first affected. Foreigners did not die from the disease, a clue that reinforces McNeill's (1976) thesis about Japan's island epidemiology. Later in the year, the ailment attacked the rest of Japan, killing more people than any other in recent memory.

In 1025, measles once again returned to Japan. The disease afflicted people of all classes who had not suffered from the disease in the 998 epidemic. The diaries of aristocrats indicate that several noble houses suffered from the illness. The focus of the disease seems to have been the capital, although one source states that "all under heaven" caught the malady.

Influenza

A third ailment was influenza (*gai byō* or *gaigyaku byō,* "coughing sickness"), which struck in 862–4, 872, 920, 923, 993, and 1015 (Hattori 1955; Fujikawa 1969). Unlike smallpox and measles, which were most active in the spring, summer, and fall, influenza generally struck in the late winter and early spring. The epidemics of 862–4 and 872 were particularly severe, killing many people in the capital region. In general, however, the death toll from influenza probably did not match the mortality from smallpox or measles.

Mumps

Mumps (*fukurai byō,* "swelling sickness") was the fourth epidemic illness encountered by the Japanese in this period. Records state that the disease flourished in 959 and 1029, mainly in Heian, the populous capital of the era. In both epidemics, historians indicated that the sickness was marked by a swelling of the neck.

The final pestilence of the age of plagues was dysentery (*sekiri,* "red diarrhea"). Epidemics are documented for 861, 915, and 947 (Hattori 1955). The season for dysentery was the late summer and fall. Often dysentery appeared in tandem with other afflictions, as in the Great Smallpox Epidemic of 735–7. The dysentery epidemic of 861 was followed by influenza in 862 and 863. In 915 and 947, smallpox was again an accompanying malady. The measles epidemic of 1025 was also probably related to dysentery infections among the Heian nobility. Their diaries indicate that when patients caught dysentery they quickly lost their appetites and suffered from fever.

Other Maladies

In addition to these five epidemic afflictions, other illnesses were common among the populace. According to *The Pillow Book,* a series of essays written by a lady at court (Sei Shōnagon) about the year 1000, the three diseases most feared by the tiny coterie of aristocrats at the Heian court were chest trouble (*munenoke*), evil spirits (*mononoke*), and beriberi (*ashinoke*). Chest trouble undoubtedly refers to tuberculosis, although Hattori (1975) suspects that heart-related afflictions were also common. Tuberculosis is one of the oldest diseases known to humanity, and it may have been that because the tuberculosis bacillus is often transmitted via unpasteurized milk, the aristocracy contracted the malady by eating a yogurtlike food product of which they were fond. Evil spirits suggest mental illnesses, and Hattori (1975) has found evidence of schizophrenia, autism, and manic-depressive behavior in the imperial line. Beriberi, a disease caused by a deficiency of thiamine (probably due to a lack of fats in aristocratic diets), is noted in several sources for the early period (Hattori 1964).

Some diseases were never diagnosed by court doctors who were trained only in Chinese medicine. Japanese records tell of a "water-drinking illness" (*mizu nomi yami*) common to the Fujiwara family, the mating line for the imperial house (Hattori 1975). According to Hattori, this disease was diabetes, and was hereditary in that family. Several prominent Fujiwara statesmen, including the great Michinaga (the model for Prince Genji in *The Tale of Genji*), complained of the malady and its related afflictions such as glaucoma and impotence (Hurst 1979).

Another malady that did not kill many victims

but had a great effect on all levels of society was malaria (*warawayami, furuiyami,* or *okori,* "the chills"). Even Prince Genji himself suffered from the malady (Seidenstecker 1985). Doctors of this era were unaware that the disease could be carried by mosquitoes, although a court lady seemed to believe that butterflies were common where the disease broke out. Japan is a land with many swamps; it is interesting to speculate about the effects of malaria on a peasantry trying to convert these low-lying lands into productive rice paddies.

In addition to the plentiful information on diseases supplied by court histories, literature, and other records, medical texts and an encyclopedia called the *Wamyō ruijū shō* also list medical terminology (Hattori 1945). Among the infections included are idiopathic cholera (*shiri yori kuchi yori koku yamai, kakuran*), leprosy (*raibyō*), elephantiasis (*gejū*), bronchitis (*shiwabuki yami*), hepatitis (*kibamu yamai*), dropsy (*harafukuru yamai*), ascarids (*kaichū*), threadworms (*gyōchū*), meningitis (*fubyō*), infantile dysentery (*shōji kakuran*), diphtheria (*bahi*), bronchial asthma (*zensoku*), epilepsy (*tenkan*), chronic nephritis (*shōkatsu*), tonsilitis (*kōhi*), osteomyelitis (*fukotsuso*), thyroiditis (*ei*), erysipelas (*tandokusō*), ringworm (*sensō*), gastritis (*iso*), palsy (*kuchi yugamu*), and scabies (*kaisō*). Records from the era 700–1050 also have led scholars to infer the existence of cancer, pneumonia, tapeworms, rheumatoid arthritis, and hookworms.

Effects of Plagues on Japanese Society

The effects of the age of plagues (700–1050) on Japanese society and culture were many and varied. Parallels with the Black Death pandemic that struck western Europe in the fourteenth and fifteenth centuries are tempting to draw, and it may be true that pestilence stimulates the same human responses in widely disparate societies. In the social and economic realm, the epidemics were responsible for several phenomena. First, disease caused population stagnation. Sawada Goichi estimated the population of Japan at 6 million in the eighth century, and it is unlikely that population grew significantly through the year 1050 (Kitō 1983).

Second, plagues caused the desertion of villages. After the Great Smallpox Epidemic of 735–7, an entire layer of village administration was abolished. Later, after the epidemics of 990–1030, the court once again abandoned the current village system in favor of new laws.

Third, pestilence inhibited agriculture, especially rice monoculture, because it became difficult to culti-

vate lands continuously. In 743, after the 735–7 outbreak, the aristocracy attempted to stimulate farming by enacting a policy giving permanent private tenure to anyone who would take up a hoe. In 1045, lawgivers countered unparalleled field abandonment by recognizing all previously banned estates.

Fourth, outbreaks of pestilence stimulated migration and made for a shortage of laborers. The court enacted legislation to bind peasants to their land throughout the eighth and ninth centuries, but to little effect. Labor shortages often made it difficult to finish temple construction or rice planting on time, and by the year 800, the court had given up capital construction and the conscription army.

Fifth, disease was responsible for a growing maldistribution of income. A new class of regional strongmen, called the "rich" in the documents, came into being by capitalizing on opportunities arising from famines and epidemics. The "rich" often resorted to violence to resist provincial tax collectors and exploit the peasantry.

Sixth, the stagnation of population growth resulting from disease reduced the demand for manufactured goods. At the same time, because epidemics kill people but do not destroy wealth, survivors of the pandemic among the aristocracy were left with great riches. Reduced overall demand and the increased opulence of a few gave rise to industry that produced luxury goods for a tiny elite.

In the political realm, epidemics brought several alterations in tax structure. After the Great Smallpox Epidemic, provincial governors were converted into tax farmers, which put them into competition for revenues with the leaders of the smaller district units that comprised the province. The competition for taxes among local officials while the tax base was shrinking helped engender a society that looked to violence to solve its problems. By 1050, the district had disappeared as a unit of administration, primarily because it could not compete with the larger province. Moreover, epidemics provided political opportunities. After the 735–7 epidemic, for example, all four of the Fujiwara brothers from a powerful aristocratic family had passed away, and Tachibana no Moroe, a bitter rival, became the new head of the government. Or again in 994, when smallpox raged in the capital and many aristocrats fell victim, a beneficiary of the deaths was Fujiwara no Michinaga, who became perhaps the greatest of all Fujiwara leaders.

In addition, disease influenced inheritance. To cope with the horrendous number of deaths of family members from plagues, the aristocracy practiced polygamy. Often property and children were retained

in the woman's line against the advent of an untimely demise by her husband. Survivors inherited unparalleled wealth and political power.

Finally, plagues reduced the size of administration. In the early eighth century, the government bureaucracy numbered about 10,000 persons. By the early ninth century, leaders were already cutting back the size of government, and although hard figures are difficult to come by, the bureaucracy did not again reach that size until the fourteenth century.

The age of plagues also influenced religion and culture. Unquestionably, the epidemics played a role in both the adoption of Chinese culture in the eighth century and a return to the native culture in the tenth and eleventh centuries. It is unlikely that the Japanese of the 700s borrowed Chinese civilization simply because it seemed superior to their own. Only coercion, such as military force or epidemic disease, would have inspired the Japanese to adopt such an obviously foreign culture. On the other hand, disease played a role in the demise of Chinese culture in Japan because the constant plagues killed off experts in Chinese language and the classics, thus making these subjects harder to learn. Disease was also a factor in the development of a major motif in Japanese literature, *mono no aware,* the ephemeral nature of all living things. Disease is a constant presence in the classic *The Tale of Genji,* which includes reference to an epidemic (Seidenstecker 1985). Many of Genji's friends and lovers pass away after the briefest time, and in most cases the villain was disease. To have reached one's forties was considered to have lived a long life (Hattori 1975).

The repeated outbreaks of pestilence also influenced Japanese religion profoundly. The introduction of Buddhism occurred amidst a plague of smallpox. As a transcendental religion, Buddhism was perfectly adapted for an environment in which disease outbreaks were common. Early believers reached out to Buddhism because of the promise of protection from illness. After the Great Smallpox Epidemic of 735–7, the Emperor Shōmu increased state support of the religion by ordering the construction of the great state temple Tōdaiji and branch temples throughout the countryside. By the tenth and eleventh centuries, Buddhism had become a faith of good works, as Christianity was during the plague pandemic in the fourteenth and fifteenth centuries. The frequency of pilgrimage in both religions is another striking parallel. By the eleventh century, Japanese religious thought was characterized by pessimism and a flight from the intellect. Millennialism, symbolized by "the latter day of the law"

(*mappō*), dominated Japanese thought. According to this doctrine, three ages of 500 years each followed the death of the Buddha: the first era, when salvation was simple; the second, when it was more difficult; and the latter day, when delivery from hell would come to just a few. Ironically, the latter day was believed to begin in 1052, just as the epoch of plagues drew to a close.

Popular culture also reflected a concern for disease. The Gion Festival, today celebrated from the July 17 to July 24 (the 14th of the sixth month according to the old lunar calendar) began as an attempt to rid the capital of Heian of epidemics. The festival was first conducted by Gion Shrine (later Yasaka Shrine) in eastern Heian in 869, just after an epidemic. Sixty-six spears, one for each province in Japan, were placed on end and marched through the city to chase the disease away. In 970 the festival became an annual affair, suggesting the growing endemicity of disease in the capital.

The smallpox pestilence of 993–5 gives another rare glimpse of popular reaction to epidemics. Late in the sixth month of 993, a festival to drive away disease gods was held in the Kitano section of the capital. Two palanquins were built by the government, Buddhist monks recited a sutra, and music was provided. Several thousand persons gathered and offered prayers to the gods. The palanquins, invested with the gods of the epidemic, were then borne by the populace several miles to the ocean to wash the smallpox affliction away (Tsuchida 1965; Fujikawa 1969).

1050–1260

The era from 1050 to 1260 marks a time of declining importance of disease in Japan. There were 50 epidemics over 210 years, an average of one outbreak every 4.2 years, compared to one epidemic every 2.9 years in the 700s and one every 3.8 years in the poorly documented 900s (cf. Hattori 1955, 1964; Fujikawa 1969). The killers of the former age retreated into endemicity. As always, the record is most complete for smallpox. Epidemics broke out in 1072, 1085, 1093–4, 1113, 1126, 1143, 1161, 1175, 1177, 1188, 1192, 1206–7, 1225, 1235, and 1243 (cf. Hattori 1955, 1964; Fujikawa 1969). Although some plagues of smallpox appear to have been severe, especially those in 1072 and 1175, the disease showed clear signs of becoming an affliction of childhood. A letter of 1085 records a mother's concern for her infant who had contracted smallpox (Hattori 1975). In the late twelfth century, Minamoto no Yoriie, the eldest son of the great warrior leader Yoritōmō, had smallpox as a boy. His sick-

ness seems to suggest the growing significance of the disease in eastern Japan, away from the greatest centers of population. The record of the 1243 epidemic of smallpox specifically states that the disease afflicted young children, which led McNeill (1976) to assert that the ailment was endemic by that date.

In the case of measles, epidemics struck in 1077, 1093–4, 1113, 1127, 1163, 1206, 1224, 1227, and 1256 (Fujikawa 1969). In the plague of 1077, young children were afflicted, although the record also reveals that many adults died. That the 1224 affliction seems to have attacked mainly young children, however, suggests to McNeill (1976) that, like smallpox, measles was probably endemic by that time. On the other hand, Jannetta (1987) has found evidence that the disease was still a foreign-borne plague as late as the nineteenth century. Analysis of additional records between 1200 and 1600 is still required to determine the precise status of measles in Japanese history, but it is important to note that at least Jannetta agrees with McNeill that the disease was not a major factor in the region's demographic history by 1200.

Influenza, a disease for which no permanent immunity is conferred, took a devastating toll in the era 1050–1260. According to the records, epidemics occurred in 1150, 1228, 1233, 1244, and 1248. The outbreak in 1150 was extremely severe, carrying off many elderly persons. The epidemic of 1244 was also harsh, afflicting all those aged 10 and above. An important reason for the grave plagues of influenza was undoubtedly the weather, which turned much colder and damper after 1150 (Kitō 1983).

Dysentery also continued to attack the populace. There is evidence of a dysentery outbreak in the year 1077, and prominent individuals contracted the malady in 1144, 1240, and 1243 (Fujikawa 1969). As during the age of plagues, the malady usually accompanied other diseases; the 1077 affliction of dysentery coincided with a measles epidemic.

In addition to diseases from the previous era, the period 1050–1260 also witnessed the first accounts of a new ailment. Fujikawa (1969) argues that in 1180 the Japanese first became aware of the existence of a smallpox-like affliction that may have been chickenpox. Eventually, doctors in Japan came to call the disease "water pox" (suitō or henamo), and chronicled an epidemic in 1200. It is unlikely that the disease had a great demographic impact, and may well have existed in Japan long before the Japanese medical establishment became aware of it.

A disease that gained new prominence in the era from 1050 to 1260 was leprosy (raibyō). Although this affliction appears in records as early as the eighth century, Hansen's disease seems to have become a serious social problem in the thirteenth century. The colder climate probably caused people to huddle together, thereby facilitating the transmission of the malady as in western Europe. Healthy commoners spurned lepers and treated them as outcasts. The Buddhist monk Ninshō became renowned for his treatment of lepers in a sanatorium at Kuwagatani. The Portuguese missionary Luis de Almeida would gain a similar reputation for his work in the 1500s (Hattori 1964, 1971).

Medical texts and other sources list other ailments as well; they include cirrhosis of the liver (daifuku suichō), bronchitis, dropsy, idiopathic cholera, hepatitis, worms, malaria, furunculosis (ōryō shi), diabetes, and tuberculosis (denshi byō). The Hanazono Emperor and Fujiwara no Kanezane were afflicted with beriberi (kakke), whereas the poet Fujiwara Teika suffered from repeated bouts with bronchial asthma (Hattori 1964).

Because the effects of disease in the age 1050–1260 were limited, especially during the period 1050–1150, decreasing mortality from both old and new afflictions possibly spurred some population growth. Demographic expansion was particularly evident in the Kantō region (modern Tokyo and vicinity), as the warriors cleared lands for cultivation. The land clearance of this epoch was the basis for the estate (shōen) system adopted in the late eleventh century. The extent of population growth, however, remains undetermined.

Yet, no matter how much the impact of pestilence on Japanese society decreased during the years 1050–1150, there is little doubt that disease combined with unusually harsh weather in the following century to restrict population growth. Temperatures turned much colder and the amount of moisture increased dramatically, especially in eastern Japan where there was the greatest potential for growth. In three years – 1182, 1230, and 1259 – the inclement weather induced widespread famine and accompanying sicknesses. The Great Famine of 1230 was said to have killed one-third of the population. In all three cases, epidemics assisted famine as Grim Reapers of the peasantry. Thus, despite the growing endemicity of many formerly severe diseases, the poor performance of the agricultural sector greatly restricted Japan's potential for population growth.

1260–1600

The final era in the history of disease in Japan before 1600 encompasses the years 1260–1600, which

are critical for any real comprehension of the role of pestilence in Japanese history. Yet this period has not been investigated in detail by historians, although they have access to thousands of unpublished records from this era. Fujikawa (1969) has listed some of the epidemics for this epoch, but, as Jannetta (1987) and Hattori (1971) have pointed out, it is likely that he has missed some. A major difficulty is that reporting mechanisms of disease were hindered by warfare, especially in the periods 1333–65 and 1460–1550. Thus, records kept at the capital in Kyoto are simply inadequate for the systematic analysis of disease in this period.

Despite problems with the sources, however, broad contours can be sketched if this age is broken down into three subperiods: 1260–1420, 1420–1540, and 1540–1600. In the first subperiod, harsh weather and war assisted disease in limiting population growth from 1261 to 1365. There were 29 epidemics over this 105-year span, or one every 3.6 years. From 1366 to 1420, there were 16 epidemics, or one every 3.4 years. The era included smallpox outbreaks in 1314, 1342, 1361, 1365, and 1374, with that of 1365 appearing to have been the only harsh epidemic. Measles is recorded for 1306–7, 1320, 1362, 1380, and 1405 and afflicted mainly children in 1306–7. Influenza struck in 1264, 1329, 1345, 1365, 1371, 1378, and 1407–8, with the attacks of 1365 and 1371 being particularly widespread; Hattori finds strong evidence that, beginning in the 1300s, more people suffered and died from respiratory diseases than smallpox or measles. No epidemics of dysentery or chickenpox are documented (Hattori 1964; Fujikawa 1969).

Perhaps the most important event in the disease history of Japan during the years 1260–1365 was one that did not occur. In 1274 and 1281, the Mongols attempted to invade the archipelago, but failed both times; in the last invasion, Japan was saved by the intervention of the "divine winds" of a typhoon. As McNeill (1976) has argued, the Mongols carried the plague bacillus from southern China, where it was endemic, to new territories such as China proper and western Europe. If the Mongols had succeeded in their invasion of the islands, then Japan, too, undoubtedly would have suffered from the plague. But Japan remained plague-free, population continued to grow, and the country moved toward an agrocentric society, a condition western Europe avoided in the plague pandemic of 1350–1450.

Although the historical record is difficult to read for the era 1421–1540, it appears that disease remained an important factor in demographic change.

The period contains 45 epidemics of various descriptions, or one outbreak of pestilence for every 2.7 years, representing an increase over the previous era. Smallpox was particularly active, coming in 1452–3, 1477, 1495, 1523, 1525, 1531, and 1537. In all years excepting 1495 and 1525, however, the disease struck only children. The Portuguese missionary Luis Frois wrote that nearly all Japanese bore pockmarks from smallpox, and he believed that the ailment was more severe among the Japanese than the Europeans (Fujikawa 1969; Hattori 1971).

Measles appeared more frequently, as well, attacking the populace in 1441, 1471, 1484, 1489, 1506, and 1513. The outbreaks of 1471, 1484, and 1512 were harsh, killing many people of all ages. Influenza is recorded as epidemic in 1428 and 1535. Dysentery and chickenpox are not documented. The era 1460–1550 was a period of chronic warfare in Japan, which leads one to suspect a link between the increased social strife and the higher incidence of pestilence (Fujikawa 1969; Hattori 1971).

The period from 1540 to 1600 was an era of great population growth in Japan, which represents the beginning of the Edo demographic explosion. Evidence of 14 epidemics has survived in the records, or one for every 4.3 years (Fujikawa 1969; Hattori 1971). An epidemic of 1593–4 should probably be linked to Hideyoshi's invasion of Korea. Smallpox was present only in 1550, and measles struck only in 1578 and 1587. Influenza was reported in 1556, when many children died, but, again, dysentery and chickenpox are not noted in the historical record.

In 1543, the first Westerners visited Japan, but unlike notable other areas, Japan did not suffer unduly from this new contact. Only two new diseases entered the archipelago at this time. The first was syphilis, which may also have been a new ailment in western Europe. The first appearance of syphilis in Japan, however, predates contact with Westerners, for it arrived in 1512 (Hattori 1971, citing Fujikawa). The Japanese immediately dubbed syphilis the "Chinese pox" (tōgasa), and often confused it with both leprosy and smallpox. Frois wrote that syphilis did not cause the embarrassment to the Japanese that it did to the Europeans (Hattori 1971). Its demographic impact was probably small.

The second new disease was introduced directly by the West, specifically by the Portuguese (Boston Globe 1984). Robert Gallo, chief of the Laboratory of Tumor Cell Biology at the National Cancer Institute, has discovered an AIDS (acquired immune deficiency syndrome) virus in the blood of many Japanese living in the southern islands. The virus is

called human T-cell leukemia/lymphoma virus (HTLV) I and II, and is somewhat different from the AIDS virus found in the United States, which is named HTLV-III. Of the southern Japanese people who are infected with the virus, only 1 person in 80 develops cancer. The rest suffer from a viral disease, characterized by fever, rash, and malaise. Gallo surmises that Portuguese sailors coming to Japan in the 1500s brought infected monkeys and African slaves, who transmitted the disease to the Japanese population. Historical records betray no evidence of this malady.

The other diseases of the early modern period in the West, such as typhus, do not appear to have been transported to Japan until the Edo period. Thus the Japanese were extraordinarily fortunate when compared to the natives of the New World or the southern Pacific, who were subjected to the onslaught of unfamiliar Western parasites. Many inveterate afflictions, such as malaria, beriberi, dysentery, asthma, pneumonia, worms, idiopathic cholera, dropsy, hepatitis, diabetes, chickenpox, rheumatoid arthritis, tuberculosis, and stomach cancer, continued to leave their mark on Japanese culture. Musō Kokushi, the Zen prelate, died of malaria, whereas several Ashikaga shoguns probably had diabetes.

Recapitulation

The history of disease in Japan over the era 500 to 1600 can be divided into four subperiods. During the first, 500 to 700, evidence indicates the importation of maladies such as smallpox, and frequent communication between the Japanese and their continental neighbors would suggest that epidemics were more common than the sources indicate.

In the second subperiod, from 700 to about 1050, the population suffered from repeated devastating epidemics of killer diseases including smallpox, measles, influenza, dysentery, and mumps. These important infections attacked a population that by and large had no immunities and killed great numbers of adults. The epidemics resulted in population loss, agricultural stagnation, a shortage of labor, revisions in laws dealing with land tenure, tax structure, and local government, a growing maldistribution of income, the rise of a transcendental religion (Buddhism) and millennialism, as well as a sensitivity to the evanescence of life in literature. Other important diseases of this age of plagues included beriberi, malaria, diabetes, and tuberculosis.

The third subperiod, 1050–1260, saw the killer infections of the former period transformed into endemicity and thus to childhood illnesses. It is fairly clear that smallpox and measles were attacking primarily children by the mid-thirteenth century, and probably even earlier. Influenza, however, may have grown in virulence, especially after 1150, when the climate turned colder and wetter. Other serious maladies included leprosy and chickenpox. The period from 1050 to 1260 may have seen some demographic expansion, notably in the east, but disastrous weather patterns and ensuing famine and pestilence began to close this "window of opportunity" around 1150.

The last subperiod, 1260–1600, represented an epoch when disease had a decidedly decreased impact on the archipelago. The Japanese escaped importation of the plague by defeating the Mongols in the 1200s, and by 1365 neither infection nor famine nor war was restricting the growth of Japan's population. The era 1420–1540 may have seen some increased virulence of disease, accompanied by civil war, but the second half of the sixteenth century was remarkably disease-free. Two new infections, syphilis and a relatively harmless variant of the AIDS virus, were brought to Japan from the West, but the effect of these ailments seems to have been limited.

Examination of the sweep of 1,100 years of disease history suggests that demographic trends in Japan were almost the mirror opposite of western Europe. Only in the eras 1050–1150 and 1500–1600 did Japan and the West both experience population growth. To the extent that one equates population growth with economic growth, it seems clear that Japan and western Europe were each led along substantially different paths by a differing biological past.

VI.6
Diseases of the Early Modern Period in Japan

The diseases of early modern Japan (the Tokugawa period) are of particular interest to the history and geography of disease. The Japanese Islands, situated as they are at the far eastern periphery of East Asia, had relatively little contact with the people of other world regions until the late nineteenth century. Historically Japan's isolation afforded the people some measure of protection from exposure to certain of the world's diseases, and in the early seventeenth century, the Tokugawa shoguns reinforced this natural protection when they imposed severe restrictions on foreign contacts. They limited official foreign trade to the port of Nagasaki, restricted the number and the nationality of ships that could enter that port, denied mobility beyond the port to the crews of foreign ships, and prohibited the Japanese from going abroad and returning to Japan. These policies were a response, in part, to the unwelcome activities of Westerners who had begun to reach the islands in the second half of the sixteenth century. They remained in effect until a

U.S. fleet forced Japan to open its ports to international commerce in the 1850s.

Elsewhere explorers, adventurers, traders, and settlers were circumnavigating the globe, carrying new diseases to previously unexposed peoples, and causing waves of high mortality among the populations of many world regions. By 1850 the increasing volume of international contacts had produced a worldwide system of disease dissemination, but Japan, remaining aloof from world affairs, had also remained largely unaffected by the epidemiological events of the early modern world. The diseases of Tokugawa Japan were, for the most part, diseases that had reached the islands centuries earlier.

Japan was part of an East Asian disease dissemination system that differed in certain respects from that of western Eurasia. Human populations in East Asia were larger and more dense than those in the West, and many human disease organisms were able to establish permanent reservoirs of infection with little difficulty. In earlier times, epidemic diseases were disseminated outward from the large population centers of China to the less densely settled regions of the periphery. Occasionally these epidemics would reach Japan, and Japan's population, which was heavily concentrated along the coastal plains, provided an environment highly conducive to disease propagation and dissemination. By 1600, Japan's population was large enough to support many disease organisms in endemic fashion that in earlier times had been imported as epidemics from China.

The most important changes in the disease environment of early modern Japan, relative to earlier periods, were brought about by domestic rather than international developments. Japan's population grew from about 18 million to approximately 30 million people during the seventeenth century, and Edo (present-day Tokyo) became one of the world's largest cities with a population of around 1 million inhabitants. Economic development, which included the commercialization of agriculture, regional specialization, and interregional trade, accompanied population growth. All these developments served to intensify disease transmission within Japan, and by 1850 few communities were remote enough to avoid either the indigenous diseases of Japan or the imported diseases that sometimes managed to penetrate the *cordon sanitaire* that served to protect the country from the international traffic in pathogens.

Sources on Diseases of Japan

Japanese sources that contain information about the diseases of Japan are abundant and of excellent qual-

ity. The most important are contemporary reports of epidemics, medical books with descriptions of the symptoms and treatment of important diseases, government documents that issued warnings or commissioned relief measures, temple registers that recorded causes of death, and general writings of the period. Early in the twentieth century, two pioneering Japanese medical historians, Fujikawa Yū and Yamazaki Tasuku, compiled references to disease from many Japanese sources. Their works still stand as basic references on the history of disease in Japan.

Some Western sources also contain references to disease in Japan, but most of these were written before or after the Tokugawa period because during that period there were few Western visitors. Thus Portuguese, Spanish, English, and Dutch adventurers who lived in Japan in the late sixteenth and early seventeenth centuries wrote of illnesses that were observed among the Japanese as well as diseases that seemed to be absent. And two and one-half centuries later, in the late nineteenth century, when Westerners again arrived in Japan, they, too, wrote of the diseases they noticed. Western observations reported at the beginning and the end of the Tokugawa period are of value as benchmarks that help to identify the illnesses that were prevalent during this period.

The diseases of early modern Japan can be divided into two general categories: those that are easily identified on the basis of their symptoms and epidemiological characteristics, and those that are not. Ailments in the first category are primarily acute infectious diseases that have distinctive symptoms, affect many people within a short period of time, and are therefore highly visible. These infections, which have well-established histories, are easily recognized in Japanese sources. Diseases in the second category present symptoms that are vague or general. They may have been very important in causing illness or death, but they cannot be subsumed under any modern disease classification.

Infectious Diseases

Smallpox
Among the acute infectious diseases that can be clearly identified from the sources, smallpox emerges as the major killer and the most common cause of premature death. Certainly, more medical books were written about this illness than any other. An old disease in Japan, smallpox was endemic in the large cities well before 1600, and by the late eighteenth and early nineteenth centuries, epidemics struck even remote parts of Japan every 3 or 4 years. Smallpox

was almost entirely an illness of children under the age of 5 years, with few escaping it and many dying of it. As late as 1850, at least 10 percent of the population died of smallpox, and Western observers wrote in the 1860s that smallpox in Japan was so common that virtually every countenance was pockmarked. The introduction of smallpox vaccine in 1849 would reduce the importance of the disease as a cause of death by the late nineteenth century.

Measles
The history of measles in Japan is unlike that of western Europe. In the parts of Europe for which there are good records, measles epidemics were reported frequently. At the end of the eighteenth century, for example, epidemics were occurring regularly in England in about one of every 3 years, and in Germany at regular intervals of about 4 to 5 years. But in Japan, only 11 measles epidemics were reported between 1616 and 1862, and contemporary accounts also provide evidence that epidemics were very rare. Consequently, measles was regarded as a dread disease because unlike smallpox, which was omnipresent, measles seemed to come out of nowhere, and infected young and old alike.

The different epidemiological patterns of measles epidemics in Japan on the one hand and in western Europe on the other seem to be related to different patterns of contact between populations in which the virus circulated. Frequent contact between the many trading centers of western Europe promoted the dissemination of the virulent measles virus and caused frequent epidemics. By contrast, the restriction of trade and the infrequent and seasonal pattern of maritime trade between Japan and other countries of East Asia may have prevented the measles virus from being imported very often.

In Japan the measles virus invariably spread from the port of Nagasaki in the southeast to the major cities of Kyoto, Osaka, and Edo to the northeast, and from there to the more remote parts of central and northern Japan. Moreover, it spread very rapidly because the population was densely concentrated along internal trade routes, and because, with infrequent epidemics, an unusually large segment of the population was susceptible to infection. In these circumstances, the measles virus quickly ran out of new hosts to infect and thus died out, which meant that a new importation of the virus was required for another epidemic to occur.

Unusually good records of measles epidemics were kept during the Tokugawa period, presumably because they infected so many people. These records

document epidemics in 1616, 1649, 1690, 1708, 1730, 1753, 1776, 1803, 1824, 1836, and 1862. The geographic pattern of dissemination, the age distribution of the cases, and other contemporary evidence suggest that measles remained an imported disease that caused infrequent but severe epidemics in Japan until after 1850.

Measles was clearly distinguished from smallpox in the Japanese records because of its very different epidemiological pattern. A person was most likely to get smallpox as a young child because the virus was always circulating through the population, whereas a person would get measles only when the virus happened to sweep through the country. Morbidity and mortality rates were high in measles epidemics because of the large proportion of the population that became ill at once. However, measles mortality over the long term was much lower than smallpox mortality.

Other Airborne Infections

Other well-known airborne infections that cause skin rashes or eruptions are also described in Tokugawa sources. Chickenpox, for example, seems to have been common. In fact, in the shogun's palace, special ceremonies were held to celebrate a child's recovery from smallpox, measles, and chickenpox, indicating that all of these diseases were considered a threat to life in Tokugawa Japan.

Influenza is also prominently mentioned in the Japanese sources from early times, and 27 influenza epidemics are described in contemporary accounts of the Tokugawa period. The Japanese accounts are similar to accounts of influenza epidemics elsewhere: They describe a coughing epidemic that spread extremely rapidly, infecting everyone – young and old, male and female. As is typical of influenza, the mortality rate was highest among the very young and the very old. Influenza epidemics, like other imported epidemics, were said to enter Japan through the port of Nagasaki. In the seventeenth and eighteenth centuries, the timing of epidemics was different from those reported in Europe; but by the nineteenth century, influenza epidemics were noted in both regions at very nearly the same time. It appears that two distinct regional dissemination systems for influenza may have merged during the early modern period as the frequency of contact and speed of transport between East and West increased.

Diarrheal Diseases

In Japan, epidemics of diarrheal diseases were reported as early as the ninth century, but severe, large-scale epidemics seem to have been fairly rare in the early modern period. Fujikawa mentions only seven epidemics of diarrheal diseases for the Tokugawa period in his chronology of epidemics in Japan. It is impossible to distinguish between the different kinds of enteric diseases known today, because the symptoms of diarrheal infections are much the same regardless of the infecting agent. Such infections were most likely to be reported in Japanese historical sources when a large city or an important person was stricken, and these occasions were quite rare.

The absence of major dysentery-type epidemics is not too surprising. Because enteric diseases are caused by contaminated water or food, they normally have a local or at most a regional distribution. Local records, however, suggest that in certain localities, diarrheal diseases were fairly common. For example, a temple death register from Hida province that recorded causes of death in the late eighteenth and early nineteenth centuries documents a fairly severe epidemic in the autumn of 1826. Dysentery claimed 59 lives within a 6-week period; the victims were mostly children under 10 years of age. But such epidemics were unusual. It was more common for diarrheal diseases to claim a few lives each year in the later summer or autumn than to erupt in major epidemics.

An enteric disease that did attract national attention in the late Tokugawa period was "Asiatic" cholera. The first cholera pandemic, which began to spread outside of India in 1817, reached Japan toward the end of 1822. It followed the pattern typical of imported diseases in Japan by breaking out first in the port of Nagasaki, where it ws heralded as a new disease. It spread from there in a northeasterly direction to Kyoto and Osaka, but died out, presumably because of the cold weather, before reaching the capital at Edo. Ironically, the disease that was known in the West as "Asiatic" cholera was known in Japan as "the disease of the Western barbarians."

There is no further evidence of cholera in Japan until 1858, when it once again arrived in Nagasaki, this time on the American ship *Mississippi*. The fact that there were no outbreaks of cholera in Japan between 1822 and 1858 is remarkable, because it was during this period that the disease became a major threat to cities of the West. But Japan's political *cordon sanitaire* seems to have been effective in keeping cholera out. By the late 1850s, however, after its ports had beeen opened to international trade by American gunboats, Japan was stricken by the same pandemics that affected other world regions.

Chronic Diseases

It is much more difficult to identify the nonepidemic or chronic diseases of the early modern period, but there is no doubt that venereal diseases were common. Gonorrhea was an old disease in Japan and presumably had a wide distribution. However, a new venereal disease that was probably syphilis reached Japan around 1513. The Japanese called it "the great pox" – the same name that Europeans had given to syphilis a short time before. The Japanese later claimed that syphilis had been brought to them by the Portuguese, but as the Portuguese did not reach Japan until 1543, this conclusion is questionable. Syphilis probably spread from Portuguese to Japanese or Ryukyuan traders in the East Indies in the early sixteenth century, and then subsequently entered Japan on East Asian ships.

By 1600 syphilis was a major health problem in Japan's large cities. Sixteenth-century European observers had reported that it was widespread among the Japanese population, and contemporary Japanese writers claimed that in Edo more doctors treated syphilis than any other disease. Fully 9.64 percent of the human skulls that have been excavated from several Edo period sites in and around Tokyo show cranial lesions caused by tertiary syphilis (8.8 percent male; 5.9 percent female). This rate seems quite high, especially when one considers that the incidence of earlier stage syphilis in the population would have been much higher than the incidence of tertiary syphilis. However, when one considers the high proportion of males in the population of Edo and the numerous licensed pleasure quarters and widespread prostitution, perhaps a high rate of syphilis morbidity and mortality was to be expected.

Other Diseases

Bubonic plague and epidemic typhus, the two most important vector-borne diseases in early modern Europe, seem not to have afflicted early modern Japan. Rather plague was first reported in Japan at the end of the nineteenth century and believed to have arrived on ships from China that carried plague-infested rats. Typhus probably arrived somewhat earlier, but typhus and typhoid were confused in Japan as they were in Europe, so it is difficult to determine which disease is being referred to in the Japanese sources. A Japanese variant of typhus, called *tsutsugamushi* disease, is fairly common in the Shinano River Valley. It is carried by a mite, and although the illness can be fatal, it has a much more benign history than European typhus.

The popular literature of the Tokugawa period mentions other common illnesses, but, as noted earlier, it is usually impossible to identify them within modern nosology. The kinds of diseases referred to, however, were those experienced by many early modern societies. Ailments of the eye were apparently very common, as they were featured in medical books and in general accounts of the period. Pompe van Meerdervoort, a Dutch physician who arrived in Japan in the 1850s, writes that he was struck by the number of Japanese people who were visibly afflicted, often blinded, by eye diseases. These people probably suffered from trachoma, a disease that was common in Japan in the late nineteenth century, and presumably in earlier times as well.

Other health problems frequently mentioned in contemporary literature include beriberi, toothaches, hemorrhoids, ringworm, coughing disease, kidney problems, and food poisoning. In addition to these common ailments, there are two others, which are called *senki* and *shaku*. These two terms, used in Japan as early as the tenth century, appear to refer to a host of diseases that cause stomach, intestinal, or back pain. *Senki* seems to refer to chronic disease, and *shaku* to more acute problems.

The various treatments recommended for these two illnesses suggest that they may have been caused by worms or other intestinal parasites, tumors, diseases of the stomach or gallbladder, ulcers, kidney disease, and various problems involving the lower back. In other words, these were catch-all terms that covered many of the different diseases that afflict humanity. The various manifestations of *senki* and *shaku* were featured in Tokugawa medical books, and, depending upon the symptoms, it was the task of the physician to recommend appropriate treatment.

There are few surprises in the kinds of disease described in the Tokugawa sources. Of greater interest is the failure to find evidence of certain diseases that were common in the West. Plague and epidemic typhus, already mentioned, are conspicuous by their absence. And Westerners who arrived in Japan in the late nineteenth century commented on the rarity of scarlet fever, diphtheria, tuberculosis, typhoid, cholera infantum, epidemic dysentery, and severe forms of malaria. Even tuberculosis seemed much less prevalent in Japan in the 1860s than in contemporary Europe, but tuberculosis death rates were rising sharply by the end of the century. The differences in the disease histories of Japan and the West suggest again that Japan's isolation from world trade gave the islands a measure of protection from

some of the major diseases of the early modern period.

VI.7
Diseases of Antiquity
in Korea

</div>

The history of diseases in Korea, especially the diseases of the early historic period, constitutes a still largely unexplored area, save for the efforts of a few pioneering scholars whose findings are not yet available in English translations (Miki 1962; Kim 1966). However, this field should be of considerable interest to students of Asian history as well as those concerned with the history of medicine.

Geography, History, and Background

Much of Korea's epidemiological past has been shaped by its geography. The country occupies a peninsula south of Manchuria that is separated from the Chinese mainland to the west by the Yellow Sea, and from nearby Japan to the east by the Korean and the Tsushima Straits. Forming a land bridge between northern Asia and the islands of Japan, Korea has time and again been subjected to invasions by armies from the Asian mainland intending to attack Japan, or by Japanese armies establishing a base from which to attack the Asian mainland. Undoubtedly, these contacts must have brought infectious diseases to Korea.

To discuss diseases of antiquity in Korea means to discuss those illnesses that occurred during the Old Choson Period (traditionally dated 2333 B.C. to A.D. 562), and the Three Kingdoms Era encompassing the Kingdoms of Koguryo (37 B.C. to A.D. 688), Paekche (18 B.C. to A.D. 660), and Silla (57 B.C. to A.D. 935), as well as the Koryo Era (918–1392). By the ninth century B.C., rice-cultivating Bronze Age cultures had been established on the Korean peninsula. During the Three Kingdoms Era, the Chinese writing system was adopted by the courts in order to ensure the writing down of state chronicles. Only fragments of these texts have survived by being incorporated in the *Samguk sagi* (History of the Three Kingdoms), which was compiled in 1145 and constitutes the oldest preserved history of Korea.

The introduction of Buddhism to Korea from China during the fourth century A.D. increased contacts with the Asian mainland. Particularly during the Three Kingdoms Era, many Korean Buddhist monks studied in China and were responsible for the influx of many aspects of Chinese culture to the peninsula. When, after long periods of warfare, the Three Kingdoms were unified in 661, the resulting Kingdom of Unified Silla extended cultural and economic contacts with China. Besides an increasing number of Buddhist monks, students interested in Confucian learning went to China. Some Buddhists even reached India, endeavoring to study their religion at its source. This period also saw increasing cultural and economic exchange with Japan, and commercial intercourse with Arab traders.

Although Korea was epidemiologically not as isolated as Japan, and the development of immunities within the population must have set in earlier and more intensively, the long periods of unrest, poverty, and famine during the wars of unification must have favored the outbreak of epidemics and famine-related diseases. Social reforms during the Koryo Era (918–1392) may have improved this situation. Relief programs, sponsored by the government and by the Buddhist church, were implemented; granaries were built as a precaution against years of drought; infirmaries were created; and a system of medical care in the countryside was established. Despite all these efforts, however, the vast majority of the population stayed in poverty and, consequently, remained particularly vulnerable to contagious diseases.

Diseases

Textual sources relevant to the study of diseases in the early history of Korea are scarce. The *Shin Jip Ban* (Anthology of Paekche Prescriptions) and the *Bup Sa Ban* (Prescriptions of the Masters of Silla), medical texts compiled in the states of Paekche and Silla, respectively, are lost. Only some passages and prescriptions have survived by being incorporated into Chinese and Japanese texts. The *Ishinpō*, a collection of mainly Chinese medical texts, compiled by the Japanese scholar Tamba Yasuyori in 984, refers to the *Shin Jip Ban* in a discussion concerning abscesses.

Korean physicians were very much influenced by Chinese medical thinking, and adopted Chinese medical terminology. But they also reinterpreted Chinese material in their own way and added information obtained from Indian sources.

Owing to the lack of genuine medical literature of that period, we have to rely on historical literature for information regarding diseases. The *Samguk sagi* mentions a first occurrence of an epidemic during the reign of Onjo, king of Paekche, in 15 B.C. There are a great number of different terms for epidemic diseases in ancient Korean writings such as "poison epidemic," "evil epidemic," "epidemic of the time," "epidemic of disease," and others. Identifications of these terms are, however, difficult. Thus, the Chinese character that could be translated "leprosy epidemic" might simply refer to a widespread disease of a very severe nature.

Diseases were discussed in terms of their major symptoms. However, often no clear distinctions were made, and death from famine was recorded with the same wording as death from an epidemic. No need for precision may have been felt in a society that attributed misfortune, disease, and death to the action of ghosts, devils, and demons. Although the more rational principles of Chinese medicine were known to the physicians, they rarely made distinctions solely based on these criteria.

The only complete extant medical book of the Koryo Era is the *Hyang-yak kugup pang* (Emergency remedies of folk medicine). This collection of simple relief measures and preparations was compiled during the reign of King Kojong, in 1236. It deals mainly with emergency measures such as employed in accidents; injuries; bites by insects, reptiles, and other animals; drowning; sunstroke; food poisoning; drunkenness; and toothache. It describes, however, also symptoms of diseases and their treatment. This book may be considered to reflect the scholarly attitude toward health care because it

leans strongly on the tradition of Chinese medicine. Thus, symptoms such as hemorrhages, blockages of the throat, loss of consciousness, and sudden death from various infectious diseases are discussed. A combined study of the *Hyang-yak kugup pang* and official annals such as the *History of Koryo* would provide more insights into the epidemiology of that period. It must be noted, however, that the official historical writings expressed little awareness of medical problems in the country except in case of extended and devastating epidemics, those that involved the capital city or its environs, or cases of illness within the royal family.

The following represents a survey of diseases or groups of diseases, endemic or epidemic, the occurrence of which can be inferred from miscellaneous textual sources:

Smallpox

Historians generally agree that smallpox originated from India. According to the *Tongui pogam* (Exemplar of Korean Medicine 1610), smallpox had appeared in China already at the end of the Zhou dynasty and the beginning of the Han dynasty (i.e., during the late third century B.C.). A first mentioning of smallpox in a Chinese source suggests a later date (*Zhou-hou bei-ji fang* by Ge Hong, first half of the fourth century A.D.), whereas a first documented smallpox epidemic can be dated A.D. 495.

A terminus antequem for the arrival of smallpox to Korea may be deduced from the fact that Korean envoys of King Song (523–54) of Paekche, who brought Buddhist scriptures and statues to Japan, transmitted the disease to that country in 552. Shortly after Emperor Kimmei legalized Buddhism, an epidemic of smallpox broke out, and led to the immediate abolition of the new religion. In 584, Japanese officials visited Korea and brought back to Japan the disease together with two images of Buddha. Emperor Bidatsu himself became a victim of the ensuing epidemic the following year. Two years later, with the epidemic still raging, Emperor Yomeī (585–7) died of the disease, too. Also the epidemics of 735–7 and of 763 are supposed to have been transmitted to Japan from the Korean peninsula. At any rate, during the Three Kingdoms Era, Korea was a frequent victim of the disease; two kings, Sondock (780–5) and Munjong (839–57), died of smallpox.

For the Koryo Era there is no evidence for the occurrence of smallpox epidemics. Yet, the *Hyang-yak kugup pang* refers to eruptive diseases in the chapter "Various Childhood Diseases"; the text speaks of "pea-sized boils" and "bean-sized boils in

the child." This could well be a reference to small-pox. If we correctly interpret this passage, and if smallpox had become one of the common children's diseases, then it would have been firmly established in Korea at this period. It should, however, be noted that measles was apparently not distinguished from smallpox until the beginning of the Yi dynasty (1392–1910).

Other Febrile Illnesses

There can be little doubt that malaria was epidemic on the Korean peninsula from time immemorial. A first mentioning of the disease, however, is as late as the *History of Koryo*. The *Hyang-yak kugup pang* contains a passage on "malaria disease" and its therapy. Although not always strictly differentiated from other febrile illnesses, the symptoms of the "3-day fever," as it was usually called, are sufficiently distinct to recognize it with some degree of certainty; various drugs were employed to obtain relief during the attacks (Miki 1962). Although typhoid fever may have been subsumed under and classified together with other febrile diseases, when one considers the social and hygienic conditions of the period, there can be little doubt of its role in Korean medical history. The same may apply to diphtheria; perhaps the term "blockage of the throat" refers to this disease.

Respiratory Diseases

The *Hyang-yak kugup pang* refers to illnesses that, in modern terms, would be classified as respiratory diseases. In fact, there seem to be references to asthma, pleurisy, and hydrothorax. Whether or not pulmonary tuberculosis and pneumonia, frequent diseases in many premodern societies, were recognized as individual diseases cannot be ascertained from the text.

Parasitic Infestations

The texts mention a disease with bloody saliva. This symptom is characteristic of pulmonary distomatosis, an infestation with *Paragonimus westermani*, which is still prevalent in East Asia, particularly in Korea.

Diarrhea and Dysentery

Taking the minute categorization of diseases accompanied by diarrhea, as found in the *Hyang-yak kugup pang,* as an indicator, this group of illnesses appears to have been common and well known. Whereas the official chronicles omitted these, the *Hyang-yak kugup pang* gives a description of an epidemic with precise details of its symptomatology,

including the twisting stomachache and bloody stools. Besides, this book mentions "cold dysentery," "dysentery with blue color," "hot dysentery with reddish-yellow color," "red dysentery with stomachache," and others.

Venereal Diseases

One of the main symptoms of advanced gonorrhea, difficult urination, is mentioned in the *Hyang-yak kugup pang*. Besides this book distinguishes five types of gonorrhea. That the nature of contagion of this disease was understood is implied in the following passage in the *History of Koryo:*

One night Mr. Hong took the previous King Chunghye (1330–1332) to his house and they feasted. The King ordered a priest-doctor to cure Mr. Hong's gonorrhea. The King always took a fever drug and visited many ladies. As a result he had disease. The King and Mr. Hong received curing methods from the priest. The King ... used the fever medicine to increase his stamina. (Miki 1962)

Diseases due to Nutritional Deficiencies

In a largely agricultural society, only sufficient local harvests could avert famine and famine-related diseases. In the early Three Kingdoms period, the king of Paekche was held responsible for crop failure and, in such cases, removed from the throne or even killed (Lee 1984). One of the most common nutritional diseases in rice-growing societies up to recent times has been beriberi, that is, thiamine or vitamin B deficiency. Although there is no description of the symptoms in Korean sources prior to the Yi dynasty (1392–1910), we may assume that this disease was common, whenever rice was polished and the husk, which contains this vitamin, was stripped from the grain.

Skin Diseases, Tumors, and Leprosy

The *Hyang-yak kugup pang* contains a section on tumors. However, whether these refer to abscesses, carbuncles, and other inflammatory swelling remains uncertain, particularly because these descriptions are mixed with those of other skin diseases such as furunculosis, dermatitis, scabies, and erysipelas; erysipelas of the head and face is emphasized in the text. Another skin disease marked by boils that is mentioned in this text most probably refers to leprosy. The *History of Koryo* frequently refers to leprosy as the "bad disease" which is widespread, malignant, and hard to cure. That persons stricken with this disease not only spread horror to the healthy population but also tended to elicit pity and gave rise to benevolent deeds is shown by a

passage from the *History of Koryo* in which a devoted son cut off a piece of his own flesh in order to cure his father's disease.

Miscellaneous Diseases and Conditions

The *Hyang-yak kugup pang* gives a clear-cut definition of tetanus by stating that a spear wound will be fatal if it has caused lockjaw and spasms. Similarly, brief descriptions are given for rabies, stroke, epilepsy, hemorrhoids, prolapsed anus, and diabetes mellitus. The latter is defined as causing much urine, being unrelated to gonorrhea, and resulting in very thin patients. Somewhat obscure is the category of "water-swelling" diseases. Obviously referring to edemas, this term may include not only primary heart or kidney disease but also edemas of wet beriberi; consequently, the symptoms of "water-swelling" diseases are also listed in this book under the heading of "paralysis," this being one of the cardinal symptoms of dry beriberi.

Finally, the *Hyang-yak kugup pang* has a section on insanity, termed "uneasiness of mind," "unusualness of mind," or, in the case of psychosis, "true madness." However, insanity was a health problem that was considered outside the confines of scholarly medicine; treatment called for the *mudang* (shaman) rather than the physician.

VI.8

Diseases of the Premodern Period in Korea

</div>

Medical Literature

In 1392 Yi Songgye assumed the throne as King T'aejo and the Yi Dynasty (1392–1910) began. His supporters initiated a sweeping land reform program that began with a cadastral survey of landholding throughout the country and the destruction of previous registers of public and private landholdings. New developments in agriculture as well as in science, technology, and medicine followed, stimulating inventions and publications. For example, the agricultural manual called *The Art of Farming,* compiled in 1430, was based on the reasonable but novel premise that because Korean climate and soil differed from those of China, agricultural methods should be designed to meet the specific conditions found in the peninsula. Improvements in agricultural techniques produced increased yields, and the spread of cotton cultivation provided improved clothing for the common people.

Important developments in medical knowledge took place in the early years of the Yi dynasty, as the government encouraged its study and created two specialized institutions for medical care. One served the royal family and elite officials, and the other was to serve the general population. Candidates who scored well on the "Miscellaneous Examinations" could be employed in the Palace Medical Office, which trained regional medical officials.

The concept that indigenous conditions must be considered was increasingly incorporated into medical as well as agricultural writings. China's influence on medical philosophy remained strong, but interest in the study and exploitation of Korea's own traditional folk remedies stimulated the development of independent medical scholarship as may be seen in the *Hyang-yak kugup pang* (Emergency Remedies of Folk Medicine 1236).

A major milestone in the development of Korean medical science was the publication of a medical encyclopedia in 85 volumes entitled the *Hyangyak chipsong pang* (Compilation of Native Korean Prescriptions 1433). A similar format was followed by the compilers of the *Uibang yuch'wi* (Classified Collection of Medical Prescriptions), which was completed in 1445. In an attempt to include all known theories of medicine, the compilers assembled 264

volumes. Unfortunately, this resulted in a massive collection unsuited for general use, and only a few copies were ever produced. In 1596 the King ordered Ho Chun to prepare a more useful text. The project took Ho Chun and his group more than 10 years to complete. It resulted in the highly respected 25 volumes of *Tongui pogam* (Exemplar of Korean Medicine 1610), which were still being reprinted in Korea, China, and Japan during the eighteenth century. The work's preparation was, at least in part, a response to the devastation caused throughout almost all of Korea during the 7-year struggle of the Hideyoshi Invasion (1592–8). In the most severely affected provinces some villages were totally destroyed, population was markedly decreased, and famine and epidemic disease inevitably compounded the misery of the people (Lee 1984).

The *Hyangyak chipsong pang* and the *Tongui pogam* served as the models for many other medical books of this era. Ho Chun, the author of the *Tongui pogam,* was a Taoist, and his medical philosophy rested on the three Taoist essences: mind, sense, and spiritual power. His classification of disease was based on causes as well as symptomatology and the physical location of disorders. The view of disease initiated by the *Tongui pogam* exerted a profound influence on the Korean medical world during the second half of the Yi Dynasty. Epidemics were collectively referred to as "bad disease" in the ancient period, but as medical knowledge developed, references to epidemic diseases became more specific. Generally, the epidemic diseases recorded as "bad disease" in the *Yijo Sillok* (True History of the Yi Dynasty) constituted those other than the eruptive fevers, among them influenza, epidemic meningitis, typhoid and typhuslike diseases, and other diseases that have no particularly well-marked external manifestations.

Typhus and Typhoid Fever Group

Clear descriptions of typhus begin to appear only in modern times, but epidemic occurrences of typhuslike diseases in ancient times can be recognized in China and Korea. For example, an epidemic that started in P'yongan Province in July 1524, and spread continuously until it reached the middle provinces of the peninsula, seems suspiciously typhuslike. The epidemic lasted until the spring of 1527, and contemporary accounts emphasized the high fever and contagious nature of the ailment. Another typhuslike epidemic seems to have occurred in 1543, and still another in 1612 in the province of Hamgyong and then spread to the south. It was because of this latter epidemic that Ho Chun was ordered to compile a new book of detailed curing methods, and certainly his account leaves the impression that this disease was a member of the typhus fever group.

As with typhus, little historical evidence of major epidemics of typhoid fever in Korea exists. Yet occasionally whole villages contracted a disease with symptoms suggestive of typhoid. It is likely that typhoid fever was endemic and epidemic during the Yi Dynasty, but few local outbreaks were noted in official records. Until recent times, typhus and typhoid were not distinguished from each other. Typhoid fever remained endemic in modern Korea, but many people viewed typhoid as a rather minor disease of about the same severity as "red dysentery."

Relapsing fever, a tick-borne disease that was considered one of the forms of typhus, may have appeared in Korea during the sixteenth century when epidemics occurred in China and Manchuria, but the evidence from the early Yi Dynasty is obscure. Two other diseases that might have existed in Korea during this time period are *leptospirosis* (Weil's disease or leptospiral jaundice) and *rat-bite fever.* Most Korean therapeutic texts included a brief account of certain curing methods that suggest knowledge of rat-bite fever.

Bubonic Plague

Although waves of devastating epidemics of bubonic plague have been recorded in China since 1331, the surviving literature from Korea does not seem to contain specific descriptions of similar epidemics (Miki 1962).

Influenza

The *Hyangyak chipsong pang,* the *Tongui pogam,* and other medical texts of the Yi Dynasty discuss symptoms of epidemic disease best explained as influenza. Although large and small epidemics of influenza probably occurred many times during this period, the historical records are ambiguous; perhaps the outbreaks were not sufficiently striking or widespread to be separated from other epidemic diseases. However, major influenza epidemics occurred in Japan during this period, and it seems reasonable to assume that there were comparable epidemics in Korea. Moreover, given the nature of influenza, epidemics could have ricocheted back and forth between Korea and Japan (Fujikawa 1934).

Smallpox

Smallpox was the most feared disease on the peninsula because epidemics were extensive and mortality

rates were high. Before the practice of vaccination was established, few people avoided an encounter with smallpox.

Most references to the epidemiology of smallpox during this era are found in the *Yijo Sillok,* historical records of the Yi Dynasty. Thus, the records are biased toward epidemics that occurred near the capital and affected the royal family. For example, in 1418 the Prince died of the "disease with bean-sized eruptions." In 1424, King Sejong's son died of an eruptive disease. In 1675, King Sukchong contracted smallpox. In 1680, an epidemic broke out in the capital city, and the Queen contracted the disease (the King had previously moved to another palace). During the seventeenth and eighteenth centuries, Western science and technology were coming into Korea and stimulating progress in science and medicine. An example of this trend was the *Makwa hoet'ong* (Comprehensive Treatise on Smallpox), a specialized medical treatise published in 1798 (Lee 1984).

Chickenpox
Although chickenpox was confused with smallpox until very recent times, the history of the reign of King Myongjong (1545–67) refers to "big" and "small" eruptive diseases. The big eruptive disease probably corresponds to smallpox; however, whether the small eruptive disease corresponds to chickenpox or measles is uncertain. In the *Sukchong Sillok* (Sukchong reigned from 1674 to 1720), a description of eruptive diseases with big and small efflorescences survives that suggests a slightly different meaning from previous records of these eruptive diseases. At this time, measles was generally distinguished from smallpox, so the small eruptive disease could have been chickenpox. In the records of the period 1724–76, references to episodes of illness and recovery of the Queen and the Prince included all the symptoms of chickenpox. Similar examples can be found following the middle period of the Yi Dynasty.

Measles
During the early period of the Yi Dynasty, medical texts such as the *Hyangyak chipsong pang* indicate a dawning recognition that measles was a disease that could be separated from smallpox. Seventeenth-century Korean texts described a "dot-eruption disease" that appears to be measles. However, doctors seemed to have had difficulty securing knowledge of this eruptive disease, suggesting that epidemics of measles were rare. It is worth noting that Ho Chun suggested that the "poisonous epidemic of the T'ang"

that occurred in 1613 was similar to measles, but was a separate disease. This epidemic may have been scarlatina, as doctors were unable to differentiate between scarlatina and measles.

Subsequent medical books say nothing significant or new about the "dot-eruptive disease" until the eighteenth century, when doctors influenced by the "School of Positivism" began to write specialized medical texts based on their own experiences and case studies. A measles outbreak that occurred in 1707 stimulated interest in the disease, and several specialized books on measles were written in response to the epidemics of 1752 and 1775. Such texts provided comprehensive discussions of the symptoms and treatment of measles and smallpox, and made it possible for doctors to differentiate the eruptive diseases.

Rubella
It is difficult to determine whether physicians of this period were familiar with rubella, for even the most specialized eighteenth-century books on smallpox and measles do not seem to describe it. In the chronicles of King Yongjo (1724–76), however, there are entries noting that the 9-year-old Prince had measles in 1743. Then, when the Prince was 18 years old, he had measles again, and two years later he had "dot-measles." There was a major epidemic of measles when the Prince was 18 years old, so presumably the Prince really had measles at that time. Because an individual has measles only once, the other episodes could have been rubella and scarlatina. There are several other examples of such cases.

Scarlatina, or Scarlet Fever
Scarlatina was not described as an independent disease in Korea at this time, but a disease that might be scarlatina occurred in 1613 under the name "poisonous epidemic of the T'ang." A detailed study of the epidemic, symptoms of the disease, and curing methods was prepared by Ho Chun.

Dysentery
Diseases with the characteristic symptoms of dysentery existed in ancient times in China, Korea, and Japan. Dysentery-like diseases were given many descriptive names, such as red dysentery, bloody dysentery, red-white dysentery, thick-blood dysentery, and so forth. The major symptoms common to the entire group were fever, stomachache, bloody excretions, spasms, and frequent diarrhea. Major epidemics are generally associated with true *Shigella* dysentery, but both bacillary and amebic dysentery were en-

demic in Korea. Compared to other epidemic diseases, dysentery was not considered very grave, and therefore, it was often omitted from official chronologies of epidemics.

The *Hyangyak chipsong pang* divided all diarrheas into 23 different forms, including red dysentery. The text also describes various diarrheas that affect children and lists 10 different forms based on the symptoms that predominated under different conditions. Medical books written during the middle and late years of the Yi Dynasty also describe dysentery symptoms.

Diphtheria

In Korea, as in China and Japan, there are no clear descriptions of a disease corresponding to diphtheria until the modern age. Differential diagnosis of sore throat diseases, such as diphtheria, scarlet fever, and tonsillitis, is just as difficult as sorting out the eruptive fevers and the typhuslike diseases. Moreover, diphtheria is not strongly associated with dramatic epidemics of high mortality. Indeed, mild cases are not unusual, and immunity is often quietly acquired at an early age. Since ancient times, however, many different names have been applied to various diseases of the throat. It therefore appears probable that diphtheria was recognized as a particular disease marked by a characteristic symptomatology.

Two diseases consistent with a diagnosis of diphtheria are listed in the *Hyangyak chipsong pang* under the heading "Throat." The *Tongui pogam* lists several different forms of throat disease, including a contagious disease that might correspond to diphtheria. Korean medical treatises of the eighteenth century also described throat diseases with symptoms similar to those of diphtheria.

Whooping Cough or Pertussis

Symptoms similar to those of pertussis appear in the *Hyangyak chipsong pang*. A list of various "coughing diseases" includes symptoms suggesting pertussis, and the section on pediatrics describes symptoms similar to pertussis under the heading "Children's Coughing." The *Tongui pogam* and texts from the eighteenth century also describe symptoms that suggest whooping cough.

Epidemic Meningitis

A disease that might have been epidemic cerebrospinal meningitis is described in the annals of the reign of King Songjong (1469–94). According to these records, in November 1471, an epidemic disease appeared in Hwanghae Province. It died out by March of the following year, but the unusual nature of the epidemic attracted the attention of the central government. Medical officials were dispatched to the province to dispense medicines and report on the causes and symptoms. According to the official observer, the disease occurred mainly within Hwanghae Province. In comparison to other epidemic diseases, its ability to spread was weak, and thus the number of individuals affected was not very large. The disease had probably occurred previously in the same province as early as 1434. Outbreaks continued into 1458, but the number and dates of outbreaks cannot be ascertained.

The first symptoms of the disease included blurred vision, loss of vision, delirium and babbling, frenzy, and finally prostration and collapse. Other symptoms were difficulty of movement of the whole body, paralysis below the waist, swelling of the lower abdomen, pains, blackening of the teeth, weakness in the extremities, coughing, and gasping. If one member of the family fell ill, the whole family might sicken and die. When all the symptoms are considered, a tentative diagnosis of epidemic cerebrospinal meningitis seems reasonable (Miki 1962).

Malaria

Malaria was the most common of the infectious diseases in Korea, where it almost always appeared as the "3-day fever" and where knowledge about it developed relatively early. The relief methods in the *Hyangyak chipsong pang* are based on a combination of Chinese remedies and those in the *Hyang-yak kugup pang*.

Sexually Transmitted Diseases

Syphilis probably came to Korea from China between 1506 and 1521, and by the seventeenth century had spread among all classes of people throughout the country. Venereal diseases were known in the Orient long before syphilis spread throughout the world. Korean texts contain descriptions of such diseases, but the venereal diseases described in the older texts were not associated with skin lesions; their main symptoms were increased frequency and urgency of urination. Other symptoms were rather ambiguous. However, references to a disease allegedly occurring only in males, involving the "bad nature of eruptions on the genitals related to consorting with women," found in the *Yijo Sillok* probably indicate syphilis.

Japan and the continent were the two possible routes for the transmission of syphilis to Korea.

Yet trade between foreign countries and the peninsula during the first half of the sixteenth century was rather limited, especially with Japan. In fact, the only contacts with the Japanese during this period would have been invasions by those marauders who had been attacking the Korean coast since the thirteenth century. Thus, the possibility that syphilis could have been brought from Japan to Korea cannot be absolutely ruled out, but it is more likely that the primary route was from the continent, for trade between Korea and Ming China occurred many times per year through special emissaries, including numerous officials and merchants. Moreover, the first Korean medical texts to discuss the new disease suggest that syphilis came from China.

At the time, it was thought that the immoral and illegal use of medicines made of human flesh and gallbladder were linked to the arrival of syphilis in Korea. Thus, the following was reported in February 1566:

There were many people in Seoul who killed people to take the gallbladder and this was said to be for the use of very promiscuous people. Many beggars disappeared from the street. After several years there were no longer any beggars and the killers turned to child murder. Officials and other people who consorted with prostitutes got the disease. They tried to cure it with human gallbladder and used up all the beggars. (Miki 1962, author's translation)

Whatever the authenticity of this story, it reflects the desperation of the sick and their willingness to resort to murder as well as superstition to procure remedies for their ailments. The exact origin of this aberration is unknown, but throughout the world there are many accounts of the use of human blood and organs against diseases such as leprosy, syphilis, and tuberculosis; Korean and Chinese pharmacopoeias included a wide range of human parts and products under the general category "human medicine" (Cooper and Sivin 1973).

The *Hyangyak chipsong pang* refers to eight kinds of gonorrhea, and the descriptions are quite detailed. The *Tongui pogam* also describes various symptoms of the eight different kinds of gonorrhea. Although the relationship between the disease and sexual intercourse was apparently recognized, the contagious nature of disease does not seem to have been understood.

The writings of the Yi Dynasty suggest the existence of chancroid, but it is difficult to separate this ancient venereal disease from gonorrhea and syphilis.

Tuberculosis and Other Respiratory Diseases

During the Yi Dynasty, medical knowledge of tuberculosis became more abundant and precise. The *Hyangyak chipsong pang* describes pulmonary tuberculosis and recognizes the contagious nature of the disease as well as the relationship between the most common form, pulmonary tuberculosis, and its other forms (Miki 1962). The *Tongui pogam* also contains a good description of pulmonary tuberculosis and the symptoms of other forms of the disease. Moreover, it describes symptoms suggesting scrofula, which was considered primarily childhood tuberculosis.

The *Hyangyak chipsong pang* discusses the symptoms of asthma clearly, and the *Tongui pogam* has a discussion of asthma under the heading of "coughing." Asthma was divided into eight different forms; asthmatic attacks were attributed to excess eating, fear, and shock. Further, under the column dealing with symptoms of "lung swelling," there is a discussion of a condition that may be related to emphysema.

Ailments that appear to correspond to modern pleurisy and hydrothorax also appear in the medical literature of this period in discussions of "heart pain" and "waist pain." The *Hyangyak chipsong pang* and the *Tonqui pogam* describe symptoms that suggest hydrothorax in a discussion of conditions attributed to the accumulation of "chest water," which indicate observations of both the accumulation of water in the chest and swelling of the whole body.

Lobar pneumonia is probably one of the illnesses included in the "harm caused by cold" category of fever diseases. Within this category, the *Hyangyak chipsong pang* and the *Tongui pogam* discuss diseases marked by high fever, coughing, and bloody mucus.

Heart Disease

The precise diagnosis of various forms of heart disease was achieved only after the development of pathological anatomy, auscultation, and the stethoscope. Under Chinese medical philosophy, abstract arguments concerning the pulse, combined with heart pain and shortness of breath, were used for diagnosis of heart diseases. Under the heading "heart pain," the *Hyangyak chipsong pang* lists nine different kinds. These entries and similar discussions in other texts composed during the later years of the Yi Dynasty suggest knowledge of angina pectoris as well as other symptoms of heart disease.

Digestive Disorders

Gastritis seems to be the major disease in the category of stomach diseases. The *Hyangyak chipsong*

pang and the *Tongui pogam* described symptoms that suggest gastritis. Gastric ulcer might be the modern diagnosis for the disorder associated with a "wound of the stomach spilling blood" accompanied by severe stomach pains.

A precise diagnosis of peritonitis, intestinal tumors, or obstructions was very difficult in both the East and West in ancient times, but some of the symptoms discussed in the *Tongui pogam* suggest intestinal tumors. Tumors behind the intestine that were not movable were called "cancer," whereas a kind of tumor that moved was ascribed to parasites. Stomach cancer, liver cancer, tuberculous peritonitis, uterine cancer, and probably many other forms of cancer were included in this category. Still, other intestinal disorders, such as acute appendicitis, enteritis, acute enteritis, and enterostenosis are also discussed.

Acute enteritis, in which the symptoms are similar to those of food poisoning and cholera, was treated in the medical texts composed in the later Yi Dynasty. Ascites and meteorism (tympanites) might be indicated in the category that contained diseases in which the abdomen swelled. Disorders of the rectum, such as hemorrhoids and prolapse of the anus, were described in detail, along with methods of treatment and dietary restrictions.

Liver Disease

The *Hyangyak chipsong pang* lists 25 forms of jaundice, but these conditions were not linked to problems of the liver and gallbladder. By contrast, the *Tongui pogam* reduced all the subdivisions simply to jaundice. Its cause was explained in terms of "damp fever," in which the blood evaporates and becomes hot and dark in color. This dark color first appears in the eyes and face, but as it spreads, the whole body becomes yellow. Causes of jaundice included alcohol poisoning, lack of appetite, excessive sexual indulgence, and yellow sweat. Some texts apparently described gallstones along with colic, but all the painful "stone diseases" were essentially indistinguishable.

Although cirrhosis of the liver was not uncommon, this disorder was not specifically ascribed to the liver. The symptoms of cirrhosis were probably considered along with ascites, meteorismus, and other disorders involving abdominal swelling.

Parasitic Infestations

Paragonimiasis or pulmonary distomiasis is caused by infection with a worm of the genus *Paragonimus,* especially *Paragonimus westermani.* In Korea the disease was usually acquired by eating raw crab meat, and references to a disorder characterized by rusty-brown mucus in the ancient texts probably reflect paragonimiasis.

In the *Hyangyak chipsong pang* under the heading "pediatrics" are descriptions if infestations of roundworms and pinworms. The section on "worms" in the *Tongui pogam* describes various disease symptoms attributed to nine different worms. Many plant remedies were used to remove these parasites. Ancylostomiasis (hookworm disease) and secondary anemia are not specifically described, but symptoms of anemia due to ancylostomiasis seem to be described among the forms of jaundice.

Kidney Disease, Urinary Disease, and Diseases of the Reproductive Organs

Clinically, the main symptom of nephropathy is swelling; thus, the "water-swelling diseases" of the ancient texts probably included symptoms due to disorders of the cardiovascular system as well as kidney diseases. Kidney disease might be found in the ancient texts under the headings of swelling, water disease, or water-"cancer" disease (ascites). "Water-swelling diseases" associated with irregular pulse probably indicated disorders due to heart disease, rather than kidney disorders. The section on "water-swelling disease" in the *Hyangyak chipsong pang* lists ten different forms.

Because symptoms of diseases of the urinary bladder are conspicuous and painful, they were the subject of considerable medical interest. The *Hyangyak chipsong pang* discusses dysuria, ischuria, pollakiuria, urinary incontinence, hematuria, gross hematuria associated with high-fever diseases, and enuresis. Various symptoms of urinary problems are also discussed in connection with gonorrhea. Some of the "disorders of urine" might have been caused by tuberculosis of the urogenital system.

The *Tongui pogam* discusses the urinary bladder and diseases of urination in detail. The five colors of urine were said to provide diagnostic clues to the origin of illness. Diseases related to difficult urination were followed by a discussion of various forms of gonorrhea symptoms.

Diabetes Mellitus

According to the *Tongui pogam* the thirst associated with diabetes mellitus was due to "heart fever." The symptoms of diabetes included intense thirst and hunger, increased eating and drinking, frequent urination, weakness, and wasting. Although the pa-

tient ate and drank large quantities, all the food consumed turned to urine, and the patient became very thin. In advanced cases the disease was accompanied by "bad boils," usually referring to ulcera cruris.

To prevent or treat diabetes mellitus, it was said that one must abstain from three things: alcohol, sex, and salty food. In patients with the disease, acupuncture and moxibustion should not be performed for more than 100 days because inflammation of the wound could lead to death. The sudden formation of bad boils in such patients could signal imminent death.

Beriberi

Several conditions described in the Korean medical texts suggest a long familiarity with beriberi, also known as "kakke." Symptoms described under this heading included swelling of the lower limbs, followed by swelling of the heart and stomach and difficulty in urination, weakness in the feet, dizziness in the head and eyes, and so forth.

Although it is likely that beriberi existed in Korea since very ancient times, true beriberi was probably not distinguished from the various forms of neuritis, heart disease, rheumatism, and other forms of malnutrition. According to the *Hyangyak chipsong pang,* beriberi was due to the "wind poison" generated by wind, cold, hot, and dampness. Later medical texts attributed the disease to "water dampness." Beriberi was most likely to have appeared during times of famine, but otherwise the disease was probably somewhat rare in Korea, even during the latter Yi period, because few people depended on polished white rice.

Stroke

The *Hyangyak chipsong pang* and the *Tongui pogam* describe the main symptoms of stroke, including collapse, loss of speech, paralysis, loss of faculties, and inability to move the extremities. Fat people over 50 were said to be most susceptible to strokes. Numbness in the thumb and fingers, weakness in the hands and feet, and a numb or tingling sensation were considered warning symptoms that a severe stroke might occur within 3 years. Treatment was provided even if the patient was unconscious. When the person could not talk or swallow, medicine could be boiled so that the patient would inhale the steam. Medicine could also be blown directly into the nose, but if the patient could not inhale, the case was judged incurable.

Skin Diseases and Leprosy

The texts describe many interesting and important skin diseases, but the most dreaded was certainly leprosy. In ancient Korea leprosy was nonspecifically referred to as "bad disease." Although various conditions that were included under this rubric were considered malignant and hard to cure, leprosy was probably the major disease. Medical texts of the Yi Dynasty referred to leprosy as "big-wind-lepra" or "big-wind-boil."

Leprosy was said to result when a "bad wind" got into the body, but the disease was also said to be transmitted from person to person. Records for 1445 in the *Yijo Sillok* describe outbreaks of leprosy in Cheju Island. According to the chronicler, the people of Cheju Island abandoned lepers in uninhabited areas along the coast because they feared them as sources of contagion. Another folk belief found in the historical records for 1613 was based on the idea that when lepers washed their boils, the fish in the river or the chickens in the house would acquire the leprosy. Then when city people ate the contaminated fish or chicken, they would be infected (Miki 1962). Leprosy was also seen as Heaven's punishment for criminal acts in this life or past lives.

The historical literature also indicates a tradition of relief work and quarantine for leprosy, especially on Cheju Island where the disease was most prevalent. However, people greatly feared infection, and so lepers were abandoned on uninhabited islands and there were also many "accidents" in which lepers fell from the cliffs. Officials did establish "relief places" and "cure places" and tried to help lepers by appointing priests and medical students to give them medicine and help them bathe in the ocean. An entry in the historical records for 1612 states: "Leprosy is the worst disease under the sky" (Miki 1962).

The ancient medical texts also describe erysipelas, carbuncles, dermatitis, furunculosis, inflammations, abscesses, tumors, pustules, lymphagitis, and gangrene, as well as scabies, which probably existed in Korea and China from ancient times. Texts from the Yi Dynasty described this condition and useful methods of cure, including sulfur poultices. The *Tongui pogam* says that there are five kinds of scabies: dry, damp, sand, insect, and pus.

Eye, Ear, Nose, and Throat Diseases

Many forms of deafness and their supposed causes are discussed in the *Tongui pogam.* The condition referred to as earache accompanied by "purulent ear" was probably otitis media. A section on major and minor nose disease includes symptoms suggest-

ing rhinorrhea, hypertrophic rhinitis, and maxillary sinusitis. There are also many diseases discussed that were associated with inflammation of the throat and mouth. Symptoms in the *Tongui pogam* are consistent with tonsillitis, diphtheria, uvulitis, tongue cancer, ranula (sublingual cyst), and various forms of tooth disease.

Because of their debilitating effect and their direct influence on daily life activities, eye diseases were readily observed and described. Although eye disorders caused by problems within the body or peculiar diseases inside the eyeballs were hard to detect, conditions affecting the surface were described in detail. The *Tongui pogam* described eye diseases, including pterygium and trachoma, in terms of more than 20 symptoms. Liver diseases were thought to cause problems behind the eyeball, which led to incurable loss of vision.

Women's Diseases

Diseases of women discussed in the texts of this era include problems of pregnancy and childbirth, amenorrhea, dysmenorrhea, hypomenorrhea, hypermenorrhea, oligomenorrhea, prolapsed and inverted uterus, cancers, and hysteria. Breast cancer is listed in the *Tongui pogam* in a discussion of lactation.

Abnormal conditions in pregnant women seem to have included eclampsia, unusual mental conditions, pyelonephritis, dysentery, malaria, and pain due to expansion of the heart and chest. After childbirth, women were susceptible to five kinds of fever due to the following: (1) excessive loss of blood leading to anemic fever; (2) uterine fever; (3) high fever caused by food poisoning; (4) high fever due to wind and cold; and (5) fever caused by inflammation of the mammary glands.

Other symptoms associated with diseases of women suggest painful disorders of the bladder and urethra, hernia, ovarian varicocele, and elephantiasis vulvae. A condition associated with inflammation, pus, and pain in the urethra and the surrounding muscles, said to come from "perverted" sexual acts, was probably due to gonorrhea. A condition called "poisonous urine" was associated with the discharge of pus and blood.

Convulsions in Children

According to the pediatric sections of the medical texts of this era, convulsions were second only to smallpox as a medical problem characteristic of childhood. Childhood convulsions included all kinds of diseases of a nervous nature, such as nervousness, spasms associated with high fever, epilepsy, spasmo-

philia, infantile tetany, night terrors, chorea minor, tics, and fits.

Insanity and Psychosis

The relationship between Ho Chun's Taoist philosophy and his medical theories are most apparent in his consideration of mental illness. He based his medical philosophy on the three essences of the Taoist religion: spirit, air, and god. To simplify, we may say that Ho Chun spoke of seven aspects of "mind": happiness, anger, melancholy, thought, sadness, fear, and fright. Injury to these seven "minds" results in disease and mental illness.

The *Tongui pogam*'s section on insanity covers symptoms that suggest epilepsy as well as insanity. Psychosis was considered "true madness," and was thought to be caused by devils. The discussion in the *Tongui pogam* makes it clear that mental disease was thought to be of two main kinds. The first was epilepsy and insanity; the other was psychosis or "true madness." In ancient times, however, insanity was outside the domain of scholarly medicine; treatment called for the *mudang* (Korean shaman) rather than the physician.

Miscellaneous

The Chinese character for epilepsy used in the Korean texts implies both seizure with loss of consciousness and insanity. The *Tongui pogam* discusses a similar condition known as "God disease," which is probably equivalent to epilepsy.

Both the *Hyangyak chipsong pang* and *Tongui pogam* discussed tetanus in connection with strokes. However, since the Koryo era, physicians had been well aware of the relationship between tetanus and wounds.

The medical texts discussed ordinary dog bites, mad-dog bites, and rabies. Treatment began with washing the bite and cleaning it to remove dirt, wood splinters, and so forth. The wound was washed with water or hot human urine to remove the poison. Medicines that had cats as their main ingredient were prescribed. Presumably, the cat in the medicine would scare away the dog poison.

A condition that appears to be polyarthritis was called "white tiger disease" because the pain was as severe as that of having been bitten by a tiger. The *Tongui pogam* also emphasizes the varying levels of pain associated with arthritis. A condition referred to as "wind pain" might have been gout, whereas another description suggests the modern diagnosis of osteomyelitis or periostitis. A condition described as a disease caused by a worm eating the synovial

fluid might have been osteomyelitis of a tuberculous nature.

Symptoms associated with rickets, including a condition referred to as "turtle chest," appear in the pediatric section of the *Hyangyak chipsong pang*. Osteomalacia, a form of adult rickets, which is far more common in women than in men, was called "gentle wind" disease.

VI.9
Diseases of the Modern Period in Korea

Medical Missionaries

Except for the addition of cholera, the diseases of Korea of the nineteenth century and the first half of the twentieth century differed little from the ones prevailing in earlier times. In fact, Westerners who came to Korea in the 1880s and 1890s thought that the illnesses found in Korea were generally the same as those in North America. George W. Woods, for example, a surgeon aboard the U.S.S. *Juniata* of America's Asiatic Squadron, reported that he knew of no diseases peculiar to Korea, but he was struck by the almost universal presence of smallpox and malaria. Woods, who spent almost 3 months of 1884 in Korea, was one of the first Americans to visit the peninsula (Bohm and Swartout, Jr. 1984).

Medical missionaries, upon whose observations we rely for much of this essay, tended to believe that Korean medical knowledge was entirely borrowed from China and that the history of real medical work in Korea began in September 1884, when Horace N. Allen of the Presbyterian Mission came to Seoul. Medical missionaries soon realized that foreign doctors could best establish a claim to medical superiority through surgery. Among the operations Allen performed were excision of the ankle, knee, shoulder, and wrist; amputation of fingers, arms, legs, cancers, and tumors; dissection of scrofulous glands; enucleation of the eyeball; treatment of cataract and pterygium; and closure of harelip. One of the most frequently performed minor surgical operations was for fistula. One Western physician, Oliver R. Avison, blamed this apparently common condition on the Korean custom of sitting on the floor instead of on chairs (Avison 1897).

After a little more than 3 years of medical work in Korea, Avison concluded that the kinds of diseases seen in Seoul were about the same as those seen in Canada, but also that the relative frequency was different. Avison, founder of Severance Union Medical College and Hospital, had come to Korea in 1893 in response to H. G. Underwood's call for medical missionaries. His Korean patients suffered from all the usual diseases of the major organs, eye diseases, conjunctivitis, ulceration of the cornea, hernias, various forms of heart disease, hysteria, epilepsy, paralysis, Bright's disease, asthma, bron-

chitis, tuberculosis, whooping cough, diphtheria, ulcerative tonsillitis, skin diseases, scabies, diarrhea, dysentery, intestinal worms, leprosy, syphilis, smallpox, malaria, typhus, and fevers of various sorts. Although he usually wrote with immense confidence in his own opinions, Avison admitted that "as we do not have the privilege of making autopsies to correct our diagnoses in case of death, many of our suppositions . . . may not be correct" (Avison 1897).

Among the cases seen in the 1920s by Sherwood Hall were the following: gangrene, enlarged spleen due to chronic malaria, enlarged liver due to liver abscess, ascites, pleural effusion, edema, distomiasis due to lung flukes, and many forms of tuberculosis, often advanced cases. Hall thought that the use of unsterilized needles in acupuncture and moxa often led to infection and painful inflammation. Among women patients, Marian Hall encountered abdomens swollen from enlarged uterine fibroids, tumors, and ovarian cysts (Hall 1978).

The early missionaries often fell victim themselves to endemic diseases such as malaria, typhus, and dysentery. Some of these deaths were obviously unnecessary even with nineteenth-century medical techniques, such as the missionary from Australia who contracted smallpox after only a few months in Pusan, apparently because he had placed his faith in Providence instead of vaccination.

Despite the obvious effectiveness of quinine, vaccination, and various surgical operations, the medical missionaries found that Western medicine was quite powerless before "continued fevers" or, put another way, that the *mudang* (Korean shaman) was equally as effective as they were. Indeed, the missionaries admitted that in the treatment of many ailments, the results obtained by Korean doctors were comparable to those of the Western doctor (Busteed 1895).

Studies of Korean village life in the 1940s found that although people died from many different diseases, no adequate accounts of morbidity and mortality patterns were available. Practitioners noted that many children died of tuberculosis, whereas many adults died of uncertain maladies of the stomach or intestines, which probably included bacillary dysentery. Among the diseases common in the villages were smallpox, typhoid, typhus, cholera, malaria, and parasitic worms. Quinine and preventive vaccines did make inroads on malaria, and some of the other diseases and health examinations were conducted in the schools where inoculations were given to students if infectious diseases were found (Osgood 1951).

Population

According to the *Korean Repository* of 1892, the only honest answer to the question "What is the population of Korea?" was that "a definite figure cannot be reached at present." Estimates varied from 5 million to 29 million. The Korean census printed under government auspices in 1885 reported the population (probably a sizable overestimate) as about 28 million (15,004,292 males and 13,003,109 females). According to Woods, the population of Seoul in 1884 was about 500,000 inhabitants, but Percival Lowell suggested that about 250,000 people lived within the 10 square miles of the city (Bohm and Swartout, Jr. 1984).

In 1944, the population was estimated at about 23 million Koreans and about 630,000 Japanese, but by this time epidemic diseases were being tamed by public health work, quarantine regulations, and vaccinations against smallpox, typhoid fever, and cholera. Nevertheless, tuberculosis, intestinal diseases, venereal diseases, and leprosy (despite isolation of lepers) remained as public health problems (Simmons et al. 1944).

Water Supply

As in most nineteenth-century cities, the streets of Seoul were "filthy, dirty lanes" flanked by ditches that drained house privies and sewage. Refuse was poured into the ditches with the hope that it would eventually disappear into the river. Wells were dug conveniently close to major city lanes, which unfortunately meant inevitable contamination with sewage from the nearby ditches and, thus, intestinal diseases such as diarrhea and dysentery. The situation was similar in small towns and rural communities using water from wells, springs, creeks, and rivers. Both produce and water were generally contaminated because of the use of night soil as fertilizer.

It follows then that much sickness and death could be attributed to contaminated water, although most adults were partially immune because of constant infection. In addition, the custom of drinking tea or water boiled in the rice kettle provided some safety.

In the twentieth century, the problem began to abate somewhat, and by 1944, the larger cities and towns had modern water facilities, and public health laboratories were involved in testing food and water (Simmons et al. 1944). The conditions that had prevailed in the nineteenth century, however, created fertile soil for not only dysentery but also cholera and typhoid.

Cholera

After escaping its original home in India in 1817, cholera began a global migration; by 1820 it had advanced into China and shortly afterward into Korea and Japan as well. According to Korean records, the first major cholera epidemic occurred in 1821, and observers were sure that the devastating disease, which reached P'yongyang by the end of July 1821, had begun in China. Within 10 days more than 1,000 people had died. The epidemic reached Seoul in August, and by the end of September was in the southern part of the peninsula and all the cities of Kyongsang Province.

Physicians could neither cure nor prevent the spread of this disease, which terrified observers claimed would kill 9 out of every 10 people stricken. Once the first cases of cholera developed, it appeared to spread instantly to surrounding areas, killing countless numbers of people. Stunned by its virulence, the King appealed to the gods, and the people held feasts and ceremonies to propitiate disease devils. Gradually as winter arrived, cholera seemed to disappear, but in April of the following year it reappeared around Seoul and once again spread throughout the country. By mid-August, the epidemic had reached Japan (Miki 1962).

Between 1822 and the 1870s, epidemic cholera made several more invasions, but the records are not precise. There are indications of several cholera interchanges between Korea and Japan during this period, and sometimes the disease spread from Japan to Korea; however, it usually followed the northern land route from Manchuria along the western coast or across the Yellow Sea. Following the 1870s, cholera epidemics were recorded for the years 1881, 1885, 1886, 1890, and 1891.

Modern cholera prevention practices began in 1880 when the illness spread from Japan to Pusan. Emergency policies included established of Disinfection Stations and Cholera Refugee Hospitals. In 1895, during the Sino-Japanese War, cholera broke out in Manchuria. The epidemic slowly but inexorably crept into Korea, finally attacking Seoul with great virulence: At the peak of the epidemic, over 300 were dying per day. During the 6 weeks of the epidemic, over 5,000 deaths in Seoul and vicinity were counted out of a population of about 220,000. The exact number of cases throughout the country is unknown, but it is estimated that some 300,000 people died (Clark 1979). The first cholera hospital organized by Avison in Seoul was closed after the mortality rate of the first 135 patients reached 75 percent.

A second hospital treated 173 cases with a mortality rate of 35 percent (Avison 1895).

In 1902 when cholera epidemics were reported on the continent, all the harbor towns in Korea established Quarantine Stations; nevertheless, epidemic cholera once again attacked Seoul, and deaths reached about 10,000. In 1907 it claimed hundreds of victims in outbreaks around Seoul, Pusan, Inchon, and P'yangyong. It appeared again in 1908, and in 1909 reached Seoul and Inchon from Manchuria. In the latter epidemic, 1,775 contracted cholera and 137 died. During still another outbreak in 1910, which also seems to have originated in China, 456 Koreans contracted the disease and 367 died, along with 722 Japanese in the country who suffered from the illness (Miki 1962). During the epidemic of 1919–20 there were some 44,000 cases, and then for several years no cases were reported. In 1929, only 18 cases were reported, but 15 were fatal, and in 1933, 70 cases were reported with 37 deaths.

One must consider that official reports may have underestimated or deliberately concealed cholera outbreaks. For example, the League of Nations listed Korea as a country in which cholera was epidemic in 1937, while the official reports noted only one case (Simmons et al. 1944). Indeed, some claimed that cholera was never endemic in Korea and always came from outside the country, but this was disputed by other authorities.

Dysentery

Diseases with the characteristic symptoms of dysentery existed in ancient times in China, Korea, and Japan, and in modern Korea both bacillary and amebic dysentery were quite prevalent. Noting that Korean patients recovered from amebic dysentery better than Japanese patients, Hall concluded that dietary habits created different intestinal environments. He advised his Japanese patients to include kimchee in their diet and thought that this improved recovery during later outbreaks (Hall 1978).

Adults probably acquired some immunity as a result of repeated infections in childhood, whereas dysentery in children was probably confused with common "summer complaints." Nevertheless, fatality rates during the 1930s were estimated at about 20 percent of those attacked. Between 1929 and 1937 the number of cases reported annually varied from about 2,000 to almost 5,000. Amebic dysentery was more common than the bacillary type (Simmons et al. 1944).

Typhoid and Paratyphoid Fevers

In Korea many people considered typhoid a rather minor disease, perhaps because most adults had been exposed during childhood. Woods's informants thought typhoid a rare disease, but he was sure that it could not be, given the poor sanitary state of Seoul (Bohm and Swartout, Jr. 1984). Avison also considered Korea to have all the conditions needed for typhoid fever to flourish, but at the same time he stated that he had never seen a case he could definitely identify as typhoid.

Nevertheless, as diagnostic procedures improved, it became apparent that typhoid fever was the most frequent of the enteric diseases in Korea. Between 1929 and 1937 about 6,000 cases were reported annually, with a fatality rate about 17 percent. During the same period, between 300 and 700 cases of paratyphoid fever were reported annually, with a fatality rate of about 7 percent (Simmons et al. 1944).

Parasitic Infestations

Intestinal infestations with parasitic worms were so widespread in early twentieth-century Korea that some public health authorities believed at least 95 percent of the people were affected. Avison (1897) noted a great demand for worm medicine and reported seeing round worms and tapeworms of prodigious size.

Infestation with flukes was also widespread because of the preference for eating raw fish and crustacea which were often contaminated with the lung fluke (*Paragonimus westermani*), the liver fluke (*Clonorchis sinensis*), or the intestinal fluke (*Metagonimus yokogawai*). Paragonimiasis or pulmonary distomiasis was most common; it was generally acquired by eating raw crab meat. The developing parasites lodge in the lungs and cause an intense inflammatory reaction that results in the production of rusty-brown sputum. Before the etiology and transmission of the disease was understood, cases of paragonimiasis numbered as many as 40,000 per year. Metagonimiasis was also quite frequent, but this disorder was considered mild. Clonorchiasis was rare, but it did cause severe damage in affected individuals (Miki 1962).

Ancylostomiasis, or hookworm disease, caused by *Necator americanus* and *Ancylostoma duodenale,* was common during the nineteenth and early twentieth centuries in Korea. Such infestations probably affected 25 to 30 percent of the people and were the cause of much malnutrition and secondary anemia. In addition, *Ascaris lumbricoides,* the roundworm, was said to infect about 95 percent of the people. By contrast, the pinworm or threadworm, *Enterobius yermicularis,* and the whipworm, *Iricouris trichiura,* seemed to have been comparatively uncommon (Simmons et al. 1944).

Tuberculosis and Pneumonias

Tuberculosis was "the great enemy of health" in Korea, as in much of the world in the 1890s. Pulmonary tuberculosis was the major form, but physicians also saw cases of bone and joint disease, scrofula, and abscesses of the lymph nodes. Avison (1897) argued that consumption was even more difficult to treat in Korea than in Canada, and in fact regarded such cases as hopeless, unless they were discovered very early and the patient was given good food and attention.

The disease remained highly prevalent in the 1940s, with pulmonary tuberculosis still the most common form, but all forms – such as nodular, cutaneous, intestinal, bone, and joint – could be found. Lobar and bronchopneumonia were also common (Simmons et al. 1944).

According to Hall (1978), who founded the first tuberculosis sanatorium in Korea, the disease affected about one out of five Koreans. Almost all adults produced a positive reaction to the tuberculin test. Unsanitary, crowded conditions among factory workers in the city contributed heavily to the spread of tuberculosis from big cities to rural villages and back again along new lines of travel. As elsewhere, an increase in tuberculosis in Korea was part of the toll of modernization and communication with the outside world.

Smallpox

Smallpox was one of the most feared diseases on the peninsula, and almost every person past the age of 10 years had smallpox scars (Hirsch 1883). In fact, children were hardly considered members of the family until they survived their bout with this illness. One woman told Avison that she had given birth to 11 children, but that all of them had died of smallpox before reaching the age of 2 years.

It is interesting that most medical missionaries never mentioned the practice of inoculation and asserted that in Korea there were no methods of prevention or treatment other than magical ceremonies to propitiate the evil spirit that supposedly caused the disease. On the other hand, Woods had no difficulty in learning about the Korean method of smallpox inoculation during his 3-month visit. In a meet-

ing with an elderly Korean physician the subject of smallpox was the major topic of discussion. According to Woods, smallpox was so common and "apparently so mild in type" that it was considered no more dangerous than measles. Perhaps he misinterpreted a situation in which mortality from measles made it almost as dangerous as smallpox. In any case, Woods noted that Koreans had practiced inoculation for centuries and that vaccination was beginning to displace the ancient methods.

Inoculation was commonly performed by powdering the smallpox scab, placing it on cotton, and introducing it into the nostrils. Alternatively, the scab was mixed with candy and given to the child. That these methods were not very effective, however, can be seen by the fact that the disease seemed to leave its characteristic sign on so many. On one occasion, when surrounded by a crowd of men and boys in Seoul, Woods amused himself by counting those who were pock-marked; he counted 40 with scarred faces among 70 people (Bohm and Swartout, Jr. 1984).

The question of smallpox scars was said to have determined Queen Min's survival in the palace intrigues of 1882. When King Kojong's father seized power, he condemned the Queen to death. Disguised as a peasant, the Queen tried to escape to the countryside, but she was stopped by guards at the city gate. Because the guards did not know the Queen, one of them suggested that they examine the woman's face, knowing other members of her family to be pock-marked. The Queen's face was perfectly smooth. Sure that a woman of good complexion could not be a member of the Min family, the guards let her go free. Eventually the King and Queen were restored, and the King's father became a state prisoner in Peking (Bohm and Swartout, Jr. 1984).

Vaccination was increasingly accepted during the early twentieth century. Hall, who was born in Korea in 1893, noted that smallpox had been very prevalent when he was a boy, but had been practically eradicated in the late 1920s (Hall 1978). In 1909, as many as 4,540 people suffered from the disease. In the following year, of the 2,425 Koreans who contracted smallpox, 445 died; 36 out of 455 Japanese who also contracted the disease died (Miki 1962). In 1921, there were 8,321 reported cases, but by 1936 this had been reduced to 1,400, with 371 deaths. In 1937, there were only 205 cases with 44 deaths, but the number of deaths rose again in 1940, which was reported to have been an epidemic year. The fatality rate estimated during the first 40 years of the twentieth century was about 20 to 27 percent (Simmons et al. 1944).

Mosquito-Borne Illnesses

Malaria seems to have been the most common, widely distributed disease in Korea. On the Korean peninsula, malaria almost always appeared as the "3-day fever" and was most prevalent in areas with numerous rice fields, which Avison thought "constitute a suitable home for the development of the malarial poison." He assumed that all the varieties of malaria would be found in Korea, but most cases were of the tertian or quartan type. The people were familiar with quinine, and there was a great demand for it, especially during the fall and winter months. Unfortunately, bogus products were often sold as quinine (Avison 1897). Malaria was still common in the 1940s, especially in the southern provinces.

Filiariasis due to *Wunchereria bancrofti* was also found in the southern provinces of Korea in the 1940s. The principal vectors of this disease were *Anopheles hyrcanus sinensis* and *Culex fatigans.*

It is interesting to note, however, that dengue fever and yellow fever were not found in Korea despite the presence of dengue fever in areas that had frequent intercourse with Korea. This is particularly remarkable because the principal vectors of dengue fever, *Aedes aegypti* (also the principal vector of yellow fever) and *Aedes albopictus,* are found in Korea.

Bubonic Plague

Although devastating epidemics of bubonic plague were recorded in China since 1331, the surviving Korean literature does not seem to reflect similar episodes. The bubonic plague outbreaks that occurred in Asia from the 1890s to the 1920s were, of course, watched with great interest by bacteriologists and public health workers. Of special concern to Korea was the epidemic that occurred in northwestern Manchuria and spread along the newly constructed railroad lines to various cities of northern China, killing 600,000 people in 1911–12. As the 1911 epidemic spread through China, Korea organized preventive teams of personnel and established a quarantine line along the northern frontier. Later plague epidemics in Manchuria, Mongolia, and northern China also failed to reach Korea.

Human plague was reported in Korea in 1919, but there were no official reports of the disease between that year and 1944. Nevertheless, sporadic cases may have occurred and some cases may have been imported during World War II. In 1939, Hall was summoned to the military hospital wing of the Haiju Government Hospital for a consultation about a mysterious condition spreading among wounded soldiers

returning from Manchuria. It was apparently a type of lung disease that had also attacked medical attendants. The Japanese physician in charge had ruled out bubonic plague because the sick had no swelling or tenderness of the lymphatic glands in the groin or axilla; however, a sudden severe headache was followed by nausea and vomiting. Other symptoms were high fever; extreme prostration; rapidly labored breathing; cough; and expectoration of a watery, frothy sputum: The afflicted died within hours, almost black with cyanosis. Hall suspected plague and found *Pasteurella pestis* in sputum from the sick. Sworn to secrecy by the Medical Officer, Hall suggested increased precautions to protect the staff and an all-out war on rats. Yet, no new cases appeared among hospital patients or staff, and the Chief Medical Officer decided that it was not necessary to alarm the public by instituting rodent control measures (Hall 1978).

Relapsing Fever

Relapsing fever, once considered one of the forms of typhus, may have appeared in Korea during the sixteenth century, when epidemics occurred in China and Manchuria. In addition, the epidemic fever that appeared in 1886 might well have been relapsing fever (Miki 1962). Reports from the 1940s indicated that this disease was very rare in Korea, although ticks that serve as vectors of relapsing fever are present.

Typhus Fever

Typhus fever was fairly prevalent in the 1890s in Korea, especially among the poor. By the 1940s observers had detected three types of typhus fever in Korea: the epidemic, or louse-borne type (*Rickettsia prowazeki*); the endemic, or flea-borne type; and the mite-borne type caused by *Rickettsia orientalis,* known as tsutsugamushi disease or Japanese river fever. The forms of typhus transmitted by mites and lice have the highest fatality rates, but endemic typhus, sometimes called "Honan fever," was the most common form in Korea. Several types of mite existed in Korea, including *Trombicula akamushi,* the chief vector of *R. orientalis*. All three varieties of human lice were prevalent in Korea.

Between 1929 and 1937 the annual number of typhus cases reported varied from 890 to 1,683. The fatality rate was estimated as 11 to 13 percent. Tsutsugamushi disease was the least frequently reported. Body lice were also found to carry *Rickettsia quintana,* which causes trench fever.

Venereal Diseases

According to Avison, veneral diseases were about as common in Korea as they had been in England, but the syphilitic patients who came to the hospital were all in the third stage of the disease. During the earlier stages the usual method of Korean treatment was exposure to the fumes of a mixture containing mercury. Similar remedies had long been popular in Europe, although the benefits were dubious and side effects of mercury poisoning included excessive salivation, ulceration of the gums, and loss of teeth (Avison 1897).

Venereal diseases were still prevalent in the 1940s. The most significant venereal diseases were syphilis, gonorrhea, and chancroid. Lymphogranuloma venereum was occasionally reported, and granuloma inguinale was quite rare.

Nutritional Diseases

Several conditions described in classical Korean medical texts suggest long familiarity with beriberi, especially in association with times of famine. However, beriberi was rare in Korea as compared to other areas in Asia. In the early modern period the disease almost never appeared in rural Korea, but it was observed among Japanese students in Korean cities. In the 1940s the disease was still more prevalent among the Japanese than Koreans, because the Japanese were more likely to consume polished rice. During World War II, however, eating white rice became more common, and beriberi was sometimes observed even in villages.

Osteomalacia, or adult rickets, a gradual deformation of improperly calcified bones caused by lack of vitamin D, was fairly common in older women. Scurvy and pellagra were very rare, but nutritional anemia and anemia secondary to hookworm infestation were not uncommon.

Leprosy

Since ancient times, leprosy has been one of the most abhorred diseases. According to Korean medical folklore, the disease could be transmitted directly by the sick or through "intermediate hosts" such as fish or chicken. It was also seen, however, as heaven's punishment for sins in this life or in previous lives. Even in the modern era, when leprosy appeared, superstitious people would say "an evil spirit remained in that house and caused disease in the descendants."

In the 1890s a few isolated cases of leprosy could be found in the general area of Seoul, but most patients came from the southern provinces. The disease generally progressed slowly, but according to

Avison (1897) it appeared in all the forms described in the textbooks.

Segregation laws were passed in the early twentieth century, but were not strictly enforced, primarily because facilities for isolation were not available. According to statistics gathered in the 1930s and 1940s, relief stations of an official and a private nature housed about 7,000 lepers, and medical workers estimated the number of lepers living outside these institutions to be another 7,000. These numbers, however, are probably grossly inaccurate, with the total number perhaps closer to 20,000. In the 1940s about 5,000 lepers lived in the government leper colony on Little Deer Island off the southern coast, and another 1,500 or so lived in mission-operated colonies. Gradually, public health policies, relief agencies, and improved living standards have reduced the number of lepers.

Scabies

Scabies probably existed in Korea and China from ancient times. Since the fifteenth century, Korean doctors treated scabies with remedies that included sulfur poultices and arsenic sulfide. Avison reported that scabies was very common among his patients, as were scalp eruptions from head lice, and various forms of suppurating sores on other parts of the body (Avison 1897). The itch-mite, *Sarcoptes scabiei,* which causes scabies, is only one of the varieties of mites found in Korea. During the 1940s, scabies, trichophytous infections, and impetigo were quite common.

Eyes, Ears, Noses, Teeth

According to Woods and Avison, eye diseases were quite common. Eye disorders included purulent conjunctivitis, ulceration of the cornea, and complete destruction of the eyeball. Often severe eye disease began with simple conjunctivitis following measles or smallpox. Surgical operations for cataract and pterygium were often successful (Avison 1897). During the 1940s, trachoma was frequently the cause of the pannus, entropion, trichiasis, and corneal ulcerations that caused loss of vision. Other causes of blindness were gonorrheal ophthalmia and smallpox. *Hemophilus influenzae* (Koch–Weeks bacillus) was one of the causes of purulent conjunctivitis reported in the 1940s (Simmons et al. 1944).

Ear diseases were quite common: Most cases were the result of smallpox in childhood. Suppuration of the middle ear often led to destruction of the drum, and sometimes there was growth of polypi. Nasal polypi were quite common, but surgical removal produced good results. The need for tooth extraction was quite low, because most people, except for those with congenital syphilis, had very good teeth (Avison 1897).

Miscellaneous Diseases

In Korea, as in China and Japan, there is no clear historical description of a disease corresponding to diphtheria until the modern age, perhaps because diphtheria is not strongly associated with dramatic epidemics of high mortality. Indeed, mild cases are not unusual, and immunity is often quietly acquired at an early age. Avison (1897) thought it very strange that diphtheria was so rare in Korea. He had seen a few cases that he was certain were diphtheria, but some physicians claimed that the disease was not found in Korea.

By contrast, twentieth-century physicians found diphtheria to be rather common in Korea. In 1937 there were 2,361 cases, with 608 deaths. The fatality rates varied from 21 to 29 percent over a 12-year period.

Scarlet fever was also quite common in the 1940s. Between 1929 and 1937 reported cases varied from 937 to 2,190 per year, with fatality rates from 10 to 15 percent. Mumps, whooping cough, poliomyelitis, and encephalitis were also reported in the 1940s (Simmons et al. 1944).

Outbreaks of cerebrospinal meningitis continued to occur in the modern period, with a major epidemic taking place in 1934–5. The disease remained endemic in the 1940s, with about 50 to 500 cases reported annually between the years 1929 and 1937. The fatality rate varied from about 50 to 60 percent (Simmons et al. 1944).

Leptospirosis, also known as Weil's disease, or infectious jaundice, was endemic in Korea. The disease is spread via food or water contaminated by the urine and feces of infected rats. Rat-bite fever, caused by *Spirillum minus,* was transmitted by the bite of infected rats.

While visiting a drugstore in Seoul with his interpreter, Woods (see the first section of this chapter) examined many roots and herbs that were all said to be "good for the stomach!" This suggests, of course, that digestive disorders were common. Gastritis seemed to be the major disease in the category of stomach diseases, although Avison thought that common complaints of chronic indigestion included many cases of stomach ulcers.

The Avison family learned that rabies was a fairly common threat when two of the children were bitten

by a rabid dog. Rabies was still a problem in the 1940s because of the large numbers of stray dogs.

And finally, according to Woods's informants, midwifery was practiced by old women, who consulted physicians in difficult cases. Many of the midwives were reportedly skillful and able to perform the manipulations necessary in correcting unnatural presentations (Bohm and Swartout, Jr. 1984). Lack of cleanliness in the instruments used to cut the umbilical cord was responsible for many cases of neonatal tetanus in infants, even in the 1940s (Simmons et al. 1944).

Diseases in the 1940s

Epidemic and endemic diseases were carefully monitored by the U.S. Army Military Government after World War II. Among the communicable diseases reported in 1946 and 1947 were typhus, smallpox, relapsing fever, cholera, meningitis, encephalitis, malaria, diphtheria, typhoid, and bacillary dysentery. The Institute for the Prevention of Infectious Diseases stocked and dispensed diagnostic tests and vaccines for many of these as well as other diseases. Although there were no cases of human plague reported in South Korea, antiplague measures, including port quarantine stations and rat control, were instituted when a case was reported in North Korea near the Manchurian border (Summation 1946, 1947).

By the end of 1947, the communicable disease picture was relatively stable. The incidences of many diseases, especially typhus, typhoid, and smallpox, were substantially decreased. In 1946, 117 cases of typhus had been reported, but only 4 were reported in 1947. Typhoid fever cases were reduced from 239 to 24 cases, and smallpox cases decreased from 41 to 2. When cholera appeared immediately after World War II, the American occupation forces were involved in managing the outbreak. Nevertheless, in the 1946 cholera epidemic there were 15,748 cases with 10,191 deaths. By 1947, however, there were only 14 cholera cases, with 10 deaths (Summation 1947).

The general decrease in communicable diseases was attributed to (1) disease control programs; (2) educational prevention programs; (3) increased availability of preventive inoculations and therapeutic drugs; and (4) establishment of clinics and health centers.

By 1948, diphtheria, typhus, and typhoid were about the only major communicable diseases still reported in South Korea. Typhus was generally the louse-borne form, but relapsing fever was often mis-taken for typhus. A few sporadic cases of relapsing fever, bacillary dysentery, and smallpox were reported and gonorrhea and syphilis were not uncommon among prostitutes in Seoul and other cities (Summation 1948). However, leprosy remained a public health problem. There were only six leper clinics in South Korea, and the authorities conceded that it would be impossible to institutionalize all of the approximately 31,000 lepers in the country (Summation 1948).

A study of mortality in children revealed that from April to December 1946, 36 percent of all deaths were of children under 5 years of age. Measles, complicated by bronchopneumonia, accounted for 18 percent of the child deaths; pneumonia for 14 percent; and meningitis for 8 percent. Influenza and dysenteries followed meningitis in order of importance. An epidemic of smallpox was the cause of another 4 percent of the deaths. Therefore, 40 percent of the deaths in children under 5 years could have been prevented by use of penicillin, sulfonamides, and vaccination (Summation 1948).

Korea in the 1980s

The history of disease in twentieth-century Korea illustrates the remarkable effect of improved sanitary conditions and public health measures. Despite the devastation caused by World War II and the Korean War and the repatriation of millions of Koreans from Manchuria, China, and Japan, many of the epidemic and endemic diseases discussed have been virtually eliminated. Moreover, Korea's traditional agrarian Confucian society has been transformed into one that is highly mobile, urbanized, and well educated. The percentage of South Korean citizens attending colleges ranks among the highest in the world.

The population of the Republic of Korea was about 32 million in 1971, giving it a population density ranking about fourth in the world. With improvements in sanitation, public health, and medical facilities, the population had been increasing at a rate of 2.4 percent per year as infant mortality fell, life expectancy was extended, and endemic and epidemic diseases were brought under control. In the 1980s the population of South Korea was about 42,643,000; one in four Koreans lives in Seoul, the capital city (Gibbons 1988).

VI.10
Diseases of Antiquity in South Asia

South Asia, also known as the Indian subcontinent, extends from the Himalayas south to form a huge triangle that juts into the Indian Ocean with the Arabian Sea on one side and the Bay of Bengal on the other. India, Bangladesh, Afghanistan, Sri Lanka, the Maldives, and the small Himalayan countries of Nepal and Bhutan are included in this area. South Asia can be divided roughly into three parts, beginning with the triangle-shaped Deccan Plateau, moving north to the fertile plain along the Ganges and Indus rivers, and finally extending to the northernmost section at the foot of the Himalayas.

Background: The Ancient Indian Texts

The Ayurvedic Texts

Ancient Indian Medicine had close ties with philosophy and religion. The basic texts of Hinduism are the four Vedas: *Rg, Sam, Yajur,* and *Atharva. Ayurveda,* meaning the "science of life," is considered to be the fifth of these texts and as important as the other four. All of the first four Vedas have sections that deal with healing and the prevention and cure of sickness. Yet the approach is usually magical or by prayer to the deities of the Vedic pantheon.

The Ayurvedic texts, by contrast, are of later origin and tend to attribute disease to divine causes less frequently. The codification of Ayurveda probably occurred around the sixth century B.C., and the texts presumably took their defined forms, in which they are still available, by the sixth or seventh century A.D. They were compiled in the northwestern part of India and in areas that today include Pakistan and Afghanistan, although, with the spread of the Aryans and their culture, Ayurveda came to be practiced over much of the country. Among other things this meant that the texts were modified to take account of the impact on health of geographic location, climate, water, seasonal variations, and diet. Indeed, many sections mention diseases due to these external factors, and one even suggests that geographic variations cause a difference in general health, and that certain locations favor epidemic disease.

The texts are known as the *Samhitas* – a Sanskrit term meaning "any systematically arranged infor-

mational collection of texts or verses." The five known Ayurvedic Samhitas are the *Sushruta,* the *Caraka,* the *Astangahrdaya,* the *Bhela,* and the *Kashyapa.* Some doubt exists about the authenticity of a sixth and incomplete text: the *Harita.*

Ayurveda deals with life (human and animal) in all its aspects including hygiene, ethics, medical education, and rules of behavior. Dietetics, geographic pathology, and even the philosophical basis of existence are also treated. Both the Sushruta and the Caraka divide medicine into eight broad areas: (1) Surgery (*Salya*); (2) Diseases of the Ear, Nose, Throat, and Eye (*Salakya*); (3) Internal Medicine (*Kayachikitsa*); (4) Mental Diseases (*Bhutavidya*); (5) Pediatrics Including Pregnancy and Its Complications (*Kaumarabhrtya*); (6) Chemicals Used in Treatment (*Rasayana*); (7) Rejuvenation; and (8) Aphrodisiacs (*Vajikarana*). The *Astangahrdaya* also mentions eight divisions of the Ayurveda, which are similar but not identical to the previous sections.

Caraka and Sushruta

Any discussion of diseases recognized during the period under scrutiny must rely heavily on the two major Ayurvedic texts – Caraka and Sushruta – because they are the most comprehensive and the least altered by later authors. These texts constitute a massive compendium that describes more than 360 separate diseases. This essay will concentrate on only the more clearly defined of these and, when possible, attempt to equate them with modern disease entities. The detailed observations of the ancient Ayurvedic physicians make available a body of information in which we can find something of a reflection of many of the diseases affecting the Indian subcontinent today.

In discussing the human being in health and disease, the Caraka mentions the necessity of examining the following facets: structure, function, causation, symptoms, methods of treatment, objectives of treatment, the influence of seasons and age, the capabilities of the physician, the nature of the meditations and appliances used in treatment, and the procedures to be used and their sequences.

Concepts of Disease

Ackerknecht (1982) summarized the ancient Indians' concern for disease and health thusly:

The ancient Indians put great emphasis on hygiene and prevention. They recommended toothbrushing, chewing of betel leaves, anointing, combing, exercise, massage, bathing, piety, taking the proper food, sitting idle, sexual inter-

course (once in four days), politeness, not being witness or guarantor, not going to crossroads, not urinating in the presence of superiors, cows, or against the wind, not sleeping during the daytime, and not eating fly-infested food. During epidemics one should not drink water or eat raw vegetables; one should run away and pray. Lest we smile at this strange mixture of Indian hygienic measures, we might remember that the Indians knew for thousands of years a technique for preventing smallpox, which the Europeans learned from the Turks only during the eighteenth century: inoculation.

In the Ayurveda, the balance of bodily health is viewed as being maintained by the healthy functioning of three *dosas* – *Vayu, Pitta,* and *Kapha* or *Sleshma* – which are somewhat akin to the Greek notion of bodily humors. Disturbances of one or more of the *dosas* caused by indiscretions in eating or by bad personal habits, such as suppression of the desire to defecate or excessive sexual intercourse or male intercourse with a menstruating woman, were seen as causes of illness. A few diseases could be triggered by riding on a horse, mule, or camel in an ungainly fashion. Others could arise because of external influences, such as injuries, whereas still others were due to heredity.

After being disturbed, the *dosas* were believed to lodge in a system of the body in an attempt to be excreted. While there, however, they produced disease. Thus specific symptoms or signs were generally viewed as disease, and consequently, the descriptions of many conditions are quite similar.

Wounds, Abscesses, Lymphadenopathies, and Superficial Neoplasms

The descriptions of wounds and abscesses in the texts are detailed and quite complete. The term *brana,* which is often used in the literature and is generally taken to mean an ulcer, has to be interpreted more liberally as a surgical or traumatic wound or even an abscess. A swelling that (1) is localized to one part of the body, (2) is hard, and (3) affects the skin and soft tissues in a particular manner is an inflammatory swelling or *shofa.* These swellings were thought to arise from various causes and were associated with manifestations of imbalance of the particular humors producing the disease.

Such inflammatory swellings were described as red, yellow, or black in color and increased in size at different rates. They produced local heat, burning, and other abnormal sensations and were said to pass through the phases of *Ama* (cellulitis), *Pacchyamana* (localization), and *Pakka* (localized abscess).

The clinical features specifically diagnostic of an

abscess or a wound are also discussed in detail in various chapters; for example, an abscess in connection with a broken bone discharges a mixture of marrow, blood, and often small spicules of bone in a fluid resembling clarified butter. Similar diagnostic features of abscesses at various sites are also given as prognostic signs of danger and curability. The exact timing for the incision of an abscess was thought to be critical, and dependent upon the clinical findings.

Deep-seated spherical or irregular swellings were called *Vidradhi*. Four types were thought to arise from the three disturbed *dosas* individually or in combination. Two other types mentioned are *Agantuka* (due to external trauma) and *Raktaja* (*Rakta* means "blood"). The descriptions of the various *Vidradhis* are often similar. They could develop anywhere in the body, and the overlying skin would have shallow ulcers of varying colors with discharges of differing natures – characteristics that identified the *dosa* responsible.

None of the *Vidradhi* involving the three *dosas* were attended with fever, which makes it difficult to accept them as being abscesses (the usual belief). The *Sannipataja* type – the most serious – resembles the description of a squamous carcinoma more than anything else, and other *dosaja Vidradhis* could quite well have been the same.

Vidradhi arising in the marrow of a bone was termed *Asthividradhi*. This seems clearly to have been acute osteomyelitis, as the bone was swollen with acute pain, and the patient had high fever. Finally the abscess discharged outside through the skin and muscles.

The two types of *Vidradhi* where high fever and thirst were prominent, suggesting an infectious origin, are the *Agantuka* type (caused by a deep wound due to an external agent) and the *Rakta Vidradhi*, arising in the pelvis of pregnant women following parturition, doubtless in many cases puerperal fever.

A variant is the *Antarvidradhi* or internal *Vidradhi*, a situation in which one developed on an internal organ such as the bladder, spleen, liver, or heart. Rectal examination and the passage of sounds into the bladder were common diagnostic techniques in these cases. A *Vidradhi* in the rectum caused symptoms suggestive of large intestinal obstructions, and one on the bladder neck probably indicated obstruction of the passage of urine. However, these symptoms also suggest neoplastic obstruction rather than abscess.

Disturbed *dosas* were also thought to produce slowly growing, cold, round swellings in the tissues,

termed *Arbuda*, which never suppurated and were probably neoplasms. A variant called the *Raktarbuda* reportedly grew rapidly and produced both a discharge and heaped flesh. Because patients suffering from *Raktarbuda* quickly become emaciated and the disease was viewed as incurable, the strong suspicion is that they were suffering from a malignant neoplasm.

Cancer, however, as a specific type of illness was not recognized in the Ayurveda, and the process of metastasis seems not to have been appreciated. Nonetheless some *Arbudas* were known to produce satellite *Arbudas* close by.

Fevers (*Jvara*)

Seven types of fevers were viewed as due to various combinations of the *dosas*, and an eighth was seen as the result of external causes. *Abhinyasajvara* and *Ojoniruddhajvara* are fevers, both of which were thought to occur when all *dosas* were defective. Their symptoms suggest typhoid fever and typhoid fever with delirium as well as cerebral malaria. The *Visamajvaras* were recurrent fevers with intermissions of normal temperature and thus seem to fit the cycles of some of the various types of malaria.

Poisons

The texts make it clear that the specialty of toxicology (*Agadatantra*) was well developed in India. Poisons from plants and minerals are discussed, as well as the symptoms and effects of insect, reptile, and animal bites and methods of treatment. In fact, 10 types of poisonous snakes and the effects of their venom are discussed together with the appropriate antidotes.

Skin Diseases

A disturbed Vayu driving Pitta and Kapha *dosas* into the skin was thought to bring on some skin diseases, whereas other skin diseases were viewed as the work of parasites. As a group, skin ailments were generally termed *Kustha*. The 7 *Maha* (or major) *Kusthas* appear to be variants of leprosy, a disease existing in India from ancient times. The 11 minor *Kusthas* were other skin diseases that are more difficult to equate with current cutaneous orders. However, it would seem that pityriasis versicolor, pemphigus, chilblains, moist eczema, dermatitis, scabies, and leukoderma were all represented.

Leprosy or *mahakushtha*, as it was known in the texts, was understood to be contagious, although it was also thought to be inherited by offspring of affected parents.

Head and Neck Diseases

Some Ayurvedic diseases of the mouth would seem to have a recognizably modern counterpart, among them (1) neoplasms of the lip (when the latter is described with raised areas of flesh that ultimately ulcerate); and (2) herpes labialis, with varicolored multiple small swellings. A condition in which the gums became spongy, retreated, and bled easily may have indicated scurvy, whereas another in which the gums and dental roots bled easily and gave off a purulent exudate may have been pyorrhea or periodontitis. *Mahashaushira* was a grave and painful condition in which teeth became loose in the gums, and the palate and the cheek were ulcerated. This seems to have been either cancrum oris or buccal carcinoma.

Impacted wisdom teeth, dental caries, and a situation in which the teeth were so sensitive that even touch was painful were also described, as were "gravel in the teeth" (tartar), and a condition in which destroyed teeth took on a blue-black color.

The diseases of the tongue discussed in the texts cannot be clearly divided into glossitis and epitheliomata, and many symptoms were taken to be disease entities in themselves. Diseases of the throat are generally termed *Kantharoga*. Among those that appear to be discussed are diphtheria, peritonsillar abscess, carcinoma of the base of the tongue, laryngeal and pharyngeal cancer, acute stomatitis, and chronic laryngitis.

Specific recognizable afflictions of the nose include nasal tumors and nasal polypi, whereas those of the ear embraced deafness, otalgia, otorrhea, and tinnitus.

In the region of the neck it was thought that Vayu and Kapha can become vitiated and lodge in the muscles and fat. The result would be a swelling called *Galaganda,* which did not suppurate, enlarged slowly, and might produce a vague noise in the throat. This disease was clearly goiter. The vague noise mentioned may be the stridor of tracheal compression, though associated difficulty in breathing is not mentioned.

In the hot, dry climate of northwestern India, eye diseases have always been common, and thus the sections on eye diseases are among the most detailed and remarkable of the Ayurveda. These diseases are divided into two broad groups: *Netrarogas,* or diseases of the eyeball; and *Drshtirogas,* or disturbances of vision. Seventy-three *Netrarogas* are described, although some seem to be different manifestations of the same disease. Four of these, for example, seem to be forms of trachoma and two more forms of blepharitis. Various types of corneal ulcers are dis-cussed, as is conjunctivitis and glaucoma. The Ayurvedic variants of a disease called *Adhimantha* are actually the progressive stages of glaucoma, producing a swift loss of vision if untreated.

The section on diseases of vision describes cataract and various forms of another disease that resulted in disturbed vision – possibly symptomatic of glaucoma. Other disturbances of vision included day blindness and night blindness.

Neurological Disorders

Disturbances of Vayu were thought to create many neurological diseases. These included *Dhanustambha* (literally a pillar curved like a bow) or tetanus. Other conditions caused by disturbed Vayu included convulsions, the two types of which may well have been descriptions of petit mal and grand mal epilepsy; paralysis of one lower extremity; paraplegia; sciatica; brachial palsy; and facial palsy. Other diseases that we now do not think of as being neurogenic are also ascribed to disturbed Vayu. These include one that appears to be synovitis of the knee joint, another that seems suggestive of paresthesias of the feet, and still another that seems to have been bowel obstruction. Dumbness, nasal speech, and indistinct speech were also seen to stem from the same cause.

Heart Disease

Examination of the pulse played an important role in diagnosis and prognosis in Hindu medicine. But the nature of circulation and cardiac function was not well understood, which helps to explain the sketchy nature of the descriptions of cardiac diseases in the texts. Moreover, the descriptions in the Sushruta and the Caraka do not exactly correspond. Heart disease due to disturbed Vayu that caused palpitations, pain, slowing of the heart rate, fainting fits, and murmuring sounds in the heart constitutes the only condition that truly suggests a cardiac disorder. Other diseases of the "heart" seem more like gastrointestinal disorders in that they could be caused by bad eating habits, and their symptoms included a sense of heaviness in the precordium, a bitter or acid taste in the mouth, tiredness, and belching. Another type of "heart disease" was due to parasites arising in putrefied food. Here, the parasites were thought to invade one portion of the heart and gradually destroy the rest.

Respiratory Disorders

Respiratory problems are discussed under two major sections of the texts: disorders of breathing and of cough. Hiccough was thought to be a precursor of

respiratory disease which, if left untreated, could help to bring on tuberculosis. Certainly tuberculosis was as common in the past as it now is in the Indian subcontinent. Also apparently described are pulmonary edema, bronchiectasis, and a number of chronic pneumonia types.

Abdominal and Intestinal Disorders

Udara is the anatomical name used in the texts for the abdomen. The term also signifies generalized abdominal disease manifested by enlargement. Most of the Udara disorders are ascribed to bad eating habits or to eating spoiled or poisonous food. A few conditions, however, can be understood by modern medicine. Among them is enlargement of the left side of the abdomen because of a large spleen. The symptoms associated with this condition suggest splenomegaly resulting from malaria or filariasis. Enlargement of the right side of the abdomen was the result of involvement of the liver and at times must have indicated cirrhosis. A particularly ominous situation resulted when all three *dosas* were disturbed: The patient turned yellow and suffered from pain, ascites, and emaciation. This could have been either advanced hepatic cirrhosis with liver failure or liver or pancreatic cancer.

A disease called *Dakodara* was clearly ascites. The abdomen enlarged with fluid that could be palpated, the umbilicus was flattened out or everted, and there were enlarged blue veins in the thin abdominal wall. Another abdominal distension arose from obstruction of the large bowel, and was manifested by progressive constipation, gaseous swelling of the abdomen, and crampy pains, all of which provides a picture of left colonic cancer or, less commonly, progressive anal stenosis. The latter was ascribed to sharp pieces of food perforating the gut and causing continuous thin and liquid anal discharge associated with vomiting, anorexia, abdominal distension, and pain. The condition could well have been acute gastroenteritis, which was, and is still, a common disease in the Indian subcontinent.

Among the discernible intestinal disorders are dyspepsia, acute diarrhea, and dysentery with some symptoms of the latter suggestive of amebic dysentery. Clearly discernible is cholera, or *Vishuchika* – the Ayurvedic term for cholera. The patient vomits, trembles, has continuous watery diarrhea, severe abdominal pain, and hiccoughs. In agonal stages there is tingling all over the body, and the patient loses consciousness and becomes cyanotic. The voice becomes weak, the muscles and joints become lax, and the eyes retract into the orbital cavity. In a variant termed *Alashaka*, diarrhea is not prominent, the abdomen distends, the patient has severe cramps and is very thirsty and nauseated. These symptoms parallel those of cholera sicca.

Miscellaneous

Hemorrhoids were clearly distinguished in the text, and were associated with or seen to be aggravated by excessive horseback riding, sitting on hard wooden seats, and friction with clothes or skin. By contrast, because the anatomy and functions of the kidneys were not well known, specific diseases due to disorder of renal function are difficult to spy. Tasting the urine, however, was an important element in diagnosis, and diabetes mellitus appears to have been understood as a disease.

Another disease, *Pishta,* which translates as "water containing ground rice" and which caused the patient to shiver as he or she urinated, may well have been *Chyluria;* this disease, which arises from filariasis, is common in India today, and probably was in the past as well. In this vein, *Shleepada,* which means "elephantiasis," the most prominent symptom of filariasis, was reported to occur most commonly in areas where stagnant water was plentiful – a desirable breeding ground for the mosquitoes that spread the disease. *Schleepada* was a progressive swelling, generally of the legs and less commonly of the hands, lips, ears, nose, and face, and in its late stages produced irregularities and vesicles on the surface of the skin.

The *dosas* could be disturbed by sexual practices that included too much abstinence or too much intercourse. Syphilis was introduced to India by the Portuguese, and thus there is no mention of syphilitic chancres in the older Ayurvedic texts. But at least soft chancre seems to be discussed under diseases of males and various forms of vaginitis under the female heading. In addition, ailments of women such as amenorrhea and possibly eclampsia can be discerned.

The above sections contain only a fraction of the immense corpus of the Ayurveda. Because of the lack of systematic dissection as well as ignorance of physiological principles, the descriptions of internal disorders in the Ayurveda are vague. However, diseases of the superficial organs and viscera are very well described and generally can be recognized for their modern-day counterparts. The detailed observations of the ancient Ayurvedic physicians have left a body of information in which we can see a reflection of many of the diseases affecting the Indian subcontinent today.

VI.11
Diseases of the Premodern Period in South Asia

Overview

A geographic notion of South Asia generally includes India, Pakistan, Bangladesh, Sri Lanka (Ceylon), and Nepal. But although these countries may be thought of as constituting a single region, they contain a multitude of ethnic groups. Nonetheless, during the medieval ages, they had a common medical heritage rooted in the Greco-Roman world. At the extremities of the system, in northern or northwestern Europe and along the Russian river system, the Greco-Roman medical inheritance was thin. But in southern Europe and throughout the Muslim–Byzantine world, that heritage was rich. The geographic position of the Arabs in Asia Minor close to Greek sources had provided them with the opportunity to know the old Greek authors, especially in philosophy and medicine; therefore, the Arabs became the channels through which Greek influences were carried back into the West once more. Many new observations about diseases and a vast materia medica of the available drugs and medicaments in central Asian countries traveled through channels containing contributions by the eminent physicians of the Christian, Jewish, Muslim, and Hindu religions. Building on Hippocrates and Galen, they all wrote in the common Arabic language, the official language of the Caliphate.

By the beginning of the ninth century, some of the most famous medical men from the East and the West were meeting in Baghdad and ushering in a Renaissance. Indian physicians learned the examination of pulse at Baghdad from Greek and Arab physicians, who were expert in this sort of diagnosis. Knowledge of and interest in alchemy, along with the use of opium and many metallic compounds for treatment of various diseases, were also acquired from contact with the Greeks and the Arabs.

The concept of the modern hospital is a Persian contribution. When the Muslims conquered large parts of the Indian subcontinent, they introduced the concept of hospitals along with other institutions and traditions, and since then hospitals have been a part of city life. One of the 12 commandments issued by the Emperor Jehangir on ascending the throne in the seventeenth century was for the establishment of a hospital in all the larger cities in his domain. Allauddin II was the earliest Muslim king of the Deccan to build a hospital, *Dar-ul-Shifa,* at Bidar, his capital during the fifteenth century where food and drugs were provided to patients free of charge.

The hospitals were mainly staffed by Muslim physicians well versed in Greek and Arabic (now called *Unani*) systems of medicine. Many of them had Ayurvedic physicians on the staff as well. From the ninth century, this tradition of having both Hindu and Muslim physicians in the hospitals continued, particularly in India.

Diseases and Epidemics

The first important Arabic medical treatise that elaborately discussed and summarized the Indian system of medicine of this age is *Firdaus-al-Hikmat,* by Ali ibn Sahl Rabban al-Tabari, who died about A.D. 855.

The work of Rhazes, written in this period, deals systematically with head, eye, lungs, and digestive and circulatory systems, along with diseases of women and midwifery. The contents of the author's studies demonstrate his competence and skill in recognizing various diseases, in differentiating similar diseases symptomatically, in making their classifications, and in adopting methods to treat them.

Appearing early in the eleventh century, *Al-Qanun fi al-Tibb* by Avicenna is by far the largest and most famous medical work of this period. The work is divided into five major books. The first book treats general principles; the second treats simple drugs arranged alphabetically; the third deals with diseases of particular organs and members of the body from head to toe; the fourth deals with diseases that, though local and partial in their inception,

tend to spread to other parts of the body; and the fifth deals with compound medicines.

The *Madanul-Shifa i-Sikandar Shahi* (Sikandar Shah's Mine of Medicine), written in 1512 by Mian Bhowa, discusses the symptoms and treatments of many diseases, including fevers, diarrhea, whooping cough, dropsy, epilepsy, rheumatism, erysipelas, heart diseases, gonorrhea, scrofula, elephantiasis, leprosy, smallpox, measles, and afflictions of children. In all, it discusses 1,167 diseases and the effects of various medicaments.

Smallpox

Inoculation for smallpox seems to have been known to the Hindus from a very early age. Long before Edward Jenner, certain classes in India, especially cow herders, shepherds, charans, and the like, had been in the habit of collecting and preserving the dry scabs of the pustules. They would place a little of this material on the forearm, and puncture the skin with a needle. As a result of this inoculation, these classes are purported to have enjoyed a certain amount of immunity from the disease.

In India, temples in which a deity of smallpox was worshipped hint at its presence prior to 1160 B.C. In ancient India, smallpox was, therefore, apparently regarded by the Hindus as a manifestation of a Hindu goddess called *Maria-tal, Mari-amma Devi, Mata,* or *Sitala.* According to W. A. Jayne (1979), "Sitala (the 'Cool-Lady' with a euphemistic allusion to the burning fever) was small-pox." The goddess was worshipped regularly so that she would not circulate among the villages. One could probably find shrines to her in any village or town in ancient India, according to O. P. Jaggi (1980).

So it seems that the Indian civilization has faced smallpox epidemics on numerous occasions, yet details regarding the complete history of the illness in South Asia remain obscure. The first clinical account of the disease appears in the Middle Ages, by the most competent physician of his age, Rhazes. Although brief mention of smallpox is made in two medical treatises of the period, the work of Rhazes is the first in which the illness is fully treated and in which its symptoms are described. Bhowa's medical treatise appearing in 1512 mentioned the disease smallpox-measles, along with its treatment. Around 1700, Hakim Mohammed Akbar bin Mohammad Muqin Arzani wrote *Mufarreh ul-Qulub,* in which he recorded his own experiments with treatments he adopted to relive the burning and throbbing sensation of the vesicles of smallpox.

The disease attacked the rich and the poor alike. A

civil surgeon of Dacca, for example, found that in the history of the Tipperah family, between the fifteenth and eighteenth centuries, 5 out of 16 Maharajahs died from smallpox. According to S. P. James (1909), an observer writing in 1767 about the prevalence of smallpox in Bengal, said:

Every seventh year with scarcely any exception, the small-pox rages epidemically in these provinces during the months of March, April and May, until the annual returning rains about the middle of June put a stop to its fury. On these periodical returns, the disease proves universally of the most malignant confluent kind, from which few either of the Indians or the Europeans escaped that took the distemper in the natural way, commonly dying on the first, second or third day of eruption.

Inoculation against smallpox has been practiced in the subcontinent since ancient times, and accounts of the procedure are available in the writings of several British writers. O. Coult has given an account of smallpox inoculation (*tikah*) as he observed it in Bengal in the year 1731. Edward Ives, who was a naval surgeon on the flagship *Kent* and who was in India in 1754–7, has given further details of the method. In Calcutta inoculation was practiced among certain classes of Europeans as early as 1785, and apparently in 1787 the government established a hospital for smallpox inoculation at Dum Dum. In 1798, after much experimentation, Edward Jenner established that prior cowpox inoculation (i.e., vaccination; the Latin word for "cow" being *Vacca* and for "cowpox," *Vaccinia*) protected the person from getting smallpox, even though he or she was exposed to it. The practice of vaccination was accepted quickly in England, western Europe, and Russia, and by 1802, only 4 years after this discovery, vaccination was introduced in India.

Cholera

The history of cholera began on the subcontinent of India. Both literary records and religious practices suggest that cholera was endemic to the South Asian region for at least 2,000 years, but it was not until the sixteenth century that European travelers, explorers, traders, and officials provided detailed descriptions of a terrible plague whose symptoms were those of cholera and which was reported to reach epidemic proportions. One authority has identified 64 separate accounts of cholera in India between 1503 and 1817, and no less than 10 of those refer specifically to epidemics. The areas of cholera's historic endemicity were in South Asia, and especially in the delta regions of east and west Bengal.

It is said that the first pandemic of the early nineteenth century remained geographically in Asia, though it approached Europe, and it may have touched Africa at Zanzibar. The following second, third, and fourth pandemics affected the entire world, though with considerable regional variations; the areas of incidence receded significantly in the fifth and sixth pandemics.

During the medieval period, court chronicles described the occurrence of pestilences, though it is difficult to identify their correct nature in terms of diseases we now recognize. G. Gaskoin (1867) refers to *Lendas da India,* a publication by a Portuguese named Gaspar Correia, who in the spring of 1543 witnessed cholera in an epidemic form at Goa. The local people called it *moryxy,* and the mortality was so great that burying the dead was difficult. In 1563, Garcia da Orta wrote a vivid description of cholera as he saw it at Goa, adding that the disease was most severe in June and July. In the 1600s, more reports of epidemic cholera appeared in Madura (1609), Jakarta (1629), and Goa (1683). Cholera was next reported in 1783, when it broke out at Hardwar and, in less than 8 days, killed approximately 20,000 pilgrims. At the same time, the Maratha armies, engaged in war with Tipu Sultan (the Sultan of Mysore), suffered severely from the disease. In 1787, there was another account of the disease in India given by an English physician (a Dr. Paisley). Again in 1796, Fra Paolino de S. Bartolomeo penned an account of cholera in India.

The appearance of the disease at Fort William in 1814 was reported by R. Tytler, Civil Surgeon of Jessore. However, the first full and accurate account of epidemic cholera dates from 1817 to 1823. The earliest notice of this epidemic was given by Tytler in a letter dated August 1817: "An epidemic has broke out in the bazaars, the disorder commencing with pain or uneasiness in different parts of the body, presently succeeded by giddiness of the head, sickness, vomiting, griping in the belly and frequent stools."

While the cholera epidemic spread in the countries to the west of India, it was also transported to the east. In 1819, Burma and Ceylon were under its influence. The next year Siam was afflicted, as was Malacca, where the disease was said to have been brought by a vessel from the coast. Shortly after some persons with cholera-like symptoms landed from a vessel, the outbreak began. This outbreak occurred after Dutch vessels coming from Calcutta had anchored at Malacca. China and the islands of the Mauritius were also overwhelmed by the disease.

The cholera epidemic of 1817–23 gradually disappeared from the countries over which it had spread, and in Bengal little was heard of the disease throughout the years 1823–5, except in the endemic areas. But during the first quarter of 1826, cholera again erupted throughout the lower Bengal. From there it spread to Banaras and extended as far as the Kanpur Division, reaching the stations on the right bank of the Jamna. It was heard of at Hardwar in April and throughout the northwestern frontier provinces and along the Himalayas before the middle of June. Bombay Presidency, Sind, and the Punjab were assaulted by the disease which reached there from the east during the year 1827. It entered Khiva and Herat via Kabul in 1829. The epidemic from Kabul, Herat, and Persia spread to Russia and Poland in 1830, to England in 1821–32, to France in 1832, and in the same year to America, where it made its first appearance, to Cuba and Mexico in 1833, again to Europe from 1835–7, and finally to Africa in 1837. Subsequent cholera epidemics were observed in Europe and America (1848–53), in Punjab (1855), in Persia (1857), and in Arabia (1858–9). It appeared again in Punjab (1861), and traveled from Bengal to Africa, Arabia, Europe, and America (1863–5).

Plague

There is uncertainty in attempting to trace the historical background of plague in South Asian territories. According to Jaggi, extant references in Indian history for some pestilences that raged from time to time could indicate epidemics of plague. One probable epidemic attacked the army of Muhammad Tughlaq in the twelfth century. Again in the year 1443, a pestilence caused great loss of life in the army of Sultan Ahmad I. Farishta, a contemporary of the Mogul emperor Akbar, mentioned the occurrence of a fatal epidemic similar to that of bubonic plague in Bihar in 1548. A very devastating plague-like pestilence raged in Gaur, the medieval capital of Bengal, in 1573. The great famine of 1590 was followed by a severe epidemic, which may or may not have been plague. Tuzuk-i-Jahangiri described the occurrence of plague near Agra in 1618.

The Gujarat plague epidemic of 1812–61 was the first in India for which a detailed account is available. It broke out in 1812 in Kutch and is said to have destroyed half of the population before spreading to Kathiawar and Gujarat. According to a statement given by D. V. Gilder in the *Indian Medical Gazette* near the turn of the century (Nathan 1898):

In tracing the origin of disease in question the natives agree in referring the period of its first introduction to the

Hindoo year or *Sumwat* 1873 (A.D. 1817) three years subsequent to the dreadful famine, which raged with such destructive fury over Gujarat and Kathiawar. The disease extended to several other areas such as Kutch, Dholera, Peeplee, and Limree, etc., and people roughly distinguished it by the term *Ghaut no roque* possessing the following symptoms: great and general uneasiness of the frame, pains in the head, lumbar region and joints on the day of attack, hard, knotty and highly painful swellings of the inguinal or axillary glands (whence the name appears) in some instances; the parotids are affected in 4 or 5 hours, fever supervenes; these symptoms go on increasing in violence, attended with great thirst and delirium until the third day of the attack, when death closes the scene.

Another British physician also gave an interesting account of disease spread from Kathiawar, according to R. Nathan (1898):

In 1813 the plague was present in Central India and Rajputana, Kutch and Kathiawar and was first noticed at Kumtakale, and spread throughout Wagar during January, February and March 1816, and by the end of that year had extended to Sunde where the mortality was great. The disease was still prevalent in Central India in 1819, and disappeared in 1821. Nothing more was heard of the disease in Central India till July 1836, when it broke out at Pali, a town of Marwar, whence it spread to Jodhpur. It prevailed at Deoghur, in Meywar, in March 1837, and thereafter extended to Jalia and Ramghat in the district of Ajmere. The disease disappeared toward the end of 1837, but in November of that year, it again broke out in epidemic form at Pali, and continued till February the following year.

The same physician also wrote of *mahamari* (*gola* or *phutkiya rog*), an endemic disease of Kumaun and Garhwal in the Himalayas. The first record of the disease is dated 1823 at Kedarnath, Garhwal. From 1834, outbreaks in these districts occurred every few years, except for a long interval between 1860 and 1875, when it appeared to remain quiescent. After 1878, the outbreaks were not severe. The disease descended to the plains in 1853. In that year it appeared in an epidemic form in towns in the district Moradabad. According to Nathan (1898), a physician there concluded that *mahamari* was identical with the uncomplicated form of glandular plague of Egypt and that it could be conveyed by contagion and spread by endemic causes such as filth, poverty, and unclean habits of the inhabitants. In 1875, the disease was prevalent in certain villages in Kumaun where C. Planck (Jaggi 1980) recorded about 277 deaths and confirmed the opinion that it was the pestis or plague in medical terminology; he also recorded the first local history of *mahamari* in 40 villages attacked. This disease continued to be reported in the surrounding regions until 1893.
