A major addition to the child's repertoire of sentence forms appears at about age 3: Children begin producing complex sentences (Limber, 1973). These forms involve either joining two sentences together by means of a conjunction such as *and*, *if*, or *because* ("I like ice cream because it tastes good."), or embedding one sentence within another ("I think *I'll have an ice cream cone*"). The sentences are important not only because they allow the child to make his or her utterances longer, but also because they allow the combination of ideas within an utterance to produce a more condensed, elaborated statement. At 3 years, 5% to 10% of the typical child's sentences contain these conjoined or embedded clauses. This proportion increases to 20% to 30% by age 6 (Paul, 1981). The proportion of complex sentences continues to increase throughout the school years, although the most dramatic increases are seen not in children's speech, but in their writing (Loban, 1976).

## Pragmatic Development

### LEARNING TO CONVERSE

By the time the first word is uttered, the child has already learned to express affect vocally and attend to adults (Dore, 1975). Indeed, as children expand the purposes for which they are communicating, their vocalizations become increasingly differentiated and closer in form to conventional, "readable," word productions (Chapman, 2000; Messer, 1994). Still, conversations with 1-year-old children are very erratic and disjointed; the child typically uses sequences of utterances that are not directed toward the listener. Throughout the one- and two-word utterance stages, egocentric language is mixed with language being used to ask for needs and make observations about the environment. It is not abnormal during this period for the child to talk perseveratively about a single topic or indiscriminately echo utterances (Fay and Anderson, 1981; Tranham and Pedersen, 1976).

Although young toddlers can respond to adult speech with the communicative means they have available—gestures, vocalizations, or words—they are not very reliable about doing so and often need coaxing to speak when spoken to. Chapman (1981) reports that children begin to answer questions more reliably at 18 to 24 months, at first responding to primarily routine questions, such as, "What does a doggy say?" and, "Where is your nose?" In addition, toddlers show their compliance with the conversational obligation to speak when spoken to by acknowledging their partner's comments, often by imitating a portion of the partner's utterance.

A new communicative function emerges in the second half of the second year. Halliday (1975) refers to this as the "mathetic" or heuristic function of language. Although children at 12 to 18 months of age generally talk about the here and now, making comments on objects and events that are obvious in the immediate context and add little new information to the listener's knowledge base, the older toddler begins to use language both to learn about the world and to provide the listener with new information. One of the first heuristic uses of language is the asking of questions. "Whazzat?" is a frequent early question with which the toddler requests the names of objects. The use of this function is a manifestation of the child's developing understanding that language can be used to learn about the world.

The child's ability to stick to a topic improves in the third year, although by 36 months still only 50% of child utterances continue the topic of the previous utterance

([Bloom et al., 1976](#)). Children of this age have difficulty sustaining a topic for more than one or two turns, particularly if the topic is one they did not initiate ( [Owens, 1999](#)).

Two-year-old children also begin to learn how to deal with conversational breakdowns. If an adult signals such a breakdown, by asking, "What?" the 2-year-old child typically responds by either repeating the utterance, usually with some phonetic change (C: I kit ball. M: What? C: I kick ball.) or by deleting an element (C: I kick big ball. M: What? C: I kick ball.). Children of this age rarely request another speaker to clarify an utterance, however.

Even at age 2, children realize that we talk differently to different people. A 2-year-old child frequently talks differently to his or her mother than to the father, for example, often using more polite language to the father. Two-year-olds frequently speak to babies in a high-pitched voice, as adults do. Another determiner of how we choose to say things is the level of knowledge we believe the listener possesses. Two-year-old children are not very good at making such judgments. They frequently make the assumption that adults know everything and fail to provide necessary information. This tendency can lead, for example, to a 2-year-old child telling his grandmother over the phone, "See, I got this for my birthday!"

Two-year-old children are still in the process of learning the obligation to say things, particularly to make requests, politely. Frequent parent reminders help facilitate this development, and politeness is one of the few aspects of language development that is explicitly taught. Two-year-old children have little flexibility in their range of politeness markers, and if told to "ask more nicely" will either add *please* to their request or produce it with a whining intonation ( [Bates, 1976](#)). They may also produce problem or need statements, such as "I'm hungry," or "I can't reach it," as forms of requests. Two-year-old children do understand some of the social parameters of polite requesting and are more likely to include *please* in their request if the listener is bigger, less familiar, or in possession of something they want ( [Ervin-Tripp and Gordon, 1986](#)).

Another way in which the child's communicative skill advances in the third year of life is through the expansion of purposes to which language can be put. Children learn to use language to convey new information, talk about past events, and imagine or pretend ( [Chapman, 1981](#)), as well as combine more than one intention within an utterance. Similarly, 2-year-old children learn to use a variety of forms to express their intentions. They may say either "I want cookie" or "I hungry" for example.

By the age of 3, pragmatic development becomes more sophisticated and interactional. Egocentric speech and echolalia gradually disappear, whereas the range of language functions increases. The child's language is now used to announce intentions and describe ongoing events. There is a growing awareness of the conversational function of language, with the child being more likely to await responses and less likely to ignore interruptions ( [Garvey and Berninger, 1981](#)).

There is rapid development of pragmatic skills between the ages of 3 and 5 years. Language is still used to announce intentions and describe ongoing events, but there is also increasing use of language to describe events and incidents from the past and relate incidents from the past to present events. The child's conversations show increasing sensitivity to the listener ( [Van Kleeck, 1984](#)) (in allowing turn-taking, responding appropriately to the other person, self-correcting speech, recognizing taboo words, and providing clarification when requested). Language play occurs in the form of rhymes, jokes, and exaggerations.

In the preschool period, language begins to be put to use for the purpose of reasoning, solving problems, monitoring thought and actions, relating events, and constructing complex imaginative play ( [Tough, 1977](#)). Language now becomes an instrument of thought, rather than just a system for mapping what one sees and does into words, as toddlers primarily use it. This new function of language is, of course, made possible by increasing cognitive development. But it also, in and of itself, contributes to the child's intellectual skill, so that the growth of language and cognition become more closely entwined during the preschool years.

Preschoolers learn a broader range of devices for making requests politely during this time. Rather than merely adding *please*, they begin to use permission requests ("Can I . . .?"), question requests with modals ("Would you . . .?" "Could you . . .?"), and indirect requests such as "Why don't you . . .?" and "Don't forget to . . ." ( [Garvey, 1975](#)). By 5 years, children are using hints and other forms in which the real object of the request is never mentioned explicitly at all. So they might request a snack by saying, "Gee, Mom, those cookies you made sure smell good. You make the best cookies in the world." In addition, in playing with peers, preschoolers demonstrate knowledge that requests must fulfill certain conditions, such as that the speaker must have some reason for making the request rather than doing the action himself or herself. [Garvey \(1975\)](#) shows that preschoolers often make adjuncts in their requests to each other, in order to establish that these conditions have been met. They might say, for example, "Get that hammer for me. *I can't reach it.*" Despite this demonstration of the forms and conditions necessary for successful requests, preschool children still have much to learn about using verbal means to regulate others' behavior. They are not very efficient at getting others' attention when it is not already directed to them or in persuading others to do something about which the listener is reluctant. During the preschool years, children learn to increase the degree to which they can elaborate on a single topic of conversation. By age 5, children spend an average of five utterances on a single topic ( [Brinton and Fujiki, 1984](#)), increasing the degree to which each utterance maintains the topic and adds new information.

Around 3 or 4 years of age, children begin to use linguistic devices to provide links between the ideas they talk about in the conversations. One of these *cohesion devices* is the use of pronouns to link referents, as in "I have a *friend* at school. *He* builds blocks with me." Use of definite/indefinite articles (a, the) is another cohesive device that emerges during this time. The indefinite article *a* is used to signal that a referent is being introduced into the conversation for the first time ("Alice saw a large cake."). When the same referent is mentioned again, the definite article *the* is used to signal the listener to retrieve the original referent from memory ("Alice ate *the* cake."). The ability to build these cohesive units or *texts* is one of the ways the child's discourse skills advance during the preschool years.

Children between 3 and 5 years also become more adept at repairing conversational breakdowns. They are able to respond to requests for clarification of specific information, such as "You went *where* for dinner?" and can reply with just the piece being requested ( [Gallagher, 1981](#)). Still, they rarely request clarification themselves when they misunderstand and cannot reformulate their message or provide missing background information when the listener looks confused.

With increasing linguistic competence, the child is able to take advantage of many more communicative situations during the preschool years than she or he was as a toddler. Not only can the child engage in a carefully scaffolded conversation with mother, but now the preschooler can talk also with peers, older children, and adults outside the family. Less conversational management is needed for the child's talk to succeed. But parent-child conversations at this time still play a very important role in structuring the child's social world, and much social learning goes on through the medium of language ( [Cook-Gumperz, 1979](#)). Parents tell preschoolers what to do in different situations, how to behave, and what to expect, and interpret situations verbally for the child, providing reasons and explanations. Language itself becomes part of the experience of social relations, and the preschool child is socialized linguistically, as well as behaviorally, into the community in which he or she will be expected to operate. Talk with peers, too, particularly in the context of cooperative play, teaches the child how language can be used to initiate and construct social relations. Much preschool interactive play is done primarily through the medium of language, and the child learns to exploit its flexibility by using language in this interactive fashion.

#### NARRATIVE DEVELOPMENT

Although conversation is one form of discourse acquired during the preschool period, narrative is another. Narratives are extended monologs that involve the reporting of the actions of people or animals or objects that take on human characteristics. Stories have particular structures that dictate their form and content; these are often referred to as "story grammars" ( [Stein and Glenn, 1979](#)). Unlike conversation, narratives almost always involve the use of *decontextualized* language, or language that refers to events outside of the immediate context. Because the use of decontextualized language is associated with acquisition of literacy skills, narrative development is encouraged from very early on ( [Peterson et al., 1999](#); [Snow, 1983](#)). Children as young as 2 can tell stories, although their narratives do not adhere to the typical story grammar structure. They are usually collections of tangentially related events without any discernible plot. Their narrations consist of elements "heaped" together and not organized in causal or thematic ways ( [Applebee, 1978](#)). As children progress through the preschool years, their stories gradually move closer to the conventional form used by adults in their culture. By age 6, most children can relate a more or less coherent narrative that follows a simple story grammar format. As children continue to develop their narrative abilities, they use increasingly sophisticated means of creating narrative cohesion. They not only maintain clarity about what happened to whom by making unambiguous reference to specific characters ( [Wigglesworth, 1997](#)), but they also are able to use inferential and perspective-taking skills to provide evaluative information regarding causes of events and characters' feelings, beliefs, and motivations ( [Eaton et al., 1999](#)).

#### METALINGUISTIC DEVELOPMENT

One new area of language use that arises during the preschool years is the ability to use language to talk about language itself. This capacity is called *metalinguistic awareness*. One way in which preschoolers manifest this ability is in their play with language. Children begin to use words just for the fun of it, in interchanges such as this one described by [Garvey \(1975\)](#):

Child 1: It's snaky because it has snakes.

Child 2: And it's hatty because it has hats.

Interest in rhyme is another manifestation of metalinguistic awareness. Here children show that they are attending not only to what a word means, but also to other properties, independent of meaning, such as the word's sound and its similarity to the sounds of other words.

Children begin to understand words with multiple meanings (such as *run*) when: (a) they have developed a sufficiently broad base of vocabulary knowledge, and (b) they have gained the awareness that one word can be "mapped" in different ways. Multiple meaning words require children to think about what is represented (the word) and how it is represented (the meaning). Use of language in role-playing also demonstrates the child's metalinguistic skills. For example, preschoolers often correct each other's usage in role-play, commenting on its appropriateness. A child might tell another, "You can't call me 'Willy.' You're the baby. The baby has to call the father 'Daddy!'" These emerging metalinguistic abilities help to lay the foundation for the acquisition of literacy during the school years.

## LANGUAGE DEVELOPMENT AFTER AGE 5

### Comprehension

The comprehension abilities that are acquired after the age of 5 years include the ability to decode syntactic structures that constitute exceptions to the usual rules of the language. By age 7 or 8, most children have gone beyond the use of comprehension strategies in processing these sentences and can decipher the intended meaning of sentences such as "The doll is easy to see" (versus "The doll can easily see"), "John asked Mary where to go" (deciphering who it is that is confused about where to go), and "John promised Bill to leave" (versus "John promised that Bill would leave") ( [Chomsky, 1969](#)). In addition, the child's growing ability to recognize the deep structures of language permits the recognition of different levels of meaning and the understanding that ambiguous sentences have more than one meaning.

Similarly, after the age of 5, the child begins to understand discrepancies between meaning and form in utterances ( [Ortony et al., 1978](#)). For example, the child gradually learns to move away from literal interpretations (e.g., of metaphoric language, proverbs) to understand connotations, to "read between the lines," and make inferences ( [Livingston, 1982](#); [Nippold, 1998](#); [Resnick, 1982](#)). This is a slow process; although the basic comprehension of figurative language is present at the age of 9 years, major improvements in the understanding of idioms, metaphors, and proverbs continue after this age (Nippold, 1998a). It is not until the teen years that discrepancies between voice and message (e.g., the sarcastic tone of voice) are fully understood.

In addition, a wider understanding develops of the concepts of temporal relations, spatial relations, number markers, emotional expressions, and abstract ideas. This development involves more than simply adding new vocabulary items; it includes refining the child's entire stored lexical network of interrelated meanings. These refinements in vocabulary comprehension are also a slow process that continues until college age ( [Nippold, 1998](#)).

### Speech Sound Production

Most children can produce all sounds of their language correctly by age 7. Sound errors that persist past this age are no longer developmental; instead they represent a disorder of speech sound development. During the years from 6 to 16, it appears that children add subtle skills to their knowledge of their sound system. These skills may include full use of appropriate morphologic derivative forms (e.g., vowel changes in the pronunciation of differing forms, such as *divide/division*) ( [Moskowitz, 1973](#)), the use of contrastive stress (e.g., to distinguish between *greenhouse* and *green house*) ( [Myers and Myers, 1983](#)), intonational contrasts, such as *pre'sent* versus *present* ( [Cruttenden, 1985](#)), use of dialectal variants (Grunwell, 1986), and, ultimately, representations of the sound system in the form of spelling skills.

### Producing Words and Sentences

The child's basic knowledge of the rules of his or her language is complete by age 5, and the child's expressive development takes the form of more subtle refinements to this essential knowledge. Grammatical errors become less common, although they may still occur in noun-verb agreement (e.g., "He haves the toy"), mass-count distinction (e.g., "I want more macaronis"), pronoun case forms (e.g., "Him and her went"), and irregular verb formations ("The candy had been ater"). Much learning about other morphologic markers, particularly about prefixes and suffixes, which augment the meaning or modify the part of speech of a word, goes on during the school years ( [Wiig and Semel, 1984](#)). Vocabulary growth continues throughout the school years, at an estimated nine words per day ( [Carey, 1978](#)). Both these developments, as well as the acquisition of more formal, literary types of syntactic structures, depend heavily on exposure to literate language forms used in written expression. Children who do not acquire good reading skills will be limited in their access to these more mature forms of expression, and their language development will begin to lag behind that of their peers.

Grammatical differences between the child's language and adult language are not apparent in general conversations by the age of 6 years. The formations and concepts that have still not been learned at this stage consist not so much of new structures, but of the ability to combine a greater number of complex structures within one utterance to produce language that is denser. In addition, children exhibit more frequent usage of complex structures more common to literary forms of language than to everyday conversation, but these changes are more likely to be seen in writing than speech ( [Barrie-Blackley, 1973](#); [Chomsky, 1969](#); [Scott, 1988](#)). The increase in the use of these low-frequency literary forms and the propositional density of utterances in written expression continues throughout adolescence.

### Pragmatic Development

Pragmatic development continues through the school years, with language being used in a more diverse range of social interactions ( [Barnes and Todd, 1978](#); [Stephens, 1988](#)), including telling stories, engaging in holiday rituals, sharing ideas, providing examples, taking perspectives, discussing problems, and appraising alternatives. The child's knowledge of rules for language usage expands to include "code-switching" (how to adapt language forms to specific environments) ( [Gleason, 1973](#)), politeness markers (e.g., "please," "sorry") ( [Leonard et al., 1978](#)), how to make indirect requests, and how to anticipate and repair breakdowns in conversations.

Gradually, the child's ability to narrate stories becomes more sophisticated, moving from a temporal chain approach toward the ability to link elements logically and develop a central theme ( [Applebee, 1978](#)). Narrative skills continue improving until college age ( [Johnson, 1983](#)), and there is an increasing ability to embed multiple episodes within stories, understand and express the motivations of characters, and imply and infer information in narratives.

Metalinguistic abilities continue to improve throughout the school years, serving as both a cause and consequence of the acquisition of literacy. One particularly important metalinguistic skill that typically emerges at the beginning of school is the ability to break words down into units of sound and associate these sounds with letters. This skill, referred to as phonologic awareness, has been shown in a large body of research to be highly related to later reading ability ( [Snow et al., 1998](#)). Moreover, it has been shown that children who do not come to school with phonologic awareness who receive instruction in counting sounds in words and associating sounds with letters do better in reading than children who do not receive this instruction ( [Blachman, 1999](#)). Phonologic awareness skills, then, have an especially strong link to literacy development.

Children also learn what a "word" is, that it can be thought of as apart from the concept it stands for, and that it can be identified as a printed symbol. They learn that words can be broken down into smaller units of sounds, and these sounds can be represented as letters that can be decoded into spoken words. Another metalinguistic skill acquired during the school years involves the ability to define words using synonymous or categorical terms instead of by simply stating a function or by giving personal association. The ability to discuss the structure of language is also included in metalinguistic skill. School-age children learn to identify parts of words—such as syllables, first and last sounds—and parts of speech. They learn to discuss similarities and differences in meaning among words and sentences and talk about ambiguities in meaning and figurative uses of language. Unlike the other areas of language acquisition we have been discussing, though, the acquisition of these metalinguistic skills is highly dependent on instruction. They are not part of the "natural" progression of language, and children not "taught" these skills, through exposure or direct instruction, do not necessarily learn them on their own.

## SUMMARY

The developmental pathway from infancy to young adulthood is characterized by increasing complexity in decoding and comprehension of words and structures, speech sound production, encoding and production of words and structures, and the use of language in interactions. Although there is evidence of certain individual differences, speech and language acquisition follows general patterns in which more and more complex structures are acquired, permitting more and more subtle distinctions in meaning and greater flexibility in form.

The enormity of the speech and language acquisition task and the speed with which it is normally accomplished helps us to understand the relatively high frequency of delays and disorders in this area of development. An intact linguistic system is crucial not only for fluid communication, but also for the acquisition of literacy skills that are so necessary to academic success. For this reason, children who demonstrate delays in the development of language are at risk not only for communicative disorders, but also for learning difficulties in school. These disabilities, in turn, may result in problems with behavior, social development, and self-esteem that can accompany learning disorders. For these reasons, early identification and remediation of language learning problems is especially important.

*I dwell in Possibility  
A fairer house than Prose  
More numerous of windows, —  
Superior of doors.  
Emily Dickinson*

Why do children play? This issue has intrigued poets, as well as behavioral scientists from the days when Friedrich Schiller first proposed his theory of surplus energy, which explained that the boisterous play behavior of boys was a necessary preparation for later work activities. Adopting a more clearly evolutionary orientation, the first major researcher on play, Karl [Groos \(1901\)](#), proposed that play emerges out of natural selection as a form of necessary practice on the part of animals or children. The playful fighting of animals or the rough-and-tumble play of children and many of the playful courtship behaviors of animals and children are essentially the practice of skills that will later aid their survival. This adaptive viewpoint is further amplified in the conception of the Viennese psychologist [Karl Buhler \(1930\)](#), who pointed to the inherently pleasurable nature of play activity as a feature of children's growing skills and abilities in his concept of *Funktionlust*.

The psychoanalytic conceptions of play originated in Freud's proposals that play itself emerged under conditions of deprivation of initial gratification in the child, which caused it to "hallucinate" the image of a satisfying object such as the mother's breast. This hallucinated image later could become a source of at least partial drive satisfaction and permit the child to delay or control random, restless movements and cries of distress. The brief interval of delay becomes a central foundation in psychoanalytic theory for the later formation of the ego ([Freud, 1908/1958](#); [Singer, 1955](#)).

Later [Freud \(1920/1962\)](#) modified the theory from its initial purely sensual, instinctual aspect to include the concept of mastery, which he exemplified in a much-cited example of his grandson's playing a kind of hide-and-seek game. Even here Freud continued to emphasize that the game involved an attempt on the part of the child to deal with a conflict over maternal attachment and resentment of the mother's leaving through repetitive efforts at mastery. Psychoanalytic theories of play continued to emphasize the libidinal and drive satisfaction features of play, but there was increasing emphasis in work such as that of [Peller \(1959\)](#) and [Waelder \(1932\)](#) on the mastery elements, which in some respects formed the groundwork for a more cognitive, as well as drive-oriented approach. With the important observations of [Erikson \(1963\)](#), this early notion of play was broadened considerably. Erikson suggested that a psychoanalytic theory of play move beyond the satisfaction of early childhood psychosexuality toward incorporating broader features of social development that were "modeled" within the play format. Play thus becomes not just a form of vicarious gratification but provides a way in which complex difficulties and problems experienced by the child can be addressed and even possibly "healed" through the creation of a miniature and manageable world.

Perhaps the most thoroughly worked out theory of the origins of play, one with a much stronger cognitive focus, has been that proposed by [Jean Piaget \(1962\)](#), who believed that play emerges in the context of children's enactment of the two fundamental characteristics of their mode of experience and development, accommodation and assimilation. The former provides an opportunity to imitate and interact physically with the environment, whereas the latter represents the attempt to integrate externally derived percepts or motor actions into a relatively limited number of schemas or differentiated motor and cognitive skills already available to the child at this age. Physical mastery games, with their repetitious and practice qualities, are more associated with the accommodation feature, whereas the symbolic play of the child is associated more with assimilation. Piaget used the two notions to argue that play therefore is critical in early childhood for the eventual emergence of concrete operational thought in the child; he tended to minimize the role of play for children in the older age groups of 7 and up.

For Piaget, play is at least analogous to the fantasy life of the adult, but he does not devote much time in his extensive writings to elaborating this notion. By contrast, [Brian Sutton-Smith \(1966\)](#), although accepting the importance of Piaget's emphasis on early childhood development, has proposed that play continues through adolescence as a means by which preschool and older children can create miniature environments in which they gain a sense of power through elaborating and reconstructing those complexities, emotional and cognitive, that they confront in the adult world that surrounds them.

It is important at the outset to be clear about a definition of play. The term has been widely extended to range from children's activity to more complex forms of adult ritual and competition. For the latter, see [Caillois \(1958\)](#), [Geertz \(1976\)](#), and [Huizinga \(1950\)](#). Indeed, the emphasis on all forms of play and their role in learning elaborated by [Bruner and his coworkers \(1976\)](#) has moved the notion perhaps too far afield from the focus of this chapter. The definition we entertain was proposed by [Klinger \(1971\)](#): Play is behavior that is neither consummatory, instrumental, nor competitive; it involves behavior that is neither socially prescribed, as in ritual, nor constrained in some way by social expectations and conventions. More concretely, then, play is behavior that is not obviously associated with direct satisfaction of biological needs such as eating, drinking, overt sexual gratification, or the overcoming of immediate obstacles in one's life situation. It is also relatively free of any effort to meet standards set up by society. At least the standards of play, one might say, are established by the players themselves within a context that may not be the same as those ordinarily observable in society.

Piaget confronted this issue more clearly in his organization of play into games that involve simple sensory pleasure and exploration, games that involve mastery and expression of physical skills, symbolic play (with which this chapter deals), and games with rules that are manifest in activities, such as the structured play of athletic contests or board or card games. The focus of this chapter is specifically on the nature of symbolic play as exemplified by games of pretend and make-believe. Such play seems of special importance not only for the child's mental development but also for the gradual emergence of the capacity for fantasy and imagination in the older child and adult. The theories we mentioned in many ways have gradually been integrated into a cognitive-affective approach that serves as the organizing focus of the present chapter.

It is becoming increasingly clear to those of us who study both adult and children's imagination that the make-believe or pretending of early childhood is fundamental for the development of all competent adult cognition and emotional functioning. [Piaget \(1962\)](#) emphasized the role of symbolic play as a precursor for those processes of logic and orderly sequence whose epistemology was his main concern. Increasingly, we can also recognize that all mature human thought and information processing is not limited only to scientific or mathematical sequences that are sequential in nature and characterized strongly by verbal expression and grammatical structure. The seminal analyses of [Jerome Bruner \(1986\)](#) have made it evident that effective thought takes on a narrative or subjunctive form as well. In our processing of information, we must not only organize it into logical structures but also examine the alternative and future possibilities or even consider the darker alternatives that appear in any new human experience. Indeed, we store information, as is increasingly clear in memory research, by organized verbal schemas, on the one hand, and through narrative episodes or possibilities in the form of fantasies and daydreams, on the other ([Singer, 1985](#); [Singer and Salovey, 1991](#)). Narrative thought and subjunctive structure reflect the human capacity for what the great neurologist [Kurt Goldstein \(1940\)](#) called "taking an attitude toward the possible." He believed this capacity reflected the optimal functioning of both a healthy and intact brain. Through this orientation to the possible, one becomes capable of exploring a range of potential futures or, in effect, traveling through time and space to a different or better childhood or maturity ([Singer and Singer, 1990](#)). [Sigmund](#)

[Freud \(1911/1962\)](#) too used the term *trial or experimental action* to characterize thought and the emergence of his concept of the ego.

This capacity for reconstructing one's past or for planning for one's daily activities through mental rehearsal or simply daydreaming about future vacations, sexual opportunities, or fantastic space adventures also serves a broader function. Our imagination liberates us from the tyranny of *this* place, of *these* particular duties and obligations, of *these* particular people in our social milieu. We accomplish this restructuring not only through the abstraction of high-level logical or mathematical processes but also through our capacity for creating narrative and for using our skills at imagery to provide us with alternative temporary environments that we can manipulate for self-help and ultimately put into the service of orderly living or simply sustaining hope and effort ( [Singer, 1974](#); [Singer and Bonanno, 1990](#); [Taylor, 1989](#)). As Bruner has proposed, the object of narrative thought is not "truth" but verisimilitude or "life-likeness." He writes: "Efforts to reduce one mode [the narrative] to the other [the paradigmatic or logical] or to ignore one at the expense of the other inevitably fail to capture the rich diversity of thought" ( [Bruner, 1986](#), p. 11).

Viewed from this perspective, the simple make-believe play of the child (pretending early on that a stick is an airplane, that a soft toy can talk or respond to nurturance or admonition, that a few blocks or dolls can become the basis of an imagined city in which a relatively lengthy story unfolds) can be regarded as a fundamental precursor of the full-blown adult imagination. This chapter proposes that we accord the imaginative play of childhood its full weight as a fundamental and significant development of competency in the child. Without an adequate development of this narrative, subjunctive, or imaginative dimension, the child is subsequently handicapped both in cognitive and emotional development. Indeed, without sufficient practice in the skill of generating fantasy for self-regulation, the child not only will experience difficulties in school adjustment but also, if psychotherapy is required at some point, may not move ahead effectively into the process. Play therapists actually find that some encouragement and even training efforts are necessary to aid young children to engage in symbolic play as part of an ongoing treatment process ([Singer, 1993](#); [Singer and Singer, 1990](#)).

## A COGNITIVE-AFFECTIVE PERSPECTIVE ON PRETENDING

### Information Processing and Emotion

In the so-called cognitive revolution that has dominated psychology since about 1960, we perceive a new model of the human being. We now look on babies and children as information-seeking organisms striving to organize and integrate novelty and complexity, curious and exploratory but also more likely to feel comfortable and smile (as the research by Papousek on infants has shown) once they can experience control over novelty and assimilate new information into prior concepts and scripts about the sequence of events. The "smile of predictive pleasure" in babies, described by [Papousek \(1987\)](#) and his collaborators, and other signs of positive emotion (smiling and laughter associated with familiarity in adults) suggest that although cognition and emotion may be different systems in terms of bodily structure, they are closely related in actual human response ( [Izard, 1977](#); [Kreitler and Kreitler, 1976](#); [Mandler, 1984](#); [Tomkins, 1962, 1963](#)).

Theoretical analyses initiated by Silvan Tomkins have contributed greatly to the paradigm shift toward the cognitive-affective view of the human organism. Tomkins' work has succeeded in putting emotions back at the center of active research in personality and social psychology. He led the way in demonstrating that a cognitive perspective that involved an emphasis on the fact that human beings are continuously assigning meanings and organizing their experience in schemas and scripts does not preclude a significant motivational role for affect or emotion. With the support of increasing empirical research carried out on both children and adults by investigators such as [Carroll Izard \(1977\)](#) and [Paul Ekman \(1973; Ekman et al., 1982\)](#) and many others, we can now regard human beings as showing differentiated emotional response patterns that are closely intertwined with responses to the novelty, complexity, and other structural properties of information confronted from moment to moment ([Demos, 1995](#); [Shapiro and Emde, 1992](#); [Singer and Singer, 1990](#)).

This cognitive-affective perspective broadens our conception of human motivation considerably. Rather than reducing all human motivation to some symbolic reflection of infantile sexuality or aggression, one can propose that the basic emotions that have now been shown to exist across human species in the research of Ekman and Izard are motivating human beings in dozens of different situations independent of presumed drive pressures. Human beings seek, as Tomkins has proposed, to reconstruct in life or in thought situations that evoke the positive emotions of interest-excitement or joy; they seek to avoid in action or thought those situations that have evoked specific negative emotions of anger, fear-terror, sadness-distress (weeping), or the complex of shame-humiliation-guilt. Human beings are further "wired up" to express emotions as fully as possible and finally to control emotional expression where social experience suggests such control is necessary, either for safety or to avoid humiliation. Situations that permit experience and expression of positive emotions or that allow for appropriate control of negative emotions are intrinsically positively reinforcing. Those situations that are more likely to evoke negative emotions, such as fear, anger, distress, or shame, or that have blocked the expression of socially adaptive control of emotions may be experienced as inherently punishing or negatively reinforcing ( [Singer, 1974, 1984](#); [Tomkins, 1962, 1981](#)).

Memory and anticipation become central features related to emotional experience. Identifying, labeling, and gradually organizing new information into mental representations that are technically labeled as schemas accomplish this. These structures include schemas about persons or physical objects, schemas about self and others, and also scripts about action sequences or prototypes that become means for encapsulating a variety of common features of situations and persons into one fuzzy concept ([Mandler, 1984, 1988](#); [Singer and Kolligian, 1987](#); [Singer and Salovey, 1991](#)).

### The Child's Task in Information Processing

The problem for the child becomes, in effect, one of making sense of a complex world through the gradual formation of schemas and scripts and through the assimilation of new situations into established organized mental structures or, as language increases, into lexical categories as well. A child may respond with fear or terror when confronted with extreme novelty that cannot at once be easily assimilated into established structures. The child may respond with a smile of pleasure once a match can be made between new information and some well-known schema, and the novelty or ambiguity of the environmental situation can be assimilated. When the new situation is only moderately complex and some overriding schema is still available, the child may move to explore the moderate amount of novelty in the situation, and this evokes the positive affects of interest and excitement. Children and adults live in a situation of a perennially delicate balance between the potential for fear or anxiety evoked by new situations and the excitement of exploring such situations. By such exploration, one can assimilate incongruity into established schemas, enrich such schemas, or start to form new ones. The persistence over time of large amounts of unexpected or ambiguous information evokes the negative effects of anger or distress and sadness ([Singer and Singer, 1990](#); [Tomkins, 1962](#)). We all learn to bring sets of expectations of what may occur to each new situation. We practice such expectations through brief anticipatory fantasies, some more realistic than others depending on our maturity, the complexity of our schema structure, and our social development. Our task in each new situation is then to examine new information and determine whether it confirms or disconfirms some of our anticipations. [George Mandler \(1984\)](#) has particularly developed the implications of interrupted sequences of action and thought and of confirmations and disconfirmations of anticipations as the basis for emotional response.

If identifying and organizing new information becomes the fundamental, overarching demand placed on the child, then we can begin to understand the evolutionary function of imaginative play and the thought processes that seem to grow out of such play. As Piaget has shown, the efforts of children to master the environment and their own motor activities involve to some extent an accommodation to the physical characteristics of the environment and also to the speech, gestures, and other physical actions of adults or older children. In these efforts, children succeed through some form of successive approximation, but at the same time, they need to be able to assimilate such new actions into organized mental structures. This assimilation process is at first expressed by children through repetitive actions and talking aloud.

What seems like the intrinsic unmotivated character of play to an adult represents the child's continuing effort to create new meaning structures and to provide itself with a sense of control and power by reducing large-scale settings, persons, or social interactions to meaningful structures that can be assimilated into the as yet limited number of schemas the child has at its command. The startle responses or terror evoked in a toddler by the size and noise of a huge passing truck may be gradually transformed into curiosity and interest as the child attempts to reproduce the noises and movements of the truck through creating its own sound effects and manipulating blocks or toy trucks. Imaginative play may thus be understood as a means by which the uncontrollable qualities and complexity of one's physical and social environment can be gradually miniaturized and manipulated. In effect, we can see that much of adult human thought involves a similar effort to create at least temporarily a world one can control through replaying memories or anticipation and fantasy. Indeed, it can be argued that the very act of rehearsal and anticipation or even of elaborating possible future events into somewhat more bizarre fantasies may gradually approximate possible situations we do encounter. Such mental rehearsal may leave us better prepared to handle these or, at least, be less frightened by them when they do occur ( [Singer and Singer, 1990](#)).

### Attachment and Individuation: A Persistent Human Dilemma

Beyond the cognitive demand for meaning assignment and organization and its link to the arousal of emotion, human beings also must confront a persisting dialectic tension in their general motivation throughout their life span. This tension becomes evident in some of the very earliest months of childhood. On the one hand, there is

the need to feel close to others, be attached to or encompassed by parents, older siblings, or other caregivers and, later, by friends, or by a group by means of some symbolic group participation (e.g., a religious, ethnic, or nationalistic association). On the other hand, we all experience to varying degrees the need to preserve some areas of personal autonomy, some sense of privacy, personal competence, and individualized skill development. We must move through life in effect struggling to preserve a balance between affiliations with others or groups, thereby gaining a sense of community, while we also strive to maintain a sense of individuality and personal power ([Anqyal, 1965](#); [Bakan, 1966](#); [Jung, 1971](#); [Rank, 1945](#); [Schachtel, 1959](#)).

More recently in the framework of an object relations psychoanalytic analysis, [Sidney Blatt \(1990\)](#) has sought to show how the early childhood struggle between attachment and individuation may, if one pole or the other is overemphasized, become a focal area of conflict and eventuate in particular forms of psychopathology. [Bonanno and Singer \(1990\)](#) have further extended this polarity to identify a series of personality dimensions that recur in the literature along with particular affective tendencies, defensive patterns, variations in physical illness proneness, and emotional disorders that had already been identified along such dimensions by Blatt.

This conceptualization, although still largely speculative, is built around some available research evidence that suggests that optimal personality functioning and a hardy physical health status necessitate a reasonable balance between one's needs or strivings for affiliation and one's abilities to experience autonomy or individuation ([Bonanno and Singer, 1990](#)).

Within this conceptual framework, the child's make-believe world is one that represents a continuous working out of the dialectical tension between the need for closeness and affiliation and the need for privacy with its concomitant experience of personal power and individuality. Indeed, the very act of beginning to form individualized images, memories, and anticipatory fantasies becomes, in our crowded and sensory-bombarded world, the last refuge for an experience of individuality and personal privacy. For the developing child seeking on the one hand to sustain relationships with parents and others and feel the warmth of what [Schachtel \(1959\)](#) called embeddedness-affect, the ability on the other hand to create private games and to engage in floor play or sustain a relationship with a personally possessed stuffed animal or invisible playmate provides that experience of individuation that also seems so necessary in our human condition.

In view of this persistent human attachment-individuation tension, the emergence of an increasingly complex imaginative dimension subject to reasonable control (a kind of cognitive skill in itself) sustains the need for self-definition, for a sense of uniqueness and private power. The child must learn gradually to establish priorities in the direction of attention, whether toward the environment or material recurring from memory or forming itself into fantasies. Our practical survival may well demand that we assign a somewhat higher priority to the processing of externally generated stimulation, what [David Rapaport \(1960\)](#) wrote of as the "permanent gradient toward the external attention-cathexis." As we will see, our affective development also must involve reflection, introspection, the capacity to enjoy private experiences, to gradually shape and direct them, plan, and also create stories and mentally manipulate the range of future possibilities. For young children with limited motor and linguistic capacities and a smaller and less differentiated range of stored schemas and scripts, the balancing of such priorities may be reflected in the varying amounts of physical, rule-oriented, or social and imaginative play in which they engage.

Of course this very dilemma of attachment versus individuation is not only reflected structurally in the degree of priorities assigned by children to social interaction or imaginative experience. It is also the basis for the content of the play behavior. The themes of play in the child often reflect the continuing tension between the desire for closeness and for assertions of personal power, importance, or the need for privacy. Such manifestations are readily identifiable in play therapy observations. For the purposes of this chapter, however, we focus more on the structural features of imaginative play and how make-believe and the gradual internalization of such make-believe into childhood fantasy serve the cognitive and affective interests of the developing organism.

## THE EMERGENCE OF IMAGINATIVE PLAY

### Forms of Play

The generally accepted definition of play has focused on its intrinsic, nonmotivated nature. [Eric Klinger \(1971\)](#) has perhaps expressed this most clearly by defining play as behavior free of consummatory, competitive, religious, or social motives or constraints.

In his review of the available literature, [Philip Smith \(1982\)](#) raises the issue of whether play in animals serves any intrinsic evolutionary function. He argues that there is little evidence of the benefits of play for later social and cognitive skills, except in a few instances for the most humanoid primates. However, he does make it clear that with respect to human children, where language, imagery, or symbolic functions are involved, play, especially imaginative games, may turn out to have more broadly useful roles.

One need not argue that pretend play serves ultimate survival or reproductive functions from an evolutionary standpoint, however. Most careful observers of childhood and adult play behavior, such as [Brian Vandenberg \(1986\)](#), [Brian Sutton-Smith \(1982\)](#), [Michael Lewis \(1982\)](#), and [Mihalyi Csikszentmihalyi \(1982\)](#), point out that play is just an enjoyable activity in its own right. From the position already presented in the preceding, one can argue that most forms of play involve situations of moderate challenge, novelty, or incongruity. The playful interactions between self and others or between self and objects or, in the case of pure fantasy play, between self and symbolic others usually result in a further reduction of novelty or incongruity, thereby invoking the emotions of joy and the smiling response. What follows from such activities may be a further learned recognition (conscious or increasingly automatic) that within the defined structure of such play one can experience moderate challenge and also some reduction of incongruity in the future. I would propose that such a conception seems more specific than [Freud's \(1920/1962\)](#) proposal of a "repetition-compulsion" to explain why children repeat games again and again. As [Ernst Schachtel \(1959\)](#) has also pointed out, the repetitive nature of play in children may reflect not so much a compulsion as a continuing discovery of novelty in what for adults may seem commonplace but for children still provides puzzling material that must be assimilated into a previously limited range of schemas. The repetition thus is characterized by a sustained affect of interest in the elements that are still novel in even a simple story like "The Three Bears."

[Jean Piaget \(1962\)](#) has proposed that play follows a particular sequence in its emergence and the service of the development of more concrete operational thought. The child begins with more purely sensorimotor play, gradually evolves the capacity for symbolic or pretend play, and then goes on to more structured and orderly games with rules. These rule games range from simple examples such as "Ring Around the Rosy" (with hand holding, circling, singing, and the dominant rule, dropping down on the signal "all fall down!") and evolve into more complex games often played outdoors, such as "Red Light," or into parlor games such as "Statues" or "Charades" and board games such as *Chutes and Ladders* or checkers. Such games are critical for mastery of orderly thought, moral judgment, and other phases of concrete operations for mature thought in Piaget's scheme.

It is important to note, however, that for Piaget the functions of play were largely delineated in relation to their role in the emergence of orderly, formal logical thought processes. Other researchers, such as [Inge Bretherton \(1984\)](#) and [Brian Sutton-Smith \(1966\)](#) have criticized Piaget because they feel he tended to devalue the importance of play as a source of mature adult imagery and as the foundation for the playfulness that characterizes all human thought. Bretherton has also pointed out that Piaget tended to think of imaginative play as declining after the age of 4 or 5 rather than recognizing the importance of play as a forerunner for Bruner's narrative thought.

The research of the author and his colleagues with large numbers of children from diverse backgrounds who were observed during spontaneous play has made it clear that pretend play goes on well into the early school years and continues either "underground" in private thought or in the more sanctioned group forms of make-believe that are observable through the life cycle ([Singer and Singer, 1981, 1990](#)). Even games with rules, which are certainly an important step in the child's development of orderly and regulatory processing and self-control, often include elements of pretending or evoke private or shared fantasies well into adult life. If one watches adults and children playing relatively structured games such as *Monopoly*, one can frequently observe the tendency for the players to introduce make-believe components, sometimes even taking on particular make-believe roles for themselves as they participate in this otherwise rule-organized game. The reordering of the "given" realities is just as much a fundamental feature of human thought as is the attempt at faithful accommodation to the environment through coherent schemas, which Piaget emphasized in his epistemology. Indeed it was only in his posthumously published work that he finally addressed the question of the origins of possibility ([Piaget, 1980](#)).

The balance of this chapter examines some of the potential advantages for cognitive development and emotional expressiveness and control of imaginative play. To assert that imaginative play has a variety of short- and long-term benefits may reflect some cultural bias, as Brian Sutton-Smith has argued in some of his papers ([Sutton-Smith and Kelley-Byrne, 1984](#)). But even the subversive quality of *Mad Magazine* cartoon humor, of cards such as the *Garbage Pail Kids*, or of the punning and teasing of adults by children may serve an important balancing function for the developing child in a world in which children are powerless. In the face of life tragedies, parental neglect or abuse, parental poverty or humiliation, abandonment, illness, or death, the ability to step back from the situation and create playful narrative offers at least some solace if not a complete way out of the distress. Those children who do not experience encouragement through storytelling or pretending that fosters the development of a symbolic dimension or through repetitive sensory or physical play or games with rules may find themselves condemned either to

impetuous instrumental activity or to the apathy of a sense of isolation or extreme dependence on conventional rituals ( [Singer, 1993](#); [Singer and Singer, 1990](#)).

### Beginnings of Imaginative Play

It is rare for adults to observe any clear evidence of what might be called pretending or make-believe play before at least the age of 2½ in children. One can observe that such play gradually emerges out of parent-child interactions, the beginnings of games of peek-a-boo.

Make-believe play or early pretending takes on two general forms in the preschool child. One involves the overt floor play or monolog of the child, often using limited props and evolving eventually into very elaborate play with a mixture of structured toys, such as Barbie dolls or robot soldiers mingled with less clearly defined objects such as blocks or cloths and bits of string, that become employed in the more general service of storytelling. Another form of imaginative play emerges from the so-called transitional object of [Winnicott \(1953\)](#), the soft cloth or furry teddy bear that becomes either a subject of feigned conversation between child and teddy bear, or eventually, an invisible playmate assigned a name and personality. I will first deal with the role of floor play and turn a little later to the issue of imaginary playmates and their role in the child's development.

The following criteria, proposed by [Greta Fein \(1981\)](#), represent symbolic or pretend play:

1. Familiar activities may be performed even in the absence of necessary material or social context (e.g., a child pretends to drink from an empty cup or puts a doll to bed on the floor rather than in a doll bed or even on the couch).
2. Activities may not be carried out to their logical outcomes (e.g., a toy presumably imprisoned in a dollhouse escapes quite magically through the roof).
3. A child may treat an inanimate object as animate (e.g., a furry animal is offered food or a cup of tea).
4. An object or gesture may be substituted for another (e.g., a block is transformed into a spaceship).
5. A child may carry out an activity usually performed by another person or especially by an adult (e.g., pretending to be a doctor, pilot, or a teacher).

Of special importance is the conception of transformation, or the emergence through play of what [Alan Leslie \(1987\)](#) in a fine paper has called a metarepresentational mode of thought. [Leslie \(1987\)](#) has proposed the challenging question,

[How] is it possible that young children can disregard or distort reality (as in using a banana as a telephone). . . . Why does pretending not undermine their representational system and bring it crashing down? (p. 412)

Leslie's argument is that a major step in development involves the "decoupling" of the direct representations that we sustain of objects, persons, or situations from their perceptual images into a new set of metarepresentations that are symbolic or mental representations of the same original set of objects but now treated as part of an entire system of thought that one can modify, manipulate, analogize, or transform to metaphor. With the help to some extent of adults but also on the basis of an inherent capacity in the child, the ability emerges to create a frame in which otherwise very stable objects can be transformed into representations that bear only a tenuous link with their original shapes. When we walk into a room and perhaps unexpectedly see an elongated object on the floor, we may jump because we think it is a snake until we recognize with relief that it is a telephone extension cord. This is an "error" because we had no reason initially to treat the objects of the room as other than percepts. When on another occasion we say to a child playing "Explorer" with us in the same room, "Look! There's a dangerous snake!" the telephone cord is already being treated in this metarepresentational mode, as cued by our remark. Its only casual resemblance to a snake suffices to permit an abuse of what ordinarily might be a fixed representational and semantic structure.

Leslie's conception of the theory of mind implies that human beings have available a domain of metarepresentations that they can manipulate to make inferences about causes, predictions about future events, recognize the consequences of ignorance, distinguish reality from fantasy, acquire a language of words and phrases depicting mental experiences or states, and infer motivations. Such a development begins perhaps in the middle of the second year but does not really reach its peak until the third and fourth years, although some children may use words such as, *know*, *remember*, *pretend*, and *dream* by the end of the second year. As Leslie puts it, "Pretend play is, thus, one of the earliest manifestations of the ability to characterize and manipulate one's own and others' cognitive relations to information" ( [Leslie, 1987](#), p. 422).

Pretend play and the beginnings of the use of this metarepresentational system can be identified by the end of the second year. [Greta Fein \(1981\)](#) in her research has shown that mothers who interact with their daughters foster the likelihood of an earlier emergence of transformation, such as the child's pretending to drink from an empty cup or at the next stage pretending to feed milk from the empty cup to a toy plastic horse, which is itself treated not as a horse but as a baby. Even with an early manifestation of pretending, such as in the case of a 2-year-old with only a limited vocabulary of perhaps a half-dozen words pretending to read a book by babbling along and pointing at pictures, turning pages and only occasionally saying a clear word, the more advanced forms of make-believe require a higher level of cognitive development ([Singer and Singer, 1990](#)). The emergence of an ability to move beyond what Piaget called egocentricity to the ability to decenter experience and identify that others may think differently from oneself is necessary for more complex symbolic play.

This is exemplified best in the so-called false belief experiment. A child (the target participant in the study) watches as another person hides a piece of candy in a box (A) and then leaves the room. Someone else then moves the candy from box A to another box (B). The child is then asked where the candy is now and correctly points to box B. The original person who had hidden the candy now returns to the room. At this point, the child is asked where this person will look for the candy. Research evidence clearly indicates that only by age 4 do children regularly begin predicting that the deceived original hider of the candy will look in A rather than B ([Wimmer and Perner, 1983](#)).

Leslie and others have actually demonstrated that this fundamental ability to penetrate the "mind" of another is demonstrable in older children who are quite severely retarded but rarely is manifest in autistic children who may actually show higher IQs than the retarded participants. The autistic children, as Leslie argues, seem to have a special deficit in such perspective taking and perhaps more generally in their ability to develop the metarepresentational world decoupled from primary representations. Indeed, one of the special difficulties observed in our own and in other studies has been that autistic children show very little capacity for spontaneous or encouraged make-believe play ([Leslie, 1987](#); [Nahme-Huang et al., 1977](#)). Recent observations in babies and toddlers born of crack cocaine-addicted mothers seem also to indicate findings comparable to those for autistic children. These children, despite apparently average general intelligence, seem deficient in play skills ([Blakeslee, 1989](#)).

It may well be the case that preschool children practicing imaginative play may also be more likely to move naturally into adopting a metarepresentational orientation. They may show an ability to demonstrate a "theory of mind," that is, an ability to be aware of their own thoughts as distinct from others ( [Harris and Kavanaugh, 1993](#); [Wellman, 1990](#); [Wimmer and Perner, 1983](#)). In a series of studies under my direction ([Rosen et al., 1997](#); [Schwebel et al., 1999](#)), it has been demonstrated that preschool children who play more imaginatively (on observation by raters on several occasions) may actually perform better on the reality-fantasy and false-belief measures used as estimates of theory of mind. As a matter of fact, even when age and other factors are partialled out in multiple regression analyses the scores on make-believe play still predict "theory of mind" results.

What I am proposing, then, is that imaginative play in childhood emerges almost necessarily as the child's cognitive capacities unfold through heightened brain capacity and inevitable social experiences. At the same time, this metarepresentational mode makes it possible for increasing complexity of play to occur, and such play provides pleasure for the children by allowing them to miniaturize complex events and objects, as well as to gain power over the objects and people around them through manipulating them in original story lines.

This practice of narrative and make-believe play further crystallizes and defines the metarepresentational ability of the child. The child reduces extreme incongruity or the initial shock of unexpectedness to more controllable dimensions. These miniaturized forms still may have many elements of sufficient novelty to excite and interest the child until gradually by play and replay they become assimilated into previous schemas or integrated into new organized schemas about a variety of social situations. The schemas formed may be "erroneous" if examined by an adult; depending on what further opportunities the child has to reshape the schemas and scripts formed in this fashion and to what extent experiences of humiliation around play or fear and terror in connection with some social setting preclude their exposure, they may persist as "neurotic beliefs." What [Sullivan \(1953\)](#) might call parataxic distortions or the transference phenomena that are manifest in the psychoanalytic situation may have been formed in the schemas of children that have not been played out openly enough to be corrected by other children or adults ([Singer, 1985](#)).

The compensatory or psychologically adaptive role of imaginative play and the adoption of a metarepresentational schema system are exemplified by an example provided by [Piaget \(1962\)](#). His daughter, just a little less than 4 years old, was told that she could not go into the kitchen because pails of hot water were being

prepared for her bath. The little girl then said, "I'll go into the pretend kitchen then. I once saw a little boy who went into the kitchen, and when Odette went past with the hot water, he got out of the way."

There is good evidence that play between parents and children is a universal experience that has a mutually reinforcing impact ( [Singer and Singer, 1990](#)). In a study by [Van Hoorn \(1987\)](#), observations of a diverse mixture of Chinese, Filipino, Mexican, and North American mothers of European descent were made during play interactions with their infants. Despite some cultural variations in games played, there was considerable evidence of mutual enjoyment. The range of interactive behaviors that promoted cooperation and successive attainments characterized games. The positive emotions of joy and surprise and laughter were consistently in evidence.

### **Imaginative Play in the 3- to 5-Year-Old Child: Research Approaches**

In studies conducted from our research center at Yale, we followed children from eight nursery schools or day care centers over a year's time. Pairs of independently recording raters who watched a given child for a period of time on two successive weeks and then returned a few months later to repeat this pattern made observations. Altogether there were eight observations spread across the year's time. In this sample of 141 3- and 4-year-olds the children were rated for variables such as specific positive emotions (e.g., liveliness, excitement, elation and joy, or sadness, anger, etc.) as well as behaviors such as imaginativeness, cooperation with peers, and overt aggression. The data clearly indicated that positive emotions such as joy and liveliness were consistently positively correlated with imaginative play. The children who showed various make-believe transformations during play emerged across the year's time as those who engaged in a good deal of smiling and laughter and who were motorically active. Imaginativeness was negatively correlated with evidence of fearfulness, sadness, or fatigue. These relationships could not be attributed solely to language usage, for when there was statistical control for numbers of words employed, the relationship between imaginative play and positive affect still remained statistically reliable ( [Singer and Singer, 1980, 1981](#)).

As [Greta Fein \(1981\)](#) has stated, "pretense provides an unusual opportunity for children to control their own emotional arousal and to maintain a level that is both comfortable and stimulating." In our own research, as well as in reports by Fein and others, it is rare that we have observed pretend play among children who are very angry, anxious, in conflict, or who are hyperactive. We did see children who used their toys as mock weapons or who played fantasy games that involved simulated aggressive acts, but the children were generally in control and used metacommunicative statements such as, "This is my bad guy . . . make believe he is chasing your good guy." Other studies supporting this generally positive nature of imaginative play as occurring in spontaneous settings confirm this general finding ( [Stoneman et al., 1984](#)).

In two separate studies, one carried out with a more clearly middle-class sample and one with children from a blue-collar background; we observed 3- and 4-year-old children over a year's time. Samples of play behavior were obtained. From the larger sample of children, 40 children who scored well above or well below the group means over the year on both imaginativeness of play and frequency of television viewing were identified. Four groups were delineated: high imaginative/high television viewers, high imaginative/low television viewers, low imaginative/high television viewers, and low imaginative/low television viewers. Each group was composed of 6 boys and 4 girls. Observers who recorded all of the children's actions for a 10-minute period and who were "blind" to the television-viewing patterns of the children recorded in detail both the verbalizations of the children and their actions during play. The data were then scored for categories such as where the play took place, the social structure of the play, the major themes (e.g., adventure, families, school, doctor), the roles assumed (e.g., mother, father, baby, super hero, victim), the type of play (e.g., sensorimotor, mastery, rules, pretending or symbolic play), evidence of psychodynamic themes (e.g., orality, anality, cleanliness, separation, rejection, sibling rivalry, etc.), and finally the references made to television in play. A play protocol analysis chart was developed, listing all of the kinds of play and the scoring procedure. Our data yielded seven statistical factors of play. These included: (a) adventurous fantasy play, (b) domestic fantasy play, (c) gross physical activity (running, jumping) versus artistic play, (d) a more general emphasis on make-believe pervading all forms of play, (e) involvement with ritual games or dancing and singing, (f) play with pet animals, and (g) games with rules.

Those children who were highly and consistently imaginative also engaged in more social play; they also participated more in ritual games and singing and were less likely to play alone. The imaginative children tended to be those who initiated games and were rarely solitary, withdrawn, or defensive. They could occasionally play alone, but they did not carve out a limited territory in their course of activities nor did they play in more bounded space. Over the year, we observed that the children tended to decrease their larger motor activity and increase their art, ritual, or singing and dancing play and in general showed increased social interaction. There was, interestingly, an increasing role of themes of danger, disaster, and physical mutilation. It may well be that these developing preschoolers had become increasingly aware of the real-life dangers and could now express these fears more verbally and work them into their play. It is, of course, also possible that the children chose such plot lines because these themes seemed to be interesting in themselves and more varied than the standard "putting the baby to sleep" and "going to the doctor" games that they had by now assimilated into organized schemas ( [Singer and Singer, 1980, 1981, 1990](#)).

The role of television viewing in play was evident in some of the content of themes. The children who were heavy television viewers and who showed in general low fantasy play tendencies were more likely simply to mention television super heroes or heroines and then, in imitation, bound around the room in a rather destructive fashion, knocking over others' toys or occasionally hitting other children. Although television may well provide a rich source of thematic content for imaginative play, it is evident from our own and others' research that heavy-viewing children are often less spontaneously imaginative in their play. Symbolic play practice may be displaced by the ease of flicking on a television set to provide entertainment. Moreover, the heavy doses of violent content and the rapid pacing and much-interrupted format of commercial television may generate influences on the heavier viewer that work against imaginative and reflective thought. In one of the few longitudinal studies of imagination in children, we found that early heavy television viewing predicted less imagination in children several years later, even when family life factors were also accounted for ( [Singer et al., 1984; Singer and Singer, 1990](#)).

### **Transitional Objects and Imaginary Playmates**

A special form of imaginative play essentially reflecting the same tendency toward the development of a metarepresentational symbol system can be found in the development of an imaginary playmate. [Winnicott \(1953\)](#) identified an early stage in such a development. From about 1 year of age many children show a tendency to carry a soft cloth about with them and often to take it to bed. Often the soft cloth may be a blanket from the crib; it may also be a spare diaper or some other item among the child's assortment of play materials to which the child has become especially attached. In its earliest forms children, especially when sleepy or hungry, may be seen sucking their thumbs and fingering a soft cloth. In later stages of early childhood, the soft cloth may simply become a kind of fetish that is sustained even as it becomes more and more ragged; eventually it may simply end up as a bit of cloth, to be tucked under one's pillow or into a purse.

Winnicott's perception was that these cloths serve the purpose of providing a concrete reminder in the absence of the mother's warmth and physical presence. Such a tendency can also be carried over to soft toys such as teddy bears. The term *transitional object* implies that the child is gradually giving up the physical clinging to the parent but sustaining some concrete and palpable feature of that experience.

The function of this soft toy is not only one of reminiscence but also one of possession. That is, although the child cannot possess indefinitely the warmth and closeness of the parent, he or she can possess the soft cloth or toy. Indeed, one can even argue that the emerging sense of individuality and personal entitlement that characterizes all of us even to the point of adults, insisting on our rights for pensions and medical care or "respect," are traceable to these humble beginnings. The child clings to his or her teddy bear, fights to retain possession, and begins to delineate a sense of self through being able to assert, "This is mine."

[Tolpin \(1971\)](#), in an extensive analysis of the phenomenon of the transitional object, has gone beyond Winnicott in demonstrating that the transition also involves the child's awareness that thought and fantasy can substitute for the palpable presence of the object. When such blankets or cloths are destroyed, accidentally thrown out by parents, or simply pulled to pieces, children gradually learn they can sustain the experience through their increasing capacity for imagery. Indeed, [Metcalf and Spitz \(1978\)](#) proposed that such transitional objects are sustained during the period when the child's cognitive capacities primarily involve recognition memory and can be gradually given up as the child develops increasing skill of voluntary recall or mental retrieval of desired objects. The extensive research of [Litt \(1986\)](#) has indicated that after 18 months and between the ages of 2 and 5 almost three-quarters of American children sampled showed evidence of play with a transitional object. Although data from other countries reveal somewhat lower levels of such play, cultural differences may in part reflect differences in forms of inquiry, availability of soft toys, and so forth. Of special relevance is the fact that the child introduces elements of make-believe with the soft toy and begins to treat this teddy as a companion, who can be talked to, admonished, and can also serve as a potential helper.

Litt's research also indicated that transitional objects serve a functional role and are not in themselves indications of emotional distress, poor attachment, or neurotic tendencies. On the contrary, the evidence seems clear from her data that children who have transitional objects report fewer sleep disturbances and are more attractable, self-confident, independent, and affectionate. Such children did not show any evidence of disturbance on personality test measures and if anything tended

to be less impulsive, aggressive, or antisocial than children who had not played with transitional objects.

Studies with children who report invisible imaginary friends indicate that the phenomenon is relatively common ( [Manosevitz et al., 1973](#); [Masih, 1978](#); [Somers and Yawkey, 1984](#); [Taylor, 1999](#)). Generally, the data indicate that at least a third of various child samples report the phenomenon. In one study comparing blind and sighted children, all of the blind children recorded a sighted imaginary friend ( [Singer and Streiner, 1966](#)).

In some of the research carried out by the author and his colleagues, with 111 3- to 5-year-old children, the parents of 55% reported that the children had shown indications to some degree of an imaginary playmate—an invisible child or animal for whom a place had to be set at the table on occasion. The children were rated for the degree of frequency of imaginary playmates and the extent of such reported play. The score generated by these data proved to be predictive of the children's spontaneous play over a year's time in day care centers and nurseries. Children who had more imaginary playmate experience were rated by “blind” observers as more imaginative in free play, showing especially more positive emotionality, more cooperation with adults, and a more extended language usage. When the imaginary playmate variable was entered as a predictor in multiple regression analyses to predict overt behavior, it proved an especially powerful variable in predicting not only imaginative play or positive affect but also greater persistence in play, less aggression and less anxiety and fearfulness. There was also considerable evidence that boys who had no imaginary playmates showed more television watching and less vivid language.

A recent impressive examination of almost every aspect of the imaginary playmate phenomenon by [Marjorie Taylor \(1999\)](#) has reviewed the available research literature on this phenomenon and provided further data on its prevalence, origins, and mental health implications. Taylor's findings in general support the research results cited in the preceding. Her studies demonstrate that, even in cultural settings where parents or other adults disapprove of children playing with or talking about such fantasy friends, careful inquiry reveals that a significant number of children are likely to reveal evidence of the phenomenon.

In effect the imaginary companion may be understood as a form of imaginative play that emerges as the child gradually acquires the capacity for heightened mental imagery. It has the adaptive function of allowing the child a means of resolving the tension described early in this chapter between the need for affiliation and for a sense of privacy and individuality. The phenomenon is somewhat greater among children without siblings and as such reflects, as in the study of the blind children mentioned in the preceding, a means of peopling one's world, maintaining some sense of control, and at the same time sustaining the experience of personal possession and privacy, because most children are well aware of the inherent unreality of an invisible imaginary friend ( [Singer and Singer, 1990](#); [Taylor, 1999](#)).

## THE ADAPTIVE ROLE OF IMAGINATIVE PLAY

### Specific Functional Correlates of Imaginative Play

#### GENERAL POSITIVE EMOTIONALITY

A number of studies consistently point to the fact that the use of make-believe in the nursery school or a variety of other settings or in the form of imaginary playmates is associated with more positive affective states in children. This consistent finding, as well as the tendency for there to be an inverse relationship between imaginative play skills on the part of the child and overt manifestations of anger and aggression, suggests the value of the use of play in a variety of therapeutic efforts with disturbed children. Thus, play therapists confronted with children who show limitations in their ability to engage in make-believe may have to find ways of subtly fostering these skills in the child, perhaps by example or gradual training exercises. Without some experience of enjoyment in the psychotherapy sessions, children are unlikely to want to sustain a treatment relationship ( [Singer, 1993](#); [Singer and Singer, 1990](#)).

#### ENHANCED LANGUAGE SKILL

One feature of imaginary play is that the children are verbalizing aloud descriptions of complex situations. Although some of their statements may reflect misunderstandings of adult remarks (as in the case of a boy lining up his toy soldiers to rescue Daddy, who was “all tied up at work”), such verbalization provides feedback to the child and may also evoke correcting responses from overhearing adults or peers. In addition, the inherent nature of make-believe play involves the development of plot sequences. This requires increased use of adjectives, future verbs, and extended utterance lengths ( [Singer and Singer, 1981, 1990](#)).

#### PERSISTENCE

Imaginative play, because it requires in effect a story line, tends to provide the child with focus and direction and then sustains concentration for longer periods. Children who have shown no tendency for imaginative play often are captives of the momentary changes of objects or toys in their environment. They seize at new things and often are embroiled in struggles for possession with other children or flit from group to group. The child engaged in symbolic play has by virtue of entering into this domain developed a sense of sequence, is moving in a privately defined direction, needs less sustenance from concrete external objects.

#### DISTINGUISHING REALITY FROM FANTASY

There is at least some research evidence to suggest that children who have experience in make-believe games are better able to discriminate real from unreal situations and have learned to identify within their own thoughts that metarepresentational realm described by [Leslie \(1987\)](#). For example, in one study with somewhat older children, those who had scored higher on indications of imaginativeness were better able to recall details of a story and then could discriminate real instances from those that were pure fantasy ( [Tucker, 1975](#)). It may well be that even those rare instances of multiple personality, the affected adults may have grown up without a clear sense of the extent to which fantasized alternative selves are natural occurrences as part of a general dimension of make-believe or metarepresentation. Because there is some evidence of early child abuse as a forerunner for such multiple personality developments, as well as for certain extremely hypnotizable or fantasy-prone individuals, it could well be that the same brutalizing family atmosphere that necessitated the child's escape to an alternative self also precluded a natural unfolding of make-believe play ( [Lynn and Rhue, 1988](#)). The abused child has had less opportunity to engage in many different sequences of fantasy play, and thus, fails to perceive the escapist alternative self as a natural part of a range of make-believe activities. Instead, dissociations may occur that are outside the control of the child.

#### EMPATHY

One of the consequences of solitary and group make-believe play is that the child often learns to take on different roles. One can be the doctor examining the real or imaginary doll, and then, one can reverse roles and pretend that the doll or another child is the doctor. Often in the make-believe play of two or three children, one observes brief struggles over who will be the “good guy” or the “bad guy,” the hero or victim. In such instances, these disputes are often resolved by reversing roles either later in the game or on other days. Gradually, the child engaged in such play learns what it is to be a victim and to experience others' dilemmas or pain. Although we do not have extensive data on this issue, careful clinical studies have supported this finding ( [Gould, 1972](#)).

#### COOPERATION

Observational studies of children at play such as those cited in the preceding consistently demonstrate that children prone to symbolic play are more likely to prove cooperative both with adults and peers. Indeed, the very necessity of negotiating roles and plots with other children in order to sustain make-believe provides useful practice in this important social skill. One can observe children who show very little spontaneous imaginative play or who have been heavy television viewers and have not been practicing any make-believe at home dashing madly about the room, disrupting others' play and in general bringing down on themselves the wrath of the adults and children ( [Singer and Singer, 1981](#)).

#### LEADERSHIP

Although studies have generally not focused on early leadership tendencies at the preschool and early school ages, there are some data to suggest that children who are active in make-believe often are the first to initiate new games. The very practice of creating a series of plots may foster the ability to introduce a new group of children into some game. The experienced make-believe player thus gets “first crack” at assigning roles and plot lines. As imaginative play becomes more internalized and children move into reading and storytelling, there are clinical indications that children who have such storytelling capacities may win the respect of others in a play group ( [Singer and Singer, 1980, 1990](#)).

## TOLERATION OF PLAY

Of extreme importance for the developing child is the ability to defer immediate gratification in the interest of a longer-term goal, or simply to tolerate naturally occurring delays. Make-believe play, whether it is sustained by the use of just few primitive toys or as it gradually becomes internalized in the form of imagery, has been shown in quite a number of studies to be associated with the ability to deal with delay ( [Singer and Singer, 1976](#)). For example, in a study with somewhat older children, those who had shown patterns of imaginary play and other signs of imaginativeness were able to sit still longer when asked to do so or could tolerate waiting in an interview situation until the reviewer was ready to speak with them ( [Singer, 1961](#); [Singer and Singer, 1990](#)). The importance of this capacity cannot be minimized. Indeed, one might argue that the entire conception of the ego in psychoanalysis is built around the notion of deferred gratification and the capacity for delay and self-control in response. Imaginative play may be an important contributor to the development of the experience of self-regulation in this sense ( [Singer, 1955](#)).

## NEW IMAGERY COMBINATIONS

One of the important features of imaginary play is that it provides a child with a general opportunity to practice imagery, that is, to try out mental representations of concrete objects or of transforming such concrete objects. I have already suggested this in connection with [Leslie's \(1987\)](#) more general notion of the metarepresentational system and of the decoupling. But skill in producing images is something that develops in its own right and can be advanced by the ongoing imagined play sequence ( [Lewis, 1973](#); [Singer, 1973](#); [Tower, 1983](#)).

## DIVERGENT THINKING

Beyond new imagery elaboration pretend play may be a basis for divergent thinking and creativity in both its verbal and imaginal forms ( [Russ, 1996](#)). A recent longitudinal study has shown that children who play more imaginatively in make-believe games not only show continuity in such tendencies over a 4-year period from ages 6 and 7 to ages 10 and 11 but also that such earlier imaginative play predicts later performance on measures of divergent thinking, a possible forerunner of creativity ( [Russ et al., 1999](#)).

## TAKING TURNS

The careful observations of [Catherine Garvey \(1974\)](#) demonstrate that one of the important features of pretend play in children is the manner in which it is associated with turn taking and a form of social interaction that has long-term socialization potential. Observations of children in various kinds of make-believe indicate that exigencies of the plot in any initially agreed on make-believe activity impose forms of self-control on the child. As in the case of cooperation more generally, turn taking provides a valuable delineation of orderliness and sequence that has special meaning for the child.

## TRYING OUT DIFFERENT ROLES

A special feature of make-believe that goes beyond empathy is the opportunity for children to try different roles and gradually identify the special qualities of the different kinds of individuals in their environment. When children play "Bus Trip," one of the children becomes a driver, others become passengers, and others become traffic policemen. Each game reduces to miniature size a variety of adults in the child's real world who are often not well understood. In their efforts to formulate a plot, children again and again try out these roles and can gradually assimilate them into structured schemas that will serve them better as they move on in life and encounter such individuals. The notion of role taking is also a critical one for the development of awareness of gender and sex role differences. There are indications from research that children who are more experienced in make-believe may also be able to develop a more androgynous orientation and are freer of very traditional and often limiting sex role attitudes or expectations for the future ( [Repetti, 1984](#)). In the psychotherapeutic situation, one important function of play therapy may be to have the child begin to try out new kinds of roles and interactions, beginning with the therapist but extending to imagined persons with whom the child may come into contact later on ( [Singer and Singer, 1990](#)).

## ORDERING AND SEQUENCE

I have already emphasized the important role that the inherent plot line of a make-believe game plays in encouraging persistence over time by the children and also in encouraging cooperation or turn taking. The very nature of make-believe play calls for a certain logic, a sense of beginning, middle, and end that gradually becomes the basis for the formation of differentiated scripts that are important forms of action schemas in the child's memory system. Extensive research in cognitive science has pointed to the importance of the ability to sustain a variety of systematic scripts about hundreds of social situations that individuals encounter, from birthday parties to restaurants to attendance at sporting events and, ultimately, to marriage or specific vocational activities. The make-believe play sequence for children provides them with opportunities to learn the necessity for sustaining and organizing miniature scripts and allows them to be free of purely impulsive associative responding to some degree ( [Bretherton, 1984](#); [Nelson and Seidman, 1984](#)).

## ANTICIPATING CONSEQUENCES

A further extension of the nature of plotting and the emergence of narrative sequences as part of thought fostered by pretend play is the awareness that actions have specific consequences. Thus the beginnings of social cause-and-effect thinking in the child are developed in the course of imaginative play ( [Bretherton, 1984](#)).

## Factors Conducive to Imaginative Play

If pretending and make-believe are so useful in the development of the child, what features of babies or toddlers' milieux generate, sustain, and enhance the predisposition to such play? Space does not permit an extensive review of this topic, but there are clear indications from research that particular parental or caregiver activities are critical. An early optimal attachment to at least one parent or consistent adult caregiver predicts later emergence of imaginative play. Parental willingness to initiate games of fantasy, to suggest plots or the use of toys but then to step back from them so that the children experience the games as their own is also an important correlate of children's pretending capacities. Parental storytelling or bedtime story reading are also regularly found to be associated with evidence of greater resort to imaginative play in children. A family atmosphere of tolerance for floor play, a physical setting that allows children to find at least some private areas for uninterrupted pretend games, and adult attitudes of acceptance rather than humiliation of the preschoolers' talking aloud or role-playing all contribute. An overall sense of playfulness in the home setting opens the way for the imagination, humor, and even that sense of illusory control that are so crucial for normal coping capacities ( [Singer and Singer, 1990](#)).

## Imaginative Play, Psychopathology, and Psychotherapy

A fuller exploration of the implications of children's make-believe play for psychopathology and psychotherapy would take us far beyond the scope of this chapter. The general thrust of this presentation suggests that pretend play, the capacity to create miniature, possible worlds, is a critical feature of the healthy development of a child. The available evidence as reviewed by Dorothy Singer and myself elsewhere has suggested that emotional disturbance and cognitive and affective difficulties are often associated with an inability to sustain imaginative play in middle and early childhood ( [Singer, 1973](#); [Singer and Singer, 1976, 1990](#)). Some classic cases in which children's play revealed elaborate, unrealistic fantasies reflecting their troubled life experiences demonstrate that those children who could sustain such play had better prognoses once play therapy was initiated ( [Singer, 1973, 1993](#); [Singer and Singer, 1976](#)).

A critical role for the psychotherapist with children is to help them to find ways of miniaturizing their private fears, brutal experiences of abuse, exposure to parental quarrels, or neglect into manageable chunks. The therapist's encouragement of play by the provision of an appropriate setting of toys or (for middle childhood) games conducive to symbolic representations of children's troubles casts the therapist in the role of the needed mediating parental figure. Delineating in play form key life issues, significant adults or siblings, and conflicts helps the child to develop new schemas and scripts and new knowledge structures that can later reduce the ambiguity, confusion, or affects of fear and terror that new situations may present.

I believe that a key feature of the play therapist's role is to provide a model for the child of a zestful, curious, lively approach to one's experience. Although the therapist must often avoid moralizing about the child's hatreds or about presumed parental or sibling cruelties or neglects reflected in play, this does not preclude an emotional response. The therapist's own professional curiosity and willingness to share thoughts and play possibilities, conveyed in a spirit of liveliness and humor, can open the troubled child to the joys of the world of introspection and fantasy. By such an approach one can change the fearful, despairing, or angry child, trapped

in a mental world of limited constructs, schemas, or scripts, into one who can savor the excitement of reshaping what had seemed like the given world of recent experiences into a domain of innumerable possibilities. By replaying and, thus, reshaping schemas, the child can gain at least some sense of control and power within a small region of a vast, seemingly impenetrable universe. The skilled play therapist, whether psychoanalytic or cognitive-behavioral in orientation, not only provides the child an opportunity to identify and work through specific problems but also enhances the child's development of the capacity for play, a powerful cognitive tool for further enhancement of a sense of self and individuation, as well as a continuing private theater for developing new scripts of affiliation and attachment. The medium of make-believe in childhood, internalized by middle childhood into a richly elaborated fantasy capacity, becomes eventually a major functional system through which all of us can entertain opportunities and possibilities for warmth, closeness, and communion with others while sustaining our sense of individuality and privacy.

[Summary](#)

[Chapter References](#)

As we have no immediate experience of what other men feel, we can form no idea of the manner in which they are affected, but by conceiving what we ourselves should feel in the like situation. Though our brother is upon the rack, as long as we ourselves are at our ease, our senses will never inform us of what he suffers . . . it is by the imagination only that we can form any conception of what are his sensations. We endeavor to examine our own conduct as we imagine any other fair and impartial spectator would examine it. . . . Our continual observations upon the conduct of others, insensibly leads us to form to ourselves certain general rules concerning what is fit and proper. . . . ([Adam Smith, 1759/1976](#))

Philosophers have grappled with the uniquely human quality of morality for centuries ([Blum, 1996](#); [Kagan, 1998](#)); however, research interest in moral development is much more recent. In 1984, Martin Hoffman could still write that guilt was a relatively neglected research topic. Morality shares many features with attachment ([Bowlby, 1982](#)). Both are systems of behavioral interactions, cognitions, and emotions, present in everyone unless pathology or environmental adversity intervene; they are biologically adaptive, promoting individual and group survival; their development forms a regular sequence, deviation from which can have serious consequences.

Much progress has been made in the exploration of the development of empathy, shame, and guilt, of prosocial behavior and moral judgment. The context within which young children become socialized and acquire moral standards and beliefs and the vicissitudes of this developmental process have become clearer, a start has been made in elucidating its psychopathology, and the stage is set for a more rational approach to the prevention and treatment of antisocial conduct.

This chapter focuses, in turn, on the classical contributions to our understanding of moral development of psychoanalysis and the cognitive-developmental studies of Piaget and Kohlberg. It deals with Hoffman's work on empathy, Kagan's observations of the development of self-appraisal and inner standards, Turiel's documentation of children's ideas about morality and convention, and with work on the emotions related to morality. Some aspects of the psychopathology of moral development are described: social learning and role modeling, cognitive attributions and expectancies, and the effect of maternal depression. Finally, the context within which children develop moral behavior is discussed, including Kochanska's imaginative studies relating parenting styles and child temperament to early precursors of conscience.

## PSYCHOANALYSIS AND THE MORAL SELF

### Freud

[Freud \(1930/1961a, 1923/1961b\)](#) saw the origins of ethical tendencies in the emotional attachments of young children to their caregivers and thought the long period of helpless dependency of the human baby was the biological basis for the development of conscience. Dependency on parents fosters fear that their love may be lost. Threat of such loss induces fear, the main emotion associated with moral development in this first stage, equivalent to social anxiety in adult life: a fear of being found out. Only in the next stage, when parental authority is internalized with the formation of a superego, do conscience and a sense of guilt arise, whereas the fear of being found out wanes. Freud stressed the lack of distinction during this stage between doing something bad and wishing to do it, between the act and the impulse, because the superego, being a part of oneself, is as aware of bad thoughts as bad deeds.

Whereas in the first stage of moral development, parental prohibitions (the "don'ts") ([Emde et al., 1987](#)) instill fear that parents will withdraw their affection if disobeyed, in the next stage the objects of attachment become internalized, and children now judge themselves critically. To recover from a sense of a flawed self, they develop an ego-ideal and strive toward its attainment. Failure to meet the standards of this fantasized ideal self (the "do's") results in a sense of guilt. James Baldwin, an extraordinary developmental psychologist, first described the functions of the ideal self in the development of moral consciousness (1897). He saw the ideal self as submissive to the exhortations of adults, whom the child perceives as superior and to be both obeyed and imitated.

Freud's most original and controversial contribution in this field has been his theory of the Oedipus complex and its attendant anxieties, which he held to be a prerequisite for identification with parents and the formation of an ego-ideal. Children identify with both parents, but become erotically most attached to the parent of the opposite sex. The rivalries, jealousies, and ambivalences toward the same-sex parent engender fears of retribution: castration anxiety, with resulting defensive repression of erotic urges and strengthening of parent identifications, especially with the same-sex parent. Freud emphasized that the introjection of the father's authority in particular lays the foundation for the superego or conscience, the basis for guilt, when one falls short of the demands of one's ideal self. He thought castration anxiety was more severe in boys than girls. The threat for girls was less because the damage seemed already to have been done. Boys, in contrast, tend to develop a harsher conscience, and paradoxically, this puts them at greater risk of antisocial conduct. An overharsh conscience, he held, instead of protecting the individual from antisocial acts, at times fosters "criminality from a sense of guilt." He also developed the contrary notion that the more virtuous a person is, the more severe his or her superego—that saints reproach themselves the most for being sinners ([Freud, 1930/1961a](#)). Thus, an exceptionally punitive superego is to be found both among some criminals and excessively good people.

The importance of Oedipus conflict resolution for conscience development has probably been overstated ([Emde et al., 1987](#)). Researchers at Anna Freud's Hampstead Clinic documented significant pre-Oedipal features of morality and found many latency children with unresolved Oedipal struggles but strong superego development.

### Anna Freud

[Anna Freud \(1966\)](#) presciently emphasized the importance of language for conscience formation and ego control and stressed the role of empathy in the development

of children's ideas, for example, about the property rights of others. She too saw the superego as an incorporation of parental strictures—"identification with the aggressor"—but also held that the acceptance of one's own culpability played an essential part. Repression and sublimation, or the displacement of instinctual aims in conformity to social values, are part of this developmental process ( [Freud, 1961](#) ). Although the defensive processes of projection, introjection, and regression develop very early in life—as soon as children can distinguish between themselves and the outside world—the defense mechanisms of repression, sublimation, and reaction formation, essential for subduing childish greed and hostility, develop later.

### Melanie Klein

[Klein \(1927/1948a;1933/1948b\)](#) placed the Oedipus complex between the first and second years and superego formation in the second year. Her timing does not tally with what we now know about children's cognitive capacities, but her descriptions of the harshness of the infantile conscience, much harsher than the real parents had ever been, have been illuminating.

### Erik Erikson

[Like Freud \(1961a\)](#), Erikson, in his scheme of personality development ( [Erikson, 1968](#); [Wolff, 1989](#) ), divides the growth of the moral self into two phases: from about 18 months to 2½ years, the “anal” stage of primary socialization, and from 2½ to 5 years, the “genital” stage of primary identifications. During the “anal” stage, toilet training and the acquisition of sphincter control are symbolic of the parents' first attempts to teach the child the basic rules of the society in which they live and, on the child's part, of the earliest efforts at self-discipline for the sake of approval. The toddler, on his feet, with arms free, is ready for action and, although still with poor impulse control, he has a choice: to throw, grab, defecate, or (in response to parental prohibition) desist. He needs the parents' presence to back his efforts to succeed but he also needs them to step in when disaster threatens. For the first time, the child gets pleasure from cooperation and pride from achievements, but also a sense of shame at failure. In contrast to the concerns of previous psychoanalytic writers with the young child's fantasies, Erikson gave due weight to actual life experiences at this stage as determinants of future self-esteem, in particular a sense of autonomy and self-confidence in relation to cooperative enterprises, or of shame and self-doubt.

Many parents, especially the socioeconomically deprived with limited occupational autonomy and little sense of control over their lives, find this stage of child rearing difficult. Although offering good nurturing care to the baby, they have unrealistic expectations of their toddler's capacity for self-restraint. Instead of physically taking over control when necessary, they exhort and admonish verbally and from a distance and, when accidents occur, they reprimand, threaten, and punish, sometimes aggressively. The anxiety engendered by such child rearing reinforces the toddlers' fears of what could happen if they were to lose control and, in line with the idea of “criminality through guilt,” induces them to act ever more outrageously. The actual consequences are never as bad as those feared; anxiety is temporarily assuaged, only to return as the cycle of interactions repeats itself.

In the second Eriksonian stage of moral development, the “genital” stage, language transforms children's social interactions and inner life, and a sense of the future is born. It is the “play age” of curiosity and make-believe, of storytelling and identification with role models, especially parents. The earliest triadic and group relationships now occur and new emotions such as rivalry and jealousy have to be mastered. The child now has more self-control and can compensate for present frustrations in play, imagination, and hopes for the future.

Erikson thought the development of girls was the more hazardous because their erotic longings for their father engender jealousy of the mother, which is the more frightening because she becomes a potentially hostile rival and is lost as a haven of security. Boys, in contrast, although now attached to their mother in a new way, still have her as a safe source of comfort. On the other hand, the role models parents provide for their children at this stage are more secure for girls than boys. Far fewer mothers than fathers are lost from the family, and the status of mothers within the home is universally high, whereas that of fathers, especially in families living in poverty, tends to be low.

As children identify with and incorporate parental standards of conduct, a powerful new source of anxiety—guilt or the pangs of conscience—arises together with a division between the self in action and the moral self (ego and superego). In Erikson's view, actual life experiences at this stage determine whether the person will emerge with strengthened capacities for initiative and intimate relationships or instead become constrained and inhibited.

Children's cognitive development during these years fosters misinterpretations of their experiences and magnifies their anxieties. The potential harshness of conscience in early childhood is understandable when we appreciate the nature of children's logic at this time of life.

Developmental psychologists now take note of children's inner worlds, their cognitions and emotions, and psychoanalysts are prepared to amend their theories in the light of observations. [Buchsbbaum and Emde \(1990\)](#) have questioned the idea that moral development depends on the resolution of the Oedipus conflict at the end of the genital stage, that is the fourth or fifth years of life. Using a play narrative technique, they found children as young as 36 months capable of articulating coherent stories about rules, reciprocity, empathy, and internalized prohibitions. Even such young children could deal with alternative outcomes to resolve a moral dilemma. In this important paper, the authors stress the dual origins of moral development—biological preparedness and early caregiving relationships.

## THE CONTRIBUTION OF JEAN PIAGET

The impetus for the objective study of moral development in childhood came from Piaget's systematic observations ( [Piaget, 1932](#); [Piaget and Inhelder, 1969](#); [Wolff, 1989](#) ). Before summarizing his studies of moral judgment, it needs to be said that his general discoveries about children's immature logic and reasoning between the ages of about 2 and 7 years have shed much light on early childhood fears and some of the psychoanalytic postulates about early emotional experiences. During the precausal, animistic stage, children cannot yet detach thoughts from the events and objects thought about, nor identify themselves as thinkers about the world. They cannot, for example, explain how it is that they are both in their bed at night and yet also in the dream they have while sleeping. Their explanations of events and circumstances tend to be psychological rather than rational, and the notion of chance events is not yet grasped. Although aware of their own viewpoint, they find it hard to conceive that this is not also uppermost in the minds of others. Piaget's ideas about a child's early egocentrism have been criticized by researchers who found children more capable of logical inferences when problems are embedded in a child centered context ( [Donaldson 1978, 1992](#) ). However, children spend much of their lives in an adult world, and the distortions and misperceptions that Piaget's work so vividly revealed are common experiences for everyone in touch with young children.

Like psychoanalytic writers in relation to emotions and behavior, Piaget held to a stage theory of cognitive development. Each stage differs qualitatively from the next, and teaching of logical operations is ineffective until the child has reached the necessary level of understanding. However, cognitive development is now held to be more gradual than Piaget thought: Not all children's thinking changes at the same time at each stage ( [Pine, 1999](#) ).

### The Rules of Games

Piaget concerned himself with children's perceptions of the rules of games and with their views about morality. He did not focus particularly on the distinction between convention and morality, as later workers did ( [Turiel, 1983](#) ), being concerned rather with identifying changing but parallel developmental sequences in how children perceive and respond to rules in both spheres.

The game of marbles is played the world over. Piaget watched how children of different ages played and questioned them systematically about their understanding of the rules and how these had originated. He found that under about 7 years, in the precausal, animistic stage of development, children grasp rules imperfectly, make errors in their application, and are content to play alongside others. Yet they think of rules as obligatory, inviolate, and inherent in the game. When asked who made them, they said the rules had always been there, and if pressed, they resorted to “God.” Older children, in contrast, played competently, knew what the rules were, but viewed them as conventions devised by “children long ago.” If everyone agrees, the rules can be changed and the game played differently. Piaget saw this shift at between 6 and 8 years of age as a move from an authoritarian to a democratic viewpoint, from a position of unilateral respect for sacred laws and duties to one of mutual respect and reciprocity.

### Ethical Beliefs

[Eckemberger \(1999\)](#) defined morality as comprising customs and traditions; ethics as justifications for these: ideally, how the world should be. Piaget systematically questioned children about their ethical beliefs. And here too, he observed a shift from an authoritarian morality in which obedience is equated with goodness and all adults are seen to be right, to a morality where concepts of justice and a more detached view of adults and ethical standards prevail. Piaget explored children's ideas

about culpability at different ages by giving them pairs of stories to evaluate; for example, one in which a child's clumsiness led to a big accidental breakage paired with one where a lesser mishap followed the pursuit of a forbidden goal (taking jam off a high shelf); stealing to help a poor and hungry child contrasted with stealing for oneself alone; inaccurate reporting of a frightening event paired with telling a deliberate but lesser untruth. Again he found a shift of moral attitude. Despite considerable overlap, younger children tended to judge actions according to their material consequences, older children, according to their underlying intentions. Children's views of naughtiness and punishment also changed with age. Younger children had notions of immanent justice—that the crime begets the punishment and that, if you are punished, you must have done something bad to deserve it. They also believed in retributive justice (the *jus talionis*)—that the punishment must fit the crime irrespective of circumstances and motivation. Moral realism is the label Piaget gave to these immature ideas, which he linked to adult constraints on young children and to the children's sense of unilateral respect or duty. Older children in contrast had different ethical beliefs based on autonomous judgments, reciprocity and cooperation, the internalization of rules, and ideas of justice and mutual service.

Piaget saw in the children he studied the development of a morality of good, deriving from affection, and a morality of rights and duties (ideas later taken up by [Turiel \[1983\]](#) in his distinction between morality and convention). Some people he thought operated only with the latter.

Although accused of ignoring the influence of the social environment in promoting development ([Haste, 1987](#)), Piaget had in fact anticipated the now acknowledged role of the peer group in socialization. He stressed the importance of interactions with other children for the transformation of an authoritarian to a democratic view of morality in middle childhood, from a position in which obedience to adults and avoidance of punishments are primary to one in which conformity to social rules and, later still, participation in rule making for the sake of universal, ethical principles predominate. Nor did he ignore the importance of emotions ([Eckenberger, 1999](#)).

Unlike Vigotsky ([Rogoff, 1990](#)), however, he paid little regard to the role of adults in children's learning. Cognitive development is facilitated in interaction with a more skilled partner, and the child is able to engage in skills beyond those he is capable of on his own. Development builds on the internalization of what was carried out in collaboration, that is, of shared cognitive processes to extend the child's existing knowledge and skills.

[Butterworth \(1987\)](#) suggested that children's cognitive and social immaturity and gullibility are biologically adaptive, that unquestioning acceptance of adult rules has to precede the doubting and self-judging phase. The culture must make indelible impressions on the very young for it to be maintained. This view parallels the notion that small stature and physical immaturity too contribute to the acculturation of the young in many species, ensuring that they are docile and noncompetitive during early socialization ([Tanner, 1984](#)).

### An Important Proviso

We must be clear that Piaget and even more so Kohlberg, as we shall see, was concerned with moral reasoning, that is, with what children and older people say about their ideas and beliefs about moral dilemmas, often concerning not themselves but other people. This requires considerable cognitive, linguistic, and social skills and is different from the way in which young children grapple with moral issues in their everyday lives, when they themselves are the central characters. As [Margaret Donaldson \(1978, 1992\)](#) made clear (see also, [Buchsbbaum and Emde, 1990](#); [Dunn, 1988](#)), when moral dilemmas are embedded in real-life or age-appropriate, child-centered play settings, tied to the here-and-now or to concrete events in the past or future, moral sophistication is seen at a much younger age. Moreover, as Vigotsky indicated, "scaffolding" by adults helps children toward greater cognitive attainments ([Pine, 1999](#)).

## KOHLBERG'S STUDIES

Lawrence Kohlberg and his colleagues ([Colby and Kohlberg, 1987](#); [Colby et al., 1983, 1987](#); [Eckenberger, 1999](#)), some 30 years ago, embarked on a long-term longitudinal study of the development of moral judgment. They constructed two sets of reliable interviews, with standard questions about stories involving people faced with moral conflicts. A detailed scoring manual was devised ([Colby et al., 1987](#)) in which the liveliness of the stories and their sensible scoring are evident. One story is about Heinz, whose dying wife needs a drug for which the pharmacist asks an exorbitant price that Heinz cannot afford. Would it be right for him to steal the drug, and if so, why? Others concern a boy who has saved his pocket money for camp when his father demands the money instead, a doctor faced with a mercy killing, and a mother who had promised to let her daughter go to a rock concert and then changed her mind. Piaget's work and theories were the starting point for these studies, but unlike Piaget, Kohlberg and his colleagues did not study very young children.

Eighty-four boys aged 10, 13, and 16 years at the outset, equally distributed by social class, IQ, and sociometric status, were individually interviewed, 58 at least twice, out of six planned occasions over the course of 20 years. The interviews and their scoring are complex, and the standard stories tap nine hypothetical but true-to-life moral dilemmas about which a series of questions are asked relating to the values and reasons underlying the subjects' judgments.

Kohlberg described six stages of moral judgment. Longitudinal stage reversals occurred less often than test-retest unreliability; that is, the sequence was always forward. No subject reached a stage without passing through the previous one; that is, the sequence was invariable. Most youngsters scored within a single or two adjacent stages at any one time, only a few in three stages, so that there was internal consistency in moral judgments. No differences were found between the three age cohorts. Relative developmental delays were modestly associated with low socioeconomic status at 10 years and with intelligence and, especially, educational level at 24 and 23 years, when both tended to have reached their ceiling. Upper levels of moral development were generally reached in the mid-20s or -30s, but not even then in a sizable proportion of individuals.

Here is an abbreviated summary of Kohlberg's six stages, grouped into three levels ([Colby et al., 1983](#)):

Level I—Premoral: The child is responsive to cultural rules but sees these in terms of pleasant or unpleasant consequences of behavior and relates them to the power of authority figures. He follows the rules for the sake of self-interest.

Stage 1: The child is oriented to obedience and punishment, with egocentric deference to authority figures and avoidance of unpleasantness for himself or herself.

Stage 2: There is a naively egoistic orientation, with concern for one's own needs but with some awareness of the needs of others, a wish for egalitarianism, and an orientation toward exchange and reciprocity.

Level II—Conventional Role Conformity: The child is now oriented toward maintaining the expectations of others close to him or her, as a value in its own right.

Stage 3: The orientation is to be a good person in the eyes of others and in one's own eyes, with a wish to please and help. Intentions of behavior are taken note of and the moral perspective includes interactions with others.

Stage 4: The orientation is toward the social order and its maintenance for its own sake and to fulfilling agreed duties in conformity to authority.

Level III—Self-Accepted Moral Principles: The individual is now concerned with defining moral values and principles apart from the supporting authority.

Stage 5: The orientation is contractual and legalistic, with a sense of obligation to the law, but also an acceptance that people can have a variety of different values and that their individual rights take precedence over the social contract.

Stage 6: The orientation has become a sociomoral one, with the recognition of valid universal ethical principles to which the person can choose to commit himself or herself.

A study in which attempts were made to induce stage skipping in 11- to 13-year-old children, by having them listen to adults reasoning at different levels about the solutions to moral dilemma stories of the Kohlberg type, found all changes to be to the next higher stage to the subject's own ([Walker, 1982](#)).

Kohlberg's interview methods, devised in the United States, have been used in other parts of the world with similar results. [Eckenberger \(1999\)](#), summarizing cross-cultural studies, concludes that it is not "Westernization" but industrialization with increasing complexity of a culture that fosters the attainment of Kohlberg's higher stages. High socioeconomic status and participation in social systems are positively associated with moral development, life in fundamentalist or small tribal societies with mainly face-to-face interactions are negatively associated with this development.

## What Causes Variations in Moral Judgments?

Cultural transmission plays a part, as do the different developmental stages outlined by Kohlberg including different domains of social judgment—moral or conventional (see the following)—and the need to judge multifaceted situations. Life experience and accommodation to the environment are also important. Individual moral decisions and actions take place within a social context, and are influenced by peer group norms.

A study of moral judgments of high school students found significant differences between children in a school that fostered democratic decision making compared to children in a conventionally organized school. Most students in the “democratic” school thought they and their peers would chose to act prosocially, whereas in the “regular” school most made the prosocial choice for themselves but thought their peers would not do the same ( [Higgins et al., 1984](#) ).

Another important factor determining moral choice is the information available. [Wainryb \(1991\)](#) studied children's moral judgments of events before and after hearing information that challenged their initial opinions. All children thought it was wrong for an irritable adult to spank a child who had not erred. But some held it was right to spank a repeatedly misbehaving child because they thought this taught children to behave better. When the responders were told spanking was ineffective in socializing children, most of them changed their mind. In this study, information profoundly affected the moral judgments of young people aged 11 to 21 years. This has implications for education but also for the information presented to the general public by the media.

## Two Aspects of Morality: Justice and Benevolence

Kohlberg's major study involved only boys. His colleague, [Carol Gilligan \(1982\)](#), developed the idea of fundamental sex differences in moral orientation, with men giving priority to justice and rights, women to care and responsibility in human relationships. She also held that hypothetical and real-life moral dilemmas elicit different types of responses. Her arguments are based on interviews concerning their experiences and thoughts about moral conflicts of three groups of people: 25 male and female college students taking a course on moral and political choice; 25 women undergoing counseling before a possible abortion; and a small number of male and female subjects, ages 6 to 60. No account of systematic analyses of the data is given.

A replication of Kohlberg's and Gilligan's work, with a bigger sample of male and female subjects between 5 and 63 years old, confirmed that there are few violations of stage sequence over time. In contrast to Gilligan's findings, no significant sex differences emerged but the types of responses to real-life and hypothetical dilemmas did differ, although not systematically, in the direction of care and responsibility for real-life problems, justice, and rights for hypothetical issues ( [Walker, 1989](#) ).

Although Gilligan's work led to the important rediscovery of benevolence, and its relationship to justice, as an aspect of morality ( [Eckenberger, 1999](#) ), the limitations of her sampling and the lack of clarity of the analyses of her findings have cast doubt on her proposition that morally men and women speak in a “different voice” ( [Okin, 1996](#) ). Yet sex differences in early socialization and early prosocial behavior do occur ( [Hay, 1994](#); [Lewis et al., 1992](#) ). In early childhood, girls tend to be more compliant ( [Kochanska et al., 1995](#) ) and share more toys, especially with other girls ( [Hay et al., 1999](#) ).

## THE ROLE OF EMPATHY IN THE DEVELOPMENT OF PROSOCIAL BEHAVIOR

Both Anna Freud and Piaget referred to the importance of empathy in moral development; but, [Hoffman \(1975, 1984, 2000\)](#) was the first see this as an intrinsic, internally based moral motive, with guilt and other emotional aspects of morality deriving from the capacity for empathy with the suffering of others.

The experience of empathy varies with cognitive level. Emotional responses to the feelings of others are seen even in the newborn: When one baby in a nursery cries, the others follow suit. This “reflexive emotional resonance” ( [Campos et al., 1983](#) ) manifests before infants can distinguish between themselves and others, between their own emotions and those of other people. Only at around 9 months are babies thought to be able to locate feelings in others. In their first year, children respond to distress in others as if it were happening to themselves; however, in the second year, they are capable of sympathy, that is, of offering comfort to others. Toddlers, for example, whose mothers suffer from depression, make active attempts to offer solace when their mothers weep ( [Radke-Yarrow et al., 1985](#) ). Such activity may be inappropriate at first. When one toddler cries, another will call on her own mother for help, even if the crying child's mother is present, or she will offer her own comforter rather than that of the toddler in distress. By the third year, however, when role-taking occurs in play and children begin to model themselves on other people, they can realize that the feelings of others are different from their own, and in the fourth year, empathic distress prompts the offering of help geared to the needs of the other person.

[Hoffman \(1975, 2000\)](#) saw empathic responsiveness together with a cognitive sense of the other person as the basis for altruism, a biological, prosocial motive to offer help, independent of self-interest and the prospects of reward. People help others in need even in the absence of approving witnesses. Moreover, popular children, emotionally secure, loved at home, and hence less in need of approval from others, are more inclined to help than children who receive little affection. Hoffman speculated that children exposed to frequent, severe distress and frustration are likely to develop egoistic self-absorption, which interferes with their sensitivity and openness to the needs of others.

[Hoffman \(1984\)](#) also suggested that empathic responses are further differentiated in middle childhood. Children withdraw when the distress of others is overwhelming. They empathize more with others like themselves, offering less help to outsiders. They now concern themselves with the more enduring sufferings of other people, even when far away or unknown, such as the victims of war or famine in other countries.

In summary, four main stages of empathic development have been described ( [Hoffman, 2000](#) ): global empathy in the first year; “egocentric” empathy in the second year, when differentiation of self from others and object permanence have been attained; veridical empathy based on awareness that others too have thoughts, feelings, and wants, and depending on role and perspective-taking capacities, at between 2 and 3 years of age; and, in later childhood, empathy for the experiences of others beyond the immediate situation, associated with the development of a sense of personal identity.

If the observer was the cause of another's misery, self-blame transforms empathic distress into guilt ( [Hoffman, 1984](#) ), which eventually becomes dissociated from empathy. Both are quintessential moral motives. Hoffman holds that a comprehensive moral theory requires both motives and principles of justice and fairness, as outlined by Kohlberg. He believes that children are best socialized to act in accordance with an inner principle of altruism if, once capable of empathic understanding of others, parents avoid power assertive methods and use an inductive style of child rearing, consistently pointing out the possibly harmful effects on others of antisocial conduct. His important work stimulated much subsequent research.

[Zahn-Waxler and Radke-Yarrow \(1982\)](#) trained 24 middle-class mothers to record observations of their young children in response to emotional distress in others (natural and simulated, caused and not caused by the child) over a 9-month period. Somewhere between 12 and 18 months, most children's behavior changed from a few interactive and merely diffuse affective responses to positive forms of reaching out toward and caring for another person in need. By 18 to 24 months, verbal expressions of sympathy accompanied such behaviors. The findings go against psychoanalytic ideas of egocentric narcissism because at this early age the responses could not have been learned. Innate, empathic distress and later observation learning, the authors hold, promote prosocial development. In their own samples this was linked to maternal disciplinary techniques, in particular to “inductive reasoning,” that is, the mothers' use of affective and moralistic explanations of the harmful effects on others of the children's hurtful actions.

Further insights into children's understanding of feelings, especially in relation to conflict, and into the earliest teaching and understanding of rules have come from [Judy Dunn's \(1987\)](#) observations of siblings and their mothers. Even at 24 months, in pretend play between siblings, social rules were explored and feeling states simulated. Some 18-month-old children with an affectionate older sibling could already take part in a shared fantasy involving the feelings of others. These very young children were clearly practicing, in play, how to conform to rules and engage in prosocial behavior.

## THE ORIGINS OF EVALUATIVE BEHAVIOR AND SELF-AWARENESS

A critical study of early moral development, supporting a biological basis for the acquisition of inner standards and self-evaluation, and for readiness to learn the morality and conventions of the culture, is [Kagan's \(1981\)](#) short-term longitudinal investigation of American and Fijian children in the course of their second year. Although reluctant to support psychoanalytic theories about the development of a sense of shame in the second year and conscience and guilt in the third, Kagan's observations led him to identify a stage in the maturation of children in which the capacity for the development of inner standards first appears.

He observed children together with their mothers at monthly intervals in a variety of standard play settings. In one the child was presented with 10 unflawed toys, 10 damaged toys (such as a doll with a missing eye or a car with chipped body work), and two undamaged meaningless objects. No 14-month-old child discriminated between damaged and undamaged toys, but thereafter, and increasingly as the second birthday drew near, children began to show unambiguous concern about the damaged objects, commenting "broke," "fix it," "yucky," or taking the broken toy to the mother. In another experiment, an adult demonstrated skilled play with toys. All 13- and 14-month-old children watched calmly or seemed bored. But from 15 months onward more and more began to fret, protest, wish to leave the room, or indicate "It's mommy's turn to play." These older children seemed to feel obliged to copy what the adult did, realized it was beyond their capacity, and became distressed. These changes occurred just before the use of "evaluative language." Between 19 and 26 months, the first references to "dirty," "can't," and "hard do" appeared, and at 20 months, most children used words like "good," "bad," "dirty," and "nice."

Kagan concluded that the acquisition of these new functions centered on children's sensitivity to adult standards and their own capacity to meet these, that is, on an awareness of what they can and cannot do. Because American and Fijian children responded similarly, this development in the second half of the second year constituted a maturational shift rather than a cultural effect. The standards now acquired relate to cleanliness, integrity of property, toileting behavior, and harm to others.

Work on this important early milestone of self-evaluation was extended by the experimental studies of [Stipek and associates \(1992\)](#). They identified three stages in its development: (a) in the first half of the second year, pleasure at mastery and joy in causality, with anger and distress but no shame at failure and no anticipation of the reactions of others to their performance; (b) from 21 months onward, pride in accomplishment, that is, an anticipation of the reactions of adults, and active seeking of positive responses to success and avoidance of negative reactions to failure; and (c) a gradual internalization of these external reactions with children beginning to evaluate their own performance and reacting emotionally to success and failure independently of their expectations of adult responses. The authors stress that they investigated only the domain of achievement, not morality, and they point out that praise is always more common than disapproval except in the moral domain.

These workers made one further observation: Winning or losing in a competitive task was not understood by children younger than 33 months, but thereafter, pleasure in completing a task was increased by winning. The timing of this development, we must note, is in line with psychoanalytic ideas about the "genital" stage, when competition was thought to enter the child's range of experiences for the first time.

## MORALITY AND CONVENTION

Even young children distinguish between morality and convention. Conventions are behavioral uniformities that serve to harmonize social interactions and form, and are themselves determined by the specific social system. Morality concerns prescriptive judgments of justice, rights, welfare, and the avoidance of harm to others and is inherent in interpersonal relationships, not tied to the social context. It is a convention that in most schools children address teachers by their second, not first, name. Such rules are arbitrary and could be changed by consensus. [Turiel \(1983\)](#) asked children from 6 to 17 years if it would be wrong to call teachers by their first names if there were no rule about that. Even quite young children thought not. He also questioned children about the rights and wrongs of a playground situation in which all swings are occupied, and a little girl eager for a turn comes along and pushes another child off a swing. All agreed that this was wrong and would be wrong even if there were no rule about it.

Most children thought that, if everyone agreed, the rules of games and social conventions could be changed, but not such inherent moral dictates as that it is wrong to hurt other people and to steal. Younger children regarded rules as more fixed, and older ones had a better understanding of their purpose. But all children, from 6 upward, distinguished between conventional rules and morality, and in an earlier study, even preschool children could do so ([Nucci and Turiel, 1978](#)). However, very young children respond more often to moral rather than social conventional events; and even in middle childhood, children are more responsive to moral events and moral injustice than conventional transgressions, which only acquire salience with increasing age ([Nucci and Nucci, 1982](#)).

It has been argued that moral ideologies too are social constructs, depending on different conceptions of the self, society, and nature; that Indian cultures, for example, are duty-based, US cultures rights-based. [Turiel and colleagues \(1987\)](#) argue that despite discretionary divergence, all cultures share a common, mandatory morality. A study of Korean children bears out their similarity to American children in their views of morality and its distinction from conventions ([Song et al., 1987](#)).

[Blair \(1995\)](#) postulated that moral behavior and the capacity for distinguishing between morality and convention are fostered by what he called a "violence inhibiting mechanism," the suppression of aggression, presumably through the activation of empathic responses, in the presence of distress cues emitted by a victim. Even in some animal species aggression is inhibited when a conspecific gives out submissive cues.

## IMPLICIT KNOWLEDGE PRECEDES EXPLICIT UNDERSTANDING

[Stipek and coworkers \(1992\)](#) found children's behavior following success or failure to be much more mature than their expressed ideas, although the sequence, from the pleasure of success, to pleasure from approval of others, to satisfaction from meeting inner standards, was the same in both spheres. Implicit knowledge long precedes explicit understanding. This is strikingly revealed in [Judy Dunn's \(1988\)](#) studies of the origins of social and moral understanding in early childhood. Detailed home observations were made of children in their second and third years in the company of their mothers and younger siblings. Dunn takes issue with the seriousness with which moral development tends to be discussed and the "bleak emphasis" on anxiety, guilt, and fear. This is what impresses clinicians in their practice with disturbed children. In the natural setting of normal children's own homes Dunn found that, even before they use many words, children are amused by rules, roles, and the relationships in their world and share jokes about these with others. Just as they play with the rules of language, so they joke about what is expected, allowed, or punishable. They find it funny to distort or exaggerate rules, make scatological jokes, teasingly misname things, and make false assertions.

From 18 months, children understand how to hurt and comfort others, what the consequences of their own hurtful actions are, what is allowed or forbidden in their own family, and how adults are likely to react to their misdeeds and to those of others.

Dunn stresses four features:

1. Understanding the feelings of others develops in the first 2 years: ". . . the foundations for the moral virtues of caring, considerateness, and kindness are well laid by three years" (p. 170).
2. Understanding the goals of others begins in the second year, as shown by children's behavior during conflicts and cooperative endeavors, and in the third year in pretend games, narratives, and questions about other people.
3. Understanding social rules is clear from children's discussions and jokes about breaking and the differential application of rules. By 2½ to 3 years, children have a practical knowledge of the idea of responsibility and of excuses on the basis of intent and incapacity. They know that rules can apply differently to different family members, rules can be questioned, and transgressions justified. They understand about authority relationships within their family and comment on the behavior of others in moral terms.
4. Understanding other minds, which also starts in the third year, is yet another new way of social understanding. Children now talk about mental states such as remembering and forgetting. Although capable of feeling embarrassment, guilt, and shame, they are probably not yet able to recognize these more sophisticated emotions in themselves or others.

Dunn describes how parents' disciplinary strategies are affected by children's growing cognitive and communicative skills. She recognizes cultural differences in parents' reactions to children's anger and aggression. Parents also respond differently to sons and daughters. Three-year-old girls, for example, show more shame than boys when they fail at experimental tasks ([Lewis et al., 1992](#)).

Emotions are very evident when moral and social rules are discussed. Children in their third year are most likely to reason during disputes, which earlier had caused them most distress. But they also learn from calm reflective discourse. Dunn holds that the child's part in the power relationships within the family, rather than an urge to conform or assuage guilt, is the main motive to learn about social and moral rules. She believes moral behavior is fostered not so much by socialization pressures, but by the child's need to assert his or her place, for example in relation to a sibling; the active enjoyment of rule breaking, teasing, and exerting power within the family; and also happy, cooperative play.

## THE MORAL EMOTIONS

Accurate descriptions of the emotions of self-assessment—pride, shame, and guilt—are a basis for the exploration of the moral emotions. According to the philosopher [Gabriele Taylor \(1985\)](#), shame and embarrassment depend on the awareness of being observed and relate to all wrongdoing and one's standing in society; however, guilt, which appears later in development, relates to law breaking and, specifically, to moral rather than conventional wrongdoing. Awareness of an authority to be obeyed plays the major role in conscience, whereas a watchful audience is the major factor in shame. Guilt and punishment relate to a bad deed or omission and are linked to a sense of responsibility for one's own actions, but shame concerns the kind of person one is. In Taylor's view, neither shame nor guilt is related to empathic feelings for others, but remorse, the “emotion of salvation,” is. Remorse is also the precursor of self-forgiveness, essential if the destructive forces of guilt are to be assuaged. Guilt, shame, and pride are reflexive emotions, guardians of societal norms, elicited when one compares one's own behavior or achievements with those of others ([Terwogt and Stegge, 1999](#)).

[Harris \(1989\)](#) explored the development of children's emotional understanding by testing 3- to 5-year-olds on a perspective-taking task. Those who excelled at this were also more attentive to their younger siblings when distressed by a temporary separation from their mother. The mothers, in turn, more often asked these more empathically competent older children to “look after your brother.” Whether the maternal responses were causes or consequences of the older child's empathic skills is not known.

Children's recognition of emotions and their understanding of what brings them about develop in a similar age sequence in different cultures. Children are born with a capacity to experience the basic emotions of happiness, sadness, anger, and fear, associated as they are with facial expressions. They come to understand that other people have them too. They learn to differentiate between morality and convention on the emotional basis of the distress that moral, but not social, rule infringements induce in the victim. This, Harris believes, is learned from other children rather than adults.

Children under about 8 years have difficulty identifying pride, shame, and guilt in others because these emotions are not accompanied by distinctive facial expressions. Understanding these more complex emotions depends on the ability to imagine the mental state of another person that gives rise to these emotions. It depends also on the availability of concepts of personal responsibility and normative standards of morality and propriety. Children experience a shift of awareness from believing that people's feelings about their behavior depend on its consequences, to attributing them to the approval or disapproval to be expected from other people in the light of social norms. Only at about 8 years do children feel proud or ashamed “of themselves” without reference to an external audience. The developmental sequence [Harris \(1989\)](#) detects is congruent with both Turiel's and Kohlberg's findings. Even 3- to 4-year-old children know that harming others causes distress and is therefore wrong. Four- to 5-year-old children know that people are happy if they get and do what they want. By 7 to 8, children know that people are happy if others approve of them and they exert themselves to gain approval. Only after the age of 8 can children work out that they themselves and other people get satisfaction from doing what they think is right.

There is further evidence that the comprehension of emotional accompaniments of immorality, as the development of empathy itself, changes with age and begins to be accurate only at about 7 or 8 years ([Arsenio, 1988](#)). In an illuminating experiment ([Nunner-Winkler and Sodian, 1988](#)), 4- to 8-year-old children were told a series of stories of moral transgressions and had to judge how the wrongdoer would feel. Most 4-year-old children thought that the story person who violated a moral injunction, got away with it, and succeeded would be happy, whereas 8-year-old children attributed negative emotions to this person because they would feel bad about what they had done. There was also a shift between 4 and 8 years in the attribution of emotions to a story character who had resisted temptation. Very young children judged according to the material outcome; older children judged according to the character's sense of virtue. When asked to judge the degree of badness of story figures, 6-year-old children already thought that happy wrongdoers were worse than those who felt sorry for what they had done.

When we compare these findings about children's expressed ideas about their understanding, with observational studies of children's behavior in response to success and failure ([Stipek et al., 1992](#)), we see again the large age gap between the attainment of behavioral accomplishments on the one hand and children's expressed ideas on the other. Yet there is a similar sequence: from the satisfaction of success, to pleasure from approval of others, to satisfaction from meeting inner standards.

An experimental study of 7- to 12-year-old children's understanding of the “self-conscious” emotions of guilt and shame ([Ferguson et al., 1991](#)) showed that shame resulted both from moral transgressions and social blunders and led younger children to feel embarrassed and older ones to feel they could not do things right. Guilt, in contrast, was aroused by moral norm violations and involved a conflict between approach toward and withdrawal from the victim as well as self-criticism, remorse, a desire to make amends, and fear of punishment.

Masking of emotions starts in the early school years, but even 3-year old children can hide their feelings, for example, of disappointment at a gift ([Terwogt and Stegge, 1999](#)).

[Harris \(1994\)](#) draws an important distinction, quite insufficiently acknowledged by legal experts and the general public, between knowing what is right and wrong and abiding by moral rules. The impulse to tease or hurt often overrides the moral code: Knowledge of right and wrong is not closely related to action.

[Harris \(1994\)](#) also believes that children's emotional experiences influence age-related cognitive changes, as well as behavior. When parents reason with children about the possible effects of their misdeeds on others instead of punishing, they induce anticipatory guilt and increase children's understanding of social emotions. When children witness parental quarrels, they become more physically aggressive with their peers. This may not owe merely to modeling, because verbal quarrels between parents without physical violence have the same effect. It is more likely that the children's state of arousal caused by the quarrels they witness leads them to attribute more malign intent to their peers and react accordingly ([Dodge et al., 1990](#)).

## MORAL DEVELOPMENT AND PSYCHOPATHOLOGY

The psychopathology of moral development is likely to be as important for child psychiatry as that of attachment behavior, and is of great relevance in understanding the origins of the most worrying child psychiatric conditions: the conduct disorders, with their high risk of adult antisocial personality disorder, but also of affective illnesses in girls. Although we know a great deal about the affectional needs of young children and the hazards of early separations from parents and deprivation of continuous care, explorations of the ingredients necessary in early childhood for the development of empathic feelings for others, inner standards of self-appraisal and morality, the capacity to feel shame and guilt, impulse control, and sympathetic prosocial behavior are less advanced.

Studies of the moral development of deviant children and children exposed to different kinds of adversity are now beginning ([Campbell, 1995](#)).

### Social Learning and Role Modeling

Learning theorists ([Chapter 10](#)) have contributed to our understanding of the genesis of both prosocial and antisocial behavior in childhood, although they have not generally taken a developmental viewpoint, although the early stimulus-response, or reward and punishment, theories of behavioral change have been too simplistic. [Bandura's approach \(1977; Bandura and Walters, 1963\)](#) was more sophisticated and included the cognitive accompaniments of behavior. His experimental studies of how and under what conditions children copy the behavior of others have been illuminating for understanding social development and in the treatment of childhood behavior disorders. We now know that the capacity for role modeling starts toward the end of the second and the beginning of the third year ([Meltzoff, 1988](#)) and that young children, after watching films of other children playing aggressively, are susceptible, especially when frustrated, to develop similar play patterns.

In what remains a classical study, [Patterson and his colleagues \(1967\)](#) found that in the setting of an unstructured nursery, with little active intervention from their teachers, 4-year-old middle-class boys learn to become ever-more aggressive in imitation of other assertive children when they see assertiveness rewarded with success (as it always is without adult intervention). Only passive children with low rates of interaction with others escape this development.

That parental punitiveness and aggression, usually directed against boys more than girls, and often associated with substance abuse, induces aggression in children has been documented repeatedly ([Chapter 29](#) and [Chapter 37](#)).

### Coercive Child Rearing

[Patterson's later work \(1982, 1986\)](#) has been unique in analyzing the mutually reinforcing processes by which coercive, punitive parents evoke counter-aggression from their children with escalating domestic violence. Contributing factors are the parents' own past experiences of coercive rearing, their failure to monitor their children's behavior, the aggressive role models they provide, maternal depression, and, on the children's part, a difficult temperament, including impulsivity. Social

and educational failure at school and low self-esteem often follow such domestic interactions, with further reinforcement of the children's antisocial conduct. Patterson also regards stealing as a form of noncompliance to unskilled parents. He found the parents of children who steal more often themselves to be delinquent and, unlike the parents of aggressive children, inadequately attached to their offspring. A recent study found that mothers of 3-year old children with behavior problems used more reactive and fewer preemptive strategies than mothers of well-adjusted children. Moreover, when behavior problems at 3 were controlled for, reactive strategies at this age predicted conduct problem at 5 years ([Gardner et al., 1999](#)).

The work of [Dodge \(1986; Dodge et al., 1990\)](#) documented mutually reinforcing processes that engender aggression between peers. He reminds us that aggressive behavior correlates with deficits in a variety of cognitive skills: self-rehearsal of responses, inhibition of premature social impulses, interpersonal problem solving, referential communication, and role taking. Socially and verbally unskilled people have limited means for handling discord and become physically aggressive with very little provocation.

### Social Attributions

In his studies of children's cognitive attributions, Dodge showed that aggressive boys tend to interpret the motives of their peers as hostile, even when they are not, and to react aggressively, thereby stimulating dislike and hostility in previously nonhostile peers. This then reinforces the aggressive boys' view of other children's hostile intent. A vicious circle of hostile attributions and aggressive behavior with peers results, similar to the coercive interactions between parents and children described by [Patterson \(1982, 1986\)](#). The long-term outcomes are academic failure, school dropout, and delinquency. Furthermore, aggressive boys tend to overestimate their peer's aggression and underestimate their own; whereas nonaggressive boys base their perceptions more on actual behavior ([Lochman and Dodge, 1998](#)).

Dodge also found that children who have been abused, especially boys, are predisposed to develop hostile attributions and aggressive behavior ([Dodge et al., 1990](#)). The effects of harsh child rearing are in part mediated by such maladaptive social information processing, induced by these child-rearing methods ([Weiss et al., 1992](#)). Such developments are more common in families living in poverty and marital conflict, but these factors alone do not account for the findings.

### Atypical Socioemotional Expectancies

Other workers have focused on different psychological predispositions to conduct disorders: impaired understanding of the emotional consequences of sociomoral events; and the role of atypical emotional expectancies in perpetuating antisocial behavior. [Fisher and Blair \(1998\)](#) studied boys in a special school for disturbed children, comparing those with high and low scores on a somewhat unfortunately named "psychopathy screening device," which identified both callous, unemotional attitudes, and impulsivity and conduct problems. High scorers on both factors were significantly poorer on a test requiring the distinction to be made between stories about moral transgressions resulting in harm to another person, and conventional stories; those with high scores on impulsivity and conduct disorders alone, also did worse on a task measuring response-set modulation. [Arsenio and Fleiss \(1996\)](#), in a more comprehensive study, compared 7- and 10-year-old behaviorally disruptive children with nondisturbed controls. Four sociomoral rule systems were investigated with case vignettes: inhibitory morality, involving victimization; conventions; prosocial morality, involving altruistic acts; and personal restrictions. Emotional expectancies varied with the domain tested, and disturbed children differed from controls, especially for inhibitory and prosocial morality. They minimized the fear associated with victimization and emphasized the victimizers' emotions related to material gains and psychological consequences, while referring less to the loss, harm, and unfairness they had inflicted. They also tended to stress prosocial actors' emotions relating to the harm, loss, and unfairness that had been avoided, rather than those of the recipients of the benevolent acts. In addition, the disruptive children more often mentioned sadness as an emotional outcome than the controls.

These studies were of children from middle childhood onward. But the capacity for empathy, developing inner standards, and learning prosocial behavior from adult role models begins much earlier—in the second and third years—as we saw. What goes on in families then is likely to have important consequences for later life.

### The Impact of Maternal Depression

[Dowdney and colleagues \(1985\)](#) observed differences in the disciplinary behavior in interaction with their toddlers of mothers who were either depressed or had, as children, been in care (i.e., in children's homes), compared with a control group. [Zahn-Waxler and coworkers \(1990\)](#) documented the relationship between maternal depression in children's toddler years and their later distorted and exaggerated expressions of guilt. Young children, highly aroused, overinvolved, and causally implicated in their mothers' distress, before they are mature enough to cope with this, are at risk of later excessive guilt and distortions of their capacity for empathy and concern for others. Such overinvolved young children are also often deprived of normal opportunities for play with peers, vital for the development of social competence and morality. Boys are more at risk when mothers are depressed, less able to adapt their behavior in a compliant and conforming way than girls ([Zahn-Waxler, 1993](#)). This sex difference is supported by the finding that daughters and sons of healthy mothers did not differ in their advocacy of aggressive solutions to conflict, whereas sons of depressed mothers, despite being more prosocial and empathic than other boys, were the most likely to advocate aggression. Daughters of depressed mothers, in contrast, who also had high rates of empathy and prosocial behavior, almost never did, even in defense of their own property, wishing at all costs to avoid conflict ([Hay, 1994](#)).

## THE EFFECTS OF EARLY PARENTING STYLES AND CHILDREN'S TEMPERAMENT

[Dienstbier's \(1984\)](#) experimental studies focused on both cognition and affect and suggest that when children are coerced by means of parental punishments, they attribute their resistance to temptation to external forces. They feel bad if they succumb because of the punishment that follows and, if they believe their transgressions will not be discovered, they capitulate. Noncoerced children, in contrast, attribute resistance to temptation to their own choice and their inner judgment that one course of action is better than another. If they succumb to temptation, they feel bad because of the transgression itself rather than its consequences, and are less likely to repeat it even if unobserved. Dienstbier's findings agree with those of Kochanska (see the following), that children with high levels of emotional tension learn better to make internal attributions about transgression and feel appropriate guilt. Children with low levels of emotional tension learn poorly, evoke ever more coercion from parents, and have their external attributions reinforced every time they transgress and "get away with it" without feeling bad. This is in line with the view that children are best socialized when parents use inductive, that is, reasoning methods, but do so with an emotional charge.

The effects of differences in mothers' early socializing styles on children's later development of guilt and conscience have been meticulously investigated by [Kochanska \(1991\)](#) in her early longitudinal study of children of depressed and well mothers ([Radke-Yarrow et al., 1985](#)). She also studied the influence on these processes of the child's temperament. Self-reported and observed coercive/noncoercive parental rearing styles when children were 18 to 42 months old, were compared with children's contemporaneously observed compliance to maternal demands and with their affective/moral orientation at the age of 8 to 10 years. The latter was assessed by means of narrative responses to semiprojective stories. The main finding was that noncoercive child rearing was associated with evidence for internalized conscience in later years, but only for children prone to fearful arousal. Early compliance to maternal demands predicted later internalized conscience. The author concluded that anxious children are well socialized by a noncoercive style of child rearing and that conscience development may be interfered with by coercive methods. How less anxious children, less responsive to child rearing style, acquire their conscience was not then clear.

In a review of moral development, [Kochanska \(1993\)](#) proposed a new framework for the study of early conscience formation that integrates parental socialization methods with the temperamental characteristics of their children. She suggests two components of conscience contributing to moral conduct: a child's affective discomfort owing to actual or potential wrongdoing and the capacity for behavioral self-control. The first was salient in psychoanalytic models, the second in social learning and cognitive models of moral development. Both have temperamental underpinnings, which may account for the differential effects of parental socialization methods. Fearfulness and social inhibition interact with high levels of moral motivation to reduce immoral behavior in situations of temptation ([Asendorpf and Nunner-Winkler, 1992](#)). Impulsivity versus behavioral control, Kochanska suggests, is a more complex temperamental dimension, and precisely how it interacts with parents' socialization efforts is less well established. Reasoning may be less effective in encouraging the internalization of standards for impulsive children. [Shaw and Bell \(1993\)](#) presciently suggested that irritable, hyperactive, demanding infants increase maternal unresponsiveness and that the resulting anxious, avoidant attachment leads to later noncompliance and hostility. Securely attached infants, by contrast, become compliant in later years, eager to please their parents.

The most impressive researches illuminating our understanding of compliance, self-control, and conscience development in young children, are Kochanska's more recent observational and experimental studies of two large cohorts of children, the first at 2 to 3½ years, and again at 3½ to 4½ years; the second at 8 to 10 and 13 to 15 months ([Kochanska, 1995; Kochanska and Askan, 1995; Kochanska et al., 1995, 1998](#)). In the first, time sampled observations were made at home and in the laboratory during a toy clearing up task (the "do" context), and with toys their mothers had forbidden them to touch (the "don't" context). Children were observed in these two situations both with their mothers and alone. "Internalization" was judged to be present when children, even in the absence of their mothers, adhered to her requests and prohibitions. Mothers were additionally questioned about their children's temperament and behavior, especially about evidence for internalization

(latency to transgression, extent of transgression and rule-compatible conduct), and about their own disciplinary methods. A distinction was drawn between children's "compliance" (when they did what was required but only passively or protesting or so long as the mother was present) and "committed compliance," when they joyfully endorsed their mother's agenda, and their verbal comments indicated that they had identified with her goals, apparently with a sense of inner obligation. In the younger children, this was greater for "don'ts" than "do's," was higher in girls than boys, and was related to shared positive affect between mother and child. Internalization at the later age was predicted by earlier committed compliance and shared positive affect.

In addition, children's temperamental fearfulness and anxiety proneness as well as their security of attachment were measured at the early age and related to later evidence for internalization. Two pathways toward internalization were discovered: gentle maternal discipline, deemphasizing power, predicted this for relatively fearful or anxious children; for relatively fearless children, the salient factor was security of attachment with positive cooperation between mother and child.

P>In a later study of even younger children, self-restraint at 8 to 10 months (after mothers had prevented their babies from touching an attractive toy) was found to be associated with committed compliance and internalization of maternal prohibitions at 13 to 15 months, and this early self-restraint was associated with sustained, or "focused," attention. A confirmatory study by [Stifter and associates \(1999\)](#) also found that infants who display regulatory skills in response to frustration are more compliant in their third year.

Kochanska proposed that committed compliance in early childhood reflects the origin of internalization and is an important antecedent to conscience formation. We need to be clear, however, that her more recent work focused not on person-related, but object-related behavior, which may yet turn out to be allied to the adherence to convention rather than morality. [Zahn-Waxler and Radke-Yarrow \(1982\)](#), as we saw, had found inductive reasoning to be important for the development of empathic concern for others. Although it is very likely that in early childhood noncoercive child rearing with shared positive affect between mother and child, as well as security of attachment, are as important for the development of interpersonal morality as for committed compliance in object related tasks, further evidence for this is needed.

## IS THERE A BIOLOGICAL SUBSTRATE FOR MORAL DEVELOPMENT?

[Hoffman \(2000\)](#) sees the capacity for empathic morality as innate, but fragile and vulnerable to power assertive child rearing. Kagan argued for a biological propensity for the acquisition of inner standards. There is evidence for a genetic basis for individual differences in empathy and other forms of prosocial behavior ( [Hay, 1994](#); [Hoffman, 2000](#)); and [Brothers \(1989\)](#), discussing the evolutionary basis for empathy, suggested that primate survival depends on the capacity for rapid and accurate evaluation of the motivations of others. He instanced the absence of empathy in some pathologic states such as autism, and speculated about its neurologic substrate. Constitutionally based lack of empathy (or theory of mind) characterizes people with other autism spectrum disorders too and is likely to contribute in an important way to failure of early socialization and the genesis of some forms of conduct disorder and sociopathy in later life ( [Wolff, 1992](#)).

The most dramatic validation of these ideas comes from the investigations in early adult life of two patients, from stable, middle-class families, who had sustained prefrontal cortex lesions before the age of 16 months, and who, despite normal intelligence, developed severe and persistent antisocial behavior, including stealing and violence ( [Anderson, 1999](#)). In contrast to six patients who had sustained prefrontal cortex lesions in adult life and developed antisocial behavior, were insensitive to the consequences of their actions, and failed to respond to behavioral treatments, the patients damaged in early childhood were additionally defective in executive functions and social and moral reasoning. The two patients with early injuries, unlike patients injured in adult life, functioned at only a pre-conventional stage of moral reasoning on Kohlberg-type tests (Kohlberg's stage 1) ( [Colby et al., 1983](#)). Adult onset patients showed guilt and remorse; not so those with an early onset, who were also more violent. Magnetic resonance imaging revealed a bilateral lesion of the polar and ventromedial prefrontal cortex in one early onset patient, and a unilateral, right prefrontal lesion in the other.

The authors speculate that adult-onset patients fail in social interactions because of disruption of the system holding overt and covert emotionally related knowledge of social situations, so that recall of socially relevant facts and their associated emotions is insufficient to ensure adequate real-life social behavior, whereas reasoning about social interactions in the abstract remains intact. When lesions are sustained very early, the authors suggest, socially relevant factual and emotional knowledge is never acquired, and even factual knowledge about accepted standards of moral behavior ( [Dolan, 1999](#)) is deficient.

Further light on these findings has been shed by Damasio's "somatic marker hypothesis." He found that patients who had sustained prefrontal damage in adulthood did not have the usual autonomic nervous system responses to seeing fleeting pictures of cruelty and disasters interspersed with neutral displays, although they could remember what they saw. Retrospectively, they indicated that the feelings they would have had in response to the pictures prior to their injury were now lacking. [Damasio \(1994\)](#) speculates that we are born with a neural propensity to generate somatic states, accompanied by pleasant or unpleasant emotions, in response to stimuli concerning personal and social behavior. In the process of childhood socialization, specific classes of stimuli are paired with specific somatic states and emotions, so that in later life, certain social situations and moral dilemmas are associated with anticipatory somatic and emotional responses profoundly affecting how we choose to act, for example, altruistically. The somatic marker hypothesis is compatible with the notion that adaptive personal and social behavior requires an adequate capacity to form theories of mind, and that cognitive and emotional processes are intimately linked. Moreover, anticipation of a good future outcome helps us to sustain immediate and transient unpleasantness. Patients with frontal lobe damage are myopic for the future. The necessary substrate for adaptive sociomoral development is an intact prefrontal cortex and effective early socialization.

## SUMMARY

The last 20 years have seen much progress in the exploration of the development of morality and prosocial behavior. Emotions and cognitions are intimately connected in all aspects of development ( [Donaldson, 1992](#)), including moral development, throughout early and middle childhood. There is a biological basis for regular developmental changes with age both of reasoning and emotional experiences. Biological factors are important also in determining temperamental differences between children, for example, proneness to anxiety or impulsive disinhibition, which profoundly affect their responsiveness to socialization. Experiences of child rearing and peer relationships, in interaction with temperamental differences, then determine the development of moral behavior and beliefs.

Prosocial impulses arise in the first year of life with manifestations of empathic responsiveness and the capacity for self-restraint. In the second and third years, children become aware of norms of behavior and their own achievements and shortcomings. Within the context of family life, even 2- to 3-year-old children display surprising knowledge about moral and conventional rules and do so with enjoyment and humor. It is at this stage that parental behavior and parents' beliefs and expectations about their children's moral development and their own contributions to this are likely to be crucial. Parents' behavior is influenced by many factors: their socioeconomic and cultural milieu, marriage, health, and children's gender and temperamental responsiveness in family interactions.

Children can reason about moral issues only at 7 or 8 years. Concepts of guilt and shame are now articulated. Children develop notions of morality independent of external approval and begin to be able to reason about principles not tied to concrete events. Abstract ideas of justice and welfare arise later still. Children's cognitions, especially their attributions of hostile intent, peer relationships, and prosocial behavior, remain crucially influenced by their experiences, now both within their families and at school.

Although psychoanalysts were right to stress the importance of attachment to parents as a basis for conscience development, and were also correct in identifying the emotions as the vital mediators in socialization and the process of identification with parental standards as crucial, they erred in their overemphasis of anxiety and threat as promoting moral behavior in childhood. Dunn's observations and Kochanska's experimental studies show that very young children best acquire moral ideas in an affectively positive atmosphere, when they joyfully comply with their mother's requests and strictures, making them their own. The importance of pleasure at doing right has long been underestimated.

The discoveries of how parental disability and different methods of child rearing interact with children's individual temperamental styles in the development of conscience and prosocial behavior, is likely to contribute in a major way to the more effective treatment of antisocial conduct in childhood and its prevention in later life.

Genetic and environmental forces interact to shape sexual development before birth and throughout life. Genetic factors establish a level of sexual responsiveness that remains fairly constant across the life span relative to other people of the same age and sex ( [Kinsey et al., 1948, 1953](#)). Genetic factors operate by determining the levels of neurotransmitters and hormones that then influence the sexual response. Dopamine and serotonin act reciprocally to enhance sexual responsiveness and to promote satiety ( [Hull et al., 1999](#)). Overall responsiveness is positively affected by norepinephrine and testosterone but negatively affected by g-aminobutyric acid and prolactin. If the person is successful in coupling, this affects the external and internal environment, enhancing levels of dopamine and interest in further sexual pursuits. Although prepubescent children have lower levels of gonadal hormones than adults, the same mechanisms apply, making some youngsters more sexual and more erotically attuned than others.

In general, men, with their higher testosterone levels, are more active and interested in sex than women. Women, with their lower testosterone levels, are relatively more influenced by psychological and social factors ( [McConaghy, 1993](#)). This difference is readily displayed in courtship, where women typically express desire through body movement, presentation, and gesture, whereas men pursue a more direct approach ( [Perper, 1985](#)). The manner of expression is interpreted through the character structure, largely genetically determined. The robust youngster who enjoys taking a chance is less likely to be influenced by sanctions against sexual activity than is the shy, inhibited child. Environmental forces that affect sexual development are many and varied and include such “nonsexual” elements as the presence of parents who are able to spend time with the child and who relate with understanding and warmth.

This chapter begins with an overview of the biological and genetic aspects of human sexual development and continues with a description of environmental influences: historical, sociocultural, and family. This is followed by a detailed description of erotic development through infancy, preschool, school age, and adolescence. The chapter concludes with some thoughts about the future and a possible end to the split between what children observe and what they are told about sexuality.

The use of the terms *sexual* and *erotic* may be confusing to the reader. In general, *sexual* refers to the objective and instrumental aspects of possessing and using sexual equipment, such as the genitals, whereas *erotic* refers to fantasies, perceptions, and feelings, such as desire. Thus a person may respond erotically to a pornographic video but sexually when prescribed a medication for impotence. Clearly the two terms overlap, and it is unusual for one to come into play without the other.

### BIOLOGICAL INFLUENCES

Researchers are just beginning to address the effect of early experience on the mapping of the sensory cortex. It is possible that early genital stimulation, be it diaper change or sexual molestation, permanently affects sexual responsiveness through recruitment of neurons and enhancement of neuronal function. In primates, peripheral stimulation can expand the corresponding areas of the somatosensory cortex, and the process includes reorganization of subcortical structures, including the brain stem and thalamus ( [Jones, 2000](#)). Stimulation evokes strong neuronal activity, producing long-lasting changes in synaptic function, learning, and memory ( [Malinow et al., 2000](#)). Therefore, child sex play could protect the sexual response against later adversity such as rejection by a lover or loss of a job. Too much stimulation could eroticize the child, leading to punishment or repeated rejection by adults such as foster parents. Based on this, it is important to understand the scope and effect of normative sexual experiences.

#### Hormonal Influences

Androgen is produced by the embryonic testes. Androgen differentiates the male external genitalia from the primordial female apparatus ( [Wilson et al., 1981](#)). If the embryonic testes are removed before the eighth week of gestation, the embryo develops as a female ( [Jost, 1953](#)). In addition, testosterone alters the migration of neurons in a manner that reorganizes the hypothalamus, preoptic area, corpus callosum, planum temporale, cerebellum, and amygdala. These changes to the brain occur between the 6th and the 12th week of gestation and are permanent, affecting emotional, behavioral, and cognitive function across the span of life ( [Rubinow and Schmidt, 1996](#)).

Testosterone-enhanced male brains become larger and heavier and have greater dendritic arborization. In boys, a nucleus of the preoptic area of the hypothalamus grows two and a half times larger, with twice the number of neurons than in girls. This nucleus is likely involved in sexual orientation and gender identity formation. The influence of estrogen on the fetal brain is poorly understood but likely includes protecting neurons, stimulating nerve growth, and enhancing neural connections ( [Seeman, 1997](#)). Although estrogen is a female hormone, a relatively small quantity may be essential for male brain development in areas such as those responsible for the coordination of male sexual behavior. In addition, estrogen functions as a neural growth factor with important influences on the development, survival, plasticity, and regeneration of the brain ( [Toran-Allerand et al., 1999](#)).

Right hemisphere development is slower in the male fetus, and this promotes greater left hemispheric specialization ( [Geschwind, 1983](#)). A number of sex-specific changes in function are the result. These include (a) language organized on the left side of the brain in men and on both sides of the brain in women; (b) increased verbal and affective communication skills in women; (c) greater logical, analytic, and visual-spatial ability in men; and (d) sex-specific repertoires of sexual and nonsexual behaviors ( [Tiefer and Krings, 1995](#)). Direct effects of testosterone in men include greater activity and aggression, with more intense erotic thoughts, feelings, and sexual behaviors. In the past, high levels of testosterone were thought to promote impulsive aggression and social maladjustment in men. More recent work indicates an association instead with social dominance and success ( [Schaal et al., 1996](#)).

At birth, testosterone levels are elevated in boys, and estradiol levels are elevated in both boys and girls. The robust erotic interest found in 2- to 4-year-old children may be due to the relatively high levels of hormones that persist during that period. From 5 years of age until prepuberty, hormone levels are relatively low, which may explain the diminished, although still significant, erotic interest observed during those years.

#### PUBERTY

Normal puberty begins between 8 and 14 years of age in girls and between 9 and 14 years of age in boys. The first sign of approaching pubescence is the adrenarche at approximately 8 years of age that generates an elevation of adrenal androgens, estradiol, thyrotropin, and cortisol. Adrenal androgens increase in girls, but to levels that are lower than those achieved by boys. Hormonal changes influence the brain, causing an increase in the size of the amygdala in boys and an increase in hippocampal volume in girls ([Giedd et al., 1997](#)). When the adrenarche commences as early as 2 to 6 years of age, as it sometimes does, it is associated with increased anxiety, depression, and behavior problems ([Dorn et al., 1999](#); [Rieder and Coupey, 1999](#)).

Girls enter puberty approximately 2 years earlier than boys, and they take 3 or 4 years to complete the process. Boys enter puberty later than girls, and they complete it in 4 or 5 years. Boys attain a testosterone level that is eight times higher than that reached by girls ([Udry et al., 1986](#)). This provokes an avid interest in sex and hair-trigger penile erections ([Udry et al., 1985](#); [Udry and Billy, 1987](#)). Girls experience a dramatic increase in gonadotropins, growth hormone, and estrogen, and a lesser increase in testosterone ([Fitschen and Clayton, 1965](#); [McCandless, 1960](#)). Girls experience a lag in progesterone secretion in the first 2 years after menarche and often have irregular periods during this time. Hormones exert a weak effect on sexual behavior in girls, but a stronger effect on motivation ([Smith et al., 1985](#)).

Leptin is a recently discovered hormone that resides in fat cells and has an important role in controlling body fat by regulating appetite, body energy, metabolic rate, and the autonomic nervous system. When the prepubescent child puts on weight, leptin increases, and the increase signals the brain that the body is ready to mature. Leptin continues to increase in girls in the postpubescent years, paralleling a continued increase in body fat. In adolescent boys, leptin levels off and then decreases. This is because boys accumulate more muscle and less fat compared with girls but also because testosterone directly suppresses leptin synthesis ([Kiess et al., 1999](#)).

## Identity, Role, and Orientation

*Gender identity* is the primary identification a person establishes with one sex. *Gender role*, on the other hand, describes culturally underwritten behavior that differentiates men from women, such as game and work preferences, social aggression, and courtship and sexual behavior. *Sexual orientation* describes the individual's erotic preference for a particular sex. Individuals are not necessarily the same in all three domains. Variation from "all maleness" or "all femaleness" is not uncommon and does not necessarily connote a pathologic process.

### GENDER IDENTITY

The human infant is born with a bias toward a certain gender identity, one that usually, but not always, matches the anatomic sex. By 2 to 3 years of age, children learn to identify themselves as boys or girls on the basis of things like hair or clothing. Gender identity develops before most children appreciate sex differences in genitals ([Bem, 1989](#); [Goldman and Goldman, 1982](#); [Rutter, 1980](#)). Girls learn about genitals and genital differences sooner than boys but do not understand the association with sexual function ([Volbert, 2000](#)).

In the past, gender identity was thought to be determined by the assignment of sex and the parents' habit of treating boys like boys and girls like girls ([Money and Tucker, 1975](#)). Although gender identity was viewed as somewhat malleable during the first 2 years of life, serious psychological disturbances were thought to result if sex reassignment was attempted after 3 years of age. Under the rubric "the earlier the better," assignment often was made in early infancy, often followed by several years of corrective surgical procedures. These assumptions are now being questioned, since [Diamond \(1996\)](#) and others described cases of early sex reassignment in which the assigned identity never seemed to fit. One patient, originally a boy, was reared as a girl and was never told of his biological sex. After years of secret discomfort, he finally sought reassignment as a male, saying that he had never felt like a female ([Diamond et al., 1996](#)). The best-fit explanation would be that fetal testosterone had caused his brain to develop as a male. After surgical removal of the testes in infancy, the male brain continued to determine his gender identity.

What are physicians to do when faced with ambiguous genitalia? Although the critical studies have not yet been done, physicians should seriously consider waiting until the child is old enough to (a) demonstrate definitive role modeling and (b) state a preference for being male or female. Children's preferences seem to be reliable indicators of the maleness or femaleness of the brain, but preferences may not be reliably expressed until 4 to 6 years of age. Therefore, infants with compromised or ambiguous genitals should be allowed to be "neither or both" until at least the preschool years. There is no evidence that holding the door open damages children, although strong parental reactions can be harmful. An additional consideration is the difficulty in constructing a functional phallus compared with a functional vagina.

An additional issue is the immutability of gender identity. Gender identity usually is constant throughout life, but there are instances in which people have successfully changed their gender identity, with or without genital modification ([Sagarin, 1975](#)). Precipitants have included change in status such as trauma, divorce, an appearance more like that of the other sex, the appearance of other-sex characteristics at puberty, and the perception of the other sex as better off or more powerful. Changes in gender identity may occur more frequently in the future as the culture comes to tolerate, or value, sexual diversity.

### GENDER ROLE

Gender role refers to a collection of attitudes and behaviors that are typically male or typically female. These include play and work preferences, friendships, extracurricular interests, and courting patterns. Gender role is consistent across cultures in that the superior strength of men makes them the more successful hunters and guardians of the territory, whereas women are more patient and proficient at repetitive activities such as planting, gathering, and nurturing the family ([Ford and Beach, 1951](#)). Men almost always are dominant and are more likely to be jealous and possessive, whereas women are less aggressive and more likely to accept male dominance for the protection it affords ([Harlow and Harlow, 1962](#); [Piacente, 1986](#); [Symons, 1979](#)).

Gender roles can be set as early as age 3 years, but it can also remain malleable until age 5, especially in girls ([Levy et al., 1995](#)). However, by the time children enter kindergarten, virtually all have adopted a set of gender-specific rules and expectations. Boys gravitate toward action, whereas girls choose social and nurturing activities. When angry, girls are more likely to attack verbally, whereas boys are more likely to lash out physically. Gender roles are enforced by peers who tease and ostracize those who do not fit the stereotype. Teasing is most severe for effeminate boys and less severe for girls who act like boys. Teasing continues and intensifies in adolescence.

Prenatal hormones influence children's choice of toys and pattern of play. Girls with congenital adrenal hyperplasia are exposed to increased androgens before and after birth. During childhood, they are not interested in doll play but prefer roughhouse play outdoors. They report few fantasies of marriage, pregnancy, or motherhood ([Ehrhardt and Baker, 1974](#)). Boys exposed to prenatal antiandrogens display lower energy levels, less aggression, and less heterosexual activity in adolescence, whereas girls exposed to antiandrogens appear more traditionally feminine than other girls ([Ehrhardt and Meyer-Bahlberg, 1981](#)).

### SEXUAL ORIENTATION

Sexual orientation refers to a person's overall sexual responsiveness to men or women ([Meyer-Bahlberg, 1993](#)). Sexual orientation has four components: (a) imagery (e.g., daydreams, masturbation fantasies); (b) use of erotica, such as magazines; (c) erotic attraction; and (d) actual partner experience. Homosexuality is not a disorder of gender identity. Homosexuality is an orientation that, once adopted, commonly is constant throughout life. Approximately 4% of men and 1% to 2% of women are homosexual ([Bell et al., 1981](#)). A smaller percentage describes themselves as bisexuals. Other cultures reveal a similar percentage of homosexuals. There are societies where men are at first exclusively homosexual and then convert to become primarily heterosexual ([Herdt, 1981](#)). Gay (homosexual) men may or may not be effeminate. As a group, they differ from the rest of the population only in being better educated and somewhat less devoutly religious ([Bell et al., 1981](#)).

Adult gay men describe themselves as having felt "different" since early childhood. Homosexual youth usually experience homoerotic fantasies in early adolescence, and this can precipitate identity conflict ([Cass, 1984](#); [Yates, 1983](#)). Heterosexual fantasies also are experienced, and this generates bewilderment ([Bell et al., 1981](#)). During early adolescence, most engage in activities such as manual stimulation with the same and with the other sex. Girls become sexually active at an older age than boys and are more likely to engage in concurrent or sequential heterosexual intercourse ([Rosario et al., 1996](#)). Vacillation, confusion, and emotional upset often persist until a clear homosexual identity is established in early adult life. Gay youth account for almost a third of all adolescent suicides ([Remafedi, 1987](#)).

Bisexual men tend to be more conflicted, alienated, and depressed than gay men. This could be related to greater biological discordance or to greater difficulty in defining an identity in a society that specifies people as only male or only female. Conversely, those individuals who are conflicted may be less able to define themselves as male or female ([Lock and Steiner, 1999](#); [Yates, 2000](#)).

Lesbian women report feeling less feminine and less beautiful during childhood. They also report having imagined that they were male, preferring to play boys' games, and being called a tomboy. However, many women who are not lesbian also recall these experiences ([Bell et al., 1981](#); [Whitam and Zent, 1984](#)). Compared

with gay men, lesbian women are more flexible and less conflicted about adopting a homosexual role and identity. Lesbian adolescents are less likely to be rejected by peers and they have more social support available. It is not uncommon for girls to experiment with female peers and for women who were heterosexual during marriage to enter a homosexual relationship after divorce. More women than men claim to be bisexual.

Cross-cultural studies support the importance of biological forces in the genesis of homosexuality. Behavioral prodromata of male homosexuality (e.g., interest in girls' toys, cross-dressing) exist in other cultures studied regardless of how the culture views homosexuality. These prodromata first occur at approximately the same age and are remarkably persistent thereafter ([Green, 1978](#); [Pillard and Bailey, 1995](#)). Primates and domestic animals often engage in same-sex sexual activity ([Adler, 1997](#)). Homosexual relationships sometimes help the animal survive. In some species, females that engage in sexual activity together are more willing to share food, to forage together, and to groom each other.

Prenatal exposure to increases in estrogenic or androgenic hormones can exert a life-long influence on attitudes, thoughts, and behaviors ([Money, 1975](#)). Women with congenital adrenal hyperplasia not treated before 8 years of age present a feminine gender identity in consonance with the sex of assignment but a masculine pattern of arousal in that they quickly respond to visual and narrative erotic stimuli, experiencing a strong sexual appetite that is localized in the genitals and that leads to masturbation or the pursuit of intercourse with a casual partner ([Ehrhardt et al., 1968](#); [Money, 1965](#)). Forty-eight percent have homosexual dreams or fantasies, and 18% have had homosexual experiences. Women who were treated earlier in childhood demonstrate an increased likelihood of becoming bisexual ([Money and Schwartz, 1977](#)).

There is strong evidence for a genetic component to homosexuality. The concordance for homosexuality is 52% among monozygotic twins, compared with 22% among dizygotic twins ([Bailey and Pillard, 1991](#)). Monozygotic female twins demonstrate a 48% concordance, whereas dizygotic twins demonstrate only a 16% concordance for homosexuality ([Bailey et al., 1993](#)). A family pedigree study by [Hamer et al. \(1993\)](#) demonstrated that nonsibling increases in homosexual orientation occur mainly in male relatives on the mother's side of the family. This suggests transmission through the sex chromosome. Indeed, researchers have correlated homosexuality with the inheritance of five polymorphous markers at the tip of the long arm of the X chromosome, in the Xq28 region ([Hamer et al., 1993](#); [Turner, 1995](#)). However, more than one gene is likely to be involved because a significant number of monozygotic twins are discordant for homosexuality ([Bancroft, 1994](#); [Meyer-Bahlburg, 1993](#)). The genetic basis for homosexuality is an important reason why children adopted by gay couples are no more likely than the rest of the population to become gay.

Genes could influence sexuality by changing the organization and structure of the brain or by affecting the production of hormones and transmitters. Minute changes in hormone balance could alter structure and subtly recast attitudes, thoughts, emotions, and behaviors. For instance, testosterone increases and ovarian hormones decrease the development of the corpus callosum, which is larger in men than in women ([Fitch and Denenberg, 1998](#)). This could differentially affect information processing, emotional ambivalence, and anxiety ([Leavengood and Weekes, 2000](#)). Two interrelated, sexually dimorphic nuclei, the stria terminalis and the medial amygdaloid nucleus, are larger and have denser projections in men. This system influences sexually dimorphic behaviors such as aggression as well as nonsexually dimorphic functions such as social recognition memory ([de Vries and Miller, 1998](#)). The recently discovered human vomeronasal system responds in sex-specific fashion to smell by changing behaviors, adjusting the autonomic nervous system response, and even instigating the release of gonadotropins from the pituitary gland ([Monti-Bloch et al., 1998](#)). Clearly, brain dimorphism is enormously complex and has far-reaching effects on cognition, emotion, and behavior.

A boy with a female-configured brain would possess a strong innate bias toward homosexuality. Whether that person would become gay would depend on the strength of the bias (degree of femaleness in the brain), the boy's internal discomfort with becoming a homosexual, and his experience with homophobia in the environment.

Steroid hormones have been found in localized areas of the brain. These hormones are called *neurosteroids* because they are produced by neurons in the same way that the gonads and the adrenals generate steroids, but independently of the gonads and the adrenals ([Roselli, 1995](#)). Neurosteroids exert their effects locally; they could organize certain areas of the fetal brain toward maleness or femaleness or could affect postnatal behavior directly ([Kabbadj et al., 1993](#)). The existence of this third, independent hormonal pathway could explain why some very masculine-appearing and -acting men are gay ([Yates, 2000](#)).

Sexual orientation in men is not correlated with androgen levels in adolescence or adulthood ([Green, 1978](#)). However, approximately one-third of lesbians show elevated levels of testosterone ([Gartrell et al., 1977](#)), although the levels remain well below the range of normal for men ([Meyer-Bahlberg, 1982](#)). [Dorner et al. \(1991\)](#) suggest that these findings are due to prenatal stress and a congenital deficiency of enzymes involved in steroid synthesis. Adrenocorticotropic hormone administration significantly increases production of the cortisol precursor, 21-deoxycortisol, in gay men and lesbian women compared with nonhomosexual subjects. A similar increase occurs in the mothers of gay men.

Homosexual men are far more likely than other men to be born later on in the birth order and to have more older male siblings ([Blanchard and Bogaert, 1996](#)). Conversely, parents who produce many sons are more likely to produce extremely effeminate or homosexual sons ([Pillard and Weinrich, 1986](#)). Several explanations are possible, one of which is based on immunology. Long before a mother gives birth to a boy, fetal cells are circulating in her bloodstream. These persist as long as 27 years after the birth of the child ([Bianchi et al., 1996](#)). The presence of male cells could provoke an immune reaction against Y chromosomal material. Theoretically, this could lower prenatal brain testosterone in later-born boys, thus affecting the structure and function of the brain. Later-born male infants and those with many older male siblings are known to have lower levels of testosterone than first-born male children. Siblings born close together have lower testosterone levels than those born 4 or more years apart. The longer birth interval would allow the number of fetal cells in the maternal circulation to diminish.

## HISTORICAL INFLUENCES

Before the 16th century, families in Britain and Western Europe did not enjoy privacy as we know it today ([Jackson, 1993](#)). Family members, employees, and servants worked, ate, and slept under one roof, usually in the same room. Children were seen as small, socially inferior adults. They were expected to contribute to the family economy and were held legally responsible for their actions. They freely observed the sexual acts of adults and heard open discussion of licit and illicit acts. They engaged in masturbation and sex play with other youngsters. Sexual crimes involving children did occur, but the effect on children's emotional well-being was not an issue. Sexual development was not regarded as problematic.

From the 16th to the 19th century, families began to live apart from the workplace. The single great room had been divided by walls, so that sleeping rooms were apart from eating and work areas. Sexual relations occurred behind closed doors. Servants had their own quarters. With the advent of Puritanism, sexuality was identified with sinfulness, except in the narrow context of procreation. Sexual relations became more and more secretive. Conversation was sanitized and sexual matters were discussed only in private. Parents tried to raise modest, notably asexual children. Children were told to cover the body at all times and not to look at or touch other potentially sexual objects ([Elias, 1978](#)). Children became ashamed of the body and of such common behaviors as blowing the nose without a handkerchief, burping, and toileting ([Whitehurst, 1971](#)). Children could not refer to "legs" or to "bellies" but were to use the correct terms, which were *nether limbs* and *lower portion*. The dinner table stood on "limbs" rather than "legs," and children could never ask for slices from the "breast" of the chicken. Girls and women were told to avoid strong foods such as corned beef and blood pudding, but boys and men could eat anything they wished.

In the 19th century, Victorian parents were tormented by the fear that their children would masturbate because "self-abuse" was thought to cause insanity, lethargy, tuberculosis, syphilis, eventual impotence or sterility, deformed children, and epilepsy. Spike-lined rings that fit around the penis, steel and leather jackets that enveloped the entire torso, electric shocks, and tight bandages were used to prevent children from pleasuring themselves. Some parents would tie their children's extremities to each post of a four-poster bed at night. Children who masturbated in spite of these measures might have the nerves to the penis severed or the clitoris cauterized with a white-hot iron. Clitorectomy by scalpel or by scissor was a common treatment for recalcitrant masturbation in young girls ([Schwartz, 1973](#)). Among the many civilizations that practice clitorectomy, ours is the only one that has used the excision of the clitoris as a cure for masturbation ([Huelsman, 1976](#)).

In the mid-19th century, under the influence of literary romanticism, attitudes toward children and sexuality started to soften. Liberal, well-educated parents began to regard children as innocent, asexual, and in need of protection ([Jackson, 1993](#)). This idea slowly spread throughout society, although it has never completely replaced the concept of the demonic child among fundamentalist groups. Because children were vulnerable, the family's responsibility was to protect them against danger, especially threats to their "natural" state of innocence.

### 20th Century

The decades from 1930 to 1950 witnessed a marked decline in the severity of the sanctions against sex play and masturbation in childhood ([Wolfenstein, 1953](#)). Parents began to caution, dissuade, or distract rather than punish or scold youngsters for sexual activities or interests ([Finkelhor, 1980a](#)). In the 1950s, a new theme

emerged: Parents were told not to worry about children's sexual interests. It was perfectly normal for children to explore the body, and once they learned about the body, they would no longer be curious. Some parents could accept sex play as "probably not abnormal," but it remained a source of anxiety. In spite of greater comfort, parents were unable to talk to children about topics such as masturbation and intercourse. Parents in upper socioeconomic classes began to name the boy's penis but continued to avoid naming the girl's genitals. The trend toward increasing acceptance of childhood sexuality continued in the 1960s and 1970s with the sexual revolution.

The tendency toward acceptance abruptly reversed in the late 1970s when concern about child sexual abuse surfaced and evolved into a social movement. The need to protect children from sexual abuse soon extended to protecting any child from any sexual experience. Sex abuse prevention programs espousing "stranger danger" and "bad touch" were presented in grade schools across the nation without prior needs assessment, outcome studies, or data on the effect on normal development. Research studies throughout the 1980s and 1990s were unable to show that the programs prevented abuse, but a recent retrospective study does suggest less sexual abuse among adults who recall exposure to a prevention program while in school. The study did not find adverse effects on erotic development in terms of diminished sexual satisfaction or avoidance of sex in adult female students who recalled exposure to prevention programs ([Gibson and Leitenberg, 2000](#)). A prospective study may or may not confirm these findings.

During the last three decades of the 20th century, while concern about sexual abuse was at a peak, the amount of erotic material in the media increased dramatically. While watching prime time television, children viewed bedroom scenes and learned about the president's preference for oral sex. MTV (music television) aired "booty-bumping" videos of stars singing about "banging on the bathroom floor." Children could read articles on how to achieve a better orgasm or the latest technique to please a partner in popular magazines about the house. Not uncommonly, a child in a single-parent household would wake up to find an extra person at breakfast or in the parent's bed. Needless to say, these events have continued to occur in the first part of the 21st century.

### Dissonance

Of most concern is the fact that children largely have been left to decipher contradictory messages in the media, at home, and at school on their own. No single standard is underwritten as correct ([Benedict, 1950](#)), but the standard for children clearly differs from the standard for adults. In Victorian times, the task was simpler: "Good" (asexual) girls grew to be "good" women who tolerated intercourse to bear children. "Good" little boys grew to become "good" men who engaged in sex because it was necessary to make babies.

Over the past two decades, it has become easier for children to acquire extensive sexual knowledge ([Volbert, 2000](#)) but more difficult for them to integrate sexual material into an understanding of self and other. Integration is compromised because most parents avoid talking to children about their concerns, are embarrassed by their questions, or categorize sex as bad, dangerous, or a reason for not being liked ([Gagnon and Simon, 1973](#)). Exposure to sexual material in the media, in conjunction with parental reluctance to discuss it could create in children the sense that sexuality exists in a compartmentalized domain apart from life experience ([Fisher, 1989](#); [Yates, 1993](#)). Unless integration is achieved later on, individuals might come to prefer visually and emotionally charged, but impersonal, sexual practices such as Web sex, lap dancing, or masturbation while viewing pornographic videos.

## SOCIOCULTURAL INFLUENCES

Child-rearing practices that are not directly related to sex can influence sexual development. In the early 20th century, especially in rural areas, children were valued because of the work they did and the security they would provide as the parents aged. By mid-century, more families had moved to towns and cities, making children less useful and more of a financial burden. Social Security allowed aging parents to be less dependent on children. The invention of the latex condom and the diaphragm enabled women to bear fewer children. Families shrank as women joined the workforce. The rationale for having children changed: Children were valued for the emotional warmth and sense of purpose they gave the family. They were no longer expected to work or to do gainful chores to support the family economy. In the affluent family, children became the centerpiece: cuddled, protected, indulged, and closely monitored instead of being allowed to roam freely in the neighborhood. However, as they grew older, they were expected to readjust, making their mark in school and eventually in a business or profession. The effect of these changes in child rearing is not known, but ample early nurturance would be expected to change sexual development for the better but make separation/individuation more difficult owing to the highly gratifying early relationship to the parents.

In the last decades of the 20th century, children were treasured as never before but also were expected to adapt to frequent placement in day care apart from the parents as mothers moved into the workforce. This increased the pressure on children to become independent at the same time that being dependent was encouraged at home. There have been no studies that examine the long-range effect of these practices, but the strong emphasis on self-sufficiency could be expected to engender anxiety about dependence and ambivalence about intimate relationships ([Yates, 1991a](#)). Although this might not affect the sexual response, it might diminish the ability to sustain an intimate relationship over time. Current high rates of sequential cohabitation and divorce and the increased number of adults who choose to live alone may, in part, be related.

### Family Influences

In Western culture, parents tend to assume that youngsters will be overstimulated if they are allowed to see parents and others nude. Cross-cultural research does not support this concept ([Ford and Beach, 1951](#)). Indeed, a recent longitudinal study from the University of California, Los Angeles found no harmful effects from exposure to nudity or the chance observation of adult sexual activity ([Okami et al., 1998](#)). Young children enjoy being naked and watching parents and siblings go without clothes. When nudity is allowed in the home, children display higher self-esteem, and less discomfort with body contact ([Lewis and Janda, 1988](#)). However, family nudity also increases children's normative sexual interests and activities ([Friedrich et al., 1991](#)), and this, in itself, may be enough to increase parents' anxiety.

In Western society, parents are concerned about letting the child, especially boys ([Roberts et al., 1978](#)), have too much body contact, and they also worry about body contact between siblings. From the time children are 3 or 4 years of age, parents restrict how, where, and when children can touch them ([Blackman, 1980](#); [Lewis, 1965](#); [Martinson, 1991](#)). Asian societies are not so concerned; children are allowed access to the body, the bedroom, and often the bed ([Barry and Paxman, 1971](#); [Frayser, 1994](#)). In Western society, body concerns are translated into a vast, elaborate set of containers for infants and toddlers such as baby carriers, car seats, prams, and playpens. While we do not know how encapsulation affects children's erotic development, we do know that when parents enjoy touching and bathing children, children become more comfortable with their bodies and with talking about sex ([Rosenfeld et al., 1987](#)).

Parents' anxiety about sexuality is mirrored in their need to restrict infants from sharing the bed with them, even though bed sharing facilitates suckling and allows the mother more time and better quality of sleep ([Mosko et al., 1996](#)). Parents worry that bed sharing will inhibit cognitive and emotional development, overstimulate through excessive body contact, and keep children from becoming independent ([Colarusso, 1994](#)). The research that exists indicates positive, rather than negative, effects of bed sharing, including better adjustment, greater self-esteem, and more affection and greater comfort with sexuality in adult life ([Lewis and Janda, 1988](#); [McKenna, 1997](#)).

### Research

In the last quarter of the 20th century, research on normal sexual development was seriously impeded by problems in funding or in receiving approval from Human Subjects Committees. Approval was not granted for studies that included asking youngsters about sexual interests and activities. Relatively little research has been published, making students and researchers dependent on studies completed decades ago. Improvements in research are not likely to occur unless the culture becomes less concerned with negative consequences and more concerned about normal development. The books and articles on which this chapter is based often are dated or imperfect, descriptive rather than sample based, and derived from sources other than peer-reviewed journals, or are journal articles that suffer from methodologic flaws. Materials include (a) child analytic case studies and journal articles published between 1930 and 1980; (b) a few well-designed older studies, such as those by Spitz in the 1930s; (c) longitudinal studies of normal development published in the 1970s and 1980s ([Chess and Fernandez, 1981](#); [Galenson and Roiphe, 1979](#)); (d) direct child interview studies by Goldman and Goldman in [1982](#) and by [Martinson in 1994](#); (e) parent or teacher descriptions of sexual behavior in groups of children; and (f) articles published since 1990 as indexed in medical and psychological databases. Reports that are heavily biased toward pathology are not included.

Human sexuality is surely as old as the human race. Although sexual activity is based on instinct, the sexual act is influenced by assumptions about sex handed down through generations, depictions of sexuality currently in the media, fear of venereal disease (especially the acquired immunodeficiency syndrome), the changing status and role of women, and medical achievements such as effective birth control and *in vitro* fertilization.

## EROTIC DEVELOPMENT

In children who are not unduly inhibited, there appears to be a developmental progression, commencing with the highly pleasurable sensations generated by the infant's transaction with the parents and continuing through (a) the differentiation and appreciation of the genitals; (b) the incorporation of the sexual parts in the concept of the body; (c) exhibitionism to "test" adult reactions; (d) mastery of a variety of self-elicited sensations; (e) expansion of erotic interest to include parents, siblings, and peers; and (f) the final integration of the genitals and genital function into the concept of the self. Erotic development is separate from, but related to, that of psychosexual development, which includes object relatedness. The concept that eroticism is separate from psychosexual development provides a better model to explain the heightened eroticism of sexually abused children ([Johnson, 1993](#); [Yates, 1982, 1991b](#)) and the well-developed object relationships of many sexually dysfunctional adults. Some of the factors that influence the process of eroticization are (a) hormones and neurotransmitters; (b) appearance and self-esteem; (c) resolution of early conflicts; (d) presence or absence of severe social and cultural sanctions; and (e) experiences such as skin-to-skin contact with parents, sex play, and observations of sexual interest and activity in others.

Erotic behavior in infants and children has been well documented ([Bakwin, 1973](#); [Borneman, 1990](#); [Kinsey et al., 1948, 1953](#); [Martinson, 1981](#)). An absolute lack of eroticism in infancy is remarkably rare and usually is secondary to a catastrophe such as severe birth injury or debilitating disease. However, a relative decrease in eroticism usually follows severe neglect, parental rejection, or frequent changes in placement.

When feeding time approaches and the infant senses the closeness of the breast, his or her activities suddenly become organized, predictable, and goal directed. The infant inhibits crying, closes the fists, opens the mouth, searches and thrusts toward the nipple, seizes it, and sucks vigorously. The infant's face is red, and his or her mood might best be described as eager and anxious. When the milk comes down, the fists relax, the eyes turn up and close, and the infant's body melts to conform to the curves of the mother. Within a few moments, the infant slides into a peaceful, pleasurable state, continuing to suck even when satiated, repetitively touching the nipple with the tongue although apparently asleep. The mother's scent, warmth, and closeness are part of this first, highly erotic experience.

At approximately the third month of life, some infants derive comfort and pleasure from sucking the thumb, but the relationship to the thumb lacks the erotic intensity of the relationship to the parent. Because thumb sucking does not occur in cultures where the breast is readily available to the infant, it would seem that this early diversion of erotic interest from the nipple to the thumb is related to the relative unavailability of the breast ([Sarlin, 1975](#)). Thumb sucking functions as an early step in the separation individuation process and is not associated with psychopathology.

By 3 or 4 months, infants clearly are intrigued and delighted by the washing and drying of the genitals. By 6 months, infants may eagerly grasp the genitals in anticipation of being diapered. Most boys begin to play with the penis at approximately 6 or 7 months, and girls begin to stimulate themselves at 10 or 11 months ([Bakwin, 1973](#)). Genital play differs from masturbation in that there is no intentioned progress toward orgasm. Parents tend to view early genital play as part of children's need to explore ([Rutter, 1971](#)).

Genital play at an early age is associated with health and good relationship to the parents rather than any pathologic process. Conversely, when the relationship with the parents is difficult or neglectful, genital play diminishes or disappears and the child is less likely to be healthy. [Spitz and Wolf \(1949\)](#) studied foundling home infants, mother–infant pairs in a prison nursery, and normal mother–infant dyads. The well-nurtured infants, without exception, enjoyed touching themselves, whereas the poorly nurtured infants, almost without exception, did not. More recent research supports this early observation ([Borneman, 1990](#); [Galenson and Roiphe, 1979](#); [Martinson, 1981](#)). However, self-stimulation is not a prerequisite for healthy development because there are healthy infants who have never stimulated themselves ([Kleeman, 1975](#)) and many others who began to do so but were discouraged by the parents.

When infants intentionally bring themselves to orgasm, this is called *masturbation*. Genital play should not be confused with masturbation. The change from genital play to masturbation is a gradual, discontinuous process that extends into the second or third year of life in many, but not all children ([Galenson and Roiphe, 1979](#)). Masturbating infants appear singularly intent and difficult to distract. They breathe rapidly, flush, grunt, and make rhythmic thrusts or, in the case of female infants, may grasp and rub a pillow or doll between the legs. When infants first begin to masturbate, they try to maintain body contact with the parent, but most parents discourage this. Contact seeking is soon replaced by the familiar averted eyes and inward gaze ([Galenson, 1993](#)). Once children have established a certain mode of masturbation, the format persists and is resistant to change ([Perper, 1985](#)). Masturbation is something the child does autonomously, an activity that usually is effective and pleasurable. The ability to do something that is independent of the parents can foster the process of separation and individuation ([Sarlin, 1975](#)).

Masturbation is less conflicted for infants than it is for parents in Western culture. Parents who had been able to accept genital play react strongly to masturbation, although they may not understand why they are so upset. [Martinson \(1991\)](#) analyzed studies from 1957 to 1985 on parent attitudes about children's sexuality and concluded that although many parents said that they thought masturbation was healthy, they experienced disgust when they witnessed their son or daughter masturbating.

The format for masturbation established in the second year of life tends to remain constant among boys, although it undergoes a further evolution among girls ([Galenson, 1974](#); [Galenson and Roiphe, 1976](#)). Girls often learn to use indirect techniques, using legs, thighs, toes, or rocking horses. Girls may cease masturbation completely in the second half of the second year or they may continue to masturbate without pleasure. Accompanying reactions include frustration, regression, fearfulness, loss of enthusiasm, sadness, and the displacement of activity to other parts of the body and to inanimate objects such as dolls and fuzzy toys. Some girls become erotically interested in the father, whereas others show an increase in hostile dependence on the mother. Frustration reactions seem to enhance girls' symbolic thought and internal complexity. However, the girls most severely affected constrict their imagination and retreat emotionally ([Roiphe and Galenson, 1973](#)). Boys show far less overt disturbance, often displacing their anxiety into physical activity.

### Anatomy

Anatomic differences have far-reaching import for psychosexual development ([Gadpaille, 1976](#); [Kestenberg, 1968](#)). Boys can easily identify a tangible, predictably pleasurable focus in the erect penis. The penis is visible, often has a name, and has a readily observable function in urination. Clothing provides a special aperture for the penis. Parents approve when boys use the hand to steady the penis during urination. Because of this, it seems easier for little boys to integrate their genitals into the body concept. Testosterone's influence on the fetal brain augments active, acquisitive striving, task orientation, pragmatism, goal directedness, and logical thought, all of which contribute to the sense of maleness.

In homes where nudity and body contact are limited, girls experience the genitals as something hidden that needs to be kept clean and covered. Direct contact between hand and genital is limited and usually involves toilet paper or a washcloth. Girls may confuse the genitals with the anus and assume that they are dirty or bad. Girls find it more difficult to integrate the genitals into the body concept when they are restricted from viewing the mother or adult women naked ([Schuhrke, 2000](#)). In the absence of easy, external, male genital eroticism, girls become more inwardly attentive and aware, more intuitive, expressive, and patient, but with less of the "male" pragmatism and goal directedness ([Galenson, 1974](#); [Kestenberg, 1968](#)).

Curiosity about genitals is quite common at approximately 2 years of age, when children have the opportunity to observe others nude. Interest in personal urination seems to be a prerequisite for developing interest in the bodies of parents, siblings, and peers ([Schuhrke, 2000](#)). Interest in parents' genitals surfaces before interest in siblings' genitals. This is likely due to the larger size and stranger appearance of adult genitals. Children often want to touch or explore parents' genitals, and most parents feel threatened by this. Curiosity about parental bodies persists until at least 6 years of age, although boys' curiosity about fathers' genitals diminishes and is displaced to some extent to the genitals of male peers.

### Preschool Eroticism

As youngsters grow older, peer relationships become more important. The focus shifts from genital play and masturbation to sex play. In an Irish community sample, one-half of all 3-year-old children were observed to masturbate or play with their genitals ([Fitzpatrick et al., 1995](#)). Genital play and masturbation help to define the sexual self, whereas sex play defines the relationship between the sexual self and others.

Infant observation studies ([Galenson, 1993](#); [Galenson and Roiphe, 1976](#); [Kleeman, 1975](#)) indicate that toward the beginning of the second year infants become interested in toilets, in observing others defecate, and in sensing their own bowel movements. This is called *anal eroticism*. At the same time, youngsters become more opinionated, stubborn, and negativistic. Continuing in the second and third year of life, toddlers enjoy watching themselves urinate and they may try to play with the urinary stream ([Galenson, 1993](#); [Rosenfeld et al., 1987](#)). They are curious about how others urinate, and they enjoy faucets and squirting devices. Children 2 to 4

years of age spontaneously engage in bathroom games. They may fondle each other's genitals as they bathe together or playfully attack each other with rubber bath toys. Some briefly experiment with smearing feces. At this age, boys and girls are especially fascinated with the genitals of boys ( [Gunderson et al., 1981](#) ), perhaps because they are larger, more accessible, and can change size. They are fascinated by father's genitals and the genitals of dogs ( [Martinson, 1981](#); [Spiro, 1958](#) ). Boys may rub the penis, so they can show off an erection or may ask a parent to rub the penis because it feels good. Girls are more likely to entice the parent indirectly by using the body as a whole: strutting, lifting the skirt, dancing provocatively, and giggling. They enjoy the genital contact involved in "playing horsie" on the parent's knee.

Parents commonly observe preschool children walking around nude, scratching the crotch, trying to look at others undressing or on the toilet, kissing nonfamily adults, showing sex parts to adults, touching breasts, or sitting with crotch exposed ( [Friedrich et al., 1991](#); [Kleeman, 1975](#); [Johnson, 1993](#) ). A reporting bias is likely because parents who report more child sexual behaviors tend to be better educated, earn more money, attend fewer religious services, and have more liberal attitudes about sex ( [Shafan, 1995](#) ).

Some 2- to 3-year-old girls insist that they have a penis and try to urinate standing up, or they hold sticks or toys protruding from the genital area. ( [Galenson and Roiphe, 1976](#) ). This represents interest in, and anxiety about, the penis rather a gender identity disorder. By the same token, boys may express the wish to grow breasts or to have babies ( [Edgcumbe, 1976](#) ). These behaviors tend to be evanescent.

Adults ordinarily cannot recall sexual and other happenings that occurred before 4 years of age, and many can remember nothing before 12 years of age, yet 20% of adults remember being sexually aroused before 6 years of age ( [Ryan, 2000](#) ). Sex play among preschool children usually is collaborative and accompanied by caressing, cuddling, kissing, hugging, sitting close together, feeling sorrow when separated, and giving each other gifts. Commonly noted formats involve looking at, touching, or rubbing the genitals. The play is noncoercive, spontaneous, and invigorating. When boys get together they may engage in games of "competitive pissing" ( [Borneman, 1990](#) ).

From approximately 4 years of age, children use themes, props, and role assignment in games such as "Doctor" and "Make a Baby." Play almost always is spontaneous, although it can also occur in response to seeing the parents having sex. Sexual activity regularly increases after children observe the erotic activities of adults, other children, and animals. This suggests that the play is part of a learning process that helps youngsters understand sexual events. After age 4 or 5 years, youngsters hide sexual activity and become less open to talking about sex to an adult. They have learned that sex is "dirty," and even if they continue active sex play, they will say that the genitals and the play are bad or nasty ( [Ames, 1966](#); [Pitcher and Prelinger, 1963](#); [Schuhrke, 2000](#) ). What causes this change in perception is not known, although parents' anxiety and inability to talk about sex likely contribute.

A common adult concern is that if children engage in sex play, this will lead to more and more inappropriate kinds of sexual activity. Yet in the sexually permissive kibbutzim, sex play follows a predictable course. Masturbation and peer play begins in infancy, becomes very intense in early childhood, but becomes less intense in the early school years ( [Shepher, 1971](#) ). Sexual shame appears at approximately 9 or 10 years of age, and at that time, the relations between sexes become strained. This tension disappears at ages 13 to 14 years, when a warm and friendly, but completely asexual, relationship ensues. People from the same peer group do not become sexually active with one another in adolescence, and they do not marry one another later on. This avoidance is completely voluntary.

### Naming the Genitals

Parents rarely say anything positive about children's genitals ( [Rosenfeld and Wasserman, 1993](#); [Yates, 1978](#) ), and they usually treat them as nonexistent or unimportant ( [Gadpaille, 1978](#) ). Many parents do not name the genitals at all, and this conveys a message. Others apply colloquial terms and a few teach children the correct names for the genitals ( [Fisher, 1989](#); [Fraleigh et al., 1991](#) ). Parents who do name the genitals are likely to be better educated, practice nudity in the home, and allow children to sleep in their bed.

Names assigned to boys' genitals are most often diminutive, such as "pee-pee," "dinky," "dickie," "peetie," "dood-dad," "froggie," "button," "twinkie," "flipper," "dippy-bird," "dingaling," "pickle," "tee-tee," "wienie," and "wormy-Willy" ( [Fraleigh et al., 1991](#); [Sanders and Robinson, 1979](#) ). Such inconsequential terms may defuse parental anxiety about children's sexuality. Rarely, parents assign a term that connotes worth or power, such as "family jewels" or "tally-whacker." How this affects children's self-perception is not known, but positive names are likely to have a positive effect on genital esteem ( [Yates, 1978](#) ).

Parents virtually never name girls' external genitals ( [Gagnon and Simon, 1973](#) ), although they may use a nonspecific term such as *vagina* for the entire area. Names assigned to girls' genitals are singularly nonspecific, such as "down there," "your privates," and "your bottom." When the term *vagina* is used, it usually refers to the entire external apparatus, including the anus. Even the occasional picturesque terms such as "bucket," "coochie-cooch," "garage," "snatch," "twat," "little-popo," "toto," and "tushie" ( [Fraleigh et al., 1991](#) ) are applied in nonspecific fashion. The lack of differentiation is reflected in the fact that most girls do not know what exists "down there" until at least 12 years of age. This lack of differentiation could affect sexual function later on ( [Yates, 1978](#) ).

The years from 3 to 6 have been called the *oedipal period* because erotic interests often are focused on the parent of the opposite sex. Some youngsters ask many questions about the body, intercourse, and reproduction ( [Robinson et al., 1991](#) ), whereas others seem unconcerned. Despite apparent sophistication, children's concepts of sexuality remain based on earlier constructs; many believe that the infant is born by cutting the mother's stomach open or that the infant exits through the mother's anus ( [Goldman and Goldman, 1982](#) ). Boys may express an overt wish to displace the father and marry or sleep with the mother. Girls become highly erotic in the context of the relationship to the father. However, they are less direct than boys and instead may attempt to achieve a sense of completion and specialness through the relationship ( [Roiphe and Galenson, 1973](#) ).

In a large study based on parents' observations of sexual activity in their children, [Friedrich et al. \(1991, 1992\)](#) associated older children's sexual activity with behavioral problems. This is likely the case in that older children who openly express their sexuality care little about rules or the feelings of others, symptoms that suggest a behavior disorder. Children who are open about their activities are, of course, the ones in whom sexual activity is observed.

### Father/s Role

When both parents cooperate in rearing children, children perceive the parents in a more balanced and realistic manner. However, in many homes, fathers are considerably less involved than mothers ( [Hochschild, 1989](#) ). Yet fathers are more likely than mothers to play with young children ( [Flerx et al., 1976](#) ), and the play is far more stimulating and unconventional than mothers play ( [Ablin, 1971](#); [Lamb, 1980](#) ).

Father involvement greatly facilitates formation of gender identity and role. Fathers who are firm, warm, and actively involved are most likely to produce masculine sons and feminine daughters ( [Spieler, 1984](#) ). When fathers are absent, sons appear less masculine ( [Mead and Rekers, 1979](#) ) and form a less successful heterosexual adjustment in adult life ( [Cinch, 1949](#) ). In general, father absence has a more profoundly debilitating effect on boys when it occurs early and lasts for a long time ( [Hetherington, 1971](#) ).

Girls learn to be feminine through a positive relationship with a masculine father ( [Spieler, 1984](#) ). Fathers who validate their daughters' sexual attractiveness enable them to accept themselves as both feminine and sexual. Conversely, girls reared without fathers have difficulty learning the feminine role; they become sexually active earlier and tend to have more partners ( [Hetherington, 1971, 1972](#) ). Yet, overall, father absence appears less damaging to the psychosexual development of girls than boys.

### School-Aged Children

A number of retrospective studies have asked university students about their recall of sex play during childhood. In one study, 85% of the women recalled sex games and 44% recalled sex games involving boys ( [Lamb and Coakley, 1993](#) ). Most remembered feeling sexually aroused or excited at the time. More than half the women indicated that no adult was aware of the sex play, and it was not subsequently reported. Most of the play involved exposing or touching the genitals. Insertion of objects in the vagina and oral contact were distinctly unusual. Three other studies ( [Bauserman and Davis, 1996](#); [Haugaard and Tilly, 1988](#); [Reynolds, 1997](#) ) confirmed that most young adult students can recall early sex play and that they view the play in a positive light as pleasurable and exciting. Negative responses are associated with feeling coerced, playing with a person of the same sex or with someone other than a friend, and with being discovered by an adult ( [Reynolds, 1997](#) ).

Modesty becomes an issue for girls between 4 and 6 years of age and boys between 5 and 8 years ( [Rosenfeld et al., 1984](#); [Rosenfeld and Wasserman, 1993](#) ). Children with older siblings become modest sooner, perhaps because of role modeling or because they are more likely to be teased for being naked. Soon after they

enter school, boys and girls learn to toilet separately and dress apart. By fourth or fifth grade, children are extremely embarrassed if their underwear shows at all. Parents also become more modest as their children grow older. It is uncommon for mothers to bathe with sons who are older than 8 years of age or for fathers to bathe or shower with daughters older than 9 years of age ([Rosenfeld et al., 1987](#)).

Modesty or shame may affect other dimensions of children's lives. A study of 8- and 9-year-old boys and girls ([Rademakers et al., 2000](#)) documented the hunger for greater physical intimacy such as cuddling with the parents. This simply did not happen for many children, and others managed to cuddle only with toys or animals. Parents seemed unaware of children's need for greater physical contact.

When children start regular school, sexual activity drops sharply, and the activity that does occur is quite secretive. This may be due to greater structure; more attention focused on schoolwork; fear of apprehension; feelings of shame, guilt, and internalization of the process ([Tanqney and Fisher, 1995](#)). Boys who have been sexually active tend to remain more active than other boys but less active than they were earlier. In part, this is because very few girls are willing to participate—one to every seven boys ([Broderick and Fowler, 1961](#); [Kinsey et al., 1953](#)).

School-aged children continue to be interested in sex but may displace the interest to “doodling” breasts or genitals on human figures, sneaking *Cosmopolitan* or *Playboy* to read, telling dirty jokes, or going to great lengths to watch animals breed ([Johnson, 1993](#)). The concept of “sex is dirty” is joined by “sex feels good.” By 9 years of age, one-third of boys (but not girls) see enjoyment as a reason why adults engage in sexual activity ([Conn, 1948](#); [Goldman and Goldman, 1982](#)).

Sex games are likely based on group consensus: “Spin the bottle” and “strip poker” are examples. Others are modeled after television contests like *Wheel of Fortune*. In “truth, dare, and consequences,” the person who is “it” is asked an ambiguous question such as “Who is the smartest boy in class?” Because no one really knows the right answer and group members are certain to disagree, the child who is “it” must pay the consequences, which may mean stripping, spreading the legs, or touching another child's genitals. Games are sexually exciting; they provide a forum where the body is accepted and sexual feelings are validated.

When children are discovered while engaging in sex play, they can suffer intense personal shame and public humiliation ([Reynolds, 1997](#)). They can be ostracized by neighbors and teased mercilessly by peers. Boys, especially, may be viewed as perpetrators, such as 6-year-old Jonathan Prevette, who kissed a classmate on the cheek and was subsequently suspended from school and charged with sexual harassment ([Nossiter, 1996](#)). Some youngsters are devastated, and others rapidly adjust. This is symptomatic of society's confusion about what constitutes sexual abuse. Children who play sex games together, parents who go nude in front of children, and fathers who kiss older children can be judged abusive ([Haugaard and Reppucci, 1988](#)).

Teasing with sexual themes is ubiquitous in the schoolyard and hallway. Taunts of “fag,” “les,” or “teenie wienie” take an emotional toll. On the playground, kissing is most often an aggressive act calculated to embarrass or drive away the other person. The fact that virtually all children get teased in one way or another has a protective effect, and learning to deal with teasing can strengthen defenses. Yet vulnerable children suffer greatly, and some are never able to contend with taunts. In the year or two before puberty, hormones rise, sexual and aggressive impulses surface, and peer groups become sharply divided according to gender. Ridicule and taunting become more frequent and brutal. Certain children become scapegoats. They can be systematically degraded or humiliated in front of others by pulling pants down to expose the genitals or ripping the shirt open to reveal the breasts ([Ryan, 2000](#)).

In spite of the taunts, romanticism is alive and well because almost all school-aged children expect and want to get married. Between 10 and 12 years of age, most children say they have a sweetheart, and by 12 years, five of six children claim to have been kissed by a peer ([Broderick and Fowler, 1961](#)).

## Sex Education

Parents often avoid or choose not to sex educate. In one retrospective study, 36% of the respondents said that their parents had never discussed sex, 17% that they had discussed it once, and 41% that it was discussed “very little but intermittently” ([Ryan, 2000](#)). Topics such as masturbation, homosexuality, and sexual pleasure virtually are never brought up, but these are the topics that youngsters are most concerned about and least likely to receive information on at school.

Sex abuse prevention programs often begin in kindergarten, whereas sex education programs rarely begin before the fifth grade. The sex education curriculum almost always omits controversial topics. Parents fear that a more liberal curriculum will be harmful or overstimulating for children. Therefore, the curriculum focuses on “safe” topics such as the dangers of sexually transmitted disease. In grade school, analogies may be used to make the material more palatable. Analogies can confuse children who come to think that eggs are brittle, encased objects produced by hens, geese, and ducks that seeds will sprout into plants growing in soil attached to the wall of the mother's stomach, watered occasionally by the father's semen ([Goldman and Goldman, 1982](#)).

[Campbell \(1986\)](#) reviewed more than 400 sex advice books for young people, published over the past 100 years. These volumes uniformly emphasized the danger of sex, the consequences of unintended pregnancy, the ravages of sexually transmitted disease, and problematic aspects of sexual deviance and dysfunction. Discussion of sensual pleasure was conspicuously absent. In the past decade, sex advice books have been joined by sex abuse prevention books and pamphlets that generally focus on the threat of sexual abuse without normalizing masturbation, body exploration, or sex play. Fortunately, a few, more positive sex education programs are now available ([Krivacska, 1990](#); [SIECUS, 1991](#)), but there is some question as to how widely they will be used, given school administrators' concern about parent protest.

## Puberty

Boys and girls follow a somewhat different developmental path in adolescence. Girls are more likely to become eating disordered or depressed, and boys are more likely to drink or be delinquent. Girls are thought to have a more difficult process of separation and individuation because of blurring of boundaries between mothers and daughters or because mothers may project their hopes and dreams on daughters ([Blos, 1983](#)). As adolescent girls attempt to resist the profound regressive need for the mother, they may turn passionately to the other sex.

Early maturing girls may be depressed, ashamed of their breasts, and anxious about gaining weight ([Brooks-Gunn and Warren, 1989](#)). Late-maturing girls appear less concerned and more competent in responding to developmental demands (Schwab-Stone et al., 1985). Menarche itself brings an increase in self-esteem and awareness of the body to most girls. Girls who learn how to insert a tampon may understand the difference between clitoris, urethra, and vagina for the first time. Girls who successfully insert the tampon feel excited and proud ([Shopper, 1979](#); [Whisnant et al., 1979](#)).

In contrast to girls' menarche, boys' semenarche or first ejaculation has been accorded little attention. In rural Ukraine, it is a memorable event traditionally celebrated by the boy digging a hole and contributing his semen to Mother Earth (L. Hrbeck, personal communication). In our society, boys are poorly prepared for the event by health classes or by parents ([Shopper, 1979](#); [Whisnant et al., 1979](#)), and it is often experienced as a frightening occurrence that is neither revealed nor celebrated. [Stein and Reiser \(1994\)](#) asked white, Jewish camp counselors, on average 18 years of age, to describe how it had been for them. They described strong feelings, including pleasure, but many felt unprepared and unsupported. Most did not reveal the event to others, and some thought they had wet the bed and felt confused, frightened, disgusted, and embarrassed.

Reactions to semenarche reflect a negative value attached to sexuality and the penis. Adolescent boys do not seriously discuss the penis even in an all-male peer group. Instead, they refer to the penis as “rod,” “unit,” or “stick,” terms that are oblique and inferential ([Sanders and Robinson, 1979](#); Schwartz, 1985). Characteristics of the penis such as relative size and appearance remain obscure, in part because boys avoid looking directly at a peer's penis for fear of appearing gay. Yet adolescent boys are concerned about penis size and often assume that their penis is too small. Pornographic films may reinforce this sense of inferiority when the protagonist is heroically endowed.

## BOYS' SELF-CONCEPT

In the past, boys' sexual self-concept was in general positive, certainly more positive than that of girls. However, men today are far more dissatisfied with the body and more concerned with appearance than they were 20 years ago. This was shown in a recent study of ours comparing male university students (average age, 24 years) with male members of a jury pool (average age, 43 years) ([Yates et al., 1998](#)). The younger men were significantly more dissatisfied with body and self. Younger men today are more likely to have eating disorders and body dysmorphic disorder, worry about appearance, engage in weight loss programs, work out, and seek plastic surgery ([Mishkind et al., 1986](#); [Moore, 1993](#); [Pope et al., 2000](#); [Striegel-Moore and Kearney-Cooke, 1994](#); [Sykora et al., 1993](#); [Zerbe, 1996](#)). These changes may be related to (a) increased status of women, with more men attempting to model after women; (b) often unsuccessful competition for the (now more independent) women; or (c) negative perceptions of male sexuality leading to greater body dissatisfaction. Negative values attached to male sexuality are common in abuse prevention

literature, media accounts of date rape and sexual assault, and talk show episodes entitled “men who have sex with their wives' best friends.”

### HOMOSEXUAL EXPERIMENTATION

The biological changes that occur with puberty are rapid and, especially in boys, intense. Incestuous and bisexual conflicts are revived and sexual orientation becomes a central issue. Many boys and girls engage in homosexual activities even though they are heterosexually oriented. This is especially so during early adolescence, when contacts are almost exclusively with the same sex. Homosexual activities are even more common at boarding schools and at camp. Boys often experiment in groups, beginning by exhibiting the erect penis and continuing on to parallel or mutual masturbation, fellatio, and interfemoral and anal intercourse. Girls tend to experiment with a best friend rather than a group of friends, exploring the body, fondling each other's genitals, and making believe they are having intercourse. Sexual experiments engender intense excitement: boys quickly establish orgasm as a goal, whereas girls may experience orgasm but rarely seek it as a primary goal, preferring to kiss, hug, and snuggle for a sense of closeness ([Kinsey et al., 1948, 1953](#); [Langfeldt, 1990](#); [Ramsey, 1943](#); [Sorensen, 1973](#)).

### ADOLESCENT MASTURBATION

Twenty-four percent of teenage girls say they masturbate, and two-thirds feel guilty about doing so ([Coles and Stokes, 1985](#)). Twice as many boys as girls masturbate, and boys do so three times more frequently than the girls ([Leitenberg et al., 1993](#)). Most commence between 10 and 14 years of age ([Martinson, 1994](#)). Those engaged in solitary masturbation often think they are the only ones who have ever done it and that it must be harmful, sinful, dirty, or a sign of weakness. They usually are trying to stop.

Early studies indicated that almost all boys have masturbated by the end of adolescence, but the figures now are much lower than in the 1940s or the 1970s ([Capes, 1972](#); [Chilman, 1983](#); [Kinsey et al., 1948](#); [Martinson, 1994](#); [Ramsey, 1943](#); [Sorensen, 1973](#)). Those who masturbate often are reluctant to report it, even on anonymous questionnaires ([Clark and Tiff, 1966](#)). The reason for the decline has not been determined. Guilt may play a role, although youngsters who masturbated in the 1940s and 1970s also reported feeling guilty about the practice. Adolescents usually assume that their parents dislike or are disgusted by masturbation. However, parental attitudes have not changed much over time and therefore are not likely to explain the sharp decrease in male adolescent masturbation.

### INTERCOURSE

When adolescent boys become sexually active, they quickly focus on foreplay and intercourse, trying to “score” as soon as possible. Adolescent girls, on the other hand, construe sexual activity in a romantic light, and they try to get to know the partner better but try not to “give in.” This discrepancy paves the way for adolescent boys to have few partners and to be abstinent for approximately 6 months of 12 ([Sonnenstein et al., 1991](#)). After initiating intercourse, girls commonly avoid coitus for an extended period. Many teens have sex once and then not again for several years. Most first sexual liaisons are spur-of-the-moment events that take place at the home of the girl or her partner. The two usually have known each other for some time and are “going steady.” Girls are serious about the relationship, whereas boys tend to see it as casual ([Whatley et al., 1989](#)). When girls do have sex, they tend to think that it was wrong, and they wish that they had remained a virgin until they were married ([Coles and Stokes, 1985](#)).

Adolescents who feel close to their parents and who share the parents' values are less likely to have sex at an early age ([Fox, 1981](#); [Jessor and Jessor, 1975](#); [Shah and Zelnik, 1981](#)). When parents control dating, adolescents are less likely to initiate intercourse or become pregnant ([Hogan and Kitigawa, 1985](#)). This reflects the fact that early and frequent dating commonly precedes the first sexual experience ([Thorton, 1990](#)). Adolescents who view their parents as “moderately strict” are less likely to be sexually experienced than those who view their parents as “permissive” ([Miller et al., 1986](#)).

Sociopolitical forces in the United States focus on how to diminish “high-risk” behaviors. The stated goal is abstinence for all youth, although few expect that this can happen. Negative statistics figure prominently in the media, but current data indicate that although the number of sexually active teens increased in the 1970s and early 1980s, teen pregnancy rates actually decreased in the 1990s, falling 15% from the 1991 high of 116.5 per 1,000 women aged 15 to 19 years to 98.7 in 1996. Among the factors accounting for this decline are decreased sexual activity, increased condom use, and the availability of depot and parenteral contraceptives ([Hofferth, 1990](#); [Ventura et al., 2000](#); [Wyatt, 1990](#)).

In the past, the assessment of whether teens were sexually active was based on a single question: “Have you had sex?” The current trend is to ask for more information such as past and most recent frequency of sexual relations and number of partners. Still absent are questions about sexual enjoyment, erotic fulfillment, or relationship to self-worth. Reliability and validity of data are hampered because the definition of “having sex” changes over time and varies from place to place and from group to group. Only 40% of students at one university thought that oral sex was “having sex,” whereas 80% thought that peno-anal sex did qualify. Genital touching was considered “having sex” by one in eight women and one in six men ([Sanders and Reinisch, 1999](#)).

### CHOICES

Adolescent contraceptive use has improved since the early 1980s, but many youth never or rarely use it ([Santelli and Beilenson, 1992](#)). In the United States, adolescents initiate intercourse at approximately the same time as teens in Western Europe and Canada, but they are more likely to become pregnant ([Jones et al., 1985](#)). Compared with Sweden, Australia, and England, North American 15-year-olds, especially girls, acquire their contraceptive knowledge late ([Goldman and Goldman, 1982](#)). There are many reasons why adolescents do not choose contraception: for boys, this is commonly related to the drive to prove themselves or to “score” quickly when the opportunity presents. In the heat of passion, contraceptive measures seem irrelevant. Boys often view contraception as the girl's responsibility. Girls may not think about contraceptive use because they do not plan to have sex in the first place. Having sex “just happens” to them because they are overtaken or persuaded by the boy or because they are in love and powerless to resist. Many teenage girls think that planning to have sex would prove that they are immoral. The net result is that adolescent girls are very unlikely to use contraception at first intercourse ([Zelnik and Shah, 1983](#)).

One-third of all abortions are performed on adolescents ([Santelli and Beilenson, 1992](#)). Girls are more likely to opt for an abortion if they are younger, doing well in school, planning for the future, have better-educated parents, have little religious involvement, and have friends with negative attitudes toward pregnancy ([Hofferth, 1987](#)). When an adolescent girl becomes pregnant and does not have an abortion, this may be related to her need to remain close to her own mother, rebellion against the parents, self-destructive or self-defeating tendencies, guilt and religious convictions, the need to be loved by an infant, or the fear of entering dating, vocational, or educational arenas. Unfortunately, the culture tends to view the unmarried pregnant teen as “getting what she deserved” for having had sex.

A common assumption is that adolescents who would feel guilty about having sex are less likely to go ahead and have sex. [Davidson and Moore \(1994\)](#) compared adolescent girls who experienced much guilt over sexuality with those who reported relatively little guilt. Those with considerable guilt felt uncomfortable with their sexuality and were unlikely to be sexually satisfied. There was a strong correlation between guilt, high-risk behavior, and low self-esteem, suggesting that guilt strongly inhibits sexual development but not sexual activity. Those who report sexual guilt react to erotic stimuli with a major increase in negative affect ([Wiebe et al., 1994](#)). We do not know if this is so for boys, but we do know that boys experience as much guilt over masturbation as girls do ([Coles and Stokes, 1985](#)).

Vocational opportunity in a tight labor market that allows teenagers to be gainfully employed is a major reason why today's motivated adolescents are less likely to have sex early or to become parents of an out-of-wedlock child than adolescents in the 1970s or 1980s. Conversely, those adolescents who have less ability and motivation, low achievement, and poor grades are more likely to have sex and to become pregnant at an early age ([Abrahamse et al., 1988](#); [Hofferth, 1987](#); [Robbins et al., 1985](#)). Recent decreases in illegitimate births may be entirely due to improved economic circumstance. Motivation and job availability also affect the sexual activity of adolescent boys. Boys who forego sex in high school are less likely to drop out of high school and more apt to go on to college ([Kinsey et al., 1948](#); [Sonnenstein et al., 1991](#)).

### SEXUAL DYSFUNCTION

Adolescents who attend college have intercourse less often and with fewer partners than they did in 1979, and they are more ambivalent about it ([Darling and Davidson, 1986](#); [Yates, 1993](#)). Female students are more anxious about the social consequences of having sex, whereas male students are more worried about disease. Fifty-five percent of male college students describe themselves as afraid to engage in sexual intercourse; 44% doubt if there is such a thing as safe sex; 11% think that they have an abnormal fear of sex; and 10% want help for a sexual problem ([Katz et al., 1989](#)). Eleven percent of male students experience erectile dysfunction and 20% have premature ejaculation ([Miller and Cirone, 1978](#)). Only 28% of sexually active female students say they are satisfied. Students are too embarrassed to talk about problems, and they rarely seek help.

A number of authors ([Kaplan, 1974](#); [Masters and Johnson, 1966](#); [Martinson, 1994](#); [Money, 1989](#); [Schaefer, 1973](#); [Yates, 1978](#)) build a reasonable case that adult sexual function depends in part on a positive process of eroticization during the early years. Parents who accept normative sexual activity and who provide constructive messages about the body are thought to enhance erotic development. Studies that address these issues are few and often based on small samples and retrospective data ([Reynolds, 1997](#)). However, [Bauserman and Davis \(1996\)](#) found that when college students recalled early sexual experiences in a positive light, they reported greater sexual satisfaction and were more accepting of sexual issues. Subjects reporting only negative early experiences were similar on all outcome measures to those reporting no early experiences. [Finkelhor \(1980b\)](#) noted that girls who recalled sexual experiences with siblings after 9 years of age reported greater sexual self-esteem as young adults. [Reynolds \(1997\)](#) found that young women who reported more frequent sex play demonstrated a sexual self-concept characterized by low sexual conflict/anxiety, high arousability, and high sexual self-esteem. Frequency of recalled sex play was associated with being involved in a sexual relationship, enjoying it more, having sex more frequently, and engaging in a greater variety of sexual behaviors. On the other hand, [Leitenberg et al. \(1993\)](#) noted that the simple occurrence or nonoccurrence of sexual activity in preadolescence or early adolescence did not seem to be related to the sexual adjustment of young adults. Although the data overall support a relationship between early positive perceptions and adult function, the likelihood of retrospective distortion is high. Only a well-designed prospective study of normal sexual development could settle the issue. Study design would need to include direct interviews of children concerning their sexual thoughts, fantasies, and activities.

## THE FUTURE

When historians describe President Clinton's legacy, they may suggest that he opened up more than world trade. His term in office was marked by a significant event: The first time that any sitting president was publicly humiliated for having an affair. The media endlessly repeated every last detail, including the semen stains on the blue dress and the specifics about oral sex. President Clinton responded first with denial and embarrassment, and was visibly shaken. But in the months that followed, he acknowledged the event, asked forgiveness, tried to make amends, was eventually able to talk openly about it, and even wrote a book. Far from being exiled, he enjoyed greater success in office and his family remained intact and supportive. The First Lady said in essence: "He's a good person who does bad things." By these tokens, sex became more understandable, a part of the human condition. The children were watching.

Critical research is on hold because researchers are not allowed to question children about sexual attitudes and events. In the distant past and briefly during the 20th century, adults were able to ask such questions. It can happen again—but not without a major shift in social policy. Perhaps when this generation of youngsters grows up, they can change social policy. They will have had access to web eroticism and to "how to" articles in popular magazines, and they will know more than their parents ever did about sex. They will remember their parents looking at, and laughing at, erotic scenes in prime-time sitcoms, and becoming so embarrassed that they could not discuss the material. They will remember in school the carefully screened and sanitized materials on the dangers of sex. When these children mature, they may decide that enough is enough. The adults are being hypocritical. What better crusade for a new generation?

## 21 FAMILY DEVELOPMENT AND THE ROLES OF MOTHERS AND FATHERS IN CHILD REARING

Kyle D. Pruett, M.D.

[Chapter References](#)

Families render humans human. Genetic endowment and maturational forces strongly predispose to the relationships and intimacies that draw the infant into the human race, one interaction at a time. But it is the family in all its permutations that ultimately embraces that child's maturational promise and, through powerful reciprocal, interactive forces, converts tissue, synapse and instinct into human development. In this chapter, we examine the unfolding of that process through the exploration of the basic unit of all emotional development, the family.

Although families vary enormously, they tend to share certain processes while moving through the life cycle of birth and burial. At first glance, it would appear that family processes would be easy to delineate because they seem linear (i.e., birth to growth to death). Family process itself, however, is more cyclical than linear. Family content is determined by the whole-family emotional system, including at least three generations. Those three generations, which have periodically lived together in large numbers in our culture, are accommodating to their own unique life cycle agendas simultaneously. At every moment in its life, the family exists at the intersection of two distinctly different linear axes. One axis is the trail of generational myths, expectations, attributes, memories, and secrets—the family's "givens." This is the family's narrative about itself, so articulately described by [Pincus and Dare in \*Secrets in the Family\* \(1978\)](#) and [Vangelisti \(1994\)](#). The narrative evolves like folk songs in the oral tradition passed on through children being taught who and what their family is now, has been, and is hoped (if not expected) to be.

The other axis is the family's forward progression through the dimension of time in its own life cycle. This encompasses the usual stresses and opportunities of the family's children's developmental requirements and the intrusion of "fateful events." Whether a family gets into trouble is determined in part by whether these two axes intersect at strong or weak points because they perpetually cross and recross each other. Real trouble seems most likely when a vulnerable stretch on the transgenerational axis intersects with an equally vulnerable stretch on the developmental axis. For example: The family narrative trail carries forward a myth/expectation that "Jones boys always marry wild women" at a time when, on the developmental track, the Jones' first-born son is beginning his adolescence by easing up on his academic discipline and starting to push against behavioral boundaries. He tells his parents less and less about his life and whereabouts (a developmentally appropriate change), especially where girls are concerned, and his and his family's fantasies about "wild women" collide with his own unique developmental course.

Family development as a phenomenon is hard to embrace in all its complexity, precisely because the clinician tends to encounter families, normal or not, at just one nodal point in time, depriving him or her of critical longitudinal perspective. Research hints that we have significantly underestimated the life cycle connections between early loss, trauma, or disturbance and later interpersonal dysfunction ([Ainsworth and Eichberg, 1991](#); [Borkowski and Ramey, 2001](#); [Bowen, 1978](#)). At the same time, we often are uncertain about which direction the causal links are moving (i.e., a vulnerable child who destabilizes the family, or vice versa?) ([Wamboldt and Wamboldt, 2000](#))

Cycles of family life are undergoing accelerating change. Lower birth rates, increasing divorce and remarriage rates, and longer life expectancies have reduced childbearing from being the major occupation of parents to what is now less than 50% of parents' lifelong commitment.

Historians urge caution in referring to "unprecedented change." Through careful research, [Demos \(1970\)](#) and [Laslette and Wall \(1972\)](#) have largely dispelled the myth of the ideal three-generational family holding sway in preindustrial family life. A process was begun then, however, that did affect major change in overall family functioning, and it is coming to fruition now. [Hareven \(1982\)](#) summarizes: "Through a process of differentiation, the family gradually surrendered functions previously concentrated within it to other social institutions. During the pre-Industrial period, the family not only reared children, but also served as a workshop, a school, a church and an asylum" (p. 460). The difficulties faced by contemporary families are rooted in this diminished capacity of the family to adapt and cope (partly because of smaller size) and the further decline in the variety of the family's socioeconomic functions.

The declining maternal and child death rates of the 1950s combined with a higher marriage rate and longer life span to create a higher percentage of children growing up in stable, two-parent families than had ever occurred in America. Beginning with the next decade, however, trends began to erode both the ideal and real traditional nuclear family. The sexual revolution uncoupled the association of sexual and reproductive behavior. From 1971 to 1998, the percentage of unmarried American girls 15 to 19 years of age who engaged in sexual intercourse rose from 28% to 56%. Curiously, figures are unavailable for boys, as though only female sexual activity is related to family formation. Second, the movement into the paid workforce of married women with children saw an increase from the 1960 level of 19% of married women with children younger than 6 years of age in the labor force to a real figure of 64% in 1999. Historian Robert [Griswold \(1993\)](#) noted that these forces, combined with attitudinal changes toward coparenting, have brought increasing numbers of fathers into the nurturing domain, regardless of whether they want to be there.

Fertility and fecundity also declined in the United States beginning in the 1960s. We are now at levels lower than those necessary for the replacement of the population, having moved from an average of 3.7 children per woman in 1960 to 1.79. This may well reflect a dissatisfaction with parenthood, in association with a significant decline in the stigma associated with being childless.

Finally, the divorce rate in America brought us past a landmark in 1974, when for the first time in our history, more marriages concluded in divorce than in the death of a spouse. Nine divorces per 1,000 marriages in 1960 became 26 per 1,000 in 1998. The percentages of single-parent families, including single by choice, unmarried and same-sex couples, and serial and stepfamilies have all increased, whereas nuclear unit percentages continue to decrease.

It is the opinion of many clinicians and researchers that the quality of life for children in the past 25 years has not improved at the same rate as it has for adults. Also, rates of distress seem to be on the rise. [Achenbach and Howell \(1993\)](#) studied the changes over 13 years in the prevalence of children with behavioral/emotional problems. He found more untreated children who needed psychological intervention in the 1989 sample than in the 1976 sample. Every child needs and longs for two biological parents in and for his or her life. Simply stated, child rearing is more successful when it involves both biological parents who are committed emotionally to the job in all its complexity. This is not to say that this is the only way to bring child development to fruition. However, it is to say that, as a group, nurturing forms other than the biological family are likely to struggle with more risk factors. In practice, however, we see repeatedly that, regardless of form, families, as opposed to institutions, promote development most efficiently by buffering, cushioning, and protecting young children while they are learning new ways to cope with the world about them. [Patterson \(1983\)](#) strongly suggests that the relation between stress and developmental outcome for isolated individuals is different from that for children who are part of a social group, the former being at more risk.

Some of these statistics illustrate an important, irreducible fact about change in the American family. Women are in the labor force to stay. Families have changed, yet the institutions the families rely on most heavily, schools and the workplace, have been much slower not only to change but to respond to the changes in the family system ([Galinsky, 1986](#)). The family structure that is most influential in the child's development, however, is the one perceived by the child as *his* or *her* family, not the one perceived by the Census Bureau.

Each child who enters the family changes it permanently and irreversibly, rendering the child's perception of the family unique to his or her own experience. [Sameroff and Fiese \(2000\)](#) have helped us move away from the restrictions of the linear, interactional model of child development, and toward one that better encompasses the progressive, dynamic, reciprocal forces that have helped children change families and vice versa. Their "transactional model" emphasizes the need for incorporating social and economic as well as biological forces. Proposing a "continuum of caretaking causality," such increased emphasis on the qualitative aspects of the nurturing

domain has encouraged clinicians and researchers to think anew about who in the family is doing what with the children, and not simply how long they are doing it.

The Berkeley Adult Attachment Interview ([George et al., 1985](#)) in its application to family development ([Main et al., 1985](#)) is an example of growing interest and skill in our capacity to assess the adult's state of mind (and not simply his or her behavior) with regard to attachment to his or her children, and vice versa. The interview for the Adult Attachment Classification System is done separately with mother and father. This is an example of how we are returning to the exploration of the overriding significance of the quality and intent of the nurturing interaction, and not merely the biological predispositions of the interactors.

Mothers, fathers, grandparents, siblings—all form unique attachments to children that, in formative settings, are welcomed and easily integrated by the child into a mosaic of consistent, predictable, comforting internalizations of the nurturing experience. Therefore, internalization of the nurturing experience, be it positive or negative, is not merely the result of a single adult attachment. Much clinical literature, however, falls short in its attempts to clarify distinct maternal and paternal antecedents to psychological syndromes. [Bezirgianian et al. \(1993\)](#) found that maternal overinvolvement paired with maternal inappropriateness combined to form pathogenic predispositions toward borderline personality disorder in children. Although paternal means were included, they were not commented on in the discussion.

Optimal child development is fostered by optimal family development. This occurs by translating the recognizable maturational stages of child development into the transactional modalities and developmental dynamics of the family. Optimal family development, as perceived by the child, begins with a secure individual attachment, which the infant must make with its primary caregiver, typically the mother, although fathers as primary caregivers certainly have the capacity to rear their children without placing them at developmental risk ([Pruett, 1983, 1987, 2000](#)). In fact, [Radin and Harold-Goldsmith \(1989\)](#) cite the advantages to young children of paternal involvement, almost regardless of the reasons for the father's presence. The other optimal phenomenon for promoting development in the family network consists of the capacity of mothers and fathers to form reciprocal, empathic relationships with the child, aided by a broad and complete range of affective expression. The parent must be ready to accept developmental progression and change because it comes rapidly, particularly in the first year. It is best if the children are appreciated for their unique and idiosyncratic traits, temperaments, skills, and weaknesses.

Despite the dramatic increase in the number of publications on fathering since the mid-1980s ([Lamb, 1997](#)), fathers continue to be so underrepresented in the literature compared with mothers that one sees a staggering deficit. A major prospective, longitudinal study on parental psychopathology and parenting styles as they relate to the risk of social phobia in children failed to include *any* data on fathers ([Lieb et al., 2000](#)). [Phares and Compas \(1992\)](#) reviewed research papers in the major journals dealing with clinical child development published from 1984 to 1991 and found that nearly half of all studies involved mothers only. Nearly one-fourth of the remaining studies did include father-related material, but did not bother to differentiate its effects. The final one-fourth did measure father-child effects and found them consistently present. So when researchers bother to look for father effects, they always find them. The authors suggested that the overreliance on mothers as research participants has fostered not only an incomplete data set with regard to child development, but also one that is heavily gender biased because "relations cannot be found among variables that are not investigated" (p. 406).

Before beginning a chronologic view of family development across the life cycle, clarification of certain phenomena that guide family function is in order. In understanding the family as a system, we are accustomed to conceptualizing change in one segment of the family as resonating throughout that system, and any negative or positive change in one segment of the system as either promoting or discouraging development in others. Homeostasis is the way that families conserve their energy, socialize their young, and balance risk and protective factors ([Werner, 2000](#)). Yet the demands of rapidly evolving maturational forces in the child offer continual perturbations to that homeostasis. Therefore, it is important for us to understand how to view a family's potential success in preparing its children for adulthood.

[Skinner et al. \(1983\)](#) created the Family Assessment Measure, consisting of a general and dyadic scale to distinguish reliably between normal and problem families. [Mrizek et al. \(1995\)](#) developed the Parenting Risk Scale, which uses a semistructured interview to rate difficulties and concerns regarding parental commitment, knowledge base, control, psychiatric disturbance, and emotional availability. [Fleck \(1989\)](#) has offered an efficient, five-factor method for assessing the system's capacity to support the development of its children, consisting of (a) leadership, (b) boundaries, (c) emotional climate, (d) communication, and (e) the establishment and accomplishment of goals and tasks throughout the life cycle. As we begin to examine the family's development across the life cycle, it is critical to remain conscious of these five factors.

*Leadership* is defined as the decision-making, facilitating source of power and discipline used by the parents who lead the family unit. It is shaped by the presence or absence of mutual support and esteem and by the effectiveness of the communication between the leaders of the family unit.

*Family boundaries* refer to (a) boundaries within the individual that define the self, (b) boundaries between generations, and (c) boundaries between the family and the community. It is important that these boundaries be semipermeable, permitting contact and discourse with others outside the family boundary. Self- and generational boundaries remain relatively stable throughout the life cycle, whereas family/community boundaries must become increasingly permeable as children cross them more frequently to participate in the community about them.

The *emotional climate* or affectivity of the family unit is the connective tissue that binds the family together into a functioning body. It sustains, or erodes, the family's capacity to care for and support one another, especially since the family has ceased to be such an essential economic unit. Chronic scapegoating of a family member, child abuse, and neglect are classic signs of failure in the family's emotional climate.

*Communication* within families is verbal and nonverbal. Communicative language itself and its uses for deepening relationships are learned best within the family. Experiences and feelings are shared through the medium of language, whereas values and culture are differentiated and reinforced by consistency of communication within the family.

Finally, the expectation that families will *nurture and socialize* their young, so that they develop into contributory members of society is the burden placed on the aforementioned functions. The success or failure of this expectation is determined by the way the family achieves its goals for individual members and sets the members' tasks toward reaching those goals. Goals and tasks throughout the life cycle change and evolve in complex ways and, unlike communication or boundaries, seem not to diminish in significance over time.

Cultural influences powerfully shape the tasks of the family across the life span. As child-rearing domains become increasingly complex, it is essential that clinicians and researchers remain vigilant for the normative cultural and functional forces that frame a particular family's expectations, strengths, and vulnerabilities in *their* context ([Johnson-Powell and Yamamoto, 1997](#); [Pruett, 1999, 2000](#)). Values about dependability, family loyalty, intimacy, autonomy, and extended family access vary widely and normatively ([Coll and Magnuson, 2000](#); [Rey et al., 2000](#)).

Appreciating values in context also is critical for the growing number of children raised in families of same-sex parents. Social and cultural isolation and conflict in certain communities often stem from the failure to appreciate such a family's contextual needs and competencies ([D'Augelli and Patterson, 1995](#)), rendering the children at greater risk in certain developmental stages, especially the transition to adolescence ([Lock and Steiner, 1999](#)).

Family development itself usually is arbitrarily divided into stages for better understanding of its predictable developmental phenomena. This approach can mask the enormous complexity of the relationship systems implied therein, which expand, contract, and realign to support the entrance, development, and exit of family members in profoundly meaningful ways emotionally, culturally, and historically. We tour these stages with an eye to the contributions made by the nurturers and the nurturants, examining the unique and differing roles of mothers and fathers as participants and facilitators of normal development across the life cycle.

## COUPLING AND FAMILY FORMATION

Family formation renews every time heterosexual gametes join. The human pair responsible for nurturing the newborn brings conscious and unconscious motivations, both libidinal and aggressive, to their coalition. The choice of mate is governed by a web of intrinsic and experiential factors, tempered by the degree of separation from the family of origin. Contemporary family formation frequently is characterized by a period of joint cohabitation. Making a deliberate, conscious decision about family formation strongly predisposes toward health, just as an unconscious, nonjoint decision predisposes to risk. One of the strongest unconscious motivations toward coupling is the wish to acquire in one's mate a longed-for or incomplete aspect of oneself. This can strongly predispose toward stability in the marriage. There is evidence to suggest that this may have an ameliorating effect on eventual family formation despite previous negative experiences, particularly on the part of the mother in her own childhood nurturing interactions. [Eichberg \(1987\)](#) has found in her research using the Adult Attachment Inventory that the father's role is positively ameliorative of a mother's ([Main, 1992](#)) negative experience with her own parents.

When the coupling results in marriage, it is a joining of two complex historical, interpersonal, emotional, and financial systems. Couples are marrying later and postponing birthing their children: The average age of marriage for women in 1998 was 22.8 and for men 24.7 years, and the birth of their first child came on average 1 year and 10 months later. This implies there is a relatively short time given to adjusting to this phase in the life cycle. Sociologists show us there does seem to be a relatively narrow window for the timing of this phase. Women are twice as likely to divorce if they marry before the age of 20 years than if they marry during their 20s. They are half again as likely to divorce if they marry after 30 years of age than if they marry during their 20s ( [Glick and Norton, 1978](#)). A variety of other factors also can contribute to difficulty at this life cycle transition: (a) the couple resides at either great distance or close proximity to either family of origin; (b) the couple meets or marries in close proximity to a significant loss; (c) the couple marries after knowing each other for fewer than 6 months or an engagement lasting over 3 years; (d) the wedding is performed without family or friends; and (e) the wife becomes pregnant before or within the first year of marriage ( [Bacon, 1974](#); [Becker, 1987](#)). It does seem that the rise in women's status is correlated with marital instability and with the increasing, although not absolute, marital dissatisfaction of their husbands. We are clearly in a successful transition toward more egalitarian relationships, and the educational and occupational equality of the sexes is a perturbation to couple formation as we currently know it ( [Burke and Weir, 1976](#)).

## FIRST CONCEPTION, BIRTH, AND NURTURANCE

This era begins with conception and ends at the end of the child's first year. There is much psychological work to be done by both mother and father in preparing for and dealing with conception. There also is enormous variability in the amount of conscious deliberation devoted to the decision to conceive a child. Once conception does take place, planned or unplanned, complex psychological responses follow in both wife and husband. The mother struggles with profound changes occurring in her body during pregnancy and after delivery.

Meanwhile, much of the psychological work is fueled by a conscious reassessment of the couple's own family experience. A new identity begins to come to fruition, that of *being* a parent, not just having one. What makes this riveting is that both maternal and paternal identifications are deeply rooted in each individual. The mother prepares herself psychologically for the coming attachment to her infant by drawing her attention to her own inner experience and her growing fetus, as her preoccupation with the outside world decreases.

Fathers are involved in psychological work of a different sort, albeit active and equally important in terms of preparation. Food cravings, somatic preoccupations such as vague gastrointestinal disorders, and nutritional changes are widely reported. Concern about his adequacy as a provider and protector may erode an expectant father's self-esteem. Mood changes, frequently expected in mothers, also occur in fathers. "Even before the birth of his child, the father's life, his body, and his mind are busy making ready in ways of which he may only have a passing awareness" ( [Pruett, 1987](#), p. 28). Birth preparation classes may be helpful and supportive to both mothers and fathers in promoting a sense of mutual commitment and in explaining the universal pleasures and fears during the pregnancy and birth phase. Both mothers and fathers have complex mental images of their children long before the child sees the light of day.

But nothing is more powerful than the parental experience of the birth in terms of its long-term impact. First impressions are enormously powerful for both mothers and fathers. Attachment and bonding research have clearly articulated for us the importance of the mother–infant haptic and tactile involvement in the hours after birth. Fathers who are present at the birth are more verbal about their babies, more accurate in describing them, and more intimately attached to them at follow-up.

The newborn's job is just as complex as that of his or her parents. The neonate must first stabilize and regulate his or her internal life to the point where he or she is able to perceive and respond to events in the external world by processing sensory, vestibular, and human interactional input ( [Ramey and Ramey, 1999](#)). Next, the newborn must use his or her repertoire of skills and intrinsic reflexes to elicit pleasurable experiences from the human world, which will make it possible for the newborn to fall in love and establish an intimate attachment to the main caregiver.

Finally, the infant must make use of pleasurable experiences to communicate with the important objects in the world around in a meaningful and personable way in order to be entertained, stimulated, fed, and have his or her bodily functions attended to. Both mothers and fathers with or without experience learn, by on-the-job training, to read, as well as anticipate their infant's signals. Empathic connections and the capacity to comfort, soothe, woo, and entertain are tasks common to both mothering and fathering. Qualitative differences are present, however, in the idiosyncratic ways in which mothers and fathers respond. Mothers tend to respond to their babies on a more intimate scale, facilitating fine motor development and affective differentiation. Fathers tend to be more active and gross-motor involved. Nevertheless, as shown by [Parke and Sawin \(1975\)](#), fathers were able to feed their babies as effectively and efficiently, although somewhat differently stylistically, as their spouses.

Infants appear quite interested in and responsive to the differences between paternal and maternal interactive styles. [Yogman \(1982\)](#) noted that by the time infants were 8 weeks old, they were responding differently to their fathers and mothers. At 6 weeks, infants hunched their shoulders and lifted their eyebrows when their fathers appeared in their visual field. The same infants, when they saw or heard their mothers, seemed to expect more routine functional handling such as feeding or diapering and became settled rather than animated.

The involvement in the first year of life of two caring and competent adults appears to have a positive effect on overall cognitive development. [Pedersen et al. \(1979\)](#) found that the more actively involved a 6-month-old had been with his or her father, the higher the infant's scores on the Bailey test of mental and motor development. Also, [Parke \(1979\)](#), in examining children over the first 8 weeks of life, found that the more fathers were involved in everyday, repetitive, boring aspects of care, such as bathing, feeding, dressing, and diapering, the more socially responsive the infants were. It is in the mutual pleasures of this early experience that the adults, who have now moved up a generation and become caretakers to the younger generation, feel their own personal development frequently propelled forward to new levels of empathic—even altruistic—connections, not only with their children but also with other important objects in their lives.

## TODDLERHOOD AND INDIVIDUATION WITHIN THE FAMILY

The child's astounding increase in mental and physical resources propels him or her out of the omnipotence of the first year of life into a much more social context, in which new skills permit more active shaping of the need-satisfying environment. The development of language, increasing sophistication in cognitive structures, mastery over motility and sphincters, and the incorporation of gender identity and gender role expectations all prepare the child for the complex sequences of the vital separation–individuation process ( [Zeanah et al., 2000](#)). Parents are alternately challenged through intense clinging and contentious interchange, giving this era ambivalence as its marquis. Aggression, care taking, love, anger, and sensuous intimacy are now part of the toddler's repertoire ( [Pruett, 1999](#)). This makes limit setting a vital companion to the toddler's adventurous experimentation with challenging, aggressive, and seductive behaviors. At the same time, the parent is wise to be led by the toddler, rather than attempt to lead the toddler ( [Lieberman, 1993](#)). By now, fathering styles are quite differentiated from mothering styles of interaction, with fathers initiating more rough-and-tumble, unusual, unpredictable, physical, and stimulating forms of play. [Billar and Meredith \(1974\)](#) noted that mothers tended to engage in more conventional, toy-mediated play, picking up their children to engage in care-taking and nurturing activities more than fathers. Because the child has increased his or her level of mastery over the internal environment, he or she has a good deal more energy available to explore the boundaries of the external environment, giving separation tasks a much higher valence during waking life. Adjustments to the toddler's new, if clumsy, drive for autonomy are necessary to avoid prolonging the child's functional dependency. Because separation from the mother sometimes is the fuel for the sleep disturbances that are common during the second year of life, the father can help decrease the virulence of nighttime disruption by being the one who goes in to soothe and settle the child, spelling the child from another separation from the mother, while helping the child feel safe and secure.

Clearly, the child's unique temperament and style interact with parental values and experience with regard to personal autonomy, separateness from family of origin, and impulse and bodily control. The unique contributions of the father during these years have been increasingly recognized as vital to the success of this developmental era ( [Greenspan, 1982](#)).

## THE PRESCHOOLER AND THE OEDIPAL CONSTELLATION

The preschool child's appropriate use of personal pronouns, ability to say "no," and increasingly adaptive capacities all draw the family as a whole further into a new domain that will be characterized by the time the stage is complete by three-party rather than two-party relationships. Curiosity, assertiveness, and the capacity to begin to delay gratification help the child regulate and moderate intense instinctual feelings and affects. Cognitive growth, meanwhile, assists the child in learning and remembering what the important objects in his or her life will or will not tolerate. By the beginning of this phase, parents should have largely discarded baby talk because both the child and the parents can have a more satisfactory communicative interaction. Reasonably adept parents are able to respond with affection, empathy, and a minimum of rejection to the preschool child's bid for intimate, controlling attention from the parent of the opposite sex. Appropriate, predictable limit setting and humor play important roles in helping the heterosexual relationships between child and parent withstand the heavy weather of strong rivalrous feelings.

Latent oedipal issues, especially incomplete or conflictual ones, often are resolved with surprising force in the parent metapsychologically. By now, parents are able to yield most control over bodily functions to the child, relinquishing him or her as a physical possession, and admiring and encouraging his or her attributes as a separate, gender-specific human being who is beginning to understand the joys of the delay of gratification.

During these preschool years, fathers interact with their children mainly through play and productivity. Through role modeling, the father provides opportunities for children of both sexes to build increasingly positive self-esteem ( [Sarnoff, 1982](#)).

The press of developmental needs during this period, highlighted in research, shows us a critical relationship between marital satisfaction and parental involvement. There is much research that indicates marital satisfaction to be at its lowest ebb during the childbearing years ( [Glenn and McLanahan, 1982](#)). [Waldron and Routh \(1981\)](#) note that marital satisfaction follows a U-shaped graph, with high levels of marital comfort before children are born and again after they leave home. Frequently, children place such significant demands on the couple that there is little energy left to fuel the marital relationship, although it is not suggested that children destroy marriages (even though in some instances they may be permitted or even encouraged to do so). [Rapoport et al. \(1977\)](#) report that marriage often is experienced by fathers as better than by mothers during this nadir of marital satisfaction because it is mothers who usually have more negative experiences with their children, feel more isolated, and are more vulnerable to psychosomatic stress ailments, including fatigue.

Although the discrepancies between maternal and paternal experience during this phase of the life cycle can be problematic, including occasional envy and jealousy on the part of the parent who is having the more difficult and challenging time with the preschool child, the long-term effects of having both parents involved intimately during this phase are strongly positive. One of the most dramatic findings in the father–infant care research is the relationship between early involvement and subsequent sexual abuse. If a man is involved in the physical care of his child before the age of 3 years, there is a dramatic drop in the probability that man will be involved later on in life with sexual abuse of his own or anyone else's children ( [Parker and Parker, 1984](#)).

## SCHOOL, LATENCY, AND FAMILY UNITY

The timely desexualization of the child–parent relationship allows the child to make powerful psychological investments in adults other than his or her own parents, initiating the first disillusionment in one's parents. Just as the child's body is relinquished from parental control, so is the child's mind. The family now helps the child separate for most of his or her waking hours to attend school and confront its social and cognitive challenges. Large amounts of energy are made available for relating to other children and adults, as well as for learning and problem solving. License must be granted for further exploration; at the same time, limits are placed in a reasonable, comfortable manner. The integration of family and tradition, as guided by societal mythology, serves as the hallmark of this period of development. Themes of internal control begin to compete with the pursuit of pleasure as the integrated 7- or 8-year-old strives for balance. During this period, it often is easier for a family to spend prolonged, uninterrupted segments of time with one another for travel, leisure activities, and neighborhood projects. Interestingly, girls may have only one or two friends they would call “best,” whereas boys may name six or seven friends, who usually turn out to be somewhat more casual acquaintances. It is acknowledged that, as children age, the disciplinary role of the father must increase. But during the school-age and latency period, a father may serve as a confidant, a pal, even a friend or teacher ( [Benson, 1968](#)). The opportunity for shared activities and mastery experiences with adults of the same sex is extremely important in terms of the solidification of gender role behavior and gender identity itself. Father absence, however ( [Pearson et al., 1994](#)), leads teachers to rate both boys and girls as more aggressive relative to mother–father families. Especially poignant was the finding that the protective factors for mother–father families were not as apparent among low-income families.

## ADOLESCENCE AND GENERATIONAL REDEFINITION

Families of adolescents must use boundaries that are qualitatively different from those in families with younger children. The boundaries must now assist the children in managing their own impulses because parents no longer have or can practice complete authority. The boundaries between the family and the outside world must become more permeable without being destroyed. There is a normal careening between independence and dependence. A sense of self is beginning to be consolidated and shaped by values, the search for pleasure, and particular goals and tasks. The primary object relationship between the parents and the teenager now must be retooled for the transition from childhood to adulthood. The teenager is involved in a regular, normative struggle between independence and dependence. The adolescent also is becoming intensely interested in his or her constantly changing body. Values and “do unto others as they would have you do unto them” beliefs are subject to greater scrutiny. Developmental stress does not necessarily doom the family to turmoil during this phase, but profound physical and psychological changes threaten the previous level of homeostasis in the family. An adolescent notices weaknesses and unusual vulnerabilities in the family, as well as in his or her own psychological functioning, but these also may be seen as possible points of departure for new adaptive functioning. But adolescent observations are notoriously selective. Bulimic teenagers and young adults rated their fathers as showing less affection and more control toward them than their nonbulimic siblings, suggesting that the paternal relationship may be a source of nonshared environmental experience associated with bulimia nervosa ( [Wonderlich et al., 1994](#)).

Adolescence often is a period of significant stress in the family because both the adolescents and their parents often are experiencing significant physiologic and mental changes at the same time. Both generations may be scrutinizing their primary attachments anew and questioning their value and trustworthiness. Just as the adolescent is beginning to make choices regarding values and career goals at the beginning of his or her work life, the parents are needing to accept that certain cherished goals may never be achieved, and they may become quite preoccupied by the limited time left in their lives.

As the adolescent begins to pull further away from the nurturing domain through going to college or taking a full-time job, the parental response can be one of either pride in their child's capacity to cope with life's new challenges or sadness over what appears to be the permanent loss of one's own progeny.

The family as a whole can have its homeostatic behavior deeply challenged by an adolescent's need to extract his or her autonomy from the parental nurturing domain.

Young adulthood and emancipation, the marriage of offspring (the middle family), and, finally, aging and senescence are the last three phases of normal family development. The kind of influence parents now have on their children is largely encompassed by their availability for discussion and advice and by bearing witness to their children's integrity, while being careful to plan and sustain their own autonomy. Grandchildren come next, providing a rejuvenation of spirit and body, not to mention occasions of joy.

The developmental tasks faced by the child and the child's caregivers are the same whether the structure of the family is nuclear or reconstituted. The energy and resources, both emotional and physical, to attend to those tasks is strongly influenced, however, by a particular family's structural limits and flexibility. Adoptive, single-parent, foster, and recombined family groupings are all subject to the same leadership, boundary, affectivity, communicative, and task and goal requirements. The issues of attachment, separation, emancipation, loss, and response to change are largely the same. Each exerts its own particular spin on normal development, but none is by dint of family structure alone doomed to trouble.

Adoptive families do not have the same biological preparation time, although given some luck, they can follow a similar psychological preparation sequence. The separate biological parents' narrative must be integrated into the family's mental history of itself in some fashion. Single-parent families, whether male- or female-headed, face depletion and isolation early and often and work best when social support systems are early and flexible enough to supplement parental and child care. Even oedipal phase resolution need not be impossible, given the child's regular access to familiar and caring adults of the opposite sex.

Recombined and reconstituted families, when a divorced, widowed, or never-married single parent forms a household with a new partner who may or may not be a parent, also are increasing exponentially. These families do face risks. Depending on the mechanism of parental singleness (death, divorce, abandonment), the new parent may be seen as a threat or solution to intimacy between parent and child. Rivalry and jealousy frequently stimulate guilt and anxiety, especially when the same-sex parent has been displaced or replaced. Interestingly, [Black and Pedro-Carroll \(1993\)](#) have shown that the effects of interparental conflict on the psychological well-being of children were mediated more by the overall quality of parent–child relationships than by interadult conflict itself. Stepparents frequently are in risk situations, being tested by their “new children” while simultaneously feeling special loyalty to their “old children” and trying to sustain a new spousal relationship. Time (measured in years), patience, and liberal, frequent communication (sometimes new to everyone as a process) plus permission to parent are all essential. Society's myths do not help either. *Stepmother* in English conjures up Cinderella's stepmother, and *stepfather* in Spanish is *padraastro*, which also means *hangnail*.

On a smaller scale, all families face some of the same issues because families are always reconstituting, biologically and psychologically. Because of the relentless push of developmental and maturational forces in the individuals of our species, like the river, one can never step into one family in the same place twice.

By definition, infancy is the period of life between birth and the emergence of language, 1.5 to 2 years later. Despite its brevity, this phase of development has long attracted a disproportionate amount of attention and interest, but infancy as we know it was not considered a distinctive and important stage of life until late in the 18th century ([Aries, 1962](#); [Plumb, 1972](#)), and it was not until the 1960s that a variety of scientific, social, medical, and political trends converged to generate professional interest in human infancy ([Kessen et al., 1970](#); [Lamb et al., in press](#)). In the three decades of intensive theorizing and research since then, a number of core issues have emerged, and these issues constitute the centerpiece of this chapter. Among the most important of these issues are the following: To what extent do “innate” as opposed to experiential factors influence infant behavior and development? How great an impact do early experiences have on later development?

### THE NATURE–NURTURE DEBATE

Although the nature–nurture debate is now centuries old, the issues at its core remain central to the study of infancy. Historically, the study of development—especially cognitive and perceptual development—was driven by the nature–nurture debate. Extreme views were put forward by the empiricists on the one hand and the nativists on the other. Empiricists like John Locke and William James asserted that there is no endowed knowledge at birth, that all knowledge comes through the senses, and that perceptual development reflects learned associations. They argued that external stimuli naturally provoke bodily “sensation” and that, through association, separate raw sensations can fuse into meaningful perceptions.

The belief that humans begin life “empty headed” was considered both philosophically intolerable and logically indefensible by nativists like René Descartes and Immanuel Kant, who proposed that humans were endowed at birth with ideas or “categories of knowledge” that assist early perception and cognition. They postulated that human beings possess innate perceptual abilities to tell size, form, position, and motion, as well as more abstract conceptions, such as knowledge of space and time.

Historically, a gradual shift in orientation can be discerned in the debates between nativists and empiricists. Initially, a so-called main effects model applied: Either environment or constitution was considered to be important. In the middle of the 20th century, however, an interactional model achieved popularity ([Anastasi, 1958](#)). Unlike proponents of the main effect model, interactionists offered an additive view, in which nature and nurture were believed to *interact* to shape development. Twenty years later, the transactional model was articulated by [Sameroff and Chandler \(1975\)](#); they argued that inherent characteristics are shaped by experience and vice versa and that a constant process of mutual influence continues throughout the life span.

Although developmental psychologists now generally agree that neither experience nor biology alone determines behavior, the 1990s have seen a renewed, transformed nature–nurture debate. Advances in genetics have led to renewed interest in behavioral genetics, and researchers with diverse interests are now collaborating on large-scale longitudinal studies, typically studying adopted children and their parents (e.g., [Deater-Deckard and Plomin, 1999](#)) or twins (e.g., [Saudino et al., 1999](#); [Segal, 1997](#)) to assess the magnitude of genetic and environmental contributions. [Scarr \(1993\)](#) and [Harris \(1998\)](#) have taken the more extreme position that, within the range of normal environments, behavioral variability among individuals is largely accounted for by genetic influences, and indeed, a surprising range of individual characteristics are heritable ([Collins et al., 2000](#)). Others argue that “the range of normal environments” is too imprecise a term and that, in fact, it is just these details of socialization patterns that are crucial to an understanding of development (e.g., [Baumrind, 1993](#)).

Like Collins, we take the view that biological adaptation and experience codetermine the course of development; infants are born with simple yet important behavioral proclivities that both constrain and direct development by delimiting the potential for experientially driven change. An infant who is congenitally distractible, for example, is likely to learn slowly about the objects seen or heard because he or she is unable to attend to or concentrate on them for long periods. Biological factors also determine which events may reinforce infant behavior because certain events inherently complement certain experiences. A bad taste, for example, will make an

infant stop eating a certain type of food much more rapidly than would a loud noise that repeatedly accompanied ingestion of that food (cf. [Garcia and Koelling, 1966](#)).

Two kinds of biologically based tendencies exist. Species-typical tendencies are those that all humans share. These include predispositions to cry when distressed; to respond to others' cries so as to alleviate them; to attend to novel sounds, smells, or sights; and to ignore those that have become boringly familiar. By contrast, heritable influences are those that distinguish one person's tendencies from those of another and are the basis of genetically rooted individual differences. Both species-typical and heritable tendencies have important influences on development. [Rothbart and Bates \(1998\)](#), for example, have reviewed recent research documenting the extent to which early differences in temperament predict later psychological maladjustment, and [Kagan \(1998\)](#) has conducted research suggesting that individual differences in behavioral inhibition are stable over time as well.

As far as experiential or environmental influences are concerned, [Gilbert Gottlieb \(1983\)](#) suggests a useful distinction among inductive, facilitative, and maintenance functions. Induction is the most dramatic form of influence. It occurs when a particular experience or set of experiences completely determines whether a capacity, behavior, or tendency will emerge. Facilitation occurs when certain experiences speed up or slow down the emergence of capacities, behaviors, or tendencies. Finally, maintenance describes a situation in which experiences preserve already developed capacities, behaviors, or tendencies.

We view both experiential and environmental influences as functioning together, so that it is impossible to assess the extent of their involvement. This chapter repeatedly notes the ways in which biology (in the form of predispositions and innate propensities) constrains or facilitates experience and learning.

## THE CONTINUITY DEBATE

The continuity debate focuses on the importance of early experiences. Some view the experiences and behavior patterns developed in infancy of crucial importance to later life. Social orientations, motivations, and intellectual predilections established in infancy set lifelong patterns. Others argue that infancy is not of overriding importance because experiences in infancy have little (if any) long-term predictive significance.

### Proponents of Continuity

Early-experience proponents arrived at this position from a diverse array of theoretical starting points. [Sigmund Freud \(1940/1968\)](#) was the first major theorist to focus attention on infancy, justifying this focus by suggesting that the ways infants are treated establish lifelong orientations and personality traits. Freud proposed that there are critical phases in development when certain sorts of experience—affecting specific types of traits—are of special significance. Infancy falls within Freud's oral phase of development, during which feeding experiences and other activities centered on the mouth are particularly relevant. Toward the end of infancy, Freud continued, the oral phase yields to the anal phase. During this period, caretaker–infant interactions center on toilet training and are likely to have long-term consequences as well. However smoothly development unfolds in this phase, though, it is never possible to override any oral problems established earlier; difficulties can be overcome only by “reliving” earlier experiences through lengthy psychotherapy.

[Erik Erikson \(1963\)](#) portrayed early experiences and their effects rather differently. From the early feeding experiences, he suggested, children develop a degree of trust or mistrust in the caretaker rather than concrete oral traits. He also believed that the quality of early interactions (i.e., how much “basic trust” the infant develops) has implications for the way the infant will negotiate the next stage of development, in which the key issue is establishing autonomy or shame. With respect to toilet training, therefore, Erikson emphasized not the anal organs but the status of toilet training as a battleground of wills as the child tries to exert initial control (by determining when to give the caretaker the prize the caretaker seeks). Erikson described eight developmental stages, each marked by a crucial issue: Basic trust/mistrust is at issue in the first stage; autonomy/shame is at issue in the second.

Erikson's view of how early experiences affect the child's later personality substantially improved on Freud's in two major ways. First, Erikson portrayed the lessons learned in each phase in more abstract, general terms (e.g., trust, autonomy) than did Freud (e.g., orality, anality), and the psychological issues described indeed seem pertinent to the stages concerned. Second, Erikson explicitly proposed that the ways in which different stages are resolved are somewhat interrelated. From Erikson's perspective, how much the infant trusts the caretaker may affect the infant's willingness to cooperate in toilet training and other matters. This initial mistrust may yield not only a mistrustful adult but one plagued by unsuccessful resolution of later developmental issues as well.

Unfortunately, the ideas of Freud and his followers, including Erikson, were phrased in mentalistic terms that rarely evoked respect from research scientists. Behaviorists and learning theorists like John B. Watson, Clark Hull, and Neal Miller dominated developmental psychology from the second to the sixth decade of the 20th century. Like the psychoanalysts, these theorists emphasized the importance of infant experiences, and Miller even attempted to rephrase many of Freud's ideas in terms compatible with behaviorism ([Dollard and Miller, 1950](#)). Learning theorists treated early experience in a fashion very different from that of Freud and Erikson, however. Behaviorists eschewed the notions of stages and phases of development. For the learning theorists, early experiences are important because they are first, have no competing propensities to replace, and, thus, yield easy and rapid learning. Moreover, early behavior patterns are believed to serve as foundations for more complex behavior patterns, such as personality traits.

A third group of theorists, most of them ethologists and students of animal behavior, adopted a notion of “critical periods” that also emphasized early experiences ([Bornstein, 1987](#)). The ethologists argue that there are predetermined periods in the maturation of organisms during which development is maximally susceptible to influence by specific types of experiences. Just as Freud spoke of an oral phase during which feeding experiences make the greatest impact on the developing personality, the ethologists spoke of a critical period for imprinting and for various other behavioral tendencies. During critical periods, lessons are learned more easily and demonstrate greater endurance than hitherto or later possible. This notion accorded biological and scientific support to Freud's own and was later integrated into [Bowlby's \(1969\)](#) theory of attachment (see later) and [Lenneberg's \(1967\)](#) theory of language development (see later). The critical periods concept, and its modern “sensitive periods” emendation, assigned great importance to early experiences because it held that once a particular critical period had passed, it was no longer possible for specific experiences to exert formative influences on the developing organism.

Although this diverse group of theorists underscored the formative importance of early experiences, popular commitment to the proposition developed as a result of some dramatic empirical observations published between 1930 and 1950. At that time, reports that children who were reared in impersonal institutions were psychologically stunted led to widespread belief that children needed close relationships in infancy and that, if they were denied such relationships, they would not develop into psychologically healthy individuals ([Bowlby, 1951](#)).

An additional perspective on the continuing importance of infancy was offered by students of cognitive and intellectual development. [Jean Piaget \(1936/1953, 1937/1954\)](#) theorized that all intellectual capacities are built on the simple developments that take place very early in life, and thus, by the early 1960s, hardly anyone doubted that early experiences were especially important. Two trends resulted: a massive increase in the amount of research on infancy and the first attempts to engineer enriching experiences for deprived children in the form of such programs as Head Start. By capitalizing on the special sensitivity of the very young, politicians hoped to “immunize” children against the debilitating effects of later deprivation. More than anything else, the apparent failure of these interventions triggered a decline of confidence in the notion that early experiences were especially influential.

### Proponents of Discontinuity

One of the most vocal opponents of the overemphasis on early experiences was [Jerome Kagan \(1971, 1980; Kagan et al., 1978\)](#), who more recently has come to emphasize the importance of continuity in biogenetic tendencies ([Kagan, 1998](#)). Kagan argued that maturation—the unfolding of genetically determined capacities and individual differences—has been undervalued, and he pointed to research indicating that major differences in rearing environments have little apparent effect on the way children behave. For example, he argued that day care and home care have remarkably similar effects on developing infants ([Kagan et al., 1978](#)) and that even the extreme impoverishment of the rural Guatemalan environment does not retard intellectual development ([Kagan and Klein, 1973](#)).

Kagan's arguments were roundly criticized by researchers who argue that his measures may not be sensitive and that the problem therefore lies in the assessment, not in the concept, of experiential influence. Nevertheless, claims that there is little continuity in development have attracted a great deal of attention. Such conclusions were inevitable because of earlier, oversimplified notions about how infant experiences influenced later development. The difficulty lies in overreliance on the main effects models of development (like Freud's), holding that early experiences have obvious and direct short- and long-term effects. Unfortunately, simple linear relations almost never are empirically substantiated ([Caldwell, 1964; Lamb et al., 1985; Sameroff, 1975; Sameroff and Chandler, 1975](#)).

### The “Transactional” View

Sameroff's transactional model has now replaced the linear or main effects model. Both child and parent are believed to bring distinctive characteristics to every interaction. The child's characteristics affect how the child behaves, how parents treat the child, and how the parents' behaviors affect the child. The parents' characteristics have the same consequences. During each interaction, both parent and child are psychologically changed, and so they enter the next round of interaction as different individuals. From this perspective, it is naive to expect any single experience to have direct long-term effects, for its impact will be diffuse, triggering multiple indirect effects (e.g., also changing the adult's behavior). Nevertheless, events in infancy are important because they initiate such multiple processes of development.

Using this model, [Sameroff and Chandler \(1975\)](#) were able to explain why prematurity, like other types of perinatal risk ([Siegel, 1981](#)), does not always have ill effects. Parents cope with atypical infants in different ways, some providing deprived environments that do not afford the types of experiences that prematurely born children need to offset their potential for developmental delay. Premature infants would be at risk over the long term only if reared in such environments. Thus, to make long-term predictions, it is necessary to consider at least the characteristics of the child, of the parents, and of the family's physical and social environment. Because linear models typically focus on only one of these factors, it is not surprising that their predictive power is poor. One implication of the transactional perspective is that continuity from infancy may be carried *indirectly*, through continuity in the supporting environment, or continuity from infancy may be carried *directly*, through continuity in the infant, or it may be that both are important ([Lamb et al., 1984, 1985](#); [Nash and Hay, 1993](#); [Thompson, 2000](#)). Grossmann and Grossmann (1986), for example, found that there was a significant level of stability in neonatal performance from day to day on the Brazelton Scales ([Brazelton, 1973](#)) and that it was possible to divide their sample into "good" and "bad" orienters. Subsequent observations of the mothers and infants at home allowed the Grossmanns to assess the mothers' behavioral sensitivity. All six of the infants who were good orienters and who had sensitive mothers developed "secure" attachment relationships at 12 months; however, poor orienters with tender and sensitive mothers did so only approximately one-third of the time. Good orienters with sober-talking and less sensitive mothers had only a 38% chance of being "securely attached," whereas only one of the eight infants (13%) who were poor orienters and whose mothers were insensitive developed "secure" attachments. Viewed together, these data suggest that the characteristics of the child and the characteristics of the mother jointly determined what sort of attachment they form—just as Sameroff and Chandler predicted. Of course, the Grossmanns' small sample made it imperative to replicate these findings independently, but they do constitute an elegant confirmation of the transactional model. In this chapter, the ways in which genetically determined tendencies interact with both early and later experiences to shape development are repeatedly described; consistent with the transactional theorists, the authors see development as a continuing process of consolidation and change.

The focus now shifts, however, from overarching issues to specific aspects of development, beginning with perception.

## PERCEPTUAL DEVELOPMENT

Perception constitutes a necessary first step in experiencing and interpreting the world, and for this reason philosophers, psychologists, physiologists, and physicists alike have been attracted to the study of perception. In fact, the study of perception was initiated by philosophers who were interested in the nature–nurture debate, but it also provides information about the quality, limits, and capacities of the sensory systems at the start of life. In this section, we selectively review research on visual and auditory perception, the modalities that have been studied most extensively.

### Visual Perception

## PATTERN PERCEPTION

In the 1960s, [William Kessen \(1967\)](#) reasoned that it ought to be possible to assess infant vision, even at birth, simply by "looking at looking." He and his colleagues photographed the reflection of a stimulus on infants' corneas and found that, even in the first hours after birth, infants looked selectively at parts of stimuli where there was information—usually high-contrast features—instead of scanning the background or central parts of figures randomly.

Subsequent research using this corneal reflection technique has asked not only what the infant looks at but how scan patterns develop and how infants scan different visual shapes, such as faces and geometric forms. Younger infants scan in a limited fashion, whereas older infants scan patterns more widely and efficiently ([Slater and Johnson, 1998](#)). From research on infant scanning, [Haith \(1980\)](#) determined that newborns actively seek visual stimulation and input, scanning the environment to find things to inspect. Newborns also focus most of their attention on the boundaries of figures, where the greatest amount of information is contained. Studies of organized scanning do not tell us *how well* infants see or *what* they see, however. To examine visual acuity in infants, [Fantz et al. \(1962\)](#) capitalized on the observation that infants prefer heterogeneous to homogeneous patterns, posting pairs of patterns for infants to look at; one member of the pair was always gray and the other a set of black and white stripes that varied systematically in width. (The two stimuli were always matched in overall brightness.) The stripe width that failed to evoke a preference was viewed as the one delimiting the infant's ability to tell stripes from the solid gray. By this measure, 2-week-olds showed 20/800 vision (in Snellen notation), whereas 5½-month-olds showed 20/70 vision. In the 40 years since Fantz and colleagues' original study, techniques for measuring infant visual acuity have grown in sophistication, but the results agree well with their findings ([Kellman and Banks, 1998](#); [Slater and Johnson, 1998](#)). Acuity improves steadily from birth and is nearly as good as that of adults by 6 months of age ([Slater and Butterworth, 1997](#)).

Several studies suggest that young infants can perceive some patterns as whole forms. [Slater et al. \(1991\)](#) showed that even newborns perceived and habituated to stimulus compounds, and [Ghim \(1990\)](#) showed that infants as young as 3 months of age recognized (and thus habituated to) the "subjective contours" of figures that did not actually exist on the page but appeared to do so. Further, [Philip Kellman \(1984; Kellman and Spelke, 1983\)](#) studied infants' knowledge of two- and three-dimensional objects when habituated to partly occluded versions of the objects or to multiple perspectives; 4-month-olds who experienced objects moving under these conditions treated them as wholes. Infants also are highly attracted to faces; either because of some innate predisposition ([Mondloch et al., 1999; Slater and Butterworth, 1997](#)) or because faces contain features such as three-dimensionality, movement, sound production, and areas of high contrast that infants find intrinsically interesting ([Slater, 1993](#)). Through everyday experiences, infants then learn to discriminate among different faces ([Bushnell, 1998; Johnson and Gilmore, 1996](#)).

Infants also seem to discriminate orientation well: They discriminate vertical from horizontal ([Bornstein, 1982; Hayes and Watson, 1981](#)) as well as other orientations ([Bremner, 1994](#)), and even adjust a reaching hand properly to match the orientation of a target ([Von Hofsten and Fazel-Zandy, 1984](#)). Patterns that are aligned vertically or horizontally are preferred and detected more readily than those aligned obliquely ([Bornstein, 1982; Held, 1989](#)), with vertical stimuli appearing to be the most preferred, perhaps because infants visually scan predominantly along the horizontal ([Haith, 1991](#)).

## DEPTH PERCEPTION

Depth perception is crucial to determining the spatial layout of the environment, to recognizing objects, and to guiding motor action. The study of depth perception also addresses an interesting psychophysical question, namely, how we perceive the three-dimensional information. Depth perception has served as a kind of battleground between nativists and empiricists. Debate on this question exemplifies the typical historical course: It began with hotly contested disputes between nativists and empiricists that spanned the 17th to 19th centuries and ended only with experimentation in the 20th century.

In the early 1960s, [Gibson and Walk \(1960\)](#) began to investigate depth perception in infants experimentally, using a "visual cliff." One side of the cliff shows the infant an illusory drop, but the other side does not. Gibson and Walk found that almost all infants they tested between 6 and 14 months of age crawled over the glass continuation of the center board on the shallow side when their mothers called them, whereas only a very small minority of infants crawled across the "deep" side. From these results, Gibson and Walk concluded that depth perception must be present in infants as young as 6 months of age. By 6 months, however, children have had plenty of experience perceiving depth. [Campos and colleagues \(1970\)](#) therefore studied precrawling infants by monitoring heart rate when the infants were exposed to shallow and deep sides of the visual cliff. They found that infants as young as 2 months of age showed defensive changes in heart rate when exposed to the deep side. These differences suggest that infants may perceive depth long before they crawl.

The visual cliff experiments represent one way investigators have sought to explore the capacity to perceive depth. Another mode of study involves observing avoidant or "looming" responses to objects approaching on a hit path. [Yonas \(1981\)](#) reported that infants as young as 1 month blinked their eyes in response to approaching objects but that the "looming response" could not be demonstrated reliably until children reached approximately 4 months of age.

A third strategy for investigating depth involves studying sensitivities to isolated visual cues that typically signal depth. Convergence, for example, depends on an organism's capacities to fixate an object binocularly and to fuse the two disparate retinal images into one. If infants rely on convergence of the eyes to cue depth, as [Descartes \(1638/1824\)](#) and [Berkeley \(1709/1901\)](#) proposed, theorists need to show that the eyes indeed converge. We have all noted, however, that infants often

seem unable to fix both eyes on an object (called *strabismus*). Researchers have observed only minimal convergence of the two eyes at 1 month, but regular convergence by 2 to 3 months ([Hainline et al., 1992](#); [Kellman and Banks, 1998](#)). It is at this time that infants also first display sensitivity to the deep side of the visual cliff ([Campos et al., 1970](#)).

In summary, studies of the visual cliff, of looming, and of monocular and binocular sensitivity in infants converge to suggest that depth perception may be relatively poor until approximately 2 months after birth. The development of depth perception is not complete by 4 to 6 months of age, however, although infants have the capacity for *relative* distance perception by this age and are known to use monocular depth cues such as relative size, interpretation, and shading by 7 months of age ([Granrud, 1993](#)), and kinetic cues, such as changes in texture, by the same age ([Kellman and Banks, 1998](#)). Because binocularity can provide information about absolute distance only if interocular distance is known, *absolute* distance calibration may depend on nonvisual sources of information. Theorists such as [Jean Piaget \(1937/1954\)](#) have argued that infants can tell the absolute distance of objects in near space only after they have had experience reaching, and the distance of objects in far space (i.e., beyond reach) only after having experienced crawling.

We know that young infants can *locate* stimuli in space, in part from studies of reaching for objects. Recording following motions, goal-directed behaviors, and types of reaches to objects located at different distances and moving at different velocities, [Von Hofsten \(1984\)](#) reported that infants as young as 4½ months reach and contact an object, even if it is moving, and that their reaching is accomplished in a way that indicates good predictive targeting of location. Until recently, it was believed that such reaching and grasping of objects resulted from visual guidance of the hand toward the object. However, [Ashmead et al. \(1993\)](#) found that it is not until approximately 9 months of age that the opportunity to see the hand helps infants make adjustments to a change in target locations. Similarly, [Clifton et al. \(1993\)](#), tested very young infants' (up to 6 months of age) abilities to reach for objects in the dark (only the targets were illuminated), and found that sight of their own hands was not necessary for reaching and grasping. Nevertheless, infants' initial knowledge of location is highly egocentric; only by the end of the second year does a more environment-centered representation of space become well developed ([Bremner et al., 1994](#); [Hermer and Spelke, 1996](#)).

Locomotion also affects depth perception: Infants who crawl or have experience in a "walker" extract form from a fluctuating display and avoid the deep side of the visual cliff earlier than those without comparable experience ([Campos et al., 1992](#)). [Adolph \(1997\)](#) subsequently showed that locomoting infants use perceptual information to adapt their locomotion and exploration "on foot" of novel surfaces.

## COLOR

By 3 months of age, infants are nearly as acute as adults when the task is to compare brightness differences between stimuli presented simultaneously ([Kellman and Banks, 1998](#)). Thus, in studies where the task is wavelength discrimination *per se*, it is possible to unconfound hue and brightness either (a) by matching colors in brightness using an adult standard in regions of the spectrum where infants and adults are known to match or in conditions testing successive discrimination (as [Chase, 1937](#), and [Bornstein, 1975](#), did); or (b) by varying brightness against hue, so that brightness differences are irrelevant (as [Peeples and Teller, 1975](#), [Mercer et al., 1991](#), and [Adams et al., 1994](#), did). In each case, infants of 2 to 4 months of age were shown to perceive color, and [Adams et al. \(1994\)](#) showed that neonates could distinguish red from gray but not blue, green, or yellow from gray.

So-called color-blind people make identifiable color discrimination errors, and they also confuse certain wavelengths with white. [Bornstein \(1976\)](#), [Teller et al. \(1978\)](#), and [Adams et al. \(1986\)](#) found that newborns, 1-month-olds, and 3-month-olds could discriminate blue-green from white and could discriminate between yellow and green, suggesting that infants are not green-blind, and even 1-month-olds are not blue-blind, a rare third kind of color blindness ([Varner et al., 1984](#)). In addition, the red/green and yellow/blue sensitivity of 1- to 3-month-olds is similar to that of adults ([Banks and Shannon, 1993](#); [Teller and Lindsey, 1993](#)). The development of color vision right after birth has not been studied very well, but it is clear that some sensitivity to color is apparent in most newborns and that these capacities improve quite rapidly.

Adults do not just see colors; they perceive the color spectrum as organized qualitatively into categories of hue, and the infant's color perceptions seems to be similarly organized. Infants as young as 4 months of age perceive the hues blue, green, yellow, and red categorically and in ways similar to those of adults ([Bornstein, 1981a](#); [Bornstein et al., 1976](#)). We do not know whether newborns also perceive color categorically because the phenomenon has not yet been studied at that age. However, after reviewing the physiologic, anthropologic, and psychological literatures, [Bornstein \(1981a, 1984\)](#) concluded that the ability to perceive color categorically probably is both universal and early appearing, reflecting the normal physiologic function of the visual system. Furthermore, there is evidence for a preference for chromatic over achromatic stimuli from birth, although preferences for particular colors do not emerge until the third month; unlike adults, 3-month-olds prefer red and yellow to blue and green ([Adams, 1987](#)).

## Auditory Perception

Even though audition is of major importance to the infant, much less is known about audition than about vision in early life ([Aslin et al., 1998](#)). Newborns can hear sounds: Make a sudden loud noise, and a neonate will startle. Further, acuity of hearing improves rapidly over the first few days after birth as amniotic fluid drains from the ear.

## BASIC AUDITORY PROCESSES

Sound is specified principally by two variables: frequency, the rate at which sound waves vibrate, and amplitude, the intensity of sound waves. Humans hear sounds in the frequency range of approximately 20 to 20,000 cycles per second, or hertz (Hz). For adults, auditory threshold varies with the frequency of the sound: Both low and high frequencies (above or below 1,000 Hz) require more energy than middle frequencies (around 1,000 Hz) to be heard. Infants clearly discriminate among sounds that differ in frequency, complicity, or pattern; they appear to hear low-pitch sounds less well and high-pitch sounds better than adults ([Olsho, 1984](#); [Schneider et al., 1980](#)), and even newborns prefer music over noise ([Trainor and Trehub, 1993](#)). Nearly continuous developmental improvements in hearing at low and high frequencies occur during the first 2 years ([Aslin et al., 1998](#)). Changes in ear structure or nervous system maturation could account for this increasing developmental sensitivity.

In addition, even though infants have smaller heads than do adults, and the locations of sound depends on the distance between the ears, infants are remarkably good at finding the sources of sounds in their environments. By 4 months of age, infants reach in the dark toward a sound source ([Clifton et al., 1994](#)), and by 6 months of age, localization responses are comparable with those of adults ([Clifton et al., 1991](#); [Hillier et al., 1992](#)).

## SPEECH PERCEPTION

Infants' excellent hearing abilities ([Aslin et al., 1998](#)) are applied almost immediately to the highly complex task of perceiving speech. In general, human speech is centered at relatively low frequencies, and numerous investigators have suggested that human speech is special for infants, who seem to be especially "tuned" to the speech register ([Eisenberg, 1976](#); [Fernald, 1984](#)). [Berg and Smith \(1983\)](#) found that even 6-month-olds are more sensitive to 500- and 2,000-Hz tones than to 8,000-Hz tones. In addition, infant-directed speech unusually includes higher pitch, more exaggerated intonation, more rhythmicity, and more repetition than adult-directed speech, and infants clearly maintain attention to infant-directed speech ([Kaplan et al., 1995](#); [Werker et al., 1994](#)).

The topic that has intrigued researchers most, however, has to do with the infant's ability to perceive special aspects of speech. Adults perceive differences in voicing more or less *categorically*; that is, although we can distinguish fine differences in the onset times of low- and high-frequency sounds, we tend to classify different examples of the same voiced (/b/) or voiceless (/p/) sounds as similar, but easily discriminate between voiced and voiceless sounds. Of course, different people say /b/ and /p/ in different ways, yet adult listeners seldom misidentify speech sounds because they use implicit category definitions to determine whether a sound falls within the /b/ or /p/ categories. Many people have assumed that phenomena so ubiquitous and significant as the categorical perception of speech sounds might have a biological foundation. To test this assumption, [Eimas et al. \(1971\)](#) asked whether preverbal infants perceive voicing categorically and found that they did: 1- and 4-month-olds distinguished between variants of /b/ and variants of /p/.

Not all languages use all voicing categories. [Eimas et al. \(1971\)](#) tested an English category distinction in American infants, but if categorical perception is innate, it ought to be universal, and infants from communities where different patterns of voicing prevail should all make the same categorical distinctions. In general, they appear to do so ([Bertoncini, 1998](#); [Plunkett and Schafer, 1999](#)). For example, Spanish has a voiced-voiceless distinction that is not in the same frequency location as the English one, yet Spanish 4- and 6-month-olds discriminate the English voiced-voiceless sound contrast rather than the Spanish one ([Lasky et al., 1975](#)). Likewise, Kikuyu (Kenyan) 2-month-olds categorize both an English voicing contrast not present in Kikuyu, as well as an idiosyncratic Kikuyu prevoiced-voiced contrast not present in English ([Streeter, 1976](#)). Interestingly, Spanish and Kikuyu adults perceive (although they do not use) the English voicing contrast, but they

perceive it only weakly; between infancy and maturity; therefore, a perceptual discrimination that is present at birth atrophies (but is not lost) if not used ( [Lively et al., 1994](#)). According to [Best \(1995\)](#) and [Jusczyk \(1995\)](#), 6-month-olds can discriminate among many phonetic contrasts but are already screening out categorical variations that are meaningless in their native language ( [Kuhl et al., 1992](#)). Thus, certain perceptions seem to be universal and developed at birth; they are maintained by linguistic experiences but may decay if absent from the language heard by the child, whereas other perceptions can be induced or altered in infants and children by exposure to certain speech sounds.

The existence of innate capacities to perceive speech sounds and color categorically underscores the perceptual competence of newborn infants. Together with tendencies to seek out stimulation and rapid developmental increases in perceptual acuity, they show that infants are designed for the efficient extraction of information about the environment. Acuity in the other perceptual modalities—the tactile and chemical (olfaction and gustation) senses—also is impressively good ([Brand, 1997](#); [Mennella and Beauchamp, 1996](#)), but unfortunately, these modalities have received little attention from researchers. The next section examines the ways in which infants build on their perceptual experiences by learning.

## CONDITIONING, HABITUATION, AND NOVELTY PREFERENCE

Learning “refers to a more or less permanent change in behavior which occurs as a result of practice” ( [Kimble, 1961](#), p. 2), and there has been considerable debate concerning the process and content of infant learning. Mechanistic theorists like Watson and Skinner believed that cognitive and emotional development depended on the infant’s ability to learn associations between contiguous actions or events. Moreover, they argued that any environmental stimulus could be associated with any response, given a sufficient amount of practice. By contrast, organismic theorists like Jean Piaget argued that learning could be understood only in light of the organism’s phylogenetic and experiential history. As is shown in this section, infants can and do form stimulus–response associations, but not between any stimulus and response. First, classical and operant conditioning and the conditions under which they have been demonstrated in human infants are discussed, followed by habituation and novelty preference and their use in investigating detection/discrimination, categorization, and concept formation.

### Classical Conditioning

The classical conditioning paradigm was developed by [Ivan Pavlov \(1927\)](#), who reported that the salivation response could be elicited in dogs by a ringing bell alone after several trials in which the bell was followed by placement of food in the dogs’ mouths. In this paradigm, salivation was the *unconditioned response*, which was reliably elicited by food powder, the *unconditioned stimulus*. The ringing bell initially had no effects on salivation and was said to be a *neutral stimulus*. However, the bell acquired the power to elicit salivation after being repeatedly paired with the presentation of food. The bell was then termed the *conditioned stimulus*, and salivation became the *conditioned response*.

Classical conditioning deals exclusively with reflexive and autonomic response systems over which the organism apparently has little control. Pavlov and his followers theorized about the importance of classical conditioning for the acquisition of language, culturally prescribed behaviors, normal and neurotic habits, and cognitive processes like thought and problem solving, but few today believe that classical conditioning plays a central role in the development of thought and language. However, many believe that it can help explain how specific emotions become associated with specific stimuli (such as in the development of phobias). Moreover, classical conditioning has provided important information about the types of stimulus–response associations newborns and older infants are “prepared” to make, allowing insights into how the infant mind is organized.

Classical conditioning is not easily demonstrated in newborns, but researchers have successfully conditioned sucking ( [Blass et al., 1984](#); [Lipsitt and Kaye, 1964](#)), heart rate ([Clifton, 1974](#); [Stamps and Porges, 1975](#)), the Babkin reflex ([Cantor et al., 1983](#); [Kaye, 1965](#)), pupillary reflexes ([Brackbill et al., 1967](#)), and head turning ([Clifton et al., 1972](#); [Siqueland and Lipsitt, 1966](#)). The difficulty in establishing conditioned responses in newborns probably is due in part to the rapidity with which newborns pass through different arousal states; state may influence the likelihood of response elicitation, latency, and magnitude ( [Fitzgerald and Brackbill, 1976](#); [Sameroff and Cavanagh, 1979](#)). [Clifton and Nelson \(1976\)](#) indicated that most periods of alertness in neonates last less than 10 minutes.

Questioning the traditional assumption that any stimulus could be associated with any response, [Seligman \(1970\)](#) suggested that organisms are prepared, unprepared, or contraprepared to associate specific stimuli and responses. Prepared associations are those that apparently require little learning and that are directly related to an organism’s survival (linking certain stimuli with feeding or food seeking). Unprepared stimulus–response combinations become associated only through learning, whereas contraprepared stimulus–response combinations are hard to associate no matter how extensive the attempts to condition them. [Sameroff and Cavanagh \(1979\)](#) argued that the most direct means of empirically distinguishing learned from prepared stimulus–response combinations is by examining the speed of association: Prepared associations, like those demonstrated in newborns, should occur rapidly, whereas learned associations should take more time. They concluded that newborns were not capable of learning by conditioning.

[Rovee-Collier and Lipsitt \(1982\)](#) argued in response that the ability to form stimulus–response associations rapidly is biologically adaptive for newborns, and thus that rapidity of association is not a sufficient criterion to judge whether learning has taken place. To bolster their argument, they noted that duration of sucking increases when followed by bursts of music of similar duration ( [Cairns and Butterfield, 1975](#)), demonstrating that changes in a biological response system can be effected by nonbiological events. According to [Rovee-Collier \(1996](#); [Weisberg and Rovee-Collier, 1998](#)), all infants are capable of conditioning, but the economics of the response demanded of the infants may sometimes require too great an expenditure of effort to be worthwhile.

After 3 months of age, classical conditioning is more easily demonstrated than in the newborn period, although the concepts of preparedness and biological constraints continue to be relevant. Instead of being able to associate any neutral stimulus with any response, infants appear predisposed to associate temporal conditioned stimuli (i.e., a specified interval of time) with autonomic responses (e.g., pupillary reflexes) and to associate tactile, auditory, and visual conditioned stimuli with somatic reflexes (e.g., eye blinks, sucking) ( [Fitzgerald and Brackbill, 1976](#); [Ivkovich et al., 1999](#)). Thus, specific classes of stimuli are most readily associated with specific classes of responses.

### Operant Conditioning

Unlike classical conditioning, in which a neutral signal comes to elicit an autonomic or reflexive response through repeated pairings with an unconditioned stimulus, operant conditioning increases or decreases the probability of a voluntary, nonreflexive “operant” response by controlling its consequences ( [Skinner, 1932](#)). The underlying principle is the “law of effect,” which states that actions followed by positive consequences (reinforcement) are more likely to be repeated, whereas actions followed by negative consequences (punishment) are less likely to be repeated.

Operant conditioning is more easily demonstrated in newborns than is classical conditioning, although here again the associations that have survival value are learned most readily. Among newborns, operant conditioning experiments typically involve sucking ( [Floccia et al., 1997](#); [Lipsitt and Kaye, 1965](#); [Sameroff, 1968](#)) or head turning ( [Siqueland, 1968](#)), two systems that are critical for newborn survival. After obtaining baseline measures of sucking rate for each 3-day-old infant, for example, [DeCasper and Fifer \(1980\)](#) divided their subjects into two groups. Infants in one group were presented with the sound of their mothers’ voice whenever the interval between successive sucking bursts was greater than the infant’s own average interval, and with the voice of another infant’s mother when the interburst interval was less than average. Infants in the second group heard their mothers’ voice when the intersucking interval was less than average, and the voice of another mother when the intersucking interval was greater than average. Eight of the 10 infants modified their sucking pattern to produce their own mother’s voice more often.

A basic principle of operant conditioning in infancy appears to be that neonatally conditionable responses are those that produce maximum gain for the infant at relative low energy cost ( [Rovee-Collier, 1996](#); [Weisberg and Rovee-Collier, 1998](#)). Higher-energy responses, such as foot kicking, do not appear to be conditionable until after the infant becomes capable of homeostatic thermoregulation, which occurs during the second month.

The propensity to learn associations that have functional significance and require minimal energy expenditure is illustrated by conjugate reinforcement ( [Hayne, 1996](#)), which involves making the frequency and intensity of reinforcement (e.g., the movement of a mobile) contingent on the frequency and intensity of a particular response (e.g., kicking). Learning is easy under conjugate reinforcement, suggest [Rovee-Collier and Gekoski \(1979\)](#), because the contingencies are similar to those that infants encounter most frequently in the real world. For example, intense infant cries are more likely to elicit responses than are weak cries, whereas intense sucking produces more milk than weak sucking. In addition, the behaviors lending themselves most readily to conjugate reinforcement impose low energy costs on the infant while providing information about the parameters that guide the infant’s manipulation of and control over the environment. In addition, merely perceiving the contingency between behavior and an environmental event becomes reinforcing for many infants ( [Weisberg and Rovee-Collier, 1998](#)).

## Habituation and Novelty Preference

Habituation refers to the progressive decline in responding to repeated presentations of a stimulus. The habituation task begins with the presentation of a stimulus, usually visual or auditory, to which the infant's attention is measured. Infants typically respond with longer attention spans during the initial presentations, presumably because the stimulus is novel, but attention declines over subsequent presentations. [Sokolov's \(1958/1963\)](#) theory of orienting and habituation, which stimulated a great deal of work on habituation, postulates that the degree of orientation to a stimulus is a direct function of whatever traces of that stimulus are in memory. The weaker the trace, the stronger the orienting reflex.

Few studies of habituation were conducted in humans before the 1960s, perhaps because it was viewed as a very primitive kind of learning, essentially unrelated to the association process considered central to perceptual, cognitive, and emotional development. In the 1950s and 1960s, however, research suggested that habituation depended on cortical processes that actually were more complicated than those involved in either classical or operant conditioning. For example, [Briullova \(cited in Lynn, 1966\)](#) found that habituation was severely disrupted in humans who had sustained cortical damage, and [Jouvet \(cited in Lynn, 1966\)](#) reported the complete absence of habituation in cats without a neocortex. The role of cortical processes in habituation is not yet clear, however. Research on anencephalic infant, for example, revealed substantial habituation of heart rate responses, suggesting that subcortical brain structures can mediate habituation in at least some instances ([Graham et al., 1978](#)). Other work on the habituation of visual attention in infants ([Cohen, 1973](#); [Jeffrey, 1976](#); [Lewis and Baldini, 1979](#); [McCall, 1971](#); [Olson, 1976](#)) suggests that habituation is a kind of "exposure" learning that reflects underlying brain plasticity. The habituation of visual attention, for example, seems to require some sort of mental representation, memory, internal comparison, and a variety of related perceptual and cognitive activities ([Rose and Tamis-LeMonda, 1999](#)).

Novelty preference involves a straightforward adaptation of the habituation paradigm. In this procedure, the infant is familiarized with two simultaneously presented exemplars of one stimulus for a fixed time and is then tested with a novel stimulus that is paired with the familiar stimulus. The proportion of time that the infant looks at the novel stimulus during the test trial is taken as a measure of novelty preference. Greater attention to the novel stimulus is believed to indicate a memory for the familiar stimulus.

Generally speaking, habituation and novelty preference are easily demonstrable in newborns ([Slater, 1995](#); [Slater et al., 1996](#)) and have been used more extensively than operant and classical paradigms to document individual differences and developmental changes in infant learning abilities. [Slater et al. \(1984\)](#) found habituation and recovery in infants as young as 3 days of age using both simple black-and-white and complexly colored stimuli. By 3 months of age, nervous system maturation and improved state organization ([Parmelee and Stern, 1972](#)) permit longer periods of alertness and improvements in learning ability and memory. These improvements continue with increasing age, along with concomitant developments in infants' information-processing abilities and motor coordination.

Habituation, novelty preference, and variants of these procedures have been used with infants to investigate the processes of detection and discrimination, categorization, and concept formation. Detection and discrimination are denoted by dishabituation when a novel stimulus is presented after habituation to the familiar stimulus. As described earlier, infants in the first few months of life successfully discriminate among various geometric forms, colors faces, sounds, odors, and phonemes ([Aslin et al., 1998](#); [Bushnell, 1998](#); [Kellman and Banks, 1998](#)). Categorization and concept formation (i.e., clustering a group of perceptually unrelated stimuli according to some underlying function, theme, or construct) usually are explored by habituating infants to several exemplars of a concept or category ([Hayne, 1996](#); [Oakes et al., 1997](#)). The formation of a concept or category is assumed when infants display habituation to familiar exemplars of the "old" concept or category, generalize habituation to novel exemplars of the old concept or category, and dishabituate to exemplars of an unrelated concept. Using this procedure, infants have been shown to form many different concepts or categories, including chromaticity, numerosity, gender, sounds, facial expressions ([Caron and Caron, 1981](#)), letters, furniture, and types of animals ([Bahrick et al., 1997](#); [Bornstein, 1981b, 1998](#); [Colombo et al., 1997](#); [Eimas, 1975](#); [Oakes et al., 1997](#); [Quinn, 1999](#); [Quinn and Bhatt, 1998](#); [Strauss and Curtis, 1981](#); [Younger and Fearing, 1999](#)). In general, it seems that infants first categorize using global categories within which they gradually recognize subcategories ([Mandler, 2000](#); [Quinn and Johnson, 2000](#); [Younger and Fearing, 2000](#)). The abilities to categorize items and to represent them internally are, of course, fundamental cognitive skills.

Overall, then, we see that infants are born with the ability not only to perceive objects and events but also to remember and associate them as well (see [Chapter 16](#)). Initially, memory span is quite limited, but improvements take place throughout the first year; within the first trimester, infants can remember an association for as long as 2 weeks, especially when prompted ([Rovee-Collier et al., 1980](#)). The easiest associations for infants to learn are those that are biologically prepared, and while these may comprise the limits of learning capacity in the neonatal period, older infants are capable of learning unprepared associations, especially when the energetic costs of responding are low. Perception and learning are the basic building blocks of cognitive development, the topic to which we now turn.

## INFANT INTELLIGENCE

Interest in the definition and assessment of infant intelligence stems from three conceptually distinct perspectives on the nature of intelligence. The Piagetians believe that intelligence exists on the "plane of action" for much of the infant's life, with true thought emerging only by the end of the second year. In the sensorimotor period of intelligence (0 to 24 months), six qualitatively different substages are distinguished (see [Chapter 12](#)). The psychometric perspective is most closely associated with the assessment of infant intelligence, guiding the construction of such measures as the Gesell and Bayley Scales (see [Chapter 40](#)). The following section selectively reviews research identifying environmental predictors of individual differences in infant intelligence and discusses the relation between effectance motivation and infant intelligence. The information-processing perspective on infant intelligence has evolved more recently and is concerned with how efficiently infants encode and store environmental stimuli in memory (see [Chapter 16](#)). It has been useful in sharpening our understanding of infant intelligence and its relation to intelligence measured at later developmental periods.

### Piaget's View of Infant Intelligence

Born in Switzerland in 1896, Jean Piaget was formally trained in biology and philosophy and was interested in the processes by which children acquire knowledge about the world. Piaget's interest in cognition stemmed from his early work in the Binet laboratory in Paris, France, where the first intelligence test was developed. Piaget found the general orientation and methodology of psychometric testing deficient in several respects. First, he found incorrect responses to be just as interesting as correct responses. Children of the same age frequently produced the same type of error; moreover, there seemed to be reliable age-related variations in the types of errors children made, variations that were qualitative, not quantitative, in nature. Second, the inflexible methodology used in administering these tests did not allow examiners to probe the "inner workings" of a child's mind. Piaget was interested in the thinking that guided children's answers and in how these processes changed with age.

Frustrated by psychometric procedures, Piaget developed a less structured means of questioning children and learned to tap thought processes by observing how children experiment with and solve simple problems. The latter approach was used extensively to probe for and document changes in intelligence during the first 2 years, using his own children as subjects. Piaget's observations and theoretical notions regarding the sensorimotor period appeared in three extremely influential books: *The Origins of Intelligence in the Child* (1936/1953), *The Construction of Reality in the Child* (1937/1954), and *Play, Dreams, and Imitation in Childhood* (1946/1962).

Piaget viewed development as a continuous process of adaptation to an environment in which the infant plays an active role. Piaget conceived of maturation as a primary driving force behind development. In Piaget's view, behavior is guided and organized around sets of psychological structures or "schemes" that become intercoordinated gradually. For example, the initially uncoordinated schemes of "looking" and "grasping" eventually become coordinated into a higher-order scheme of "visually guided reaching." According to Piaget, all infant schemes are action oriented; he considered infants incapable of true thought (imagery and the mental manipulation of symbols) until late in the second year. By contrast, older children and adults possess schemes that are thought oriented as well as action oriented.

In the view of Piagetians, adaptation to environmental demands depends on the complementary processes of assimilation and accommodation. Assimilation involves the application of an existing scheme to a novel external stimulus. By contrast, accommodation involves the modification of an existing structure to permit its application to a new, unfamiliar stimulus. For example, accommodation of the grasping scheme occurs when the infant attempts to grasp a novel object and has to modify the width of the grasp and the tightness of the grip. Of course, grasping the new object also involves some assimilation because a generalized grasping scheme already has been established. All actions are believed to involve both assimilation and accommodation.

Piaget believed that all infants passed through the six substages of the sensorimotor phase (0 to 24 months) in an invariant sequence, although there could be substantial individual differences in the rate at which infants negotiate each stage. The progression through the six substages is associated with a decline in

sensorimotor egocentrism, as the infant becomes increasingly aware that he or she is a unique entity, separate and distinct from other people and objects in the environment. Despite the fact that Piaget may have underestimated the age at which some abilities emerged (e.g., the intercoordination of perceptual schemes like looking and hearing appears to exist at birth), subsequent research has generally confirmed the developmental sequence he proposed. In addition, there is now widespread acceptance of the view that children are active participants in their development, not passive reactors to environmental stimuli. Key features of the six substages are provided in [Table 22.1](#).

Substage	Approximate Age	Major Developments	Key Concepts	Typical Activities
1	0-1 month	Reflexes, sucking, grasping, looking, hearing, crying, smiling	Reflexes, basic sensory-motor coordination	Feeding, holding, looking at faces, hearing voices
2	1-4 months	Primary circular reactions, reaching, grasping, sucking, looking, hearing, crying, smiling	Primary circular reactions, object permanence (beginning)	Feeding, playing with objects, looking at faces, hearing voices
3	4-8 months	Secondary circular reactions, reaching, grasping, sucking, looking, hearing, crying, smiling	Secondary circular reactions, object permanence (beginning)	Feeding, playing with objects, looking at faces, hearing voices
4	8-12 months	Tertiary circular reactions, reaching, grasping, sucking, looking, hearing, crying, smiling	Tertiary circular reactions, object permanence (beginning)	Feeding, playing with objects, looking at faces, hearing voices
5	12-18 months	Symbolic play, language, problem solving, social interaction	Symbolic play, language, problem solving, social interaction	Feeding, playing with objects, looking at faces, hearing voices
6	18-24 months	Symbolic play, language, problem solving, social interaction	Symbolic play, language, problem solving, social interaction	Feeding, playing with objects, looking at faces, hearing voices

**Table 22.1. Sequence of Some Important Sensorimotor Developments in Piagetian Theory**

The Piagetian perspective is not commonly associated with formal assessments of infant intelligence because Piaget was not concerned with assessing individual differences in intelligence or in identifying the conditions that speed up cognitive development. Of the few Piagetian tests that have developed, the [Uzgiris and Hunt \(1975\)](#) Ordinal Scales of Psychological Development have been most widely used (see [Chapter 40](#)).

### Environmental Correlates of Infant Intelligence

Interest in the links between infant intelligence and environmental quality stemmed from early studies demonstrating that older children from middle-class environments score significantly higher on IQ tests than do children from lower-class environments (see [Duncan and Brooks-Gunn, 1998](#); [Gottfried et al., 1995](#); [Huston, 1999](#), for reviews). Of course, socioeconomic status (SES) is a marker variable based on parental income, education, and occupation and reveals little about the types of experiences enjoyed by infants of different social classes. Compared with lower-class parents, middle-class parents experience qualitatively different family life stresses ([Hunt, 1969](#); [Ramey et al., 1976](#)), put greater emphasis on their children's motives, feelings, self-direction, and academic success ([Hoff-Ginsberg and Tardif, 1995](#); [Kohn, 1987](#)), are more aware of their influence on their children's intellectual development ([Tulkin and Kagan, 1975](#)), provide more verbal and object-mediated stimulation contingent on infant behavior ([Hoff-Ginsberg, 1991](#); [Hunt, 1969](#); [Kagan and Tulkin, 1971](#); [Klaus and Gray, 1968](#); [Tulkin, 1977](#); [Tulkin and Kagan, 1975](#); [Wachs et al., 1971](#)), provide less punitive modes of discipline ([McLoyd, 1998](#)), and provide a greater variety of daily experiences ([Kagan et al., 1978](#)). Interestingly, reliable SES differences in standardized measures of infant intelligence are more easily demonstrated after rather than before 12 months of age ([Ramey et al., 1982](#)), suggesting that these tests are not as sensitive to variations in environmental stimulation during the first year as during the second. Infant intelligence tests during the first year tap sensory and motor functions whose development may be more influenced by maturational rather than by environmental factors, whereas environmental quality may have more readily observable effects on functions like language, symbolic play, and problem solving, which emerge during the second year. Environmental quality during the first year is important, but enduring environmental influences have the most pervasive and lasting impact on intellectual development.

By the second year, SES differences in parental behavior and in infant intelligence suggest that cognitive performance is in part associated with the quality of infant–parent interaction. However, there also is considerable variability in the cognitive outcomes of infants of lower SES, highlighting the importance of identifying specific social experiences that reliably predict intellectual performance within and across social class. Global measures of maternal involvement, verbal responsiveness, organization of the physical environment, variety in daily stimulation, and provision of play materials at 6 months predict 3-year intellectual performance ([Bradley and Caldwell, 1976](#); [Elardo et al., 1975](#)), and intellectual performance after the first year is predicted by earlier measures of mothers' verbal stimulation, positive toy play, and contingent responsiveness to infant social cues ([Clarke-Stewart et al., 1979](#); [Cohen and Beckwith, 1979](#); [Feldman and Greenbaum, 1997](#); [Tamis-LeMonda et al., 1996](#)). Mothers who respond to their toddlers in an “options-promoting manner” encourage their children to play in more sophisticated ways ([Stilson and Harding, 1997](#)). [Belsky et al. \(1980\)](#) speculated that dyadic play with toys may foster the ability to engage in competent, self-directed explorations, and [Lewis and Goldberg \(1969\)](#) suggested that positive social experiences that are contingent on infant behavior facilitate cognitive growth by fostering the sense of control over and motivation to master the environment. Eight-week-olds who perceived a contingency between their head movements and the movement of an overhead mobile not only increased the frequency of their head movements but showed a much higher frequency of smiling and cooing, an apparent indication of the pleasure derived from perception of the contingency ([Watson, 1972](#)). Conversely, infants may show displeasure and distress when their efforts to elicit contingent feedback are violated, as when mothers respond noncontingently to distress and positive social bids ([Lamb and Malkin, 1986](#); [Trevarthen, 1977](#)). Competent infants, therefore, are those who have learned from past experiences of contingency to explore, adapt to, and control their environments ([Goldberg, 1977](#)).

Studies by Bornstein and his colleagues revealed that the types of activities and experiences provided by parents influence specific areas of mental growth, such as visual, tactual, and perceptual–cognitive competence in infants younger than 6 months, and language and play in 13-month-olds ([Bornstein, 1989](#); [Bornstein and Tamis-LeMonda, 1997](#); [Tamis-LeMonda et al., 1996](#)).

### Continuity of Infant Intelligence

Despite the environmental correlates of intelligence in the second year, the relation between measures of intelligence in infancy and in later life is not at all straightforward. With few exceptions, correlations between measures of intelligence during the first year and IQ scores in later childhood are very low ([Harris and Langkamp, 1994](#); [Palti and Adler, 1994](#); [Wyly, 1997](#)). Prediction from scores obtained in the second year of life is somewhat better ([Reich et al., 1984](#); [Wilson, 1983](#)), perhaps because by that time scales like the Bayley Mental Development Index tap verbal, symbolic, and problem-solving skills that are similar to the abilities assessed by childhood intelligence tests. In addition, predictive relations tend to be higher for high-risk infants ([Siegel, 1989](#)).

The lack of relation between infant and later intelligence has spurred a heated debate about the nature of intelligence across the life span. Some theorists argued that there was no general intelligence factor, *g*, whereas others argued that if *g* exists, it is not fixed or stable across the life span. Still others argued that *g* may exist but that infant intelligence, with its basis in sensory and motor activity, differs from later intelligence. In any case, being highly intelligent in infancy would not ensure high intelligence later (see [Eysenck and Kamin, 1981](#); [Kopp and McCall, 1980](#); [Lewis, 1983](#); [Vernon, 1980](#), for discussions of these issues). A third perspective on intelligence, the information-processing view, demonstrates that the apparent discontinuity in intelligence from infancy to later periods is due in part to the conceptual dissimilarity between the abilities tapped by standardized tests administered to infants and older children. When conceptually similar abilities are assessed on both occasions, the degree of prediction improves.

### Information Processing and Infant Intelligence

The information-processing view of intelligence holds that attention is an important aspect of infant cognitive functioning, conceptually related to measures of intelligence across the life span ([Rose and Tamis-LaMonda, 1999](#)). Recall from our earlier discussion of habituation and novelty preference that infant attention to a stimulus event traditionally has been indexed in two ways: decrement of attention to repeated presentations of the same stimulus (habituation) and recovery of attention to a novel stimulus after habituation (novelty preference). Efficient information processing is assumed when habituation is rapid or when novelty preference is especially marked ([Rose and Tamis-LaMonda, 1999](#)).

Reliable individual differences in habituation rates in infants younger than 6 months have been reported using such stimulus configurations as geometric shapes, multicolored drawings, and social patterns ([Bornstein and Benasich, 1986](#); [DeLoache, 1976](#); [McCall, 1979](#)). Further, [McCall \(1979\)](#), and later, [Bornstein and Benasich \(1986\)](#) identified three basic habituation patterns in 5-month-olds: infants who habituated rapidly, infants who first increased looking and subsequently habituated, and infants who showed idiosyncratic and highly individualized looking patterns. These individual differences covary with various other measures of infant cognition. For

example, rapid habituation in infancy and childhood is positively associated with preference for complex patterns ( [Greenberg et al., 1973](#)), advanced sensorimotor development ( [Johnson and Brody, 1977](#)), competent exploration of the environment ( [Tamis-LeMonda and Bornstein, 1989, 1993](#)), sophisticated play ( [Kagan, 1971](#); [Riksen-Walraven, 1978](#)), and rapid problem solving ( [Lewis et al., 1969](#)). In addition, perinatal risk and developmental disability adversely affect decrement of attention and its recovery ( [Carlson and Werkman, 1996](#); [Jacobson et al., 1993](#); [Rose, 1994](#); [Rose et al., 1998](#); [Zelazo and Stack, 1997](#)).

Of course, infants also show individual differences in standardized test performance before 12 months of age, but the predictive validity of the attentional measures is better than that for the more traditional infant measures. Several recent studies document that infants who show efficient decrement or recovery of attention in the first 6 months of life perform significantly better on traditional assessments of cognitive and linguistic competence in early to middle childhood ( [Bornstein et al., 1997](#); [Colombo, 1993](#); [Dougherty and Haith, 1997](#); [Fagan and Haiken-Vasen, 1997](#); [McCall and Mash, 1995](#); [Rose et al., 1998](#); [Sigman et al., 1997](#)). There also is evidence to suggest that infant novelty responsiveness across modalities, such as being familiarized with a stimulus tactually and then distinguishing a novel stimulus from the familiar one visually, also is predictive of later cognitive competence ( [Rose et al., 1998](#)).

In a comprehensive review, [Bornstein and Sigman \(1986\)](#) noted that the median percentage variance shared between infant attentional measures and childhood intelligence is 21% (a correlation of approximately 0.44). Although the predictive validity of attentional measures is far from perfect, it certainly is better than that of traditional tests. Moreover, it indicates that, when researchers choose measures of early intelligence that tap the same processes as the measures used to assess intelligence later, some continuity is found.

## COGNITIVE CONTINUITY AND THE NATURE–NURTURE ISSUE

It is virtually impossible to demonstrate either an environmental or a genetic basis for any characteristic in children reared by their biological parents because genetic endowment and environmental influences are so closely intertwined ( [Scarr and Weinberg, 1983](#)). The significant correlations between parental IQ and infant intelligence ( [Rose et al., 1979, 1980](#)) could be due to a shared gene pool or to parental behavior. There is some evidence, however, that there are inherent individual differences in infant attention. Newborns show individual differences in habituation ( [Field et al., 1982](#); [Friedman, 1975](#); [Siqueland, 1981](#); [Slater et al., 1984](#)), and identical twins are more alike in the developmental pattern of scores on standardized tests from 3 months to 6 years than are fraternal twins ( [Wilson, 1983](#)). In addition, [Hardy-Brown et al. \(1981\)](#) found that the linguistic and communicative competence of adopted infants at 12 months of age related more strongly to the cognitive abilities of their biological mothers than to the cognitive abilities of the adoptive parents or to measures of the adoptive parents' communicative styles.

The fact that individual differences exist in relatively homogeneous samples, however, suggests that at least some variation is not accounted for by heredity, and several investigators have found concurrent associations between parental behavior and infant attention. For example, [Bornstein \(1985\)](#) found that mothers' tendency to encourage infants to attend to properties, objects, and events in the environment was related to habituation efficiency in 4-month-olds. [Sigman and Beckwith \(1980\)](#) reported relations between fixation time in 4-month-old preterm female infants and concurrent measures of verbal and social interaction. Of course, correlations between contemporaneous variables preclude conclusions about causal influences, but studies designed to help identify causal patterns suggest that the direction of influence is from parent to child, not the reverse. [Belsky et al. \(1980\)](#), for example, showed experimentally that parents who focus their infants' attention on objects promote infant competence. In addition, [Riksen-Walraven \(1978\)](#) demonstrated that infants of mothers who participated in a stimulation program habituated more efficiently than infants of control mothers.

It appears, then, that both genetic and environmental factors influence information-processing capacities. Of course, no direct measures of “genetic quality” exist, rendering moot questions about how much of an individual contribution genetics and environment actually make to intelligence. As [Yeates et al. \(1983\)](#) point out, however, questions about the relative contributions of genetics and environment to a developmental process can be asked using measures such as parental IQ, which presumably reflects some genetic variation. [Yeates et al. \(1983\)](#) examined the relative contributions of maternal IQ and measures of environmental quality of the home (e.g., maternal involvement, provision of play materials) to child IQ from 2 to 4 years of age, statistically controlling for the effects of one while assessing the effects of the other at various age points. They found that environmental quality became a more important predictor and maternal IQ a less important predictor over the 2-year period. Although infant cognitive capacities were not assessed, the results suggest that early variation in cognitive abilities may be more attributable to genetic than to environmental factors, with environmental factors playing an increasing role with age.

Although the predictive validity of infant attention to childhood intelligence is better than that of more traditional tests, [Bornstein and Sigman \(1986\)](#) reported predictive correlations ranging in absolute magnitude from 0.28 to 0.77. Some of this variation may be due to differences among the techniques used to measure attention, the measures used to assess childhood intelligence, the intervals between the ages at which infant attention and later intelligence were assessed, and measurement error. However, a potentially important source of variance that has not yet been addressed systematically is the degree of stability in children's environments from infancy to the later assessment. [Lewis and Goldberg \(1969\)](#) have argued that effectance motivation, and hence cognitive development, is facilitated by social environments that are emotionally warm, sensitive, and contingently responsive to children's needs. Further, [Bond \(1982\)](#) has noted that pervasive effects on cognitive development seem to occur when environmental influences also are enduring and long lasting. Thus, the predictive validity of infant attention measures should be relatively high when environmental stability over time also is high, whereas weaker predictive validity should be found when there are fluctuations in environmental quality (e.g., variations in the quality of the parent–child relationship).

Overall, the qualitative (Piagetian) and quantitative (information-processing and psychometric) perspectives on intelligence are complementary, addressing different questions about infant cognition. Although the Piagetian approach has proven useful for normative descriptions of infant cognitions, the information-processing approach is clearly in the ascendancy today, whereas the psychometric approach remains useful for assessing the current developmental status of individual infants. Except at the extremes, however, these scores have no predictive validity, whereas measures of information processing are predictive of performance on later measures of symbolic and analytic functioning. Perhaps the most dramatic aspect of symbolic function is represented by language, the topic of the next section (for a general overview of the development of communication, see [Chapter 17](#)).

## LANGUAGE DEVELOPMENT

As mentioned earlier, very young infants seem to be especially tuned to frequencies within the range of human speech sounds. Infants like to listen to voices and will perform some act in order to do so: When speech (but not other sound) is contingent on nonnutritive sucking, the amount of sucking increases ( [Trehub and Chang, 1977](#)). In addition, 4- to 16-week-old infants are able to perceive categorically many of the acoustic cues that underlie speech ( [Aslin et al., 1983](#); [Eimas et al., 1971](#)). Thus, it appears that young infants are primed for hearing the components of language. These perceptual capacities presumably play a role in shaping the infant's vocal output, facilitating the development of language.

### Vocal Production

During the first month of life, infants make reflexive cries, fusses, and vegetative sounds ( [Lenneberg, 1967](#); [Oller, 1980](#); [Tal and Bornstein, 1992](#)). As early as 5 weeks to 3 months of age, cooing and laughter emerge, typically in response to the voices and faces of others ( [Lenneberg, 1967](#)). These cooing sounds involve repeating the same vowel or velar consonant (“g,” “k”), sounds in which tongue movements are relatively undifferentiated ( [Kent, 1981](#)). Between 4 and 6 months of age, infants explore a variety of vocalizations, such as squeals, yells, growls, and vowel-like sounds. Thereafter (7 to 10 months of age), canonical or reduplicated babbling occurs, with infants producing syllables and reduplicating the same consonant and vowel (e.g., “da, da, da”). Between 11 and 12 months, nonreduplicated babbling (also termed *jargon* or *protowords*) emerges; at this stage, infants produce a variety of sounds in which syllables, consonants, and vowels may vary, such as “dakee,” “babe.” Finally, at approximately 12 months, infants produce referential words.

Changes in these vocal abilities are paralleled by changes in the anatomy and physiology of the vocal apparatus, which suggests that the developmental changes in vocal behavior are related to structural changes in oropharyngeal anatomy ( [Kent, 1981](#); [Lester and Bourkydis, 1991](#)), as does evidence that initial sound production follows a universal pattern ( [Jakobson, 1941/1968, 1971](#); [Vihman, 1991](#)). Infants brought up in Spanish-, Japanese-, Arabic-, or English-speaking homes show no great differences in their basic sound production repertoire, suggesting that very different linguistic experiences do not affect the elements of babbling very much ( [Nakazima, 1975](#); [Oller and Eilers, 1982](#); [Vihman, 1993](#)). In addition, infants with little language experience (e.g., infants with deaf parents) vocalize much like infants in sound-rich environments until they are approximately 6 months old ( [Lenneberg, 1969](#)). Thus, infants appear to use a universal core of sounds.

This does not mean that sound production is unaffected by environmental input: Infants eventually do produce the sounds they commonly hear, and they correctly mimic the rhythm and intonation of their native language long before they know what the words mean ( [Crystal, 1979](#); [de Boysson-Bardies et al., 1984](#); [Weir, 1962](#)). Routh (in [Oller, 1981](#)) stimulated 2- to 7-month-olds with either consonant- or vowel-like sounds and thereby selectively increased the number of consonants or vowels the infants produced. By contrast, [Webster \(1969\)](#) found that when 6-month-olds were stimulated with vowel sounds, they increased the proportion of

consonants produced, and vice versa. Taken together, these studies suggest that infants can modify their own vocalizations in response to the vocalizations of others, by either matching or contrasting the sounds that they hear ([Oller, 1981](#)).

The amount and patterning of babbling is affected by environmental factors as well. Infants vocalize substantially more when they are socially stimulated by others than when they are not, regardless of whether the stimulation is contingent on the infants' own vocalizations ([Bloom, 1979](#); [Rheingold et al., 1959](#)). In addition, when adult vocalizations or adult silences are contingent on infant vocalizations, infants suppress their own vocalizations just after the contingent stimulation or silence, as though listening for something. Responding contingently to infant vocalizations thus allows infants to learn the basic conversational pattern: talk, then listen ([Bloom, 1979](#); [Bloom and Esposito, 1975](#)).

The influence of social input on sound production is highlighted in studies contrasting the vocalizations of deaf infants with those of normal-hearing infants; the former appear to fall behind the latter ([Gilbert, 1982](#); [Oller, 1981](#); [Stoel-Gammon and Cooper, 1984](#)). Hearing-impaired infants produce fewer consonant types, show a decrease in types over time, and use a lower proportion of multisyllabic utterances than normal-hearing infants ([Oller and Eilers, 1988](#)). It, thus, appears that in the first half-year of life, infants do not require acoustic information to produce common precanonical sounds, but that the acoustic environment does influence vocalizations, such as babbling, later. Babbling, however, is not restricted to vocalizations. When deaf infants are exposed to sign language from birth, they babble manually in much the same way that hearing infants do through speech ([Petitto and Marentette, 1991](#)).

### First Words

Gesell ([Gesell and Armatruda, 1962](#)) observed that children regularly say their first words approximately the time they celebrate their first birthday. At this age, children are interested in movements and actions they can perform, both with and without objects, and their first words typically reflect their sensorimotor schema; often they refer to objects that move or can be held rather than to equally common words on which infants seldom act (e.g., diaper, crib, shoe) ([Nelson, 1973](#)). In addition, early words (e.g., bye-bye, bang) often express and are accompanied by actions (e.g., waving, hitting) ([Corrigan, 1979](#)).

Although many early words refer to objects ([Benedict, 1979](#); [Bowerman, 1976](#); [Leopold, 1949](#)), infants also use “expressive” words to engage in social interactions. [Nelson \(1981\)](#) found that infants' early vocabularies consisted of both kinds of words and that infants could be categorized according to the proportion of each in their repertoires. For most children, early vocabularies contain a large proportion of object names, with some verbs, proper names, and adjectives; Nelson termed this style of early word use *referential*. A large minority of children, however, have a more diverse vocabulary, with a large number of social routines, such as “stop it” and “what’s that” included among the nouns, verbs, and adjectives; Nelson called this style of early word use *expressive*. Although children may use one style more than the other, only rarely do they exclusively use either one ([Bretherton et al., 1983](#)).

In addition to individual differences in the style of first words used, individual differences in the timing of early word acquisition are common. [Bayley \(1969\)](#), in her assessment of 1,200 infants, found that the most advanced imitated a word by 9 months of age, and the least advanced by 18 months of age. Similar variation was found in the number of words in the vocabularies of 13-month-olds; production ranged from 0 to 45 words, and comprehension varied from 11 to 97 words ([Snyder et al., 1981](#)). In general, comprehension of words precedes their production.

### Sharing a Referent: Development of Gestural Communication

Producing and comprehending words necessitates an understanding of shared referents. Before language, such shared reference to objects and events first comes about through gestural communication. During the second half of the first year, infants begin to use and understand various communicative signals to potentiate mutual attention to external topics ([Bakeman and Adamson, 1984](#)). Joint attention and external reference are the bases of symbolic communication, be it gestural or vocal ([Bates, 1979](#); [Schaffer, 1984](#)). There is some evidence indicating that infants who experience more of these joint attention experiences tend to talk earlier and show faster vocabulary development ([Dunham and Dunham, 1992](#); [Tomasello, 1990](#)).

Toward the end of the first year, infants begin to share objects and events with others by using conventional gestures such as pointing, offering, and showing objects ([Hay and Rheingold, 1983](#)). [Leung and Rheingold \(1981\)](#) note that pointing and reaching function to direct another's attention to objects that arouse the infant's interest. Reaching is characteristic of 9- to 10-month-olds, entering the repertoire before pointing, which is first displayed by most children at 12.5 months and is a common gesture at 16.5 months of age ([Leung and Rheingold, 1981](#)). Because pointing is modeled and reinforced by adults, it replaces reaching as a referential gesture ([Leung and Rheingold, 1981](#); [Murphy and Messer, 1977](#)), gradually being refined until it assumes the conventional form. Language acquisition involves a similar process of learning the conventional means by which to refer to phenomena (Acredolo and Goodwyn, 1990). As with language, the ability to comprehend or to follow another's points precedes the infant's own pointing. By the start of the second year of life, infants frequently use conventional gestures (such as showing and offering objects) with mothers and fathers, as well as with unfamiliar men and women ([Hay, 1979](#); [Rheingold et al., 1976](#)) and with peers ([Bakeman and Adamson, 1986](#); [Eckerman et al., 1975](#); [Nash, 1985](#)).

Conventional gestures and language follow a parallel developmental course. Infants begin to use shared referents, both gestural and verbal, at approximately 1 year of age, the age at which Piaget suggests that the capacity for symbolic representation first emerges. Other forms of symbolic representation, such as play, also emerge at approximately this time ([Nicholich, 1981](#)). In addition, social gestures (such as pointing) and speech both pass through an initial noncommunicative phase ([E. Bates et al., 1982](#); [Leung and Rheingold, 1981](#); [Schaffer, 1984](#)). Both are first tied to specific routines or “action formats” (routines between adult and infant such as peek-a-boo, “So Big,” and reading) and occur only in these contexts ([Acredolo and Goodwyn, 1985, 1990](#); [Bakeman and Adamson, 1984](#); [Bates, 1979](#); [Ratner and Bruner, 1978](#)). Later, they are used in other contexts to stand for objects and events that are not present, thus serving a symbolic communicative function.

### Prelinguistic Conversations and Behavioral Dialogues

Besides helping infants understand semantics, interactive routines also help infants learn the pragmatics of language and the rules of conversation, such as mutual attention, sharing a topic, and taking turns ([Bruner, 1977](#); [Schaffer, 1984](#)). Dialogues between infants and caretakers begin in the newborn period: The communicative exchanges between parents and 3-day-old infants are smooth, with a high degree of turn taking ([Bakeman and Brown, 1977](#)). At this stage, however, adults more frequently initiate, follow through, and complete behavioral sequences.

At 2 months of age, infants regularly respond to attentive, talking adults by orienting to their faces, focusing on their eyes, smiling, becoming more active, and vocalizing, then shifting their gaze to the adults' mouths or away from their faces ([Rheingold, 1961](#); [Trevarthen, 1977](#)). Infants, thus, seem to alternate between attending and expressing themselves. During the expressive phase, they make mouth movements, often accompanied by sounds and gestures. Mothers frequently respond to such prespeech with talk of their own. By 3 months of age, infants and parents tend to alternate their vocalizations, taking turns ([Bloom, 1988](#)). Mothers are primarily responsible for initiating exchanges and attempting to elicit responses from infants, but infants at this age sometimes vocalize after silences, as if attempting to keep the “conversations” going. Turn taking becomes more and more refined and predominates in the vocal exchanges of 6- to 16-month-olds and their mothers ([Davis, 1978](#)). Similarly, [Schaffer et al. \(1977\)](#) found that turn taking occurs equally often in the vocal exchanges of 12- and 24-month-old children. At both ages, overlaps were rare and brief.

During the first 6 months, conversations and dialogues are sustained mainly by adults, but after this, infants begin to take more responsibility. [Rogoff et al. \(1984\)](#) observed 7-month-olds reaching toward an adult's arm while looking at the handle of a jack-in-the-box, as though attempting to make the adult wind the handle and thus continue the game. The role of infants in the management of joint activities was shown to increase rapidly from 6 to 13 months ([Mosier and Rogoff, 1994](#)). [H.S. Ross \(1980\)](#) reported that, when an adult stopped a game by not taking her turn, 12-month-olds reacted as though they had some understanding of the rules of turn taking; for example, they guided the adult's hand to the appropriate object, thus helping the adult to take her turn. The infant's role in taking turns is illuminated by behavior with peers from the start of the second year, when “games” may include turn taking ([Goldman and Ross, 1978](#); [Nash, 1986](#)).

[Snow \(1977\)](#) suggests that 1-year-olds understand the rules of conversational turn taking as well, and [Schaffer \(1984\)](#) proposed a mechanism by which even very young infants help sustain a vocal dialogue: They suppress their own vocalizations when stimulated by the sounds of others. [Webster et al. \(1972\)](#) found that infants vocalize less when presented with other sounds and increase them when the sounds stop. Furthermore, infants reduce their own vocalizations, particularly when they hear preferred voices ([Barrett-Goldfarb and Whitehurst, 1973](#)).

Although 12-month-olds understand some rules of social exchange and take an active role in keeping exchanges going, adults still take the major responsibility. [Schaffer et al. \(1977\)](#) examined speaker-switch pauses in vocal interchanges between mothers and 1-year-olds and found that child–mother switches were characterized by shorter pauses than mother–child switches, thus highlighting the mothers' greater competence in responding. In addition, by keeping their own

vocalizations very brief and pausing often, parents give infants a chance to join in ( [Schaffer, 1984](#)).

That vocal and behavioral interactive routines follow the same developmental course is illustrated by [Bruner's \(1977\)](#) descriptions of "Give and Take" games and [Snow's \(1977\)](#) examinations of vocal conversations. At 3 months, Bruner found the game of "Give and Take" to be one sided, with mothers offering objects to their infants most frequently. At 6 months, the infants played a more active role, accepting the objects. By 12 months, children both gave and took objects. The number of exchanges and offers of objects initiated by the children increased from 0% to 50%, so that "Give and Take" became a game involving reciprocal roles. Similarly, Snow found that mothers took the major responsibility for maintaining conversations by responding to their 3-month-olds' smiles and vocalizations as if they were intending to communicate. When infants did not respond, mothers often filled in. By the end of the first year, children more often initiated turns, actively assuming the roles of speaker and listener.

Early interactive routines may thus teach the basic pragmatics of speech. In addition, [Bruner \(1977, 1983\)](#) suggested that they also provide a strong foundation on which infants build syntax, while learning the sequence of agent, action, object, and recipient. Thus, Bruner argues that, before actually speaking, infants, with adult guidance, have learned language formats. This language support system may thus provide a stepping stone to [Chomsky's \(1965, 1986\)](#) notion of a language acquisition device, an innate mechanism that provides toddlers and preschoolers with an understanding of grammar.

Gestures, nonverbal sounds, and words are important means whereby infants communicate with others. Emotional expressions, discussed in the next section, also serve important communicative functions. Whether the signals are gestural, verbal, or emotional, furthermore, their prevalence and universality underscore the intrinsically social nature of human infants.

## SOCIAL AND EMOTIONAL DEVELOPMENT

### Emotional Development

Many theorists consider the ability to produce and respond appropriately to emotional expressions to be innate and cite four types of evidence to support this view ([Campos et al., 1983](#); [Darwin, 1872](#); [Eibl-Eibesfeldt, 1970](#); [Ekman and Oster, 1979](#); [Izard, 1971, 1979](#)). First, facial expressions are indeed quite similar in different cultures ([Camras et al., 1992](#)), and expressions posed by Westerners are correctly identified by people in other cultures, including preliterate societies that have had little or no exposure to Westerners ([Ekman, 1994](#)). Second, the development of emotional expressiveness seems to be under maturational control; blind infants begin full smiling at the same age as sighted infants ([Fraiberg, 1979](#)), and premature infants begin to smile at environmental stimuli at the same conceptional age as full-term infants ([Dittrichova, cited in Bower, 1977](#)). Third, monozygotic twins are more alike than dizygotic twins with respect to fear of strangers and smiling over the first 4 months ([Freedman, 1974](#); [Plomin and Rowe, 1978](#)), suggesting a genetic component to these emotions. Finally, the ability to recognize certain expressive displays has an innate basis in nonhuman primates. [Sackett \(1966\)](#) found that rhesus monkeys raised in total isolation responded with fear to pictures of monkeys making threats and showed positive reactions to pictures of infant monkeys. [Mason \(1985\)](#) found that experience has little influence on several facial and vocal emotional displays in rhesus monkeys.

To study the development of emotions, the investigator must decide whether to focus on internal state or on outward expression because there may not be a direct correspondence between the two ([Saarni et al., 1998](#)). Some theorists assume a correspondence ([Darwin, 1872](#); [Ekman 1972](#); [Izard, 1979](#); [Malatesta, 1985](#)), and there is some physiologic evidence to support this assumption. Correlations have been found between various facial expressions and distinct patterns of autonomic nervous system activity in adults ([Ekman et al., 1983](#)), and between the amount of separation distress ([Tennes, 1982](#)) and distress to inoculations ([Lewis et al., 1993](#)) and levels of infants' cortisol production. Other researchers have emphasized the lack of synchrony between infant expressions and internal states, however. Citing examples of early asynchrony in relation to infant smiling ([Emde and Koenig, 1969](#); [Wolff, 1963](#)), [Lewis and Michalson \(1985\)](#) argue that the relation between internal state and outward expression during infancy is in fact U-shaped, with no synchrony at first, a high degree of synchrony later in infancy, and then less correspondence as infants get old enough to use expressions to communicate intentionally or withhold them to mask certain states. This concern about the correspondence between emotional state and expression is important not only to theorists but to parents and caretakers, who must understand infant signals and act appropriately, deciding whether such signals necessarily correspond to particular emotional states.

To clarify the relation between expressions and underlying emotions, it is helpful to ask about the likely function of a correspondence between feelings and expressions. [Campos and colleagues \(1983](#); [Saarni et al., 1998](#)) argue that emotions play a primary role in organizing the individual's behavior and signaling others about the individual's tendencies. They assume that the communicative functions of emotions are evident from birth and that there is, as a result, a direct although imperfect correspondence between emotional expressions and internal "feeling" states.

## DEVELOPMENT OF FACIAL AND VOCAL EXPRESSIONS

By responding "appropriately" to infants' facial and vocal expressions, parents indicate that infants are able to communicate effectively with others. The same facial movements used to express distinct emotions in adults are used by infants ([Ekman and Friesen, 1976, 1978](#); [Izard and Dougherty, 1982](#)). As a result, even untrained observers can accurately identify the emotion displayed by photographed infants ([Emde et al., 1978, 1985](#); [Izard et al. 1980](#)) and show differentiated psychophysiological responses to infant smiles and cries, as well as to cries with different characteristics ([Frodi et al., 1978a, 1978b](#)). As infancy proceeds, expressions change from basically reflexive signals to more flexible, graded, instrumental signals, which may be used intentionally as well as unintentionally in social communication ([Thompson et al., 1998](#)). Indeed, one of the tasks of infancy is to modify expressions in light of societal expectations and rules. The frequency of facial expressions also changes, with decreases over the first 6 months ([Malatesta and Haviland, 1982](#)) and increases in the next 2 months ([Malatesta et al., 1986](#)).

The first emotional expressions involve crying. [Brazelton \(1962\)](#) and [Rebelsky and Black \(1972\)](#) have charted the developmental course of crying, noting an increase over the first 6 weeks and then a decrease, with maximum crying initially in the evening, but later near feeding times. Both researchers also noted much variability in and between infants. The communicative function of crying is indicated by the ability of others to identify different kinds of cries. Adults are able to distinguish among and interpret the cries, not only of 6-month-olds, but of 1-month-olds and newborns ([Leger et al., 1998](#); [Thompson et al., 1998](#); [Thompson and Leger, 1998](#); [Zeskind et al., 1985](#)). It also is possible to distinguish spectrographically among the cries of newborn infants with malnutrition, asphyxiation, neurologic abnormalities, and chromosomal deviations ([Hollien, 1980](#); [Lester and Boukydis, 1985](#); [Zeskind, 1981](#)).

Newborns can communicate emotions through facial expressions as well ([Oster and Rosenstein, 1998](#)). [Rosenstein and Oster \(1988\)](#) recorded the facial expressions of 2-hour-old infants who were given sour, sweet, salty, and bitter substances to taste. They responded to pleasant tastes with apparently positive facial expressions and to unpleasant tastes with negative expressions. [Field \(1982\)](#) reported that facial expressions of surprise were elicited from newborns by some items in the Brazelton Neonatal Behavioral Assessment Scale examination. And, of course, newborns are able to smile, although unlike later smiling, which involves both ocular and lower face muscles, neonatal reflex smiling involves only the lower face muscles ([Korner, 1969](#); [Wolff, 1963](#)). Newborns smile quite readily, but only during rapid eye movement states in sleep ([Emde and Harmon, 1972](#)). According to [Sroufe and Waters \(1976\)](#), who charted the ontogeny of smiling and laughter, smiling progresses from internal to external stimulation. At first it occurs during sleep, later in drowsiness, and finally in attentive states. Sounds are initially the most effective external stimuli, but by the fifth week, visual stimuli become more effective. Six- to 12-week-old infants smile at faces, as well as at a wide range of nonsocial stimuli, such as bull's-eye patterns and bells ([Emde and Harmon, 1972](#)). Gradually, smiling becomes more selective, progressing from any human face, to particular faces, to particular expressions. Newborns do not laugh; the development of laughter trails the developmental course of elicited smiling by approximately 1 month ([Rothbart, 1973](#)). [Sroufe and Wunsch \(1972\)](#) reported that tactile and kinesthetic cues were the strongest elicitors of laughter, that 7- to 9-month-olds laughed more and to a greater variety of stimuli than did 4- to 6-month-olds, and that the frequency of laughing at visual and social stimuli (such as during a peek-a-boo game) increased with age.

One- to 9-month-old infants display all the facial expressions displayed by adults—interest, joy, surprise, sadness, anger, disgust, contempt, and fear ([Izard et al., 1980](#); [Malatesta and Haviland, 1982](#))—although the initial expressions are not always complete or used appropriately. Stenberg and coworkers ([Stenberg et al., 1983](#); [Stenberg and Campos, 1990](#)) took a closer look at the development of anger expressions by examining infants' responses to the removal of teething biscuits and to restraints of their arm movements. They found the 1-month-olds showed few clear expressions of anger, but 4- to 7-month-olds showed clear expressions of anger. The oldest infants directed their anger expressions toward the person who was restraining their arms or removing the biscuit. In addition, anger in response to inoculations increases with age ([Izard et al., 1983](#)).

The last emotional expression to occur appropriately is fear. Between 6 and 9 months, infants begin to display fear to a variety of social (e.g., separation from a parent, approach of a stranger) and nonsocial (e.g., heights, looming stimuli) stimuli ([Campos and Stenberg, 1981](#); [Cicchetti and Hesse, 1983](#)). Not all infants display fear in response to each of these stimuli, however. In particular, fearful reactions to strangers, once thought of as a developmental milestone ([Bronson, 1972](#);

Freedman, 1974; Hess, 1970; Spitz, 1950a), vary depending on the particular stranger involved, his or her behavior, and the context in which infant and stranger meet (Clarke-Stewart, 1978; Rheingold and Eckerman, 1973; Thompson and Limber, 1991). Nevertheless, although fear of strangers is not universal, it emerges during the second half of the first year if it does occur (Bronson, 1972; Haith and Campos, 1977).

Nonhuman primates go through the same developmental sequence, with positive expressions toward social stimuli being used appropriately before negative ones. In this way, sociability is fostered; nonhuman and human infants form ties with fellow conspecifics before they begin to fear particular individuals. In addition, because young infants do not have the motor skills to protect themselves from potentially dangerous situations, fear is not adaptive for protection until later (Izard and Malatesta, 1987). Indeed, although infants can distinguish the two sides of a visual cliff (a shallow and deep side) by 2 months of age (Campos et al., 1970), they show no fear of the deep side until the third quarter-year of life; that is, they begin to show fear of heights at approximately the same time they are beginning to locomote and thus are able to flee (Campos and Bertenthal, 1989). This is one example of a tendency for changes in the child's motor capacities to bring about changes in social relationship and the manifestation of emotion. Biringen and colleagues (1995) reported that upright locomotion also had profound effects.

In summary, infants are able to express all the primary emotions at or soon after birth; during the next 6 to 12 months, infants learn to express these emotions fully and appropriately, so as to communicate successfully with others. Next, the ability to respond to the emotional expressions of others is considered.

## INFANTS' RESPONSES TO THE EMOTIONAL EXPRESSIONS OF OTHERS

As members of a social species, humans must constantly modulate their emotions in response to the emotions of others (Nelson, 1987). Newborns are able to discriminate among happy, sad, and surprised faces (Field et al., 1982), and at 3 to 5 months of age they are able to discriminate among expressions of joy, surprise, anger, and sadness (Barrera and Maurer, 1981; LaBarbera et al., 1976; Young-Browne et al., 1977), as well as degrees of such expressions (Kuchuk et al., 1986). Between 5½ and 7 months of age, infants can discriminate happy and surprised expressions (Caron et al., 1982), and at 7 months, infants also show generalized discrimination (across several models) of happy and frightened faces and prefer looking at frightened rather than happy faces (Nelson and Dolgin, 1985). Interestingly, this preference for looking at frightened faces emerges at approximately the age when infants themselves begin to express fear appropriately.

Emotional contagion occurs in a variety of social species (Hinde, 1970), and human newborns may be capable of some such modulation; they appear to match ("imitate") both facial expressions (Field et al., 1982; Meltzoff and Moore, 1977, 1983) and vocal expressions (crying; Martin and Clarke, 1982; Sagi and Hoffman, 1976; Simner, 1971). In addition, 3-month-olds become inactive when their mothers act depressed (Cohn and Tronick, 1983; Lamb and Malkin, 1986). As infancy proceeds, this immediate response to the emotion of others becomes less automatic. Although newborns readily cry when they hear other newborns crying (Martin and Clarke, 1982; Sagi and Hoffman, 1976; Simner, 1971), 6-month-olds do not cry so rapidly in response to the cries of their peers. Hay et al. (1981) found that the probability of a 6-month-old's crying in response to the distress of a peer increased the longer the peer cried; if the peer cried for 2½ minutes, the listening infant was sure to cry. Further demonstrating that automatic responding decreases as infants age, Nelson and Horowitz (1983) found that 2-month-olds respond to expression changes in holograms of faces, whereas 5-month-olds do not.

Older infants use more deliberate means to match the emotions of others than do younger infants. By 12 months of age, infants in ambiguous situations use other peoples' emotional expressions as cues for their own, a phenomenon termed *social referencing* (see Feinman, 1992; Mumme et al., 1996). Infants are more likely to cross a visual cliff of ambiguous height when their mothers look happy than when they look afraid (Sorice et al., 1985) and are more likely to approach and explore novel toys and animals when an adult signals joy and to seek reassurance from the adult when she or he signals fear (Hornik et al., 1987; Hornik and Gunnar, 1988; Klinnert et al., 1983; Mumme et al., 1996; Zabatany and Lamb, 1985). By 18 months of age, infants are able to respond with recognizable empathy to the distress of their companions, offering teddies or restoring desired toys to distressed peers (Hoffman, 1978).

Responses to particular auditory displays are more difficult to document, although most theorists agree that emotions are reflected in vocalizations (Darwin, 1872; Scherer et al., 1972; Zahavi, 1982). Newborns cry in response to the distress of others, whereas exposure to recordings of their own cries calms newborns, indicating that they can discriminate their own cries from those of others and do not merely become distressed because they find crying irritating (Martin and Clarke, 1982). This differential responding may be an early precursor of empathy. Twelve-month-olds avoid crossing a visual cliff of ambiguous depth when their mothers' vocal tone is negative (angry or fearful) but cross immediately when the mothers speak positively (Svejda and Campos, 1982). Such social referencing in response to vocal expressions of emotion has been found in other situations as well (Walden and Baxter, 1989). Studies have indicated that infants begin to coordinate vocal and facial features of emotional expression early in infancy—between 4 and 9 months of age (Caron et al., 1988).

## SOCIALIZATION OF EMOTIONS

The fact that the production and recognition of emotional expression is innate does not mean that experience plays no role in emotional development. As Fraiberg (1979) reported, social smiling in response to familiar voices first emerges at approximately the same age for blind and sighted infants, but smiling by blind infants subsequently becomes less frequent and more muted. Unlike sighted infants, furthermore, blind infants do not initiate interaction by smiling. Similarly, Ambrose (1969) reported that smiling to external stimuli occurred later in institution-reared infants, who receive little social feedback, than in home-reared infants.

Experimental studies indicate that emotional expressions can be modified by conditioning and social learning (reviewed by Campos et al., 1983), processes that characterize interactions between mothers and infants throughout the first year of life (Goldberg et al., 1994; Malatesta and Haviland, 1982, 1985; Malatesta et al., 1986). According to Malatesta, maternal expressions typically changed less than a half second after the infants' expressions changed, the optimal delay for instrumental conditioning. Mothers contingently responded to their infants' positive expressions more than to their negative expressions, thus producing an increase in positive emotional expressions and a decrease in negative expressions. Contingent maternal responses also led to increases in the overall rate of infants' facial expression changes.

Malatesta's studies also implicate observational learning in the modification of infants' emotional expressiveness. Malatesta and Haviland (1985) reported that mothers on average changed their expressions eight times per minute. From this they estimated that mothers change their expression 362 times per day in face-to-face play, and 32,580 times over the 3-month period of peak face-to-face play. As these investigators remarked, "This is not a trivial learning opportunity for the infant" (p. 104). The amount of joy and interest modeled by mothers at 5 months predicted increases in the amount of joy and interest expressed by infants at 7½ months (Malatesta et al., 1986).

The infant's role in the socialization of emotions is underscored by comparing the face-to-face interactions of preterm and full-term infants. Mothers of preterm infants matched their infants' facial expressions less and ignored their anger expressions more than did mothers of full-term infants. The former also responded randomly rather than contingently to their infants' sad expressions. These differences in maternal behavior were attributed to the fact that preterm infants expressed more negative emotions and gazed at their mothers less than full-term infants did (Malatesta et al., 1986).

In addition to being an arena in which instrumental and social learning can take place, early face-to-face play reflects cultural values concerning emotional expression (Super and Harkness, 1982). Among the Gusii of Kenya, for example, social interaction is characterized by bland countenances. Face-to-face play is rare, and when it does occur, eye contact is avoided (as it is between adults). When infants become excited, mothers respond with a variety of strategies to dampen the infants' emotional displays, looking away or blinking rapidly to break visual contact. The cultural norm of avoiding emotional displays is thus taught in the earliest social interactions (Dixon et al., 1981).

During early face-to-face interactions, North Americans instill cultural norms concerning the greater acceptability of emotional displays by girls (Malatesta, 1985). Malatesta and Haviland (1982) found that, although female and male infants display similar facial expressions, American mothers respond differently to them. As infants grow older, mothers smile increasingly in response to their sons' smiles and decreasingly in response to their daughters' smiles. Similarly, Lewis and Michalson (1985) found that after 6 months mothers responded less to boys' crying than to girls', were more likely to imitate their sons' expressions, and were more likely to show a wider range of expressions, both imitative and dissimilar, to their daughters. Girls were reinforced for a wider range of emotional expressions than were boys, which may explain why girls are better at decoding emotional expressions than are boys at all ages (Hall, 1978).

In summary, infants' abilities to communicate emotionally are well documented. These abilities allow for the formation of close, special, relationships. Such attachments to particular individuals typically emerge during the second half of the first year of life. We next discuss the development of such attachments.

## Development of Attachment

The most popular explanation of attachment formation was provided by [Bowlby \(1969, 1988\)](#), a psychoanalyst who was much impressed by the capacity of ethologic theorists to explain early emotional communication between nonhuman infants and their parents. Bowlby's influential theory consequently emphasizes the infant's innate capacity to emit signals to which adults are biologically predisposed to respond. Adults' responses to these signals may account for the development of attachments, as we show shortly.

Bowlby began with the assumption that the behavioral propensities of infants and parents are most profitably considered in the context of the environment in which our species evolved. In that "environment of evolutionary adaptedness," the survival of infants would have depended on their ability to maintain proximity to protective adults. Unlike the young of many other species, however, human infants are unable to move closer to or to follow adults for several months, and they are even incapable of clinging to adults. Instead, human infants rely on signals to entice adults to approach them. For these signals to be effective, adults must be predisposed to respond to them. The best example of such a prepotent signal is the infant cry, which very effectively entices adults to approach, pick up, and soothe the infant ( [Bell and Ainsworth, 1972](#); [Frodi et al., 1978b](#); [Korner and Thoman, 1970, 1972](#); [Murray, 1979](#)). As they grow older, infants develop a variety of means of achieving proximity or contact, including independent locomotion. Throughout infancy, children seek proximity to protective adults to obtain nourishment, comfort, and security. Gradually, infants come to focus their bids on those people with whom they are familiar and on whom they can count, and this is one crucial aspect of the process called *attachment formation*.

## BASIC PHASES OF SOCIAL DEVELOPMENT

[Bowlby \(1969\)](#) described four phases in the development of infant–parent attachments. The first phase in the attachment process (indiscriminate social responsiveness, 1 to 2 months) is marked by the development of a repertoire of signals, labeled *attachment behaviors*. The defining or common characteristic of these behaviors is that they all help achieve comfort and security by bringing the infant close to protective, caretaking adults.

From the time of birth, there is one very effective signal at the infant's disposal—the cry. A second potent attachment behavior enters the infant's repertoire in the second month of life—smiling. Like crying, smiling is a signal that powerfully affects adult behavior. However, smiles are effective because they encourage adults to stay near and continue interacting with the infant because adults find the interaction pleasant, whereas cries encourage adults to approach the infant to terminate a signal that they find aversive ( [Ambrose, 1969](#); [Frodi et al., 1978b](#)).

From birth, therefore, infants are capable of affecting the people around them, but in this phase, infants use proximity-promoting signals indiscriminately. They are satisfied when anyone responds to their attachment behaviors.

Frequent encounters with caretakers at times when infants are alert also may facilitate infants' capacities to recognize caretakers, and Bowlby suggested that acquisition of the ability to recognize specific people marks the transition to the second phase of attachment development (discriminating sociability, 2 to 7 months). In fact, infants seem able to recognize their parents much earlier than Bowlby believed. [Macfarlane \(1975\)](#) provided anecdotal evidence that infants could distinguish between their mothers' smell and that of other nursing mothers within the first 2 weeks of life. After teaching infants to suck in one way to turn on a tape recording of their mothers' voices and in another way to produce the voice of another woman, [DeCasper and Fifer \(1980\)](#) found that 2-day-old infants not only could discriminate between two voices but worked harder (i.e., sucked in a special way) to hear their own mothers' voices.

Presumably because significant others (such as parents) have been associated with pleasurable experiences (e.g., cuddling and play) and with the relief of distress from early in life, familiar people become persons with whom infants prefer to interact. Initially, these preferences evidence themselves in fairly subtle ways: Certain people are able to soothe the infant more easily and to elicit smiles and coos more readily, broadly, and frequently. According to Bowlby, these preferences are initially based on recognition only: Infants do not even have a primitive conception of the permanent existence of their parents. Following various psychoanalytic theorists ( [Freud, 1965](#); [Spitz 1950b, 1965](#)), [Bowlby \(1969\)](#) and [Ainsworth \(1973\)](#) believe that infants cannot be said to love parents until they understand that their parents exist even when they are neither interacting with nor visible or audible to the infants. Consequently, Bowlby argued, we cannot claim that 3- or 4-month-olds have formed attachments, although they have taken another step toward this achievement.

The third of Bowlby's phases (attachment, 6 to 7, to 24 to 30 months) is marked by the emergence of intentional and focused attachment behavior. Seven-month-olds clearly understand and respect the rule of reciprocity in their interactions. Their confidence in others reinforced, 7-month-olds enjoy the newly acquired ability to creep around and to take responsibility for getting close to their parents at will, instead of waiting for others to come in response to their cries or coos. Intentional social behavior is now possible ( [Lamb, 1981a](#)), and 6- to 12-month-olds are increasingly likely to initiate interaction using directed social behaviors, whereas mothers more frequently initiate games, terminate or redirect their infants' activities, and issue verbal requests ( [Green et al., 1980](#)). Caretaking becomes less prominent. One sign of the increased intentionality of infant behavior is that 7-month-olds begin to protest more reliably when parents leave. Wariness of strange adults also may become more prominent around this time.

Especially from the parents' point of view, the transition between phase 2 and phase 3 is not abrupt because infants have been showing preferences for parents over others for several months. Nevertheless, the beginning of phase 3 is marked by two major behavioral changes. First, when infants protest when left by an attachment figure, they are no longer satisfied by the appearance of substitute interactive partners ( [Stayton et al., 1973](#)). According to Bowlby, separation protest should be viewed as a signal aimed at making attachment figures come back to the infant, and its emergence can be linked to the attainment of some primitive conception of person permanence—the notion that people have a permanent existence independent of the infant ( [Ainsworth, 1973](#)). Second, the emergent ability to crawl permits exploration of the environment on a scale hitherto inconceivable, affording infants the capacity to move toward attachment figures when they want to be near them. From this point on, infants assume an increasingly active role in their relationships with attachment figures.

Of course, major changes in social relationships occur between 6 and 7 months (the beginning of phase 3) and approximately 24 to 30 months (the end of this phase): Infants become increasingly sophisticated in their abilities to behave intentionally, to communicate linguistically, and to respond appropriately in a variety of different contexts. As infants grow older, they initiate an increasing proportion of their interactions. They can tolerate a growing distance from attachment figures as they grow older ( [Anderson, 1972](#); [Rheingold and Eckerman, 1970](#)).

According to [Bowlby \(1969\)](#), the next major transition occurs at the beginning of the third year of life, when children become able to take their parents' needs into account when interacting with them (phase 4, goal-corrected partnerships). For example, they are now able to respect others' differing perspectives and appear to recognize for the first time that parents must sometimes give priority to other activities, while the child's needs or wants wait ( [Marvin, 1977](#); [Mossler et al., 1976](#)). The beginning of phase 3 is, thus, the time at which the first infant–adult attachments are formed. Most theorists define attachment as a specific, enduring, emotional bond whose existence is of major importance in the process of sociopersonality development.

To whom do attachments form? In many places in the world, infants are cared for primarily by their mothers. The universality of traditional parental roles has led psychologists to assume that the first persons to whom infants become attached are their mothers. Until very recently, in fact, most theorists assumed that the infant–mother relationship was not simply most important but uniquely important ( [Ainsworth, 1973](#); [Bowlby, 1969](#); [Maccoby and Masters, 1970](#)), thus accepting [Freud's \(1940/1968, p. 48\)](#) dictum that the mother–infant relationship is "unique, without parallel, established unalterably as the prototype of all later love relations . . . for both sexes." Fathers were not considered important until the oedipal period began, around 3 years of age.

In fact, most infants become attached to their fathers at approximately 7 months of age, the same age at which they form attachments to their mothers ( [Lamb, 1976b, 1977, 1981b](#), in pressb), although many U.S. mothers are the primary or preferred attachment figures in the sense that infants prefer mothers at times of stress ( [Lamb, 1976a, 1976c](#)). In many parts of the world, infants may have several caregivers who are emotionally involved in their lives, and, thus, may form several attachments ( [Dunn, 1993](#); [Nash and Hay, 1993](#)).

In the United States, infant–mother and infant–father relationships offer different sorts of experiences for young infants. A detailed analysis of face-to-face play between parents and very young infants (2- to 6-month-olds) shows that fathers provide more unpredictable, less rhythmic, and more exciting (rather than calming) physical and vocal stimulation than do mothers ( [Yogman, 1982](#)). Naturalistic home observations of older infants and their parents yield similar findings ( [Lamb, 1976b](#)). In addition, mothers hold their infants most often for caretaking purposes; fathers hold their infants most often to play with them ( [Lamb, 1976b, 1977](#)).

These differences are significant because they show parental roles being translated into distinctive styles of interaction. Children learn to expect playful stimulating interactions with their fathers and, thus, come to prefer playing with them ( [Clarke-Stewart, 1980](#); [Lamb, 1977](#); [Lynn and Cross, 1974](#)). In addition, the playfulness of

fathers may increase the salience and importance of the limited amounts of time that many infants spend with their fathers.

## SECURITY OF INFANT–PARENT ATTACHMENTS

Attachment theory was developed by clinically oriented scholars primarily interested in how early attachment relationships might affect subsequent development. Much research on this issue involves use of the “Strange Situation” for assessing “the security of attachment” ( [Ainsworth and Wittig, 1969](#); [Ainsworth et al., 1978](#)). [Ainsworth et al. \(1978; Ainsworth and Bowlby, 1991\)](#) also provided an elegant and persuasive account of the relation among prior infant–mother interaction, security of infant attachment, and subsequent child development. We emphasize these developmental associations in this chapter, even though a great deal of research has recently focused on the ways in which different aspects of parental behavior affect child development (Bornstein, in press).

The Strange Situation can be used only when infants are old enough to have formed attachments and be mobile (e.g., older than 10 months), yet are young enough to be stressed by strangers and brief separations from their parents (e.g., younger than 24 months). The procedure has seven episodes, which are outlined in [Table 22.2](#), and is designed to expose infants to increasing amounts of stress to observe how they organize their attachment behaviors around their parents when distressed. Stress is stimulated by the unfamiliar environment, by the entrance of an unfamiliar adult, and by two brief separations from the parent. This procedure has been used widely, although increasing numbers of researchers instead use an alternative procedure, the Attachment Q-set ( [Vaughn and Waters, 1990](#); [Waters and Deane, 1985](#)). Interestingly, scores on the Attachment Q-set are much more highly correlated with temperament measures than are Strange Situation measures, perhaps because both measures of temperament are verbal report measures ( [Seifer et al., 1996](#); [Teti et al., 1996](#); [Vaughn et al., 1992](#); [Wachs and Desai, 1993](#)).

Episode*	Persons Present	Change
1	Parent, infant	Enter room
2	Parent, infant, stranger	Unfamiliar adult joins the dyad
3	Infant, stranger	Parent leaves
4	Parent, infant	Parent returns
		Stranger leaves
		Parent leaves
5	Infant	Stranger returns
6	Infant, stranger	Parent returns
7	Parent, infant	Stranger leaves

\*All episodes are usually 3 minutes long, but episodes 3, 5, and 6 can be curtailed if the infant becomes too distressed, and episodes 4 and 7 are sometimes extended. Adapted from Ainsworth MD, Wittig BA: Attachment and the exploratory behavior of one-year-olds in a strange situation. In: Fox RM (ed): *Determinants of Infant Behavior*, vol 4. London, Methuen, 1969, pp 113–136.

**Table 22.2. The Strange Situation**

### A Typology of Infants

According to Bowlby and Ainsworth, infants in the Strange Situation should be able to use their attachment figures as secure bases from which to explore the novel environment. The stranger's entrance should lead infants to inhibit exploration and draw a little closer to their parents, at least temporarily. The parents' departure should lead to attempts to bring them back by crying or searching, and to less exploration and affiliation. After the parents' return, infants should seek to reengage in interaction and, if distressed, may wish to be cuddled and comforted. The same responses should occur, with somewhat greater intensity, after the second separation and reunion. In fact, this is how approximately 65% of the infants studied in the United States in the Strange Situation behave. Following the practices of Ainsworth and her colleagues, these “securely attached” infants are designated type B.

By contrast, some infants seem unable to use their parents as secure bases from which to explore. Furthermore, although they are distressed by their parents' absence, they behave ambivalently on reunion, both seeking contact and interaction and angrily rejecting it when it is offered. These infants are conventionally labeled type C and typically account for approximately 15% of the infants in American research samples. Another group of infants seem little concerned by their parents' absence. Instead of greeting their parents on reunion, they actively avoid interaction and ignore the parents' bids. These infants are said to exhibit type A attachments; they typically constitute approximately 20% of the infants in American samples.

Although the behavior of most infants allows them to be classified into one of these categories, some infants are difficult to classify ( [Main and Solomon, 1986, 1990](#)). [Main and Solomon \(1986\)](#) observed such infants and found that, rather than using different patterns of behavioral organization, these infants appear disorganized. They have designated a new category, type D attachment, to reflect infants who show behavioral indices of disorganization and disorientation in the Strange Situation. Main and Solomon have compiled a list of behaviors that reflect such disorganization and disorientation, thought to reflect a conflict between behavioral systems (e.g., “cries while moving away from parent” or “falls prone on reunion”).

### Determinants of Strange Situation Behavior

According to ethologic attachment theorists, infants count on attachment figures to protect them and to be accessible when needed and so use them as secure bases from which to explore and interact with other people. However, not all infants trust their attachment figures equally, and these differences in security of attachment might affect how willingly infants use their attachment figures as bases of security. In fact, Ainsworth has argued that the A, B, and C patterns of attachment behavior in the Strange Situation indeed reflect individual differences in attachment security. Moreover, Ainsworth has developed hypotheses concerning the ontogeny of these individual differences.

Almost from birth, infants learn about people from their interactions with them ( [Lamb, 1981a; Watson, 1985](#)). The extent to which their behaviors—particularly their cries—are answered depends, of course, on the responsiveness of the infants' caretakers. When caretakers hear the infants' signals, interpret them correctly, and make consistently appropriate responses, infants develop confidence in their own “effectance” (ability to act on the environment successfully) and trust in the reliability or predictability of the persons concerned. Evidence gathered in an exploratory longitudinal study ( [Ainsworth and Bell, 1974; Blehar et al., 1977](#)) led Ainsworth to propose that caretakers' sensitivity is important from the first months of life—the months during which infants come to understand what it means to be social. Because adults differ in their sensitivity, there would be differences among infants in the extent to which infants had confidence in their own effectance and in the reliability of others. Ainsworth equates these with differences in the security of attachment ( [Ainsworth et al., 1974; Ainsworth and Bowlby, 1991](#)). Since Ainsworth's hypotheses were proposed, many other researchers (see reviews by [Belsky and Cassidy, 1994; Thompson, 1998](#)) have attempted to test them in independent longitudinal studies (e.g., [Bates et al., 1985; Belsky et al., 1984; Egeland and Faber, 1984; Erickson et al., 1985; Grossmann et al., 1985; Miyake et al., 1985; Sagi et al., 1985](#)). After reviewing the complicated results of these many studies, [Lamb and his coauthors \(1985\)](#) concluded that there was general support for the notion that more socially desirable parental behavior, that is, nurturant, attentive, nonrestrictive parental care, was associated with type B infant behavior in the Strange Situation, at least when studies were conducted in the United States. [DeWolff and van IJzendoorn \(1997\)](#) reached the same conclusion after a metaanalysis of the available data. Both reviews agreed that the mothers of infants who behave in type A or type C fashion (often called *insecurely attached*) manifest less socially desirable patterns of behavior: They may overstimulate or understimulate, fail to make their behaviors contingent on infant behavior, appear cold or rejecting, and sometimes appear inept to observers. Unfortunately, there is too much variability in the results to identify precisely what aspects of parental behavior are formatively important. Some studies identify warmth but not sensitivity; some identify level of stimulation; some, patterning of stimulation but not warmth or amount of stimulation, and so forth. Infants who behave in a disorganized fashion often have experienced abuse at the hands of their parents ( [Carlson, 1998](#)).

### Stability and Prediction

**Stability.** The notion that Strange Situation behavior reflects something meaningful is supported by findings showing stability over time in patterns of infant behavior. Both [Waters \(1978\)](#) and [Connell \(1976\)](#) reported remarkable stability between 12 and 18 months of age in the way infants behave in the Strange Situation when observed twice with the same parent. According to Waters, 48 of 50 infants (96%) obtained the same classification on both occasions! However, test–retest reliability is not always so high. [Vaughn et al. \(1979\)](#) showed that, in an economically disadvantaged sample, many infants changed from one mode of behavior to another between 12 and 18 months of age. Changes were systematic: When the families had experienced considerable social stress during the 6-month period, type B attachments often changed to types A or C, although when families experienced a low degree of stress, types A or C attachments did not necessarily become type B. Later, [Thompson et al. \(1982\)](#) found equivalent instability in a middle-class sample. In this study, major changes in family circumstances or caretaking arrangements

(e.g., the onset of maternal employment) led to changes in Strange Situation behavior, but they did not necessarily engender change from the more desirable type B to the less desirable types A and C any more often than the reverse. Because parents' sensitivity to the infants' signals appears to influence Strange Situation behavior ([Ainsworth et al., 1974, 1978](#)), these data might mean that changes in the amount of stress to which the mothers were subjected affected the manner in which they interacted with their infants. [Teti et al. \(1996\)](#) showed that this might be true in a study concerned with the effects of a second child's birth on the attachments between older siblings and their mothers. Attachment security declined most dramatically when mothers were most psychologically distressed and had the poorest marital relationships.

**Predictive Validity.** Another reason why attachment classifications intrigue developmentalists is that they sometimes predict aspects of the child's future behavior ([Thompson, 1998](#)). Attachment theorists believe that when infants encounter people for the first time, they tend to assume that those persons will treat them in the same way that others have treated them in the past. Thus, infants who have developed trust in their attachment figures tend to regard new people they encounter as trustworthy too. As infants get to know each individual, of course, they develop a set of expectations about that specific individual.

The relation between Strange Situation behavior and styles of interaction with unfamiliar adults has been well documented (see [Thompson, 1998, 1999](#) for reviews). [Main \(1983\)](#), for example, showed that infants who had type B attachments to their mothers were later more cooperatively playful when interacting with a friendly stranger than were type A or C infants. Type A infants (who were avoidant of their mothers) later avoided the stranger, whereas type C infants were later resistant with the stranger. [Main and Weston \(1981\)](#), as well as [Thompson and Lamb \(1983\)](#), confirmed that type B infants were more sociable with unfamiliar adults than type A or C infants were. Similarly, [Lieberman \(1977\)](#), [Easterbrooks and Lamb \(1979\)](#), and [Pastor \(1981\)](#) showed that Strange Situation behavior was associated with social behavior in initial encounters with peers, as well as over longer periods in preschool play groups ([Booth et al., 1991](#); [Sroufe, 1983](#); [Waters et al., 1979](#)) and summer camp at 11 years of age ([Elicker et al., 1992](#)). Type B infants engaged in more frequent and more mature forms of interaction with their peers, sharing more and showing a greater capacity to initiate and maintain interactions, for example. For reasons that are not clear, however, [Jacobson and colleagues \(Jacobson and Wille, 1984; Jacobson et al., 1983, 1986\)](#) have reported contrasting results, suggesting that the relation between attachment classification and peer competence is neither direct nor powerful (see [Lamb and Nash, 1989](#), for a review of the studies and issues concerning the influence of attachment relationships in infancy on later peer relationships).

Other research ([Arend et al., 1979](#); [Frankel and Bates, 1990](#); [Matas et al., 1978](#); [Sroufe, 1983](#); [Suess et al., 1992](#)) addresses the relation between attachment classifications and aspects of achievement motivation. These researchers found that Strange Situation behavior at 12 or 18 months predicts cognitive performance in problem-solving situations and in a variety of stressful and challenging contexts, at least until kindergarten age. Placed in cognitively challenging situations, children who, as infants, had type B attachments to their mothers persisted longer and more enthusiastically than did children who had type A or C attachments. Type B infants also seemed to be more resilient and robust when stressed or challenged ([Block and Block, 1980](#)). In addition, type B infants appeared more socially competent and independent when they later entered preschool ([Sroufe, 1983](#); [Sroufe et al., 1984](#)) and also showed fewer behavior problems ([Bates et al., 1985](#); [Erickson et al., 1985](#); [Lewis et al., 1984](#)). In general, although some researchers have found that insecure attachments may be associated with severe behavior and adjustment problems, others have not ([Belsky and Cassidy, 1994](#); [Belsky and Nezworski, 1988](#); [Fagot and Kavanaugh, 1990](#); [Lyons-Ruth et al., 1993](#); [NICHD Early Child Care Network, 1998](#)).

Evidence concerning the temporal stability of Strange Situation behavior and its relation to measures of earlier infant–mother interaction and later child achievement and personality suggests that the Strange Situation measures some meaningful aspect of mother–infant attachment and has important implications for understanding and predicting development. Presumably, Strange Situation behavior with fathers affects development in analogous ways, particularly because paternal sensitivity significantly affects the security of infant–father attachments ([van IJzendoorn and DeWolff, 1997](#)). However, the recent attention given to multiple attachment figures for many infants—mothers, fathers ([Lamb, 1981b, Lamb, in pressb](#)), siblings ([Teti and Ablard, 1989](#)), grandparents ([Myers et al., 1987](#)), day care providers ([Howes et al., 1988](#))—highlights the need for a comprehensive model of such combined influences ([Nash and Hay, 1993](#); [Tavecchio and van IJzendoorn, 1987](#); [Thompson, 1990](#)). Are these influences additive, such that a secure attachment to one parent and an insecure attachment to the other leads to intermediary levels of functioning later on ([Easterbrooks and Goldberg, 1990](#); [Pipp et al., 1992](#))? Or are these influences compensatory, such that a secure relationship with a day care provider, for example, can compensate for an insecure attachment to a parent ([Goossens and van IJzendoorn, 1990](#))? (See [Nash and Hay, 1993](#) for a fuller discussion of the issue of combining influences from several early close relationships.)

Even for the relatively simpler infant–mother predictions, [Lamb et al. \(1985\)](#) and [Thompson \(1998\)](#) have pointed out that the predictive validity of longitudinal associations is far from perfect. Rather, the relation between Strange Situation behavior and subsequent child behavior is found only when there is stability in the caretaking arrangements and family circumstances, which (as we noted previously) seems to maintain stability in patterns of parent–child interaction. Thus, the question first encountered when considering the stability of cognition in infancy arises again: Is the prediction over time attributable to individual differences in the quality of early parent–child interaction, or is it attributable to the continuing quality of child–parent interactions? If the latter were true, it would imply that the quality of early relationships was predictively valuable, not because it caused later differences directly, but because it presaged later differences in the quality of relationships, which, in turn, would cause differences in the child's behavior. Such a pattern of findings would place the locus of stability in the continuing quality of parent–child interactions rather than in some aspect of the child's personality. Research ([Thompson, 2000](#)) has shown that both early and later relationship patterns appear to shape the child's development

Although attachment security, measures of prior infant–parent interaction, and measures of the child's later behavior are all interrelated, the relations are not very strong. This suggests that factors other than quality of attachment, such as temperament or familiarity with strangers and brief separations, influence children's Strange Situation behavior. In turn, this means that researchers and clinicians need to rely on multiple convergent methods to assess constructs as complex and as important as the quality of infant attachments, rather than relying on a single measure like the Strange Situation in which behavior is influenced by factors other than quality of attachment.

### Cross-Cultural Research

Some of the most provocatively informative recent work on Strange Situation behavior has been conducted outside the United States. The distribution of infants across the A, B, and C categories in many other countries differs from that typically found in American samples ([Lamb et al., 1985](#)). One could interpret these results by concluding that parents in the cultures are either much more or much less sensitive than American parents, but that ethnocentric interpretation seems improbable. Rather, these results may demonstrate the importance of factors other than the quality of parental behavior in explaining Strange Situation behavior ([Lamb, in pressb; Lamb et al., 1985](#)). For example, the high degrees of stress manifested by Japanese and Israeli infants leads to increases in the proportion of infants classified as type C. It may be that Japanese infants appear inordinately distressed because they have much less experience with separations from their mothers than American infants typically have; thus, the situation is not psychologically similar for Japanese and American infants. For infants growing up on Israeli kibbutzim, encounters with strangers are unusual and may thus elicit great distress. Again, therefore, even though the procedure was structurally the same for Japanese, Israeli, and American infants, the psychological experiences or meanings for infants from each culture might be very different. In addition, [Miyake et al. \(1985\)](#) reported that the Japanese infants who were later classified as type C were temperamentally more irritable than type B infants from birth. Thus, it appears that culture-specific rearing practices or temperamental differences account for at least some of the variance in Strange Situation classifications across cultures. Scholars have developed an increasingly sophisticated understanding of the ways culture may shape human development, and this is likely to refashion much of developmental psychology in the next decade ([Parke and Buriel, 1998](#)).

The picture emerging from the many studies in which Strange Situation behavior was assessed is a complicated one. Strange Situation behavior appears to reflect individual differences in patterns of infant–parent interaction, with type B attachments potentiated by warm, sensitive, and supportive parental behavior. However, other factors seem to be important as well, notably culture-specific rearing practices and (perhaps) infant temperament. To understand the formative importance of infant–parent attachment, we need to obtain multiple measures of attachment, rather than rely exclusively on the observation of Strange Situation behavior. In addition, we need to understand better how several early attachment relationships together may affect later functioning.

The next two sections take into account such a diverse social milieu, which for many infants involves not only parents but grandparents and other adults, siblings, and peers. We now discuss infants' relationships with nonparental figures and illustrate similarities and differences among the infant–adult, infant–sibling, and infant–peer systems.

### Sibling Relationships

Siblings in many nonindustrialized countries assume a major responsibility for infant caretaking ([Zukow-Goldring, 1995](#)). These siblings may spend relatively little time playing with the infants; most of their interactions, like those of Western parents, involve protection or caretaking. In our society, by contrast, siblings seldom assume any responsibility for infant caretaking, and sibling relationships appear to incorporate features of both the infant–adult and infant–peer systems (Teti, in press). On

the one hand, sibling dyads share common interests and have more similar behavioral repertoires than do infant–adult dyads. On the other hand, sibling pairs resemble infant–adult pairs to the extent that they differ with respect to amount of experience and levels of both cognitive and social ability. These discrepancies often lead to differences in the ways younger and older siblings relate to each other, differences that distinguish them from the infant–peer system (see later). Observational studies of sibling interaction in a laboratory playroom reveal consistent asymmetries between the roles assumed by older and younger children ( [Abramovitch et al., 1979](#); [Lamb, 1978a, 1978b](#); [Teti et al., 1986](#)). Older siblings “led” the interaction: They engaged in more dominant, assertive, and directive behaviors than their younger siblings. The infants, meanwhile, appeared inordinately interested in what their siblings were doing; they followed them around, attempting to imitate or at least explore the toys just abandoned by the older children. This is, of course, a strategy that maximizes the amount the infant can learn about the environment from the older child. As [Zajonc \(1983\)](#) suggests, older siblings offer young children cognitive models, albeit less sophisticated ones than do adults. In a home observational study, [Abramovitch and colleagues \(1979\)](#) reported patterns of interaction similar to those reported by [Lamb \(1978b\)](#), although siblings at home engaged in much more interaction than in the laboratory. In a longitudinal study, [Lamb \(1978a\)](#) found remarkable stability across time in the amount of interaction engaged in by siblings. The pattern of correlations, furthermore, suggested that the sociability of the younger infants determined the amount of attention they later received from their siblings, rather than the reverse.

Individual differences in the quality of sibling relationships also were the focus of a longitudinal study conducted in England by [Dunn and Kendrick \(1980, 1981a, 1981b, 1982a, 1982b\)](#). [Dunn et al. \(1998\)](#) found that same-sex siblings got along better than different-sex siblings. In addition, siblings interacted more poorly when mothers and first-born girls had very positive relationships before and immediately after the birth of the second child and when there was frequent interaction and play between the siblings and their mothers. These findings suggest that parents exert an important influence on the mutual affective involvement of siblings who may compete for parental attention.

In a variety of studies, researchers have found that older siblings spend at least some of their time teaching object-related and social skills to their younger siblings (including infants) and that the amount of teaching increases with the age of the older child ( [Cicirelli, 1973, 1974](#); [Minnett et al., 1983](#); [Pepler, 1981](#); [Stewart, 1983](#)). These studies, along with the finding that infants monitor and imitate their older siblings ( [Lamb, 1978a, 1978b](#)), confirm that older siblings may influence the cognitive and social skills of infants through some combination of teaching and modeling ( [Zajonc, 1983](#)). [Dunn \(1988\)](#) very richly documents the enhanced arena for the development of social understanding provided by siblings, and infants' considerable practical understanding of the feelings and intentions of other family members, siblings and parents alike. Infants also form attachments to their older siblings ( [Dunn, 1993](#)), which affect the infant's levels of aggressiveness, distress, and conflict ( [Teti and Ablard, 1989](#); [Volling and Belsky, 1993](#)).

Not only do older siblings influence infants, but the reverse occurs. For example, [Howe and Ross \(1990\)](#) found that friendly interactions between preschoolers and their infant siblings increased the older children's perspective-taking abilities.

The effects of age spacing on the patterns of interactions between infants and their preschool-aged older siblings are unclear; [Abramovitch and her colleagues \(1979\)](#), like [Dunn and Kendrick \(1981b, 1982a\)](#), found no age-spacing differences in amounts of positive, negative, and imitative sibling behaviors. Suggesting that broad summary measures may not have been sensitive enough to detect actual differences, [Teti et al. \(1986\)](#) used a more fine-grained coding scheme and found that older preschool-aged first-borns indeed created more “intellectual” (e.g., language mastery) and “social” (e.g., game) experiences for their infant siblings than did younger preschool-aged first-borns. In addition, [Gibbs et al. \(1985\)](#) found that widely spaced siblings were more interactive and responsive to one another than were closely spaced siblings. In neither of these investigations, however, did the researchers uncover relations between measures of infant cognitive or linguistic level and either sibling age or measures of sibling interaction. Thus, the net impact of siblings on infant development remains unclear, partly because such influences depend on sex of the siblings, birth order, and family size ( [Wagner et al., 1993](#)), and partly because both parents and the children themselves help to create very different rearing experiences for children in the same family ( [Dunn and Plomin, 1991](#); [Kowal and Kramer, 1997](#)), and behave differently before and after the birth of later children ( [Bayder et al., 1997](#); [Sakin et al., 1996](#)).

### Infants' Interactions with New People

Before the 1970s, it was commonly believed that infants were uninterested in their peers and afraid of strangers. Studies conducted since then, considered alongside earlier studies, indicate otherwise ( [Bridges, 1933](#); [Buhler, 1933](#); [Maudry and Nekula, 1939](#); [Ross and Goldman, 1977](#)). In fact, infants are both interested and competent in their interactions with strangers, whether peers or adults.

## INFANT–PEER INTERACTIONS

Although infants younger than 1 year of age do not have sustained interactions with peers ( [Rubin et al., 1999](#)), even newborns are responsive to their peers. As described previously, they respond to the distress of their peers by becoming distressed themselves ( [Martin and Clarke, 1982](#)). Two- and 3-month-olds attend to the activities of their peers ( [Bridges, 1933](#)) and increase their own activity level in a peer's presence ( [Field, 1979](#); [Fogel, 1979](#)). By 6 months of age, peers do not simply elicit responses in infants; infants respond to one another in socially complex ways. They initiate interactions by touching, vocalizing, or smiling at peers ( [Hay et al., 1983](#); [Vandell, 1980](#); [Vandell et al., 1980](#)), and their increased sensitivity to social cues is indicated by tendencies to continue interactions when peers are responsive and to stop when they are not ( [Hay et al., 1983](#)). In addition, 6-month-olds do not automatically cry in response to their peers' cries but instead attend to a peer's distress, becoming distressed themselves only if the other's distress is prolonged ( [Hay et al., 1981](#)).

Between 6 and 12 months of age, infants direct increasing numbers of social behaviors toward peers ( [Jacobson, 1981](#); [Maudry and Nekula, 1939](#); [Vandell, 1980](#)), although the amount of physical contact decreases ( [Vandell, 1980](#); [Vandell et al., 1980](#)). Perhaps this reflects an increasing reliance on distal rather than proximal modes of interaction, for during the second half of the first year infants begin to use conventional acts (gestures and words) to communicate with their peers ( [Bakeman and Adamson, 1986](#)). The structural complexity of peer-directed acts also increases with age so that by 9 months infants can synchronize several social behaviors ( [Becker, 1977](#); [Vandell et al., 1980](#)) and can attend simultaneously to objects and peers and thus engage in joint play ( [Adamson and Bakeman, 1985](#)). Infants at this age also express more affect during periods of joint engagement with peers than when alone ( [Adamson and Bakeman, 1985](#)) and begin to distinguish between familiar and unfamiliar peers ( [Dontas et al., 1985](#); [Jacobson, 1981](#)).

At the start of the second year of life, both cooperation and conflict begin to occur in interactions between peers ( [Eckerman and Whatley, 1977](#); [Goldman and Ross, 1978](#); [Hay et al., 1991](#); [Howes, 1988](#); [Nash, 1985, 1986](#)). The ability to engage in conflicts over toys and personal space, not present among 6-month-olds ( [Hay et al., 1983](#)), is found at the start of the second year of life ( [Caplan et al., 1991](#); [Nash, 1986](#)). The social nature of such early conflicts is suggested by [Hay and Ross \(1982\)](#), who found that 21-month-olds did not simply grab toys from one another but used gestures and vocalizations to resolve disputes. In addition, when children yielded possession of objects to peers, the winners often turned their attention elsewhere, as though the interaction itself, and not obtaining the object, was important. These infants spent only 5% of their time with one another in conflicts.

Studies comparing interactions with peers and mothers indicate that infants demonstrate similar social competencies in their interactions with peers and mothers ( [Adamson and Bakeman, 1985](#); [Bakeman and Adamson, 1984, 1986](#); [Nash, 1985, 1986](#); [Vandell and Wilson, 1982](#)). In addition, several studies of 10- to 19-month-olds revealed that interactions with peers were more frequent than those with mothers when both were present ( [Eckerman and Whatley, 1977](#); [Eckerman et al., 1975](#); [Nash, 1986](#); [Rubenstein and Howes, 1976](#); [Rubenstein et al., 1982](#)), even though mothers of 13- to 15-month-olds initiate more interactions with their infants than vice versa and initiate as many interactions as do peers ( [Nash, 1986](#)). Novelty is not the issue either: When given the opportunity to interact with peers, mothers, and unfamiliar adults, infants interact more frequently with peers than with unfamiliar adults ( [Eckerman and Whatley, 1977](#); [Lewis et al., 1975](#)). On the other hand, parents are more sensitive to infants' developmental needs and thus are more likely to act in ways that foster their cognitive development ( [Tamis-LeMonda et al., 1994](#)). Some researchers believe that individual differences in peer instruction reflect differences in the security of prior parent–child attachments ( [Belsky and Cassidy, 1994](#); [Rose-Krasnor et al., 1996](#)), others suggest that skills honed in interaction with nonparental care providers are crucial ( [Howes, 1989](#); [Oppenheim et al., 1988](#)), whereas others point to generalized and perhaps inherent differences in sociability ( [Kagan, 1997](#); [Lamb and Nash, 1989](#)).

## INFANT–ADULT INTERACTIONS

The fact that infants prefer to socialize with peers rather than with adults does not mean that they are uninterested in, or wary of, unfamiliar adults. Indeed, they are quite adept in their social relations with new adults as well. When infants are approximately 8 months of age, they begin to distinguish between unfamiliar and familiar adults by showing signs of apprehension about the former ( [Bronson, 1972](#); [Emde et al., 1976](#)). This wariness was at one time termed *stranger anxiety* and was treated as a developmental milestone. More recent studies have shown that in many situations, infants do not always behave anxiously and that infants' responses to strangers depend to a large extent on the strangers' behavior. When an unfamiliar adult approaches an infant in a warm, friendly manner, the infant usually responds in kind ( [Bretherton, 1978](#); [Bretherton et al., 1981](#); [Clarke-Stewart, 1978](#); [Rheingold and Eckerman, 1973](#)). The parent's behavior, too, can affect the infant's response:

Infants whose mothers talked to them in a happy tone about a stranger were friendlier toward the stranger than infants whose mothers talked about the stranger in a neutral tone ([Feinman et al., 1986](#)). Thus, when placed in a situation conducive to socializing (i.e., when those present act in a friendly manner), infants respond accordingly.

A variety of studies have indicated that infants are quite interested in and able to interact with new people. [Rheingold and Eckerman \(1973\)](#) found that nearly all the 8- to 12-month-olds in their study looked and smiled at strangers and appeared comfortable in their presence. Many let the stranger pick them up while their mothers were out of the room. With both their mothers and a friendly, interactive stranger present, 12-month-olds approached the stranger and spent more time with her than with their mothers ([Ross and Goldman, 1977](#)). Furthermore, 9- to 12-month-old infants were as likely to follow an unfamiliar woman as their mothers into another room ([Hay, 1977](#)) and also actively interacted with strangers, willingly sharing objects with them ([Hay and Murray, 1982](#); [Rheingold et al., 1976](#); [Ross and Goldman, 1977](#)). One-year-olds engaged in cooperative play ([Bretherton, 1978](#)) and games ([Ross and Goldman, 1977](#)) with unfamiliar adults, whereas 18-month-olds imitated unfamiliar adults as much as they imitate their mothers ([Hay et al., 1985](#)), and will help unfamiliar adults to shelve groceries ([Rheingold, 1982](#)). Infants also can request help from unfamiliar adults effectively ([Mosier and Rogoff, 1994](#); [Rogoff et al., 1984](#)), and in one study used social referencing with adults they had known for only 10 minutes when confronted with a mildly frightening toy ([Klinnert et al., 1986](#)).

Infants' interest in and abilities to interact with people other than their parents can set the stage for the formation of relationships with others. Thus, 10- to 14-month-olds who were cared for by an unfamiliar adult for 2½ hours during each of 3 consecutive days formed bonds to the caretaker: They consistently approached her and cried when she left them with a person they had seen for only a few minutes ([Fleener, 1973](#)). One-year-olds who had interacted with a stranger for 8 minutes either did not cry when left alone with the stranger or were more effectively soothed by her than were infants who had interacted with a stranger for only 1 minute ([Bretherton, 1978](#)). Furthermore, infants cried when a stranger whom they had only recently met departed, leaving them alone in an unfamiliar room ([Ipsa, 1981](#)). Not surprisingly, infants can feel secure with people in addition to their parents. Thus, infants formed attachments to care providers both in day care centers ([Ahnert and Lamb, 2001](#); [Ainslie and Anderson, 1984](#); [Goossens and van Ijzendoorn, 1990](#); [Ricciuti, 1974](#)) and in Israeli kibbutzim ([Fox, 1977](#); [Sagi et al., 1985](#)). As with parents, the type of attachments infants formed with major care providers affected aspects of their personality several years later ([Howes, 1990](#); [Howes et al., 1988](#); [Oppenheim et al., 1988](#), reviewed by [Nash and Hay, 1993](#)).

Findings like these highlight the roles played by social interaction in shaping development in infancy. Born with the ability to express emotions, infants effectively engage adults from the start. Over time, the infant's expressive and social skills improve as a result of social experiences; the interactions between infants and their care providers establish dispositions that, when maintained by a stable social environment, may predict aspects of the children's functioning years later.

We began this chapter with a discussion of the transactional model; its portrayal of development as a joint function of infant and exogenous influences improves on the more static main effects and interactional models. It is fitting, then, to conclude the chapter with a discussion of infant temperament. From a transactional perspective, temperament appears to be an early emerging and direct way in which infants affect other individuals and, thereby, their own development.

## INFANT TEMPERAMENT

Developmentalists traditionally believed that individual differences in infant behavior were determined by differences in infant–mother interactions, with genetic/constitutional factors playing a minor role, such as in explaining susceptibility to separation distress. Today, however, theorists and researchers agree that individual differences may play a far more important role than this, and consequently issues concerning the definition, measurement, and origins of temperament have moved to the forefront of infant research ([Rothbart and Bates, 1998](#)). Temperament is generally viewed as having a genetic/constitutional base and as being somewhat stable over time, although theorists disagree over the stability and modifiability of temperament and the relation between infant temperament and later personality ([Buss and Plomin, 1975](#); [Caspi, 1998](#); [Rothbart and Bates, 1998](#); [Thomas and Chess, 1977](#)) (see [Chapter 15](#) for a general historical account of the concept of temperament).

### Conceptualizations of Infant Temperament

Temperament can be thought of as a constitutionally based source of individual variation in personality functioning, emerging early in life. Most measures of temperament sample aspects of infant affect, attention, and activity, attending to temporal (e.g., latency of response) and intensive (e.g., strength and sensitivity of response) characteristics of certain behaviors.

Although [Gesell and Ames \(1937\)](#) first suggested research on infant temperament, it was not until Thomas and Chess began the New York Longitudinal Study (NYLS) in the 1950s that research on infant temperament began in earnest ([Thomas and Chess, 1977](#); [Thomas et al., 1963, 1968](#)). The subjects of the NYLS were followed at regular intervals from infancy through adolescence and adulthood. Mothers were first interviewed when the infants were 2 to 3 months of age, and from these interviews Thomas and Chess derived nine dimensions of infant temperament: activity level, rhythmicity, approach/withdrawal, adaptability, intensity of reaction, attention span and persistence, distractibility, quality of mood, and threshold of responsiveness. Four behavior styles were ultimately identified. “Easy infants” were positive in mood, regular in body functions, and adaptable; these infants (comprising approximately 40% of the entire sample) approached new situations positively and reacted with low to moderate intensity. By contrast, “difficult infants” (10%) were negative in mood, irregular, and slow to adapt; they withdrew from new situations and reacted with high intensity. “Slow-to-warm-up infants” (15%) were negative in mood and slow to adapt; they withdrew from new situations, reacted with low to moderate intensity, and were low in activity. “Average infants” (35%) were not rated highly on any dimension.

Thomas and Chess reported that individual differences in infant temperament were fairly stable over time. However, one of their most important and provocative findings was that a child's behavioral style was not always predictable from knowledge of behavioral style in infancy. [Thomas et al. \(1968\)](#) reported that in approximately 70% of infants characterized as “difficult,” behavior problems eventually developed. Not surprisingly, these “difficult” children created special challenges for parents, who were described as behaviorally and emotionally inconsistent with their children; they frequently blamed themselves for their children's problems. Parents of those “difficult” infants who had no significant problems in later childhood adapted much more successfully to their children's difficult behavior, however; they were tolerant, patient, and consistent. Rather than blaming themselves, these parents accepted their children's temperamental difficulties with good humor. The major differences between these two groups of “difficult” children suggested that temperamental characteristics early in life can be modified by environmental experience. [Thomas et al. \(1968\)](#) argued that the “goodness of fit” between the child's temperament and the demands of the environment determined whether outcomes would be favorable or unfavorable.

Like many pioneering studies, the NYLS has been the target of much criticism. One major question concerns the close contact the investigators maintained with their subjects, raising the possibility that knowledge of the child's temperament at one point may have inadvertently influenced investigators' judgments of the same child's later behavior. Second, most of the information about temperament and behavior was obtained from parental interviews, raising questions concerning the extent to which data were influenced by parental perceptions. A third criticism arose from the conception of temperament as a behavioral “style,” which implies a kind of pervasiveness that seldom occurs in human behavior. Fourth, other researchers have failed to find evidence of the nine NYLS divisions. Instead, researchers have suggested that five or six independent dimensions of temperament are distinguishable ([Caspi, 1998](#); [Rothbart and Bates, 1998](#)).

Despite these criticisms, however, the growing recognition of constitutional differences at birth led [Brazelton \(1973\)](#) to develop an objectively administered Neonatal Behavioral Assessment Scale (NBAS). This scale was originally designed to assess neonatal behaviors having clear social significance to parents. Thus, it has many of the features of a measure of temperament, although the scale was not specifically designed as such. NBAS items assess states of alertness, capacities to self-soothe, responses to adult ministrations, and the abilities to respond and cease responding to animate and inanimate stimuli of various types. The NBAS also assesses motor abilities, muscle tone, and some neurologic reflexes. Early reports suggested that NBAS scores tended to correlate with later parental reports of temperamental traits, such as distractibility ([Sostek and Anders, 1977](#)).

During the 1970s, the NBAS became popular for documenting individual differences in the social capacities of neonates. Unfortunately, however, researchers failed to find significant reliability in neonatal performance on the NBAS, even from day to day ([Sameroff, 1978](#)). This could have a variety of explanations. First, infant social capacities may be genuinely unstable. Second, these social capacities may be stable, but fluctuations in infant state may mask stability. Third, the type and dosage of medication administered to mothers during childbirth, as well as the time elapsed between birth and testing, also may affect the temporal stability of the NBAS. Despite these limitations, the NBAS has become popular as an intervention tool for demonstrating infant capacities to parents ([Nugent et al., 1986](#); [Nurcombe et al., 1984](#); [Rauh et al., 1986](#)).

From the original interview responses obtained by Thomas and Chess, [Carey \(1970\)](#) developed the Infant Temperament Questionnaire (ITQ), which was later refined by [Carey and McDevitt \(RITQ; 1978a, 1978b\)](#). The ITQ and RITQ measure the nine dimensions derived by Thomas and Chess and also allow summary

characterizations of infants as easy, slow to warm up, difficult, intermediate low, and intermediate high. [Bates et al. \(1979\)](#) also have developed a parent-report measure, the Infant Characteristics Questionnaire (ICQ), measuring the dimensions of “fussiness-difficult” (on which they place greatest emphasis), “unadaptable,” “dull,” and “unpredictable.” [Rothbart \(1981\)](#) developed a third parent questionnaire, the Infant Behavior Questionnaire (IBQ), which measures the dimensions of activity level, soothability, fear, distress to limitations, smiling and laughter, and duration of orienting. Finally, [Buss and Plomin \(1975, 1984\)](#) have developed a parent questionnaire measuring the dimensions of emotionality, activity, sociability, and impulsiveness. Three additional temperament measures involve more objective home or laboratory assessments. [Bornstein et al. \(1986\)](#) have developed a measure that couples home observations and parent reports, which is built around infants' spontaneous activity and infant responsivity in structured vignettes. This measure assesses the dimensions of positive affect, negative affect, persistence, and motor activity. [Matheny and Wilson \(1984; Matheny, 1980, 1983\)](#) have created a laboratory-based assessment of temperament, measuring the dimensions of test extraversion, activity level, and task orientation. Finally, [Goldsmith and Campos \(1982, 1986\)](#) have developed a laboratory observation technique, tapping 10 task-specific dimensions. All of these measures remain in use today, despite concern about their validity and reliability ( [Rothbart and Bates, 1998](#)).

Overall, little consensus exists regarding the prominent characteristics of infant temperament, and the psychometric properties and convergent validity of temperament measures are poor ([Hubert et al., 1982](#)). Most instruments also show only moderate temporal stability, low interparent and parent–observer agreement, and inconsistent relations to observed interaction patterns. Nevertheless, it may be desirable to obtain information from both parents and observers, even if scores on the two measures differ, because temperament is so complex a construct. Both may measure valid aspects of infant temperament, and although parental ratings may be colored by idiosyncratic perceptions and parental personality ( [Goldsmith and Campos, 1982; Kagan, 1998; Sameroff et al., 1982](#)), these perceptions may be more important predictors of infant–parent relationships than “objective” measures of the infant's temperament would be ( [Bates, 1980, 1983](#)).

During the 1990s, investigators began focusing on physiologic measures of temperament, after its successful use in studies of toddlers and preschoolers during the 1980s (see [Kagan, 1998](#), for a review). Individual differences in positive and negative emotionality are thought to reflect difference in temperament. Thus, measures of neural and endocrine processes (related to genetic differences) should correlate with other measures of emotionality. In support of this, [Gunnar and Nelson \(1994\)](#) have found that differences in event-related potentials were associated with differences in emotionality and cortisol levels. Higher cortisol levels have been reported for behaviorally inhibited infants compared with uninhibited infants in several studies by Gunnar and associates ( [Gunnar et al., 1992, 1995; Larson et al., 1991; Nachmias et al., 1996](#)). [Stifter and Fox \(1990; Fox and Stifter, 1989\)](#) included measurements of vagal tone in their longitudinal study of emotional reactivity in infants and found that at 5 months infants with high vagal tone were emotionally more reactive to negative events, and at 14 months they were quicker positively to approach a stranger and a new toy than were infants with lower vagal tone. [Porques et al. \(1994\)](#) reported that vagal tone was higher in fussy infants, and that 9-month vagal tone predicted temperamental difficulty at 3 years of age. Apparently, individual differences in parasympathetic control (as indexed by vagal tone) affect socioemotional organization, such that infants with higher parasympathetic control (higher vagal tone) are better organized socioemotionally and more behaviorally responsive to others ([Porques, 1998](#)).

### Stability of Infant Temperament

Given the expected relation between infant temperament and later personality, temporal stability was initially seen as a necessary component of temperament ( [Buss and Plomin, 1984](#)). However, the age-to-age correlations for different dimensions of temperament are variable and may be especially low in the first years of life ([Rothbart and Bates, 1998](#)). This apparent instability was first attributed to measurement error or to environmental flux, but most recently, researchers have begun to ascribe the fluctuations to the discontinuous actions of genes over time ( [Matheny, 1980, 1983; Plomin, 1983; Scarr and McCartney, 1983; Wilson, 1983, 1984](#)). In fact, temperament seems to follow a complex fluctuating course in the earliest years, as befits characteristics regulated in part by “on again, off again” gene programs ([Plomin, 1983; Plomin et al., 1993](#)). The patterns of developmental acceleration and lag also appear to be more synchronous in more genetically similar organisms, suggesting that the fluctuations are meaningful, not random ( [Matheny, 1983; Wilson, 1978, 1983, 1984](#)). Most likely, certain dimensions of temperament [e.g., behavior inhibition ( [Kagan, 1998](#))] may show greater longitudinal stability than others.

### Temperament and Infant–Parent Interaction

It was widely assumed for many years that individual differences in parent–infant interaction were determined by prior parental behaviors, but parental behavior may itself be influenced by the infant's temperament and behavior ( [Bell, 1968, 1971](#)). Parents are extremely sensitive to their infants' temperaments, and different temperaments can be expected to elicit different behaviors from caretakers. Difficult infants demand and receive more attention than easy infants in the United States ([Bates et al., 1982; Petit and Bates, 1984](#)), Israel ([Klein, 1984](#)), and Kenya ([deVries, 1984](#)). Moreover, the perception of difficultness in early infancy increases the likelihood of later maltreatment ([Sherrod et al., 1984; Vietze et al., 1980](#)). Furthermore, [Vaughn and Bost \(1999\)](#) have argued that parental perceptions affect parent response, which in turn shapes the infant's future behavior.

Temperament also is constructive. An infant's temperament affects those around the infant, who in turn are likely to treat the infant in consistent ways that help construct the infant's own personality. A temperamentally active infant might be considered “inquisitive”; a temperamentally inactive infant, by contrast, might be seen as “thoughtful” or “passive.” Insofar as parents believe that their infants' temperaments fit a particular mold, they may mold their infant's environment to suit these expectations. In this sense, parental perceptions are important regardless of their relationship to objectively defined characteristics.

More than any other investigators, [J. Bates \(1980, 1983, 1986\)](#) and colleagues ([Bates et al., 1985a, 1985b; Petit and Bates, 1984; Rothbart and Bates, 1998](#)) have explored the assessment and clinical implications of infant “difficultness.” Difficultness has at its core frequent and intense expressions of negative emotion that are part of the child's disposition. If difficultness is dispositional, it ought to appear early, have a biological basis, and endure. Bates has confirmed that difficultness manifests itself in infant crying, and [Lounsbury and Bates \(1982\)](#) found that hunger cries of difficult infants are higher pitched and are perceived as aversive and demanding even by unrelated adults. [Bates et al. \(1984\)](#) believe that the excessive demands for social interaction made by difficult infants also lie at the root of their mothers' attributions of difficulty, because mothers interpret this “coercive control” negatively. Further, difficultness is relatively stable between 6 and 24 months ( [Fish and Crockenberg, 1981; Lee and Bates, 1985; Snow et al., 1980](#)). Finally, difficultness assessed by maternal report at 6 months predicted maternal perceptions of aggressiveness and anxiety at 3 to 5 years ([Bates et al., 1985a, 1985b](#)). Therefore, it is possible that difficult infants have troublesome dispositions that endure, or it could be that, as infants, they behave in ways that encourage their parents to treat them so that they act out, years later, as a result.

In addition, difficultness can have distinctly positive connotations in some circumstances. [DeVries \(1984\)](#) studied 4-month-old Masai infants in Kenya, where drought and malnutrition take the lives of many infants. In an admittedly small sample, difficult infants—those who were intense, irregular, unadaptable, and fussy—tended to survive, whereas easy infants tended not to survive. DeVries hypothesized that the demandingness of difficult infants is an advantage in the Masai society. The moral here is that temperamental concepts like difficultness must be understood in context; in our culture, difficulty may be associated with behavior problems, but in the Masai environment, it may promote survival and health.

Of course, difficultness is not the only infant characteristic that may predict later behavior problems. Activity level could be associated with a propensity to childhood accidents, whereas many psychiatric syndromes, including manic–depression and anxiety neurosis, could involve premorbid characteristics even in infancy. Perhaps the study of infant temperament, in conjunction with a certain parental personality or disciplinary styles, will lead to the identification of significant early indicators of risk, and, more generally, of the diverse ways infants contribute to their development.

[Failures of Development in the School-age Period](#)

[Chapter References](#)

The middle years of childhood, spanning the age from when a child enters primary school through age 10 years, are also called the *school-age period* because of the critical importance of school in development in our society. This time has been characterized by many classical theorists as the period when a child enters society and begins to establish the basis for becoming a contributing member of his or her community. Sigmund Freud proposed that this was a sexually quiet “latent” period following the mastery of oedipal strivings and establishment of the superego. He likened the period to the glacial epoch in the earth's history, both quiescent periods necessary for the birth of civilization ( [Buxbaum, 1980](#)). It has since been established, however, that latency is a myth. [Erik Erikson \(1950\)](#) lent a more enduring characterization of this period when he described the critical psychological issue: “Industry versus Inferiority.” In formal schooling, a child is attempting to master the basics of the industry of our society, to build on academic abilities. Failure to progress in school and in the peer context can establish a sense of inferiority rather than support the momentum of a drive for competence. Neofreudians (i.e., Sullivan, Horney, Thompson) added an emphasis on social context as the critical shaping force on how this developmental period is negotiated. Harry Stack Sullivan, for example, observed that this “juvenile era” provides the first opportunity for society to correct the influence of the family.

Freud, Erikson, and Sullivan have defined the important work of this period. Research into the details of cognitive, emotional, and social development confirm that civilization and being-in-society are the developmental challenges of the school-age period. Thus, thinking about the child's psychological well-being must extend beyond the child to include not only the family but the social, economic, and political contexts that define its functioning. Vygotsky's concept of “mind in society” and Bateson's “ecology of mind” point to the dynamic exchange of experience, accomplishment, and social response and effectiveness.

The best way to emphasize the remarkable growth that occurs during middle childhood is to contrast the skills of children when they enter and exit grade school ([Table 23.1](#)).

**Table 23.1. Neuropsychiatric Examination of the School-Age Child**

[Table 23.1](#) describes what can be seen in normal, average children in the United States, whether they come from poor, inner-city neighborhoods, rural settings, or more privileged educated family backgrounds. Children may be more advanced if they have been provided with educationally stimulating experiences. Children who do not perform at the levels indicated in the table bear closer examination to determine whether “delays” are due to disabilities, emotional factors, or contextual factors.

In this chapter, we review current information about how children advance from preschool to preadolescence, examining the areas of physical maturation, emotion, gender differences, moral development, social development, and cognition. These areas must be understood in the contexts of the child's internal life and in relation to family, peers, and school. We focus greater attention on issues of schooling—because school-aged children spend most of their waking lives in school, the school environment is vital to every aspect of the child's development, including how the child views the family and how the family views itself in relation to the child.

### MATURATION OF THE CENTRAL NERVOUS SYSTEM

The brain undergoes a period of rapid growth to 2 years of age and grows at a much slower rate until puberty. At birth, the brain is estimated to be approximately 10% of adult volume: it grows to 90% of adult volume by 5 years of age and completes its growth slowly over the next 9 years. What is more significant than actual volume, however, is the modification of anatomic structures and myelination, which is almost completed by the age of 7 years ( [Shapiro and Perry, 1976](#)). Synaptic pruning in the prefrontal cortex (the area affecting social judgment) continues as an ongoing process through adolescence.

Magnetic resonance imaging studies of school-aged children's brains have confirmed these observations. By 7 years of age, the child's brain is approximately the size of the adult brain. Boys' brains are approximately 10% larger than girls', and this total volume difference persists into adulthood ( [Giedd et al. 1997](#); [Reiss et al., 1996](#)). Differences, too, are found in the basal ganglia, where the globus pallidus is larger in boys, whereas the caudate is larger in girls. Boys show a relatively greater increase in size of the amygdala, whereas girls have more growth of the hippocampus. These relative differences are consistent with findings of androgen receptors in the amygdala and of estrogen receptors in the hippocampus. There also are findings of greater lateral ventricular expansion in boys ( [Giedd et al., 1997](#)). [Caveness et al. \(1996\)](#) found that subcortical gray structures are at adult volume in girls and are greater than their adult volumes in men, whereas the volume of central white matter is smaller in the female brain. The significance of these findings in terms of social development, regulation of focus and attention, management of activity and aggression, and the like is not yet described. However, the stage of concrete operations characterizing the cognitive functioning of school-aged children may be correlated with findings of reduced slow frequencies in the delta and theta bands and an increase in higher frequencies in the alpha band of the electroencephalogram between 5 and 7 years of age (for more detail, see [Chapter 5](#)).

Some data on neurotransmitter development may further sharpen our view of the intrinsic maturational schedule of the child and elucidate the emergence of the abilities of school-age children. In contrast to noradrenergic systems, which develop early and exert early influence on the formation of the cortex, dopaminergic systems, associated with attention regulation, and serotonergic systems, associated with mood and aggression, have a more gradual establishment of crucial

connections between brain stem nuclei and cortical structures. Cholinergic systems, associated with memory and higher cortical functions, develop relatively late ([Coyle and Harris, 1987](#)).

These refinements in brain structure and function result in the maturation of higher cortical functions, correlating with improved abilities in motor coordination, increased attention and focus, increased self-regulation, and expanded consideration for others. For example, tasks of writing, organizing work on a page, coordinating sounds with visual cues (as in deciphering words and spelling phonetically) require control in ear and eye–hand coordination. Children who enter the school-aged period with the ability to write letters or words backward or who may write their names with the correct letters but in a different order, are not necessarily showing signs of learning disability. Rather, they have not yet developed mastery of the conventions involving direction and order that are necessary to read and write and perform arithmetic functions. It is normal and expectable not to master these conventions until second grade.

## GENDER DIFFERENCES IN DEVELOPMENT

### Psychosexual Development

According to psychoanalytic theory, sexual development is biphasic, with a “latent” period during the school-age years. Freud believed that latency was a distinguishing feature of humans over animals and hoped to discover anatomic evidence of this through then-promising studies of changes in the interstitial portions of the “sex glands” ([Buxbaum, 1980](#)). Contemporary studies of sex hormones do not support the biphasic theory, however. Infants have relatively high but varying proportions of sex hormones in cord blood. The levels of sex hormones fall after birth and begin to rise, owing to endogenous production, during the school-age period (ages 7 to 8 years in girls, and approximately 2 years later in boys). Sex hormones begin a gradual upsurge at approximately 8 years of age, continuing through the pubertal peak, children engage in some sexual play with self and others, and retrospective interviews with homosexual adults usually pinpoint middle childhood as the time when sexual preference was established. Some have postulated that school-age children's greater sexual awareness may be reflected in their expressed feelings of disgust and shame and the strong sense of modesty that develops during the school years. Others have reported that sex play among school children is a natural extension of that of preschoolers ([Rutter, 1971](#)). Infants and toddlers masturbate; preschoolers also engage in mutual exploration. Psychoanalytic theory posits that sexual strivings in the oedipal child are overcome with the development of defense mechanisms. Children often enter middle childhood with a few good friends of the opposite sex. Around 8 years of age, however, the same-sex groupings become polarized, with the opposite gender having “cooties” and generally avoided or teased. Moving toward preadolescence, however, the “yuckiness” of the opposite sex gradually gives way to admiring certain individuals from a distance. Older school-age girls' budding attraction to movie stars and rock idols serves a group interactional function, as well as helping to define identity. As with preschoolers, if school-age children are preoccupied with sexual themes, it is wise to look for the possibility of sexually stimulating experiences, such as sexual abuse or witnessing sex acts.

There is a wide range in both the timing and tempo of pubertal onset, and it begins for many girls near the end of what traditionally is termed middle childhood. The onset of puberty at 9 to 11 years of age, as measured through breast growth, correlates with a positive body image, positive peer relationships, and superior adjustment in girls ([Brooks-Gunn, 1988](#)).

It is well established that children adopt a firm gender identity by age 3 years. This expression of their maleness or femaleness is manifested early by choices of role models and friends. With gender differences, as with so many of the other issues discussed in this chapter, the question of what is innate and what is the outcome of socialization is very intriguing.

Money's studies of infants with ambiguous genitalia established that gender identity was primarily determined through socialization. But explorations of differences in sexual preference and transsexual behaviors have raised questions about the roles of sex hormones in determining gendered behaviors. [Carol Jacklin \(1989\)](#) reviewed a number of purported relationships of hormones with behavior. There were no consistent findings and many weaknesses with the studies. Jacklin proposed that the internal representation of a person's gender, which she refers to as *schemata* (changing and evolving networks of associations to filter and organize information about oneself, one's gender, and its meaning) evolve out of diverse information, including modes of behavior, properties of objects, attitudes, and feeling states. Information is both presented and processed differently for boys and girls. For example, Jacklin notes, it is rare to see someone compliment a girl on how strong she is getting or a boy on how nurturing he is. Gender schemata and their expressions are evolved and maintained in a gendered society where it is most likely that girls will keep the company of women and other girls, and boys will do likewise with men. Cross-cultural studies do show male and female characteristic distinctions, but it appears that association with children and adults of the same sex is a powerful influence. We become the company we keep.

A number of characteristics are associated with being male or female in the school-age period. [Carol Gilligan \(1982, p. 9\)](#) cites Janet Lever's studies of 181 fifth-grade children at play. She observed that boys play outdoors in large and heterogeneous groups, and they play competitive games that last longer than those of girls. The games played by boys are full of disputes that seem to add interest to the interaction and do not derail the game. Similar observations of children playing led Jean Piaget to conclude that boys were more advanced in moral development because of their fascination with legal procedures and experience at generating fair arbitration of disputes. Many others concluded similarly that in the area of moral development and the development of the capacity to exert effective leadership in complex groups, boys preceded girls; few girls ever caught up.

In proposing that women listen to the demands of socialization and morality “in a different voice,” [Gilligan \(1982\)](#) added new value to this “instrumental- versus expressive” gender dichotomy. Gilligan's descriptions of different lines of moral development for boys and girls is discussed later in the review of moral development during school age.

Recognizing that in general boys develop instrumental functions and girls develop expressive ones has provided explanations for other observed differences between boys and girls. In academic achievement, for example, girls traditionally tend to do better in verbal areas, whereas boys have done better in math and science. Even as the causes of these differences are being explored, they also are being denied and recharacterized. Feminism apparently has had its effects on gender identity and gender role behaviors in both girls and their mothers. For example, the widely held view that boys are more mathematically capable than girls has been demonstrated to be more an effect of socialization than innate capability. Math anxiety was related to gender-stereotyped beliefs of parents, the mothers being most influential ([Eccles and Jacobs, 1986](#)). Furthermore, gender differences in academic skills that had been previously noted now are not found on many tests of academic competence ([Jacklin, 1989](#)). It is likely that other so-called innate gender differences will be similarly reevaluated in the future. Still, [Gilligan et al. \(1990\)](#), in a Harvard research study, describe “hitting the cultural wall”—when preadolescent girls realize that society values appearances more than accomplishment, they become more self-critical and worry about their weight. A negative body image was found to be associated with high IQ. In the American Association of University Women's “Shortchanging Girls, Shortchanging America,” a study of 3,000 girls and boys in fourth through tenth grade, concluded that girls lose their positive self-esteem and switch to appearance as the primary way to measure themselves ([Greenberg-Lake Analysis Group, 1991](#)). Other studies ([Debold et al., 1993](#); [Sadker, 1994](#)) support that preadolescent girls are more likely to get depressed, have their IQ scores drop, and decline in math and science.

### Cognitive Development

The standard by which school-age children's cognitive competence has been evaluated has been the achievement of what Jean Piaget termed *concrete operations*. The preschooler's preoperational thought is a creative effort to grasp causality and make meaning of experience using idiosyncratic and egocentric logic. In contrast, school-age children master important operations that increase their objectivity and their ability to be conventional. For example, 4-year-old Jocelyn demonstrates “jumping” by doing calisthenics, and when asked to stand still and hold her hands out, quickly evolves the motion to a pirouette. Seven-year-old James makes a concentrated effort to do exactly what was requested and refuses to lift his shirt, so the examiner can look for periumbilical movements, because he does not show naked parts of his body to strangers.

Classification and conservation are the two crucial achievements of concrete operational thinking. Classification is the ability to group objects or concepts; conservation is the ability to recognize constant qualities/quantities of material even when the material undergoes changes in morphology. The concrete logical operations are

1. Composition—combining elements leads to another class (e.g., red triangles and blue triangles leads to another group, i.e., triangles)
2. Associativity—combinations may be made in different orders with the same result
3. Reversibility—being able to return mentally to an earlier point in the process

The concrete logical operations enable the child to deal systematically with hierarchies and categories, series and sequences, alternative and equivalent ways of

getting to the same place, and reciprocal relationships ( [Minuchin, 1977](#), p. 14).

Logical operations are crucial to mastering basic reading and mathematics skills, and they also are necessary for conducting social interaction, with its increasing complexity of groups, games, and rules. Acquisition of the ability to do conventional and objective mental operations is associated with an interest in the scientific workings of the birth process, and a grasp of the finality, universality, and inevitability of death.

Successful school-age children have not just the ability to perform the specific concrete operations themselves but the ability to communicate about them in conventional ways. They understand that there are conventions of conversation, responses to questions on tests, and social comportment. With cognition, as with almost every other aspect of the school-age youngster's development, joining society and sharing conventions is the key to success. This interest in conventions and rules frequently is accompanied by a fascination with ordering and ritual. For example, school-age children often develop favorite numbers, magical rituals ("Step on a crack, break your grandmother's back") or the need to do things in even pairs. They also may become collectors of coins, stamps, insects, baseball cards, comic books, and the like, and may spend a great deal of time reviewing and ordering their collections.

## Morality

Along with the development of concrete operations, a child's sense of morality, that is, the appreciation of consequences and justice, evolves from an egocentric and idiosyncratic, and often harsh system of evaluation of behaviors by punishment, to the adoption of internalized rules for evaluating behavior.

[Piaget \(1948\)](#) posited that school-age children's morality is in the "interpretation of rules" stage. This accomplishment permits the child to understand the spirit of a rule and to make subjective moral judgments.

[Kohlberg \(1969\)](#) described the moral development that most school-age children reach as the level of "conventional morality." Conventional morality contains two stages: "interpersonal concordance" and "orientation toward authority." In the stage of "interpersonal concordance," a child measures behavior and judges it on the basis of whether it pleases those he looks up to. These mutual interpersonal expectations are those of a "good girl" or "good boy" who wants to please her or his parents and teachers and obeys the Golden Rule ("Do unto others as you would have them do unto you"). The next stage in conventional morality, "orientation toward authority," reflects the societal values of duty, respect, and law and order. This differs from the stage of interpersonal concordance in that the child's moral compass is now set by the social system instead of the immediate social context of family, school, or neighborhood. The child supports the rules of society, believes that it is essential not to break these rules for society to function, and makes moral judgments based on how well an individual situation conforms to the rules of the social system.

Gilligan's studies of girls' and women's moral development led her to emphasize the importance of relationship. In contrast to the masculine quasimathematical system for evaluating moral choices, Gilligan finds that girls use a form of narrative that evolves solutions within conversations and interpersonal action. Thus, Gilligan interprets the fifth-grade girls' play observed by Lever (described earlier) not as poorly developed or socially immature but as valuing different aspects of the social experience. Gilligan describes the different responses of an 11-year old boy and girl, both of whom were at the top of their sixth grade class in a private elementary school in an academic community. The moral test question was that of the man whose wife is gravely ill and whose survival depends on receiving a specific medicine. The medicine is too expensive and the pharmacist will not reduce the price. The man breaks into the pharmacy and steals the medicine for his wife. In responding to the question of what should happen to the man, the boy thoughtfully weighed the problem of laws against stealing and a higher law valuing life. The girl, on the other hand, felt that the various parties needed talk to each other, and could not render an opinion about what should happen to him. She was aware of the rules but found the conflict was such that she felt that mediation was needed to reach a resolution.

There has been significant critical reanalysis of Gilligan's data and conceptualization of the gender differences in moral reasoning. For both girls and boys, the development of morality reflects conventional thinking and measuring their evaluations against the rules of their society, as they understand them. Although moral reasoning continues to evolve through and beyond adolescence, many of the standards that are developed for our own behavior during middle childhood are likely to remain internalized and used as self-evaluation measures into adulthood.

[Stilwell et al. \(1997\)](#), in a study of 132 students aged 5 to 17 years, describe moral development as a natural outgrowth of attachment, evolving through five stages. First, the child's sense of security and experience of empathic responsiveness become paired with a sense of moral obligation. Next, the caretaker's rules are incorporated. Then, an understanding develops of how empathy can modify strict rule-following. Next, ideals and role models are selected that reflect earlier learning in attachment relationships. Finally, the self is visualized as a keeper of moral standards. These stages roughly correlate with Kohlberg's stages of morality, but emphasize the grounding of morality and conscience in the early and fundamental experience of attachment and a secure base, out of which empathy develops.

## EMOTIONAL ISSUES

The most significant emotional issues in the lives of school-aged children concern personal worth, which is determined by a sense of competence and place (in family, peer group, and communities). Competence is reflected in all of the places a child may live, at home by accomplishing tasks of caring for self (completing dressing, including tying shoes) and at school by addressing the academic material presented. [Robert White \(1959, 1960\)](#) postulated a "drive" to competence that he thought was as important as libidinal drives. In the school-age period, a sense of competence is determined not just by the child succeeding at a task, but by others' evaluation of his or her performance.

As Erikson warned, the emotional risk for the school-age child is the possibility of feeling inferior if the child evaluates himself or herself as not being able to accomplish tasks. This evaluation comes first from outside, from a teacher expressing disappointment or frustration, from other children laughing, from parents' disappointment with grades or a teacher's report. Increasingly through the school-age period, children can evaluate their own performance and measure it against that of others. Failures in one area may be compensated by accomplishments in another, eventually, but the early school-age child who has not yet learned about compensation simply may feel bad. By the end of middle childhood, each child has constructed a composite evaluation of his or her own relative areas of competence and weakness and has come up with his or her own answer to the questions, "What am I good at? Can I get the job done?" Again, these characterizations tend to persist into adulthood.

The fears of a school-age child are quite different from those of a preschooler. Because school-aged children are out and about in society, they are much more likely to witness or hear about catastrophic events that could happen to them. Their vulnerability to catastrophic fears is increased by the development, during the school-age period, of understanding of the irreversibility and inevitability of death. Many school-age children's dreams reflect efforts to master these fears by setting themselves up as heroes who save whole families or communities from robbers, murderers, fires, storms, or other disasters. Children who do not feel competent may be overwhelmed by these fears and have repeated dreams in which they are attacked and victimized and helpless.

[Harry Stack Sullivan \(1953\)](#) was one of the first to emphasize the social influence on development. He described a series of internal processes by which the child gradually substitutes his or her own standards of evaluation for those of family members. Stimulated by models outside the family, these processes unfold throughout the early school period.

- *Social subordination* reflects a change in the child's acceptance of authority from the specifics of personal caretakers to general categories such as principal, police, crossing guards, and teachers. The child first evaluates peers in terms of how they are regarded by these authority figures.
- *Social accommodation* is a process of acknowledging that there are differences between people. Early school-age children are intolerant of differences and can be cruel, but with socialization and education, differences gradually may come to be respected.
- *Differentiation of authority figures* is the child's emerging ability to compare adults, comparing parents with school-based authorities.
- *Control of focal awareness* refers to the child's response to social pressure to abandon some of his or her egocentric ideas and to adopt a more conventional stance.
- *Sublimatory reformation* refers to the reorientation of focal awareness to the group-approved satisfactory behavior.
- *Supervisory patterns* reflect an awareness of one's behavior in groups. The supervisory patterns are almost like imaginary characters who develop, so that the child can monitor himself or herself and eventually become internalized.

## SELF IN SOCIETY

The most salient achievement of the school-age period is a sense of oneself as a member of society. To accomplish this, maturation is required, as has been

described. But the most significant arenas for advancing and refining the sense of self, both in the present and in anticipating the future, are the interpersonal arenas of family, peers, and school.

## Home and Family

According to Heinz Kohut, the development of self occurs through a process of mirroring and idealization. To develop healthy narcissism, the child needs grown-ups to admire him or her and demonstrate attunement to his feelings (“mirroring”). Children also need to be able to look up to their parents and to other role models and aspire to be like them without being unduly distracted by their faults and shortcomings (“idealization”).

Similarly, parenting styles have been classified by [Diana Baumrind \(1996\)](#) according to “responsivity” (accurately assessing and responding to children’s needs) and “demandingness” (setting high expectations). Parents with high responsivity and high demandingness (“authoritative” style) tend to have the best outcome, with children who do well academically and socially. Low responsivity/low demandingness describes the neglectful or uninvolved parent; and high responsivity/low demandingness describes the permissive parent. Low responsivity/high demandingness is characteristic of an authoritarian style, which may be predictive of a positive outcome in some minority families.

The parent’s optimal role in middle childhood may be that of a consultant or facilitator, coaching the child’s development of his or her own skills and opinions, assisting as needed when help is requested, but allowing mistakes to be made and independent striving to occur in a supportive environment whenever feasible. This can be congruent with an authoritative style, in that high responsivity and high expectations can coexist with allowing self-exploration on the part of the child.

The familiar social context of the family and neighborhood (which also includes involved extended family and religious communities with which the family may be involved) is altered in the school-age period through several processes. The first is a practical one: When children spend more time in school, parents may spend more time doing things other than caring for their children. For parents who already were working or who remain at home caring for younger children or who choose to home-school their children, this may not be a significant change. In general, however, this creates a significant shift from the family organized for care of itself and its young children, drawn inward by primarily centripetal forces, to the more outwardly oriented family of adolescent children, where forces seem to be centripetal, drawing family members out into interactions with the society at large. [Combrinck-Graham \(1985\)](#) described the school-age child’s family: “The family’s opening up is like a house in the summertime; it is sturdy but has doors and windows open for circulation. Everyone comes in to share the family meal, to take shelter from the rain, and to sleep” (p.147).

A second process that changes the family environment is the evaluation that comes from children bringing home their experiences with other children, other children’s parents, and other adults whom they meet independently of their own families. Children make statements: John’s mother lets him do this; Martha’s mother doesn’t do that; Sandy’s father doesn’t live with them. Or they ask questions: Why doesn’t Daddy stay home with us they way George’s father does? How come you don’t pick me up at school, Randy’s mother does? Are we rich or poor? Are we Republican or Democrat? Why don’t we celebrate Christmas? And so on. Or children reflect frank criticism: You don’t know as much as my teacher. Smoking is bad for you; you shouldn’t smoke.

A third process of family change is through children’s relatively greater involvement in activities outside the home. Visits to friends, after-school activities, membership in clubs, or participation on teams takes time out from family routines after school and on weekends. Adolescents are far more involved in activities outside the home, but most school-age children’s families have the opportunity to assemble for dinner and an evening routine that allows for completing homework and some form of age-appropriate bedtime routine. Exceptions are largely due to complicated work schedules of caregivers who may work second shift or overtime.

A fourth process of family change is the possible social enrichment of all family life through involvement with the school as a community. This can be through socializing with families of other children, involvement in school and after-school activities, and through advocacy about school issues (e.g., PTA or participation on the school board). All family members usually become more involved in social experiences outside the family during the school-age period (not just the children).

Family/community relationships that had been stable before the school-age period are subject to change in similar ways. In the early school-age period, children are developing skills that facilitate interaction with peers in the neighborhood (e.g., mastering a two-wheel bicycle; accomplishments in the pick-up sport of the neighborhood, such as soccer or basketball). Children may have different experiences with other children in the home area and in school. At home, in the neighborhood, a child may be included in a group of different-aged children and accepted because of familiarity or the relationships between the families. For example, children may be a part of a Sunday school group that also is part of the social context of the congregation. This peer group reflects the child’s place in a family’s place in a community. As the school-age child grows older in such a community, he or she becomes more identified by distinct contributions to the community (e.g., participating in the music program, mastery of religious lessons, contributions to recreational activities) rather than just by membership in a family.

Children may assume more distinct roles in their neighborhood society or Sunday school group as they develop in school, or they may be less involved, as they become more interested in other things. Hobbies and collections are characteristic passions of school-age children and often become the basis for formation of new social groupings. Social contacts may be conducted online as children come together around a particular interest.

## Peers

The peer group can be one of the most facilitating influences in school-age children’s development, or it can be disastrously inhibiting. As with other developmental tasks, each child brings a particular pattern of prior experience to the task of developing a social self. There is considerable evidence that peers themselves have their own attractions and that a substantial if not primary influence over a child’s social self-development comes from the outside, predominantly through peer culture and its particular draw on the child’s drives for mastery and competence. Robert White’s ( [1959, 1960](#)) description of the growth of competence drive in the school-age period emphasizes how to get along with others in the sense of competing, compromising, learning the rules of the game, and protecting oneself from injury. He points out that other children afford an opportunity to do something interesting with the environment and that gradually the world of contemporaries competes with the family circle. [Bemporad \(1984\)](#) describes the juvenile era as a period between separation and procreation in which peers are the intermediaries. Erikson’s concentration only on how children master industry places too much emphasis on individual development and gives insufficient attention to cooperation. In a cross-cultural comparison, [Kagan and Klein \(1973\)](#) credit the society of peers for advancing the development of children in San Marcos, Guatemala. They describe rural Guatemalan Indian infants and preschoolers who by all culturally relevant measures are “retarded” but who at 11 years of age perform at the same level as American children in tests of cognitive functioning. The Guatemalan infant is unstimulated and left alone; only basic physical needs are attended to. Thus, Guatemalan infants do not have the assertive interaction with environment that is so prized in American infants and preschoolers. Kagan and Klein suggest that in the school-age period, where the relative neglect of these children by adults leaves them to form their own social groupings, Guatemalan youngsters begin to practice and learn assertiveness through jockeying for social position. [Grunebaum and Solomon \(1980\)](#) refer to Harry Harlow’s studies, concluding that young rhesus monkeys leave their mothers because peer relationships are interesting, not because their mothers reject them. There has been some recent debate about the relative influence of peer group versus parents on development, with some taking the view that the peer effect is significant and the parental effect is negligible ( [Harris, 1998](#)). Regardless of the relative weight placed on each of these factors, it is clear that the drive for inclusion and acceptance, and the judgments of the other children whom the child selects as his or her peer group, have a heavy impact on the school-age child’s development of self-image and values. At the same time, the child’s ongoing internal self-definition in turn influences his or her selection of peers to identify with and measure himself or herself against. By approximately 8 years of age, there has been a significant shift in a child’s ability to compare and assess his or her own skills, both through comparing him or herself with others, and through using feedback from parents, teachers, and peers. The child begins to rank himself or herself in various arenas and to combine these multiple assessments into his or her own ongoing “report card.” This constant evaluation of self in social context becomes internalized into the child’s own kinetic sense of identity. For better or worse, the opinions and descriptions we form of ourselves in middle childhood tend to continue throughout life. Personal “style,” preferences, values, and self-assessment in comparison with others all have their foundation during the school-age period.

Stages of peer development have been identified and described by [Grunebaum and Solomon \(1982\)](#):

- Unilateral partners and one-way assistance—the preschool child
- Bilateral partners and fair-weather cooperation—middle childhood
- Chumship and consensual exchange—preadolescence (pp. 288–291).

The first school-age phase is characterized by membership in peer groups and is based on playmates’ willingness and ability to play the way the child wishes. The second school-age stage (from approximately age 9 years) advances friendship to a closeness that Sullivan referred to as *chumship* with a peer of the same sex with whom an intimacy is formed, which paves the way for heterosexual intimacy and caring beginning in adolescence. A study that examined second, fifth, and eighth

graders' attitudes about and choices for companionship and intimacy found that family members were the most important sources for companionship for both second and fifth graders. Same-sex peers were important throughout the school-age period but were increasingly important as the subjects grew older. Only for eighth graders did opposite-sex peers become at all interesting. Girls tended to report intimate disclosure to peers earlier than boys, probably reflecting that girls may value intimacy more than boys ([Buhrmester and Furman, 1987](#)).

Just as peer interaction and the view of self in relation to others is vital to cognitive and intellectual development, so cognitive operations are vital to a child's emerging social self in the school-age period. [Minuchin \(1977\)](#) points out that children move from games such as "Simon Says," "Mother May I," and "Follow the Leader," in which the children in groups follow the directions of a leader, to games in which the rules are set and governed by the players themselves, to games that involve contributions to the efforts of a team. This evolution involves shifts in the ways in which others are evaluated. Children begin the period by deeming others good if they give them things and bad if they take things away, and move to recognizing skills and personal attributes, to finally acknowledging and valuing social attributes, such as fairness. This shift, in turn, requires the expansion of perspective, which permits a child to see a situation from another's point of view. This decentering may be seen as a cognitive component to empathy and the development of more sophisticated morality.

With social development, as with intellectual development, preparation and prior experience are substantial influences. Patterns of behavior involving aggression are established early, and generalized aggressive disposition and the tendency to exhibit aggression in the context of specific relationships are quite stable ([Cummings et al., 1989](#)). Aggressiveness also is associated with social rejection in the school-age period ([Boivin and Begin, 1989](#); [Rogosch and Newcomb, 1989](#)). One view of the stability of aggression is that it is constitutionally determined. Another view is that aggression develops and is maintained in interpersonal sequences. For example, one researcher reported that "early-timing" mothers, those whose first children are born when they are in their 20s, have more difficulty setting limits on their children than "late-timing" mothers do ([Hartup, 1989](#)). Children of early-timing mothers are more likely to be aggressive, and in the absence of good limit setting in the family, the aggression becomes less amenable to social intervention. It is most likely that aggression levels are determined by an ongoing interaction of biological tendency with psychosocial context.

Sociometric studies of school-age children yield up to five groups: popular, average, rejected, neglected, and controversial. There are two subgroups of rejected children, those who undervalue themselves and have low self-esteem, even compared with their teachers' evaluations of them; and those who have a positive view of themselves but are seen as defensive and aggressive ([Boivin and Begin, 1989](#)). When children in different sociometric groups were asked to evaluate themselves and one another, it was expected that aggressive children would show attributional biases not shown by nonaggressive children. In fact, however, these children's evaluations of others were not out of line, even though other children clearly identified the reputation of rejected children. In addition, negative reputation increasingly separates the rejected group at older ages ([Rogosch and Newcomb, 1989](#)). Aggression and consequent rejection and social isolation during middle childhood is a primary predictor of maladjustment in later years.

### Schooling

Schooling refers to the ecological setting in which children learn. It refers to the environment, the size, the philosophy, the characteristic transactions between teachers and students, and the culture of the school. How the child *can* function, what he or she can do, how the child perceives himself or herself, especially in terms of competence and the accompanying confidence in the ability to accomplish tasks, and, finally, how the child is a part of communities/societies, are substantially forged and reshaped in the school environment.

We discuss four aspects of schooling:

1. Preparation: the effects of prior experience
2. Attunement to children's learning styles and needs
3. Concordance or discordance with the patient's family/community ethos
4. How the school serves as a model for a community in which a child finds a role

## THE EFFECT OF EXPERIENCE AND PREPARATION ON CHILDREN'S SCHOOL FUNCTIONING

Children arrive at school with diverse experiences. Most dramatically different are the experiences of children from middle-class, educated families and those from poor, minority, inner-city families. The former are more likely to have attended educationally oriented preschools, have traveled at least in their own communities, have visited libraries and museums, and have been read to by their parents and teachers, whereas the latter have more likely been involved with complex family and "adoptive" family relationships ("play" mamas and many "aunts" and "uncles"), have experienced comings and goings of people in their daily worlds, and have been exposed to situations of danger and hardship with little sense of control over these situations. Children from immigrant families may not speak English, or, alternatively, may be the only members of their family who do speak English. Some minority youngsters may never have seen a book or a piece of paper or a crayon by the time they enter school. But many of them may have been assuming responsibilities in the household, such as caring for younger children, getting meals, caring for themselves while adults are away, and translating for their parents. The former group has been prepared to enter school since toddlerhood, whereas the latter group is prepared to manage an entirely different set of experiences, which may not be compatible with what is expected in school ([Heath, 1989](#); [Miller-Jones, 1989](#); [Wilson, 1989](#)) (see [Chapter 106](#)).

Studies of the effects of model preschool programs and general application of Head Start programs for poor and minority children demonstrate that there is some advantage to having had a preschool experience, and this advantage is more dramatic and more lasting if the experience was in a model preschool program ([Haskins, 1989](#)). In follow-up throughout the remainder of their school lives, children from model preschools were significantly less likely to be placed in special education programs than control subjects, but most often the effects disappeared in 3 to 6 years, after the children entered formal public school ([Bradley et al., 1988](#)). This suggests that preparation, alone, does not suffice to ensure a positive school experience. The most effective early education programs involved the parents in the school effort, so that the fit between home culture and school culture was enhanced.

Reading comprehension largely is thought to be text based (i.e., content oriented) and interactional (i.e., develops within a relationship). It is increasingly evident that reading success is heavily influenced by the preparation of the reader, who brings to the task his or her expectations, prior knowledge of the content and structure of the material, and cultural background ([Hall, 1989](#)). Studies support this observation. One study, for example, reported that a group of 4-year-olds given simple instructions in segmenting and blending words of two and three syllables 10 minutes a day for 13 weeks resulted in dramatically higher reading scores than those of children involved in nonspecific reading-related activities ([Coles, 1987](#)). Coles reported that a study of the families of children with reading disabilities found that there is a significant lack of preparation of these children for reading. Other studies found that in some families, messages about expectations of failure were transmitted, in others there were failures to provide exposure to preparatory material, and in still others there was obvious evidence of "communication deviance" whereby the explanatory frameworks of language were so odd or idiosyncratic to the family that the child had unusual difficulty mastering conventional rules needed to learn to read ([Ditton et al., 1987](#)). In addition to insufficient preparation, other etiologies of reading difficulty must be considered. These include learning disability (due to underlying processing deficits, auditory discrimination problems, decoding difficulties), mental retardation, and knowledge deficits in oral language or vocabulary. Basic prereading skills include the ability to bring background knowledge to bear on a new situation, self-questioning behavior, and predictive skills.

## ATTUNEMENT TO CHILDREN'S LEARNING STYLES AND NEEDS

The second aspect of schooling involves the interaction around learning. Many use Vygotsky's ideas about the evolving mind in society to understand better how children learn successfully. In this framework, learning represents the transfer of responsibility for reaching a particular goal ([Belmont, 1989](#)). This transfer takes place in the "zone of proximal development" (ZPD), which is defined as "the distance between the actual developmental level as determined by independent problem solving and the level of potential development as determined through problem solving under adult guidance or in collaboration with more capable peers" (Vygotsky, cited in [Slavin, 1987](#), p. 1162). The ZPD is a useful measure of learning potential because it includes the instructional context (or, in the case of psychometrics, the relationship between child and examiner) as indispensable to the measured achievement. When children are presented with strategies in the process of "strategy instruction" (whether children can adopt a strategy and apply it to other, similar situations without further instruction), those presented in the lower area of the ZPD are readily generalized, those in the midrange are adopted and gradually generalized, and those toward the higher end of the zone may not be adopted at all ([Belmont, 1989](#)). The child's readiness and the instructor's attunement to presenting material at a level that stretches already established abilities but is not so novel as to be overwhelming, are crucial to the "transfer of responsibility" that defines successful learning.

Fellow students, as well as teachers, provide assistance with developing more sophisticated problem solving, as is stated in Vygotsky's definition of the ZPD. There are specific methods of peer involvement in learning that have come to be known as *cooperative learning*. Cooperative learning refers to any number of types of

student groupings for learning but differs from peer tutoring in that the material is presented by the teacher rather than by the peers. Students are given problems to solve or projects to complete, and the incentive to work together is encouraged by either rewarding the group's efforts, rewarding each individual child on the basis of the group's efforts, or rewarding the group on the basis of each child's achievement. Children can and will positively influence one another's progress. This is particularly true when some children in the group are more advanced than others, but it also is true when all children are struggling to solve a new challenge. For example, using the Piagetian description of the accomplishment of conservation, nonconserving children learn from peers who have mastered conservation, but they also progress in conservation skills when struggling with conservation problems with other nonconserving children ( [Slavin, 1987](#)). The process of working together must be specifically supervised and rewarded because otherwise the more competent children take most of the responsibility for accomplishing the objectives or completing the project, while the less competent children do not contribute. Properly conceived, however, the value of cooperative teaching extends beyond the opportunities it creates for learning. It also provides a framework for learning about others, valuing differences, observing and using the strengths of others, helping one another, and making a contribution to a community goal.

Regardless of the rate at which children learn and the specific strengths and weaknesses they may have in mastering certain materials, attunement to each child's ZPD and pitching the new material to the appropriate level will inevitably enhance not only the child's success but his or her enthusiasm for learning.

[Howard Gardner's \(1999\)](#) theory of multiple intelligences is echoed in Mel Levine's neurodevelopmental profiling ( [Levine et al., 1993](#)). In these and other approaches being used in innovative educational strategies, the principle is that different children have specific learning styles. According to these theories, it is incumbent on the teacher to ask, "How does this particular child learn best?" and to design an educational strategy that uses the appropriate mode.

## CONCORDANCE OR DISCORDANCE WITH THE PATIENT'S FAMILY/COMMUNITY ETHOS

Two facets of congruence between the style of school and family as interfacing systems have been studied. The first involves expectations in the areas of educational goals, what is expected of the child, rules, and areas of permissiveness. Because the education system has been established by the majority culture, goals in general are congruent between school and majority families. Parents expect their children to attend school regularly, to be respectful, to be motivated, and to achieve. Problems come up when children cannot or do not fulfill these expectations, which are ordinarily shared by family and school systems. They also come up, however, when these expectations are not shared by family and school systems. Then, the all-too-common complaint that the child misbehaves at school but is fine at home, or, less commonly, the reverse, is brought to the attention of a counselor or mental health professional. This type of problem is most likely to be found in children from ethnic and cultural minority families ( [Phinney and Rotheram, 1986](#)) and can be ameliorated when parents are intimately involved in school life, as James Comer has so elegantly demonstrated (see [Chapter 106](#)). The second facet concerns the congruence of the way school and family systems are organized. In general systems terms, interpersonal systems can be open and relatively closed, referring to characteristics of freedom of exchange with other systems, definition of system boundaries, and amount of variety that is encouraged or tolerated in the system. Some schools that have been founded around specific religions are examples of closed systems, and these often serve a specific population with shared rules and values, constituting a good fit. Rules about conduct, limits, and privacy are consistent across school and family and may differentiate each from the rest of society. Some schools have a more closed system than many of the families of children attending. That is, the schools have clear rules and expectations about everything from dress to punctuality, whereas the families' rules are more loosely organized. The school personnel tend to see these families as irresponsible and incompetent, and themselves as more capable caretakers. Open families sending their children to closed schools feel criticized and defensive, and a child is caught between the two systems because he or she may want to conform to the school's expectations but depends on the family to provide appropriate support. Open school systems allow for variability and have the potential for being flexible. In many instances, however, open school systems interfacing with open family systems may have such a lack of definition that the children have no clear framework within which to define themselves. This kind of "congruence" between open family and open school systems often results in the involvement of the child with more systems, such as welfare, juvenile justice, or mental health ( [Rotheram, 1989](#)).

## HOW THE SCHOOL SERVES AS A MODEL FOR A COMMUNITY IN WHICH A CHILD FINDS A ROLE

A list of characteristics of effective schools includes strong leadership, an atmosphere that is orderly and not oppressive, teachers who participate in decision making, school staff that has high expectations of students, and frequent monitoring of student progress ( [Linney and Seidman, 1989](#)). A specific aspect of school environment that has been studied is school size. It has been shown that large schools often are "overmanned," meaning that there are more students than role opportunities. This means that there are not enough opportunities in student government, arts, or sports programs, or for individual distinction to recognize more than a very few children. In "undermanned" schools, there are opportunities for students to be involved in activities and to take more initiative. The environmental role demands on the students in undermanned schools increase the levels of student participation so that they can contribute to the school community, develop identified roles in this community, and become known to themselves and each other as distinctive individuals. In large schools, there is the danger of anonymity and ultimately a high rate of dropping out and involvement in antisocial behavior and substance abuse. The movement to consolidate schools thus increases the chances that students will not have a positive experience in school, unless the student population is broken down into smaller units within which students experience a manageably sized community ( [Linney and Seidman, 1989](#)).

## SUMMARY OF SALIENT FEATURES OF SCHOOLING

For school to be most effective at supporting the crucial development in school-age children, there has to be attention to the preparation children have had before entering school, and assistance to those whose experience has not primed them to take advantage of the school experience. Second, each child's learning style and readiness needs to be understood sufficiently that educational material is presented that stimulates a child's drive to competence, without being so overwhelming that the child gives up. Most curricula are established to meet the levels of most children in the grade, but there are always children who are either more advanced or slower to whom learning tasks need to be thoughtfully and individually offered. Third, attention needs to be given to the congruence between expectations of school personnel and those of parents. Involving parents in school activities is the most effective way to collaborate and close any gaps that could cause confusion and loyalty conflicts for the children. Finally, schools need to form manageably sized communities in which children can distinguish themselves. Even if the total school size is very large, there are ways to subdivide into smaller communities.

There are cultures where children learn the "industry" of their society other than in school, primarily through various forms of apprenticeship. Schools in our society offer both the opportunity for learning the industry and for learning one's place in society. We would be remiss if we did not point out that children in our Western society are privileged to have time set aside in their development for schooling. Although child labor is almost nonexistent in the United States and Europe, there are currently 250 million child laborers in the world between the ages of 5 and 14 years (90% in Asia and Africa), living in extreme poverty, engaged in repetitive and physically demanding tasks who do not have the opportunity to go to school at all, and have limited opportunity to play and learn ( [Jones, 2000](#)).

## FAILURES OF DEVELOPMENT IN THE SCHOOL-AGE PERIOD

From this discussion of normal developmental processes and influences on developmental outcome, an understanding of the many failures of development is straightforward. maturational deviations or delays (e.g., developmental disabilities, mental retardation, or pervasive developmental disorders) limit a child's developmental progress in all the spheres we have discussed. The child is able to master neither the learning nor social tasks. In addition, the family does not develop the independence and social integration characterized by the school-age family, often because these families are tied into attending to the needs of their special children. Similar limitations of development also often occur in families with children with chronic medical illnesses. The challenge for mental health professionals who use a developmental approach in their work is to find arenas where handicapped children can be competent and interact socially. Lowering expectations of performance, providing ability-appropriate responsibilities for children to meet, and encouraging reciprocal social interaction are interventions that can maximize developmental accomplishments of these special youngsters.

Interference with learning may be based on immaturity, or, as is more commonly diagnosed, may be due to disorders of focus, attention, or impulse management or to specific learning dysfunction. Understanding the crucial developmental issues of establishing a view of oneself as a functioning person in a community can focus the mental health consultant's attention on helping the child, family, and teachers find strategies for managing areas of difficulty. Medication often is used to support such efforts but is most effective when the child and the people closest to him or her are concentrating on competence and strategies for becoming competent.

Inferiority and defeat are the principal emotional pitfalls of school-age children because of the importance of mastery and recognition in the communities in which children participate. Depression is both a cause and an outcome of failure to progress in the manner that the child believes others expect. Assessment and treatment of depression in school-age children always must include assessment of the developmental issues of competence and how a child is viewed by his or her peers so that in addition to psychotherapy and medication, assistance with social functioning and academic mastery will be included. Externalizing behavior disorders drastically interfere with children's developmental progress in this era by disrupting learning and social accomplishment. Many such behaviors may be viewed as a

defense against a sense of failure and inferiority (better to be seen as bad than dumb). Developmental approaches to treatment must include attention to academic progress along with several approaches to helping such children be accountable for their behavior. Behavioral management with consequences may be helpful but will be more so in this age group if there are exercises in putting oneself in others' places and developing empathy, so that these children can function in society.

We are born, so to speak, twice over. Born in existence and born into life; born a human being and born a man.  
—Rousseau, *Emile*

Adolescence in contemporary Western industrial society is shaped and defined by the interplay of complex biological, cultural, economic, and historical forces. This lengthy transitional state, which may last a decade or more, is a distinctive period in which a youngster is no longer a child nor yet fully adult, but partakes of some of the challenges, privileges, and expectations of both epochs. Adolescence is a period of paradoxes, as youngsters reach physical and sexual maturity well before they are fully cognitively and emotionally mature. On one hand, a secular trend towards earlier and earlier puberty over the past century and half means that by 13 years of age many youngsters are potentially fertile and sexually attuned, if not yet fully active. On the other hand, the educational demands of a complex modern economy have prolonged formal education and raised the age of mandatory school attendance to approximately 16 years, whereas social welfare concerns have abolished child labor and legally restricted adolescent employment, thus postponing entry into the world of work. [Some measure of this shift may be seen in the contrast between 1900, when many Americans still lived on family farms, and only 0% of 14- to 17-year-olds attended high school and the present 95% high school attendance rate ([Arnett, 2000](#)).]

As a result, full economic emancipation usually is not possible until the later teens, at the earliest, and in the case of young people pursuing college or postgraduate education, often not until the middle to late twenties.

In the United States, the legal status of adolescents is a confusing mixture of privileges and strictures that attempts to balance the need for control and protection with the incremental granting of autonomy. For example, a 14-year-old may fly a plane, but not legally drive a car, whereas a 17-year-old may serve in the army, but not vote until 18 years of age, when he or she still is not legally allowed to drink. In many jurisdictions, a 14-year-old may legally obtain an abortion without her parents' knowledge or consent but needs her parents' permission to be absent from school to do so.

Despite the restrictions on their full-time employment, young adolescent consumers are a potent economic force, controlling billions of dollars in disposable income annually. Teenagers, hence, comprise an eagerly sought-after demographic target for marketers, advertisers, and the broadcast, print, and electronic media. In turn, to attract and hold these young viewers and readers, media programming directed to them increasingly emphasizes sex and violence as prominent themes; sexual themes are estimated to make up approximately one-third of the content of prime time shows popular with teens ([Chapin, 2000](#)).

Winnicott once remarked aphoristically, "There is no such thing as a baby," meaning that the baby could not be considered apart from its relationship with its mother. Although adolescence is the epoch *par excellence* of individuation and autonomy striving, it is similarly impossible to have a full understanding of adolescent development apart from its specific biological, family, community, cultural, and historical contexts ([Lerner and Galambos, 1998](#)).

The interactions among these factors are complex and multidirectional. Not only are adolescents influenced by their families, but they reshape their families' dynamics as they grow. Although important aspects of adolescents' development are genetically and biologically determined, the effects of these determinants may be mediated or influenced by psychosocial factors. For example, family factors influence not only the impact of the timing of puberty but may actually affect the timing of puberty itself, with earlier and more rapid maturation in adolescents raised in more conflictual, less supportive homes ([Graber et al., 1995](#), [Graber et al., 1996](#); [Steinberg and Morris, 2001](#)). Behavioral genetics studies that have revealed the importance of nonshared environmental factors suggest that adolescent siblings evoke different interactional and social environments even within the same family ([Reiss, 2000](#)).

It is important to bear in mind the great diversity of social and family contexts in which today's adolescents grow up. In the United States, despite some commonalities, the experiences of adolescent who are immigrants, gay or lesbian, or growing up in poverty, foster care, single-parent, or other nontraditional family structures differ in important ways from the general patterns presented later in this chapter. Even greater differences exist between the majority culture of the West and more traditional societies, with less emphasis on individual autonomy and fewer expectations that adolescence should be a period of vocational choice or attaining full independence from families ([Arnett, 1999](#)). Some anthropologic studies have concluded that in such preindustrial societies, there may be less adolescent turmoil and conflict with parents ([Cote, 2000](#); [Schlegel, 2000](#); [Schlegel and Barry, 1991](#)). One important research question concerns the impact on adolescence in such societies as the process of globalization exposes more and more teenagers to the same media and cultural influences as in the West ([Arnett, 1999](#); [Schlegel, 2000](#)).

### PHYSICAL CHANGES AT ADOLESCENCE

The term *puberty* (from the Latin *pubertas*, meaning "age of manhood") is used to refer to the physiologic and morphologic changes that mark the transition from childhood to adulthood.

#### Hormonally Mediated Changes

The most visibly dramatic aspects of adolescence relate to the hormonally mediated changes of puberty: the development of primary and secondary sexual characteristics; marked growth in stature, muscle mass, and strength; and increased sebaceous gland activity.

Adrenarche, the steady increase in adrenally produced androgens, begins as early as 6 to 8 years of age, leading to increased skeletal growth and the beginning appearance of body hair even before the surge of gonadal hormones associated with puberty proper.

Puberty proper is marked by the pulsatile release of gonadotropin-releasing hormone, producing increased pituitary release of follicle-stimulating hormone and luteinizing hormone that in turn drive the production of gonadal hormones (primarily testosterone in boys, estrogen in girls) ([Petersen, 1987](#)). Together with these gonadal hormones, increased release of growth hormone stimulates the pubertal growth spurt.

The triggers for this activation of the pituitary–gonadal axis are unclear, but have been speculated to include leptin (serving as a metabolic signal of adequate body weight/composition), neurotransmitter-mediated attenuation of inhibitory tone or increased excitatory tone at the level of the hypothalamic gonadostat, and altered

hypothalamus–amygdala interactions (for review, see [Spear, 2000](#)).

The process of puberty takes approximately 4 to 5 years from start to finish, with girls (in the industrialized world) beginning the process on average at 9 to 11 years of age, approximately 2 years earlier than the average onset for boys. The various stages of this process, as indicated by pubic hair, breast development, height spurt, and menarche in girls and pubic hair, penile and testicular growth, and height spurt in boys, have been classified by [Tanner \(1974\)](#) into stages I through V. Although Tanner staging of a child's pubertal development is done most accurately by direct physical examination, alternative methods include the self-report Pubertal Development Questionnaire or asking youngsters to identify their stage of development using a set of standard, gender-specific photographs ([Graber et al., 1996](#)).

The first harbinger of impending puberty usually is an acceleration in linear growth, as much as 10 cm per year, which usually precedes increases in muscle mass and strength, thereby producing the gangling appearance of many early adolescents.

For girls, the initial stages of puberty are the beginnings of breast development [mean age 8.87 years (Standard deviation [SD], 1.93) for African-American girls and 9.96 years (SD, 1.82) for white girls] and the appearance of pubic hair [mean age 8.78 years (SD, 2.00) and 10.51 years (SD 1.67), respectively] ([Herman-Giddens et al., 1997](#)).

The clearest marker of puberty in girls is the onset of menses, or *menarche*. Girls' periods initially remain irregular for some time, and despite the high rates of early teen pregnancy, ovulation and full fertility may require 2 years to develop. Most modern girls have been well prepared for menarche by health classes, peers, and mothers, and news of who has (or has not) yet begun her periods is the topic of excited exchanges of confidences among middle school girls.

A critical body weight and fat/muscle ratio appears to be a necessary condition for menarche; hence, girls who train intensively for athletics or dance or who are anorectic may have delayed menarche. Probably related to the permissive role of adequate nutrition and body weight, there has been a steady secular decrease in the age of menarche since the Industrial Revolution, at the rate of approximately 2.3 months per decade. Currently, the average age of menarche is 12.88 years (SD, 1.20) in white girls and 12.16 years (SD, 1.21) in African-American girls ([Herman-Giddens et al., 1997](#)). (As in preindustrial Europe, the age of menarche remains approximately 17 years in many developing countries). In recent years, there has been controversy about the appropriate norms for deciding at what age female pubertal development should be considered premature because one large study found that by 7 to 8 years of age, 5 % of white girls and 15.4 % of African-American girls were at Tanner stage II or greater for breast development and 2.8% and 17.7%, respectively, were at Tanner II stage or greater for pubic hair. Further study is needed as to whether this represents an increased prevalence of very early puberty in girls, and if so, what its implications are regarding potential causes and indications for suppressive treatment ([Kaplowitz and Oberfield, 1999](#); [Endocrine Society and Lawson Wilkins Pediatric Endocrine Society, 2001](#)).

In boys, growth of the penis and testes and beginning spermatogenesis occur in early and middle adolescence. In contrast to menarche, however, “semenarche” or the beginning of ejaculation, whether by masturbation or spontaneous nocturnal emissions, usually remains a very private matter among Western boys ([Stein and Reiser, 1994](#)).

Detailed longitudinal studies reveal considerable variation in the onset and progress of the various stages of puberty, both within and between genders. Thus, peak growth velocity in girls occurs approximately 2 years earlier than in boys, whereas pubic hair appearance often is only approximately 9 months earlier.

Much research has examined the question of the developmental impact on adjustment of early versus late maturation in boys and girls ([Brooks-Gunn and Paikoff, 1997](#); [Graber et al., 1997](#)). In general, these studies show that, for boys, early maturation is advantageous in terms of popularity, self-esteem, and intellectual abilities, but does confer some increased risk for delinquent or problem behaviors, perhaps because of friendships with older peers ([Steinberg and Morris, 2001](#)). For girls, the picture is more complex, with early-maturing girls tending to have more adjustment difficulties (including lower self-image and greater vulnerability to depression, anxiety, and eating disorders), to engage in more risky behaviors, and to experience early sexual intercourse. The impact of early versus late maturation in girls, however, also depends on social context variables such as social class, pubertal status of peers, cultural norms, and timing of concomitant changes (e.g., school transition), as well as prepubertal adjustment ([Ge et al., 1996](#); [Steinberg and Morris, 2001](#)).

For many decades, an emphasis on the psychological effects of pubertal hormonal changes dominated discussions of the psychobiology of adolescence—what might be termed the “raging hormones” theory of adolescent psychology. However, only limited and equivocal associations have been found between various forms of adolescent psychopathology and gonadal hormonal levels ([Brooks-Gunn et al., 1994](#); [Buchanan et al., 1992](#)), with hormonal levels accounting for only a very small proportion of the variance in negative affects, compared with the influence of social factors.

### Neurobiological Changes in Adolescence

Recent research has underlined the magnitude of neurobiological changes in the adolescent brain, especially in the forebrain and mesocortical and limbic regions. To what extent these are influenced by or dependent on prenatal or pubertal hormonal factors is not clear. Studies of schizophrenia and mood disorders have shed light on the pathogenic potential of these adolescent brain developments (see extensive review by [Spear, 2000](#)). For example, [Weinberger's \(1995\)](#) developmental theory of schizophrenia draws on the observation that although the infectious, neuromigratory, and nutritional insults predisposing to the disorder occur prenatally (usually in the second trimester), overt schizophrenic symptoms typically do not appear until late adolescence. Drawing on various animal models, Weinberger and colleagues suggest that the behavioral effects of early lesions remain largely silent until unmasked by abnormalities in the usual late-adolescent maturational changes in the prefrontal cortex, hippocampus, or other limbic regions; these maturational changes are hypothesized to lead to the overt symptoms of schizophrenia, perhaps because of increased sensitivity to normative adolescent stressors.

One of the most dramatic changes in adolescent brain reorganization is a massive elimination or “pruning” of cortical synapses, with an estimated loss of up to 30,000 synapses per second during adolescence ([Bourgeois and Rakic, 1993](#); [Rakic et al., 1994](#)). The resulting loss of approximately half of the cortical synaptic connections present before puberty is believed to affect preferentially excitatory synapses and is accompanied by declines in brain glucose metabolism, oxygen utilization, and blood flow; decreased overall electroencephalographic amplitude; and more complex and focal patterns of brain activation. The neuropsychological and neurochemical consequences of this synaptic remodeling are especially prominent in the prefrontal cortex, with loss of excitatory glutamatergic inputs, but also marked changes in dopaminergic input.

Longitudinal scanning magnetic resonance imaging studies find a rostrocaudal wave of growth in the corpus callosum during childhood, with peak growth rates in the fibers connecting the temporoparietal cortical association and language areas peaking in early adolescence and then declining (perhaps paralleling the ending of the critical period for second-language acquisition). Cortical volume changes varied by region, with enlargement in the temporoparietal regions, but up to 50% loss in the subcortical gray matter of the head of the caudate ([Thompson et al., 2000](#)).

The full extent and significance of these changes in brain architecture and functioning are not yet clear ([Giedd et al., 1999](#); [Sowell et al., 1999](#); [Spear, 2000](#)). It seems likely, however, that they are reflected in the adolescent's burgeoning intellectual capacities, as well as a shift in various motivational, attentional, and emotional realms. For example, various neuropsychological tasks of executive functioning and inhibition that are believed to involve prefrontal cortical functioning continue to improve through adolescence ([Welsh et al., 1991](#)).

### Other Biological Changes

Along with puberty come changes in appetite and sleep patterns.

Across species, the adolescence-associated growth spurt results in more time spent feeding and foraging for food. Most families with teenagers can attest to their youngsters' elevated metabolic rate and what has been termed *developmental hyperphagia* ([Post and Kemper, 1993](#); [Spear, 2000](#)).

Adolescence also sees a shift in sleep patterns, with a sleep phase delay or tendency to fall asleep later and wake up later ([National Research Council and Institute of Medicine, 2000](#)). On average, 10- to 12-year-old children sleep approximately 9.3 hours a night and awaken spontaneously. In contrast, the mean length of sleep for high school students is 7.5 hours per night, with one-fourth of students sleeping 6.5 hours or less per night. Adolescents also have greater difficulty getting up and suffer from frequent daytime drowsiness, accompanied by impaired alertness and cognitive functioning.

Part of this phase shift appears to be biological; later night-onset and later morning-termination of melatonin secretion make it difficult for the adolescent to go to sleep earlier or to wake up alert in time for school, which, deleteriously for many teenagers, may begin as early as 7:20 AM. This shift in sleep patterns also has a

psychosocial component. Adolescents are given greater autonomy by their parents in controlling their own bedtimes, whereas the expansion of social contacts outside the home and increased social stimulation (in the form of phone and e-mail) keep the teenager up later.

## COGNITIVE CHANGES IN ADOLESCENCE

Adolescence is marked by dramatic quantitative and qualitative growth in cognitive abilities ( [Keating, 1990](#)). Although not a universal achievement, adolescence marks the attainment for many youngsters of what Piaget termed the stage of formal operations, with the ability to construct “contrary-to-fact” propositions and a growth in hypothetico-deductive problem-solving ability and understanding of propositional logic and probability ( [Coleman and Hendry, 1990](#)). Along with a greater capacity for abstraction, adolescence often sees the flowering of passionate intellectual and aesthetic interests, with impressive achievements in areas such as music, mathematics, computer science, or physics. Interestingly, adolescent works of genius are more commonly in these abstract areas than in those involving the empirical sciences or the humanities.

Although the validity of Piaget's views have been debated, there is a general consensus that adolescents' cognitive abilities are characterized by growing complexity, the ability to think about possibilities, and increased speed and efficiency of information processing.

These cognitive changes also have their counterpart in the adolescent's social cognition and moral development. The development of formal operational thinking permits a growth in social perspective-taking and a decline in childhood egocentrism; it enables the adolescent to contemplate better what a social situation might look like from another person's point of view ( [Selman, 1980](#)). As described by [Kohlberg \(1969\)](#), moral reasoning becomes more complex and expands to include orientation to interpersonal relationships, maintenance of social order, notions of social contract and general rights, and, finally, reference to universal ethical principles. [ [Gilligan \(1982\)](#) has criticized Kohlberg's purportedly universal hierarchy of stages of moral reasoning as male-oriented in its emphasis on rules and universal principals and “moral logic of justice,” in contrast to what she sees as the more interpersonal and nurturant bases of women's values in the “moral logic of care.”]

Despite greater cognitive abilities, however, adolescents do not always use these capacities for sound decision making, in part, perhaps, because their cognitive performance in real-life situations (as opposed to optimal test conditions) is more vulnerable to disruption by everyday stresses ( [Beyth-Marom and Fischhoff, 1997](#); [Keating, 1990](#)).

On a practical level, the adolescent develops a more mature time sense, a greater awareness of the finality of death, and, along with wider knowledge of the outside world, a keener sense of the diversity and relativity of moral codes. This moral awakening may be accompanied by an intensified interest in and sophistication about politics, ideology, or religion. This wider vision, as most eloquently described in the work of [Erik Erikson \(1963\)](#), provides both opportunities and hazards. Along with a penchant for philosophical musings, the adolescent may experience a sense of moral confusion and at least transient feelings of anomie. The anxieties of what [Seltzer \(1989\)](#) has termed *frameworklessness* may lead some adolescents to a fanatical embrace of some ideology or religion on one hand or a posture of nihilism on the other.

## PSYCHOLOGICAL TASKS OF ADOLESCENCE

The physical, neurobiological, and cognitive changes described previously herald dramatic shifts in the adolescent's relationship to his or her own body, appetites, parents, peers, and self-image. In this next section, we turn to the psychological tasks of adaptation these shifts impose on the developing teenager ( [Table 24.1.](#))

Task	One Third One	Two Thirds	One Third One
1. Independence	Defiance breaks for parents and peers leads to role	Independence about aspects	Integration of independence issues
2. Body image	Adjustments to adolescent changes	“Try on” different images to find self	Integration of existing body image with personal self-perception
3. Sexual drive	Sexual curiosity, attraction, masturbation, sexual arousal in sex	Sexual experimentation, possible	Integration of sexual drive and identity
4. Relationships	Increased peer group social status	High interpersonal peer group relationships	Individual relationships now important for peer group
5. Career plans	Vague and often unrealistic ideas	=	Specific goals and specific steps to attain them
6. Conceptualization	Concrete thinking	=	Ability to abstract
7. Moral system	Deep in values; taking of moral system of parents	Internalized =	Adolescent's own concept of right and wrong (Theoretical decision)

From [H. H. Adelman, \*Seven Crucial Years: How to Deal with Your Adolescent's Developmental Tasks\*, 1983, p. 13-14](#)

**Table 24.1. Growth Tasks by Developmental Phase**

The normative psychological tasks of adolescence are:

1. Developing a satisfactory and realistic body image
2. Developing increased independence from parents and adequate capacities for self-care and regulation
3. Developing satisfying relationships outside the family
4. Developing appropriate control and expression of increased sexual and aggressive drives
5. Identity consolidation, including a personal moral code and at least provisional plans for a vocation and economic self-sufficiency

### Coping with a Changing Body Image

Save for pregnancy or devastating illness, no other epoch sees such dramatic changes in the body and its self-representation as does adolescence. Although often welcome, these changes also are unsettling. Body and facial hair begins to grow. Menstrual discharges, erections, or ejaculation can occur at unexpected and embarrassing times. Acne and body odors make their appearance and are a source of anxiety. Boys' voices may break unexpectedly as they deepen. Changes in the distribution of fat and muscle alter body outlines. Not only must girls deal with breast development, but, to their embarrassment, many boys develop gynecomastia.

Adolescents compare their development carefully with that of their peers and are acutely aware of their self-perceived imperfections. Much time is spent brooding in front of the mirror, examining every potential blemish and trying to catch a glimpse of the self. A single pimple may seem to loom as large as the Matterhorn, its stigma increased by the sense that it is as glaringly obvious to everyone else as it is to the adolescent.

In Western society, girls in particular are very preoccupied with the body image ideal of thinness held up to them by the media. Girls' levels of satisfaction with their bodies and physical appearance decline as they pass through adolescence. This is especially problematic for girls who are earlier maturing. The National Health Examination Survey ( [Gross and Duke, 1983](#)) found that most adolescent boys with body weights less than the top 10th percentile were satisfied with their weight; in contrast, even among girls whose weight was in the 50th percentile, 25% of lower socioeconomic group girls and over 40% of high socioeconomic group girls wanted to be thinner. The Youth Risk Behavior Survey ( [Centers for Disease Control and Prevention, 2000](#)) found that although 29% of high school boys and 22% of girls were overweight or at risk of being overweight (defined as having a body mass index equal to or greater than the 85th percentile for age and sex), only 24% of boys thought they were overweight, compared with 36% of girls; furthermore, only 26% of boys were trying to lose weight during the preceding 30 days, compared with 59% of girls. Compared with black girls, a higher proportion of white and Hispanic girls considered themselves overweight or were trying to lose weight. Pathologic eating behaviors are common in adolescent girls. For example, a survey of two private girls' secondary schools found that 18% of the girls reported at least one major symptom of an eating disorder: 8% to 15% thought about food all the time, 6% to 12% induced vomiting to control their weight, over 2% used laxatives for weight control, and 7% often fasted or starved to lose weight ( [Hendren et al., 1986](#)). These endemically high levels of body dissatisfaction and pathologic eating attitudes provide a large reservoir of vulnerable adolescent girls from whose ranks those with frank bulimia and anorexia are recruited.

More research is needed, however, to understand better the cultural factors that influence the wide variations in the prevalence of disordered eating attitudes and

behaviors across different communities and ethnic groups and over time ([Ponton, 1996](#)).

The adolescent's body also is a representation of the adolescent's self. Hence, not surprisingly, teenagers spend great amounts of time, energy, and money trying to make their appearance conform to some perceived ideal. Boys in middle adolescence may try to bulk up their gangling habitus or firm up a pudgy physique by weight lifting, body-building, nutritional supplements, and even anabolic steroids in an effort to transform their self-image from weak, dependent, or vulnerable to that of a "hard body"—tough, masculine, and strong. Girls endlessly experiment with makeup and consult friends and teen magazines regarding "makeovers." Both sexes may go through a dizzying panoply of clothing and hairstyles, trying on in rapid succession a kaleidoscope of fashions and styles that also represent possible social selves: slut, punk, home-boy, preppie, grunge, jock, goth, and so forth. Multiple body piercings and tattoos convey more permanent, but potentially disfiguring personal statements. [By tattooing on a lover's name, the bearer seeks self-reassuringly to reinforce the permanence of a relationship ([Martin, 1997](#))].

Beyond its role as a source of anxiety or pleasure, the body also may be the vehicle for painful or self-destructive means of reducing psychic tension (e.g., through delicate cutting) or dealing with conflicts over dependency or instinctual longings (e.g., bulimia, anorexia nervosa) ([Ritvo, 1984](#)).

### Changing Relations with Parents

Surveys such as those of [Offer and Schonert-Reichl \(1992\)](#) have emphasized that most adolescents regard their relations with their parents as stable, trusting, and sustaining and continue to turn toward parents as important, primary sources of advice, comfort, and assistance. Although this appears to be objectively true for most adolescents, on a subjective level, for both the parents and youngster, there are important shifts in the emotional terms of the relationship ([Steinberg and Morris, 2001](#)).

#### LOOSENING TIES TO PARENTS

Time spent with family decreases during adolescence, from 25% of waking hours for high school freshmen to only 15% for seniors ([Csikszentmihalyi and Larson, 1984](#)). Furthermore, there is a shift in the affective tone of time spent with parents and in the adolescent's view of the parents.

The teenager's own parents often are de-idealized. This is a painful process for parents as their previously admiring child develops a keen (sometimes distorted, sometimes all-too-accurate) sense of their shortcomings. Even those many teens who retain warm and supportive relations with their parents experience an increased sense of loneliness because the youngster feels no longer able or willing to share many intimate concerns or longings as of old. The adolescent may alternate between wishes for autonomy and wishes to be taken care of. Feelings of dependency may have to be warded off with disparagement, indifference, or oppositionality ([Freud, 1958/1969](#)). As a result, well-meaning parents often are bewildered as to which side of the child's ambivalence they are dealing with at any given moment [hence, the titles to various guides for the parents of teens, such as *Get Out of My Life, but First Could You Drive Me and Cheryl to the Mall?* ([Wolf, 1991](#))].

#### CONFLICT WITH PARENTS

[Csikszentmihalyi and Larson \(1984\)](#) remark that "friction appears to be an endemic feature of family life" in families with adolescents (p. 138), noting that "adults and adolescents live in separate, if overlapping, realities" (p. 140), often viewing the same events quite differently. This is true not only of specific events, but of family life in general, with adolescents tending to underestimate parental influence on them, and parents tending to overestimate their influence. Similarly, parents usually perceive the family's cohesion and adaptability as more satisfactory than do their teenagers ([Coleman and Hendry, 1990](#)) who, in turn, report more conflicts with their parents than do the parents themselves ([Laursen et al., 1998](#)).

Conflicts between parents and children increase with the beginning of adolescence. In early adolescence, these clashes concern household rules, chores, room cleaning, bedtime, diet, friends, dress, and hygiene; later in adolescence, issues such as dating and curfews become more prominent. [Montemayor and Hanson's \(1985\)](#) naturalistic study of early adolescents found that conflicts with parents and siblings occurred at the rate of approximately 20 per month, or 1 every 3 days. Metaanalytic studies find that although the frequency of parent-child conflicts declines from early adolescence through late adolescence, the negative affective intensity of conflicts peaks in mid-adolescence ([Laursen et al., 1998](#)).

Mothers appear to bear the brunt of most of these clashes, especially with early adolescent daughters ([Graber & Brooks-Gunn, 1999](#)); father-son clashes in particular take on greater affective intensity in mid-adolescence ([Laursen et al., 1998](#)). Early maturation in girls and problems such as adolescent depression or substance abuse increase the likelihood of conflict ([Arnett, 1999](#)).

This squabbling and bickering take a toll on the psychological well-being of the parents, as well as the adolescent, with many parents reporting difficulty adjusting to their teenager's strivings for autonomy ([Steinberg and Morris, 2001](#)).

The quality of daily family life, thus, becomes more turbulent in families with adolescents, with minor, but frequent "daily hassles"; for example, as boys approach puberty, there is a deterioration in family communication as both parents and child interrupt each other more frequently and explain themselves less (Steinberg, 1981, cited in [Csikszentmihalyi and Larson, 1984](#)). Time sampling studies find that when with their families, adolescents' negative thoughts outnumber positive ones by 10 to 1 ([Csikszentmihalyi and Larson, 1984](#)).

The apparent decrease in parent-child conflict in middle adolescence coincides with decreased time spent with parents and a turn toward greater involvement and reliance on peers, leading [Laursen et al. \(1998\)](#) to speculate that "it is likely that parents and children disagree less simply because they are together less. Increases in conflict affective intensity coincide with increases in autonomy and emotional dysphoria that occur as adolescents spend more time alone and with peers" (p. 828).

Despite the mutual stresses of increased conflict, most parent-child relationships remain solid. As [Arnett \(1999\)](#) notes, "Even amidst relatively high conflict, parents and adolescents tend to report that overall their relationships are good, that they share a wide range of core values, and that they retain a considerable amount of mutual affection and attachment" (p. 320).

Seen from one perspective, the immediate *causa belli* of many typical parent-adolescent clashes appear seemingly trivial: hairstyle, clothes, chores, curfew, or volume and taste in music. The intensity of conflict, however, usually reflects the parents' or child's perception (accurate or not) that vital issues are at stake: for the parents, issues of loyalty, respect, responsibility, and the dangers of sex, substance abuse, or other risky behavior; for the adolescents, issues of autonomy, control of their own body, and connections to friends.

Adolescents whose parents are able to hold firm and maintain balance in the face of these upheavals, without being overly permissive, harshly authoritarian, or indifferent, appear to do best. Numerous studies conclude that what has been termed *authoritative parenting*—combining warmth and responsiveness on one hand with firmness and demandingness—is associated with a wide range of adolescent competencies, academic achievement, and positive outcomes.

By later adolescence, in most cases, volatility and strife decrease and some degree of equilibrium is restored to the parent-adolescent relationship, albeit on a newer and more egalitarian basis, with the youngster having more autonomy and involvement in family decision making.

#### TRANSITION TO SELF-CARE

As adolescence progresses, youngsters gradually claim or are ceded greater control over their diet, hygiene, sleep schedule, and dress, as well as responsibility for their school work. Nonetheless, these remain topics of frequent minor skirmishes, at least in early adolescence, with much parental nagging about junk food, skipped meals, slovenly or inappropriate dress, time spent on the phone (or Internet), and the like.

Although adolescence is a time of general good physical health, it also is the period during which many attitudes and habits are established with respect to diet, exercise, substance use, smoking, driving, and sexual behaviors that will constitute long-term risk (or protective) factors for health in later life ([DiClemente et al., 1996](#); [Millstein et al., 1993](#)).

Ironically, for many youngsters with serious chronic illnesses, such as type 1 diabetes mellitus or cystic fibrosis, despite their greater cognitive understanding of the exigencies of their condition, the quality of their care frequently deteriorates as they take over the responsibility for adherence to their treatment regimen

([Brooks-Gunn, 1993](#); [King and Lewis, 1994](#)) Thus, many adolescent diabetic patients fail to adhere to their diet, blood glucose testing, and insulin regimen. Adolescent diabetic girls may even deliberately permit themselves to spill sugar in their urine as an ill-advised form of weight control. Some chronically ill youngsters may stop their medication, including chemotherapy or immunosuppressant therapy, with potentially fatal consequences.

Unlike health-conscious adults, many adolescents perceive the need to pay extra attention to their physical condition as anxiety provoking, stigmatizing, or frighteningly threatening to their wish for autonomy and invulnerability; hence, rather than responding to their medical condition with heightened attentiveness, they may try to avoid thinking about or dealing with their illness altogether.

### Developing Satisfying Relationships Outside the Family

As dependence on parents becomes less acceptable to adolescents, they turn increasingly to peers for companionship, advice, support, and intimacy. [Csikszentmihalyi et al. \(1977\)](#) found that during the school year, adolescents spend one-third of their waking time talking with peers, but less than 8% of waking time talking with adults. Talking with friends was the activity that teens reported made them the happiest.

Parents may be bemused or annoyed by their adolescent's intense need to hang out with and be with peers, regardless of any family plans. As [Seltzer \(1989\)](#) points out, this is not merely for the immediate pleasures of the event. Rather, the need for continuing access to peers is driven by an intense need to relate, to compare, and to try out aspects of the developing self. It is this developmental need that explains "why adolescents never seem to tire of being with one another. ... [I]t is not the overt social activity or the content of the event (e.g., a rock concert, a football game, a dance) that feeds the drive. It is *being with one another*—looking, listening, and resultant comparing. Adolescents report details of who was there, what they did or said, and what they wore in far greater detail than they describe the content of the event" (p. 41).

With adolescence, the communicative, supportive, and intimate aspects of friendship take on increased importance. Although nonromantic opposite-sex friendships occur in later adolescence, close friendships in early adolescence tend to be with the same sex. Among girls, intimate conversations are most often the cement of friendships, whereas for boys, it tends to be shared activities. With age, the need for control and conformity decreases, and there is greater tolerance for differences between friends ([Steinberg and Morris, 2001](#)).

The choice of friends is a complex matter. Although the range of possibilities is defined by the given community and school population, the adolescent's specific choices of friends reflect an important and often fateful aspect of self-definition. Adolescents most often choose friends who share their behaviors, attitudes, interests, and identities ([Steinberg and Morris, 2001](#)). Friends, however, also may be chosen on many other grounds, including perceived virtues or aspects of the self that the adolescent consciously repudiates or feels he or she lacks. Friends may serve as sources of support or admiration, as collusive companions for regression or delinquency, objects of sexual or aggressive exploitation, targets for projection—the list is endless. The choice of friend may be used to try on or borrow self-attributes; for example, a girl who perceives herself as unattractive or unpopular may hang out with a girl whom she sees as beautiful or popular. A boy who feels himself to be overly compliant, timid, or passive may choose to hang out for a while with a more venturesome or delinquent peer. Friendships pursued out of such interests may be transient or unstable as the youngster comes to feel in greater possession of the desired attribute himself or herself, or repudiates the wish for it.

Empirical studies have examined what personal attributes of peers are most salient to adolescents. For example, Midwestern high school students were asked to rate a list of attributes as to the frequency with which they were noticed in age mates. The top 10 attributes most frequently rated as "always of interest" were (in decreasing order): cleanliness, loyalty to friends, clothes, dependability, trustworthiness, general physical appearance, maturity, popularity with opposite sex, figure/build/physique, and honesty. Despite some gender and age differences, appearance and dependability were widely viewed as very important, whereas specific skills and abilities were of little interest ([Seltzer, 1989](#)).

Over the course of high school, adolescents shift in the gender and group size with whom they associate ([Brown, 1990](#)). Thus, freshmen hang out predominantly in same-sex groups, sophomores in same-sex dyads, juniors in mixed-sex groups, and seniors predominantly in small groups of heterosexual couples ([Csikszentmihalyi and Larson, 1984](#)). In early adolescence, the adolescent's crowd consists of a large group of peers with similar reputations and role stereotypes (e.g., preppies, goths, brains, jocks, nerds). Younger adolescents value crowd affiliation as fostering friendships, providing support, facilitating interactions, and providing a source of identity and status (according to where the adolescent's particular crowd fits in the school or community hierarchy). Attitudes toward being "part of a crowd" do, however, change over the course of adolescence ([Brown, 1990](#)). Older adolescents are more likely to be dissatisfied with the perceived conformity demands of crowds and prefer smaller, more intimate groups. By the later high school years, the salient peer group may be the clique, a smaller group of peers similar in terms of activities, attitudes, status, age, and race.

Ironically, many adolescents, while resisting parental advice in the name of autonomy, are slavishly compliant with the perceived tastes and values of peers, especially regarding fashions and preferences in dress, slang, music, television, and movies.

As [Steinberg and Morris \(2001\)](#) point out, however, peers influence each other in positive ways, including prosocial behaviors and academic achievement, as well as in negative ways, such as delinquency or substance use. These influences are not necessarily coercive or conformist, but also stem from emulatory admiration and a community of attitudes and interests that form the basis for the friendship in the first place.

Adolescents' relationships with their parents are an important influence on peer relationships. Authoritative parenting styles appear to lessen the negative effects of peer influences; conversely, teenagers from less cohesive families are more likely to be influenced by peers than by parents ([Steinberg and Morris, 2001](#)). A tendency to look to peers rather than to parents for guidance and values, especially when combined with a choice of peers with delinquent behavior, low academic aspirations, or with values markedly divergent from the adolescent's parents, is an important risk factor for a wide range of problem behaviors ([Jessor, 1991](#)).

### Sexual and Aggressive Drives

Adolescence sees the epochal development of experiencing sexual attraction toward others and perceiving oneself as the object of others' sexual desire. How these subjectivities unfold and are given individual and social meanings is a complex process with physiologic, cultural, and individual dimensions. The interplay of these factors has been the focus of much anthropologic, psychoanalytic, and developmental study (see [Chapter 20](#)) ([Cote, 2000](#); [Brooks-Gunn and Paikoff, 1997](#); [Herdt and McClintock, 2000](#); [Katchadourian, 1990](#)).

After a period of fairly open genital interests and play during the preschool years, overt sexual behavior and interests diminish markedly during the school years ([Friedrich et al., 1991](#)). Although even in these years before adolescence, sexual interests are never completely latent, masturbation, if it continues, is more furtive, and the child becomes more modest and inhibited about discussing sexual and romantic matters.

Beginning at approximately 10 years of age, feelings of sexual awareness and attraction make their conscious appearance. This development, which appears to be linked to rising adrenal androgens, occurs even before the onset of gonadal puberty proper. The reticence of children at this age makes the phenomena difficult to study in Western culture, but in many preliterate cultures, such as Melanesia, sexual rites of passage, at least for boys, occur as early as 10 years of age ([Herdt and McClintock, 2000](#)). It is also around the age of 10 to 11 years that some children become aware of same-sex attractions and homoerotic fantasy.

In early adolescence, genital excitement and sexual interests often occur independently of liking, intimacy, or wish for emotional closeness. For young adolescent boys, the objects of sexual fantasy and masturbatory excitement frequently are magazine models or television and movie figures, rather than actual acquaintances. In keeping with their burgeoning attunement to social relationships, early adolescent girls are usually intensely interested in the romantic relationships, real and fantasied, of their peers, with endless discussions of who is "going out" or has broken up with whom. However, the early teen boys who are their age-peers often are unpromising candidates as romantic partners, hence many girls' crushes and eroticized longings focus on media figures, such as the various "boy bands" marketed to this audience. Although movies and television have long provided the raw materials for adolescent sexual fantasy, it is not yet clear what the recent increases in the ubiquity, sexual explicitness, and violence of mass media (including now the Internet) will be on the sexual socialization of teens ([Chapin, 2000](#)).

With adolescence, there also is a resurgence of overt sexual activity (see [Chapter 20](#)) ([Friedrich et al., 1991](#); [Rutter, 1971](#)). The rate of explicit masturbation increases from approximately 10% at age 7 to approximately 80% at age 13 years, whereas that of heterosexual play rises to approximately 65% at age 13 years; homosexual play also is not uncommon in early adolescence, with 25% to 30% of 13-year-old boys reporting at least one episode of same-sex play.

The transition from childhood masturbation to that of adolescence involves more than an increased physiologic capacity for arousal and orgasm. Most teens report

consciously fantasizing when masturbating to orgasm, and even those who do not seem aware of some sort of sexual imagery ([Katchadourian, 1990](#)). Sexual fantasies (which also occur without overt masturbation) become an intense and important part of the adolescent's psychological inner life. Beyond serving as a source of pleasure and compensatory wish fulfillment in lieu of other sexual outlets, these fantasies provide the occasion for the adolescent to elaborate or explicate his or her idiosyncratic and personal erotic scripts: who, doing what, with whom, with what body parts, with what implicit and explicit emotional tone and interpersonal interactions, and with what admixture of dominance or submission, control or abandonment, sadism or masochism, and admiration or degradation. [[Laufer \(1976\)](#) has coined the term *central masturbatory fantasy* to describe the organizing aspects of these not always fully conscious fantasies in relationship to arousal and orgasm.] These fantasies are more than just a form of rehearsal or anticipatory coping; they help the adolescent explore and become aware of what is pleasurable, anxiety provoking, transgressive, or deeply compelling in his or her longings and to become familiar with his or her individual preconditions for erotic excitement and fulfillment.

A key task of adolescence is to bring these erotic longings adaptively into the interpersonal arena as a vehicle for intimacy, emotional closeness, and ultimately the formation of a stable partnership for the conception and rearing of the next generation.

Although early adolescence sees the transition from largely autoerotic sexual activity to sexual interactions with peers, this takes place at different rates in different social and ethnic groups and with different interpersonal meanings (see [Chapter 20](#)) ([Brooks-Gunn & Paikoff, 1997](#); [Katchadourian, 1990](#)). For girls, the relational aspect of sexual involvement usually is paramount, and girls may engage in petting, oral sex, or intercourse as an attempted means of winning or retaining a boy's perceived interest, affection, or commitment. For young adolescent boys, sexual activity often has a more exploitative nature, with less interest in the relational aspect of the activity [for a detailed account of the epidemiology and other aspects of adolescent sexuality, as well the implications for prevention of pregnancy and acquired immunodeficiency syndrome (AIDS), see [Chapter 20](#)].

Falling in love is an important part of adolescence, even when not accompanied by sexual intimacy. Adolescence's most intense longings, keenest pleasures, painful frustrations, and bitterest disappointments center on the quest for a reciprocated love that helps to define the still inchoate self and assuage the loneliness of individuation.

Adolescent sexuality stirs in adults a variable reactive mixture of envy, apprehension, or repressiveness. Parents who may be facing their own midlife crises must contend with their sons' or daughters' burgeoning sexuality. Many of the parent-child conflicts in mid-adolescence, such as those around clothes, friends, dating, curfews, and driving, although seemingly trivial, have the subtext of the parents' attempts to control the pace, scope, and direction of their adolescent's sexual activity. (A few parents who are overidentified with their adolescent's sexuality or take too much vicarious excitement in it collusively encourage their teen's transition to sexual activity.)

Despite much forgetfulness about the travails of their adolescence, most adults retain evocative, bittersweet memories of their own adolescent romantic longings. It is not surprising then, that from *Romeo and Juliet* on, the pangs and passions of adolescent love, whether thwarted or fulfilled, have remained an enduring theme of plays, novels, poetry, movies, and songs.

## Identity

In his seminal work *Childhood and Society*, [Erik Erikson \(1963\)](#) describes the challenge of identity formation as follows:

[I]n puberty and adolescence all samenesses and continuities relied on earlier are more or less questioned again. ... The growing and developing youths, faced with [the] physiological revolution within them, and with tangible adult tasks ahead of them are now primarily concerned with what they appear to be in the eyes of others as compared with what they feel they are, and with the question of how to connect the roles and skills cultivated earlier with the occupational prototypes of the day. ... To integrate all identifications with the vicissitudes of the libido, with the aptitudes developed out of endowment, and with the opportunities offered in social roles. [The desired outcome] is the accrued confidence that the inner sameness and continuity prepared in the past are matched by the sameness and continuity of one's meaning for others (p. 261).

One of the most influential empirical extensions of Erikson's work was Marcia's taxonomy for classifying adolescents into four identity statuses: the *identity-confused* subject who has not yet experienced an identity crisis or made a role commitment; the *foreclosed* subject, who has made unexamined commitments, usually as received from parents and others; the *moratorium* subject, who is actively struggling to define values and commitments; and the *identity-achieved* subject, who has resolved these crises ([Muus, 1988](#)). In contemporary society, many of these identity issues are not fully engaged until the college years or beyond ([Arnett, 2000](#)).

Empirical research has shifted away from global notions of identity to focus more on the development of specific self-concepts ([Offer et al., 1988](#); [Steinberg and Morris, 2001](#)). With their growing cognitive sophistication, adolescents' views of themselves become more differentiated and better organized. [Harter \(1999\)](#) and others have examined the distinct dimensions of adolescents' self-concept across several realms, such as social relations, appearance, academics, athletics, and morality, and their relationship to global self-worth. Adolescents weigh these dimensions differently depending on whether they are interacting with peers, parents, or teachers, and it is only over time that these discrepancies decline to produce a more consonant, better-integrated self-image. [Behavioral genetic studies of siblings suggest that heritable factors may exert more of an influence than do shared environmental factors on perceived scholastic and athletic competence, physical appearance, and general self-worth; perceived social competence appears to be primarily determined by nonshared environmental factors reflecting each sibling's unique family and social experiences ([McGuire et al., 1999](#); [Reiss, 2000](#))].

In addition to the ubiquitous categories of adolescent self-concept described by Harter, ethnic and sexual minority adolescents also must consolidate a sense of identity vis-à-vis both their minority group and the mainstream culture ([Steinberg and Morris, 2001](#)).

## CLINICAL ASPECTS OF ADOLESCENCE

On the basis of many epidemiologic studies, it now appears that only approximately 20% of adolescents have diagnosable clinical disorders. However, it is equally clear that during adolescence, a substantial proportion of youngsters experience increased conflicts with parents and mood difficulties and engage in risk behaviors.

### The Storm and Stress Debate Revisited

For many years, debate has continued over the frequency and severity with which adolescent turmoil occurs and the extent to which it should be considered normative in American culture or universal across epochs and cultures (for a review of this issue, see [Arnett, 1999](#)).

Classical writers, such as Aristotle and Plato, saw the period we now call adolescence as a time of changeability and vulnerability that required careful character education and social constraints. Aristotle noted in his *Rhetorica*:

Young men have strong passions, and tend to gratify them indiscriminately. Of the bodily desires, it is the sexual by which they are most swayed and in which they show absence of self-control... They are changeable and fickle in their desires, which are violent while they last, but quickly over: their impulses are keen but not deep rooted... They cannot bear being slighted, and are indignant if they imagine themselves being unfairly treated" (quoted in [Muus, 1988](#), p. 8).

Although, over the centuries, adolescents have at times been idealized for their beauty and grace or as bearing the hope of the future, they also have been regarded by their elders with deep misgivings and dismay as potentially disruptive and subversive, not only difficult to handle, but threatening to undermine society's strictures regarding sex, aggression, and respect for elders. Hence, the old shepherd laments in *The Winter's Tale*:

I would that there were no age between ten and three-and-twenty, or that youth would sleep out the rest, for there is nothing in between but getting wenches with child, wronging the ancients, stealing, fighting... (Act III, scene iii).

In his seminal 1904 work, G. Stanley Hall noted "a period of semicriminality is normal for all healthy [adolescent] boys" (vol. 1, p. 404, quoted in [Arnett, 1999](#)). Speaking of the internal upheavals of adolescence, rather than overt deviant behavior, Anna Freud noted, "the upholding of a steady equilibrium during the

adolescent process is in itself abnormal" (1958/1969, p. 164). She observed that

it is normal for an adolescent to behave for a considerable length of time in an inconsistent and unpredictable manner; to fight his impulses and to accept them; to ward them off successfully and to be overrun by them; to love his parents and to hate them; to revolt against them and to be dependent on them;...to thrive on imitation of and identification with others while searching unceasingly for his own identity; to be more idealistic, artistic, generous and unselfish than he will ever be again, but also the opposite—self-centered, egoistic, and calculating (pp. 164-165).

In more recent years, this view of adolescence as inherently tumultuous has come under attack as an overgeneralization from mental health professionals' clinical samples or from popular authors' vivid portrayals of their own idiosyncratic adolescent experiences. For example, in an article polemically entitled "Debunking the Myths of Adolescence: Findings from Recent Research," Offer and [Schonert-Reichl \(1992\)](#) characterize the "myth" that normative adolescence is tumultuous as assuming that "[t]he 'typical' adolescent is ... out of control, in constant conflict with his or her family, and incapable of rational thought (p. 1003)." In contrast, they observe, on the basis of nonclinical samples, that "adolescence is not a time of severe disturbance for all adolescents. Moreover, ... a significant percentage of adolescents (80%) do not experience adolescent turmoil, relate well to their families and peers, and are comfortable with their social and cultural values.... [T]eenagers who exhibit little disequilibrium are normal ... [and] ... adolescence is a period of development that can be traversed without turmoil and that the transition to adulthood is accomplished gradually and without undue upheaval" (p. 1004).

As with many debates, the truth lies somewhere in the middle of these dichotomies and depends on the terms of the argument and matters of degree (e.g., what type and severity of turmoil). In a review of the topic, [Arnett \(1999, p. 324\)](#) concluded

[T]here is support for [Hall's \(1904\)](#) view that a tendency toward some aspects of storm and stress exists in adolescence. In their conflicts with parents, in their mood disruptions, and in their heightened rates of a variety of types of risk behavior, many adolescents exhibit a heightened degree of storm and stress compared with other periods of life. Their parents, too, often experience difficulty—from increased conflict when their children are in early adolescence, from mood disruptions during mid-adolescence, and from anxiety over the increased possibilities of risk behavior when children are in late adolescence. However ... there are cultural differences in storm and stress, and within cultures there are individual differences in the extent to which adolescents exhibit the different aspects of it.

[However], [e]ven amidst the storm and stress of adolescence, most adolescents take pleasure in many aspects of their lives, are satisfied with most of their relationships most of the time, and are hopeful about the future.

Having examined conflicts with parents, we turn to a more detailed consideration of mood problems and risk behaviors.

### **Mood Difficulties and Perceived Stress**

Adolescence is a time of rising incidence for major depression, with the risk of depression and the preponderance of affected girls versus boys increasing not only with age, but more specifically with advancing pubertal status.

Only a minority of adolescents develop a full-blown affective disorder. Nonetheless, adolescence sees a marked increase in emotional lability, depressed mood, and negative emotions (e.g., anxiety and self-consciousness), with over one-third of adolescents in nonclinical samples reporting high levels of depressed mood ( [Arnett, 1999](#); [Buchanan et al., 1992](#); [Larson and Richards, 1994](#); [Petersen et al., 1993](#); [Rutter et al., 1976](#)). For example, the national Youth Risk Behavior Survey ( [Centers for Disease Control and Prevention, 2000](#)) of high school students found that, during the preceding year, 36% of girls and 21% of boys felt sad or hopeless almost every day for at least 2 weeks in a row and 25% and 14%, respectively, seriously considered attempting suicide. Mood disruptions are associated with higher levels of negative life events ( [Brooks-Gunn and Warren, 1989](#)). Comparing fifth graders and ninth graders, [Larson and Richards \(1994\)](#) describe the dramatic decline in the proportion of time youngsters feel "very happy," "proud," or "in control" as an emotional fall from grace.

Girls appear especially prone to negative moods. For example, [Offer and colleagues \(1988\)](#) found marked gender differences in emotional vulnerability across adolescence. Compared with boys, girls described themselves as moodier, sadder, lonelier, more prone to uncontrollable crying, more easily hurt, less autonomous and more other-directed, and more ashamed of their bodies.

Adolescents also report a substantial increase in the number of negative life events. It is difficult to determine to what extent this reflects a more stressful environment, greater sensitivity to events, or shifts in the types of situations that precipitate negative emotions ( [Larson and Asmussen, 1991](#); [Wagner and Compas, 1990](#)). The nature and sources of perceived stress change over the course of adolescence, with early adolescents experiencing stress in relationship to peers and older adolescents with respect to academic issues. Especially in early adolescence, girls appear to experience more stress than at other ages and to perceive more stressful events than do boys ( [Ge et al., 1994](#); [Vik and Brown, 1998](#); [Wagner and Compas, 1990](#)). Although significant life events, such as parental separations or unemployment, moves, or deaths, have a serious impact on adolescents, many of the fluctuations in adolescent mood reflect the less dramatic daily hassles—homework, tests, disagreements with friends—the minor disappointments, stresses, and embarrassments that form the fabric of adolescent life. It may be deceptive, however, to try to conceptualize and quantify these hassles as completely independent external variables because unlike many major life events, the intensity, valence, and even the occurrence of such episodes often lie largely in the eye of the adolescent beholder ( [Csikszentmihalyi and Larson, 1984](#)).

Time sampling studies of adolescent mood in community samples find that, compared with adults, adolescents have greater mood variability as measured by both the width of their mood swings (between extreme highs and lows) and the evanescence of these extremes ( [Csikszentmihalyi and Larson, 1984](#)). In the nonclinical high school population studied, greater subjectively experienced mood lability was not associated with poorer adjustment or other pathologic processes.

Neurobiological factors also may influence the changes in mood regulation and stress reactivity observed in adolescence.

A longitudinal study by [Angold and colleagues \(1999\)](#) found that reaching Tanner stage III was associated with increased levels of depression in girls; however, hormonal levels of testosterone and estradiol were more closely associated with levels of depression than age or Tanner stage *per se*. Although this suggests that it is not morphologic body changes themselves that render pubertal girls more prone to depression, it is unclear whether these findings reflect direct depressogenic endocrine influences on the central nervous system or hormonally mediated changes in responsivity to life events and stress.

[Spear \(2000\)](#) proposed that age-related changes in the balance of dopamine regulation in the prefrontal cortex relative to mesolimbic brain regions lead to shifts in the incentive value and motivational power of different reinforcers. Drawing on both human and animal data, Spear proposes a transient relative "reward deficiency syndrome" or "adolescent anhedonia" that results in previously pleasurable activities being experienced as less rewarding and leads to a compensatory search for new and more intense forms of stimulation (e.g., greater novelty seeking, risk taking, and increases in consummatory behaviors, such as food and drugs).

### **Risk-Taking Behaviors**

Risk-taking behavior is a significant source of morbidity and mortality for young people. In contrast to persons 25 years of age or older, for whom two-thirds of all deaths are due to cardiovascular disease and cancer, three-fourths of all deaths for youths 10 to 24 years of age are due to motor vehicle crashes, other unintentional injuries, homicide, and suicide, with AIDS also becoming a rapidly rising cause of death for young adults. Behaviors that increase the risk of these adverse outcomes are common among teenagers. The [Centers for Disease Control and Prevention \(2000\)](#) national Youth Risk Behavior Survey found that for the 30 days preceding the survey, 16.4% of high school students reported rarely or never wearing a seat belt, one-third had ridden with a driver who had been drinking, 17.3% had carried a weapon, 50% had drunk alcohol, 34.8% had smoked tobacco, 26.7% had used marijuana, and 7.8% had attempted suicide in the prior 12 months. Other health-impairing behaviors also were common. Half of the students had had sexual intercourse; of these, 42% had not used a condom at last intercourse.

These risk behaviors are not uniformly distributed across the adolescent population. For example, among ninth graders, 22% are estimated to be at low risk, with no involvement with any risk behaviors such as substance use, sex, depression/suicide, antisocial behavior, school problems, unsafe vehicle use, or bulimia ( [Dryfoos, 1998](#)). Another 29% report only one such risk indicator, 18% report two, and 31% report three or more. High-risk youth (those reporting multiple risk behaviors) are characterized by early onset of high-risk behaviors, absence of nurturing parenting, child abuse, lack of involvement with school, susceptibility to peer influence, depression, disadvantaged neighborhoods, and lack of gainfully employed role models. Certain patterns of autonomic reactivity may also predispose to increased risk-taking under certain circumstances ( [Liang et al., 1995](#)).

It is important to distinguish between occasional experimentation and persistent patterns of dangerous behavior ( [Steinberg and Morris, 2001](#) ). Although most adolescents will experiment with alcohol or minor delinquent behaviors, in most cases these behaviors do not persist into adulthood. The prevalence of problem behaviors does increase in adolescence and early adulthood, but persistence in problem behaviors, such as substance use or antisocial behavior, usually is associated with difficulties in earlier childhood ( [Arnett, 1992](#) ).

The work of [Jessor \(1991\)](#) and others ( [Igra and Irwin, 1996](#) ) suggests that risk-taking behaviors such as sexual activity, substance use, reckless driving, and delinquency not only increase over adolescence but frequently are associated with each other and share common psychosocial antecedents. These behaviors are not simply arbitrary, perverse, or motivated only by sensation-seeking or exploratory motives, but are in part purposeful, meaningful, goal-oriented, and functional. For example, [Jessor \(1991\)](#) observes that such behaviors also can serve the instrumental ends of gaining peer acceptance, establishing autonomy from parents, defying conventional authority, relieving anxiety or frustration, or affirming the transition to a more adult status.

## ETHOLOGIC PERSPECTIVES

Examination of the transition from youth to adulthood in other mammalian (especially nonhuman primate) species suggests animal models for the counterpart of human adolescence. Like human adolescents, the young of other species exhibit increases in peer-directed social interactions and greater novelty-seeking and risk-taking behaviors ( [Wilson and Daly, 1985](#) ). In a thought-provoking review, [Spear \(2000\)](#) has suggested that these shared behavioral features represent ontogenetic adaptations that help individuals in this transitional period in “acquiring the necessary skills to permit survival away from parental caretakers. Increased affiliation with peers and the taking of risks via exploring novel areas, behaviors, and re-enforcers may also help facilitate the dispersal of adolescents away from the natal family unit” ( [Spear, 2000](#), p. 418 ), with the adaptive goal of avoiding inbreeding. Similarly, human adolescents and many pubertal nonhuman primates spend increased time in social interactions with peers, including aggressive fighting, but also in reconciliatory and affiliative behaviors; paralleling this shift in social orientation from adults to peers is an increase in conflicts between the adolescent and parents, which also may help to encourage separation from the natal family unit ( [Steinberg, 1989](#); [Steinberg and Belsky, 1996](#) ). Increased risk taking also is seen across species, with increased exploratory behavior and novelty seeking, but also increased mortality. From an evolutionary perspective, such risk taking “may be—or at least once were—means of securing physical resources, attracting mates, and denying mating opportunities to competitors” ( [Steinberg and Belsky, 1996](#), p.117 ).

## THE CLOSE OF ADOLESCENCE

The pubertal changes that are the hallmark of adolescence provide a relatively clear marker for the beginning of adolescence. In contrast, the close of adolescence in contemporary society is less clearly defined. At one time in the United States and even today in traditional societies, the end of adolescence and assumption of adult status was usually marked by a discrete event, such as marriage, beginning of full-time employment, or military service. Currently, however, the same forces that have helped to create adolescence as a distinctive period of life in industrial and postindustrial society also have blurred the end of adolescence ( [Arnett and Taber, 1994](#) ). College and postgraduate education has become increasingly important, and the proportion of youth pursuing post-high school education has risen from 14% in 1940 to over 60% in the 1990s. Correspondingly, the median age of marriage in the United States rose from 21 years for women and 23 years for men in 1970 to 25 years for women and 27 years for men in 1996. Thus, for many young people, entry into adult roles regarding work, marriage, and parenthood is delayed until the late twenties or even early thirties.

[Arnett \(2000\)](#) has proposed that the period from the late teens through the twenties be considered a distinctive period he terms *emerging adulthood*. In contrast to adolescents, 95% of whom live in a parental home, most young people age 18 years or older in the United States leave home, approximately one-third to live in a college setting and approximately 40% to live independently and work full time. Approximately two-thirds cohabit for a time with a romantic partner. However, despite high rates of residential mobility in the twenties, many young people retain some degree of dependence on their parents. Hence, adolescence gives way to a prolonged period of quasiautonomy and continued identity and vocational exploration that only gradually draws to a close in the third decade of life.

[Chapter References](#)

Advances in neuroscience have generated increasingly sophisticated understandings of brain function. This understanding initially applied to basic aspects of perception and motor control and was subsequently extended to cognitive constructs, such as language and attention. More recently, advances in neuroscience have generated novel insights on emotion, and “anxiety” has emerged as an emotion for which a particularly sophisticated understanding has been reached. This has been possible because of the considerable cross-species reservation in the underlying neural circuitry that moderates anxiety, as reflected in cross-species parallels in physiologic and behavioral aspects of anxiety. Using a modern neuroscience approach, this chapter outlines understandings of how symptoms of anxiety arise in human beings. The chapter begins with a summary of current knowledge on the underlying neural circuitry involved in anxiety. This summary is followed by a review of data documenting the wide range of parallels between humans and animals in phenomenologic and neurophysiologic aspects of anxiety. Finally, the basic science and clinical literature is integrated to delineate briefly current views on the origin of anxiety in humans.

It is vital to begin such an integrative perspective on anxiety with a review of current definitions applied across basic science and clinical domains. Because animal-based research cannot rely on subjective reports to define one or another emotion, basic science definitions draw heavily on behavioral factors. For the current chapter, the term *emotion* refers to a brain state associated with perception of either a reward or punishment. The term *reward* refers to any stimulus for which an organism will extend effort to obtain, whereas the term *punishment* refers to any stimulus for which an organism will extend effort to avoid. Some controversy remains over defining individual emotions, such as anxiety or fear, because families of emotions may exist on continua, varying in terms of both valence and arousal. For the current chapter, the term *fear* refers to a family of brain states that result from the perception of punishments or overtly dangerous stimuli; the term *anxiety*, in contrast, refers to a family of brain states associated with fear or apprehension that is inappropriate to the context. As an example, “fear” is the emotion that a person would experience when confronting a large snake in the woods, whereas “anxiety” is the emotion a person would experience when confronting a large snake in the zoo. The current chapter considers the relevance of basic neuroscience research in this area for understandings of normal human fears, as well as for understandings of selective anxiety disorders, comprising phobias, spontaneous panic attacks or panic disorder, separation anxiety disorder, and generalized anxiety disorder. Clinical aspects of these disorders, as well as both clinical and biological aspects of other anxiety disorders, are considered elsewhere in this volume.

### BASIC SCIENCE PERSPECTIVES ON ANXIETY

#### Fear Conditioning

Recent interest among neuroscientists in emotion and particularly in anxiety can be traced to work conducted since the late 1970s on the construct of fear conditioning (Davis, 1998; Davis et al., 1997; LeDoux, 1996, LeDoux, 1998; Maren, 1999). As illustrated in Fig. 25.1, in a fear conditioning experiment, an organism, typically a rodent, is placed in an experimental chamber and an aversive or punishing stimulus, such as a shock or a blast of air, is paired with a neutral stimulus, such as a sound or a light. The aversive stimulus is considered the unconditioned stimulus (UCS), whereas the neutral stimulus is considered the conditioned stimulus (CS). In this situation, an organism's reaction to the CS changes with repeated presentation, such that the organism begins to exhibit behaviors such as freezing and physiologic changes such as altered heart rate and respiration, associated with states of fear. Fear conditioning is an amazingly robust phenomenon, repeatedly demonstrated across a diverse array of animal species (Davis, 1998; Davis et al., 1997; LeDoux, 1996, LeDoux, 1998; Maren, 1999).

**Figure 25.1.** The protocol for two types of fear conditioning that can be produced after a single learning trial. The trial consists of a single foot shock and produces context conditioning (to a box) and cued conditioning (to a tone). CS: conditional stimulus. (From Squire RL, Kandel ER: *Memory: From Mind to Molecules*. New York, Scientific American Library, 1999; with permission).

The conceptual importance of fear conditioning emanates both from its ubiquity among organisms and from the degree to which neuroscientists have delineated the underlying neural circuitry. Through the work of (LeDoux 1996,1998), Davis (1998, 1997), and others, a key role in fear conditioning has been ascribed to a collection of nuclei that lie in the amygdala, a medial temporal lobe structure lying in primates immediately anterior to the hippocampus. Much of this work relies on processing of auditory CS stimuli, which are perceived at the ear and further processed in a circuit extending from the thalamus to the basolateral nucleus of the amygdala. Processing of the aversive UCS stimulus also is thought to extend to the basolateral nucleus, where information on the UCS and CS can be integrated. This information is transmitted to the central nucleus of the amygdala, which, in turn, interfaces with multiple brain systems involved in an organism's physiologic and motor responses to danger. For example, this nucleus interfaces with the paraventricular nucleus of the hypothalamus, which regulates hypothalamic–pituitary–adrenal (HPA) axis activity, the parabrachial nucleus in the brain stem, which regulates respiratory activity, as well as components of the vagus nerve that regulate cardiovascular activity.

Precise delineation of underlying neural circuitry for a behavioral phenomenon, such as fear conditioning, enables a comprehensive understanding of mechanisms behind such a phenomenon. Such understanding, in turn, facilitates molecular and genetic insights into the phenomenon. For example, fear conditioning represents an elemental form of learning, during which contingencies between two stimuli, the CS and UCS, are perceived. Beginning with the insights from Hebb, a series of studies over the past 50 years outline the cellular and molecular basis of such learning (Mayford et al., 1996; Squire, 1992). At a cellular level, learning results from changes in an outflow neuron after the delivery of temporally linked action potentials from two afferent neurons. When these action potentials are delivered in phase, the threshold for stimulating the outflow neuron is lowered, resulting in a state termed *long-term potentiation* (LTP). Applied to fear conditioning, learning the nature of

the relationship between the CS and UCS is thought to involve LTP in neurons in the basolateral amygdala ( [Maren, 1999](#)). Because LTP is understood in molecular terms, work on the role of LTP in fear conditioning generates a set of explicit hypotheses about the role of genetic factors in fear conditioning among various species, including humans.

### Fear and Anxiety as Heterogeneous Constructs

Research on the relatively simple construct of fear conditioning has stimulated an array of experiments focused more broadly on the range of reactions organisms typically exhibit to a range of dangerous stimuli or scenarios. These experiments demonstrate considerable heterogeneity in behaviors associated with distinct stimuli and scenarios. This heterogeneity is thought to reflect differences in the underlying neural circuitry linked to unique brain states associated with one or another form of danger. Considerable disagreement persists on the most appropriate means for categorizing brain states associated with such distinct forms of danger. This disagreement relates to incomplete understandings of the underlying neural circuitry. Nevertheless, general agreement has emerged on the view of fear and anxiety as a family of relatively specific constructs. A brief summary is provided of ranging views on distinctions among fear-related behaviors.

Stimuli differ in the degree to which they are naturally perceived as aversive or punishing. For example, in the fear conditioning experiment, the UCS consists of a stimulus that is innately fear-provoking, capable of eliciting withdrawal in the absence of prior training. The CS, in contrast, comes to elicit fear-related behaviors through learning. Organisms exhibit distinct reactions to stimuli that induce fear innately as opposed to through learning. Moreover, within categories of innate or learned fears, organisms exhibit considerable heterogeneity in their reactions, depending on particular features of the fear-inducing stimulus.

For innately fear-inducing stimuli, organisms' reactions depend on various characteristics of the feared stimulus. Work by Blanchard et al. (1997) has documented such a range in the reactions of rodents when confronted with overt danger. For example, when a rat is placed directly in the presence of a cat, the cat elicits an immediate flight response in the rat that typically is followed by a prolonged period of freezing when the rat reaches the safety of the burrow. In contrast, indirect evidence of a cat, perhaps related to the smell of a cat or signals from other rats suggesting that a cat may be near, typically elicits immediate freezing without flight. Similarly, organisms exhibit a range of reactions to innately aversive stimuli based on the proximity of the stimulus ( [Rodgers, 1997](#)). A distal threat typically elicits freezing, whereas an immediate threat typically elicits either flight or attack.

For learned fears, organisms also exhibit a range of reactions to distinct components of the fear. In the classic fear conditioning experiment, an organism learns to fear the CS, such as the tone or the light, owing to a process known as *cue-specific fear conditioning*. The organism also learns to fear the experimental chamber within which the UCS had been delivered through a second process known as *context conditioning* (see [Fig. 25.1](#)) ( [LeDoux, 1998](#)). Although some controversy persists over the precise details of the underlying neural circuitry for context conditioning ( [Davis, 1998](#); [Davis, 1997](#); [LeDoux, 1998](#); et al.), cue-specific and context conditioning are generally thought to involve distinct components of the nervous system. Whereas the amygdala is involved in both phenomena, either the hippocampus or the bed nucleus of the stria terminalis may play a selective role in context conditioning.

Based on pharmacologic and neuroanatomic data, [Davis \(1998\)](#) devised a scheme for categorizing fear-related behaviors. Learned fears, as classically modeled by cue-specific conditioning, represent one such family of behavioral construct. Such learned fears are acquired through experiences with relatively abrupt or phasic temporal cues, such as a light or sound presented for a brief period, that signal a soon-to-be-delivered aversive stimulus. Such learned fears extinguish relatively easily with repeated presentation of unpaired CS and UCS stimuli. For the second category of fear-related behavior, [Davis \(1998\)](#) uses the term *anxiety*, which is reminiscent of the broader use of this term as defined previously. In contrast to learned fears, anxiety for Davis typically applies to stimuli in animals that are innately dangerous or punishing. Anxiety-provoking stimuli involve more protracted temporal cues, such as a well-lit open field in which a rodent is placed where it would be vulnerable to attack. Similarly, unlike learned fears, the response to anxiety-provoking stimuli is relatively resistant to extinction and may even become sensitized on repeated presentation.

### Neurochemistry of Fear-Related Behaviors

From a clinical perspective, the importance of work by Blanchard et al. (1997), [Davis \(1998\)](#), and others ( [Rodgers, 1997](#)) on the heterogeneity of fear states lies in the neurochemical insights these studies may ultimately provide. Neurochemical regulation of activity in brain circuits associated with fear states is understood in increasingly precise detail. Projection neurons involved in fear states rely on glutamate as a neurotransmitter. This includes, for example, projections involved in fear conditioning from the thalamus to the amygdala and from the amygdala to effector organ systems. Activity in these glutamatergic synapses is, in turn, modulated by local g-aminobutyric acid (GABA) neurons in the amygdala and locally secreted neuropeptides, as well as by distal neurochemical inputs from noradrenergic or serotonergic neurons ascending from the brainstem, hormones such as cortisol, and peripherally secreted compounds, such as epinephrine ( [Blair et al., 1998](#); [Gray and McNaughton, 1996](#); [McNaughton, 1997](#); [Mongeau et al., 1997](#); [Quartermain et al., 1993](#); [Roosendaal et al., 1999](#); [Stutzman et al., 1998](#)).

Although this basic neurochemical architecture applies to many fear-related behaviors, distinct forms of fear are associated with unique forms of neurochemical regulation. For example, Davis has elucidated distinctions in the degree to which various fear-related behaviors are influenced by the neuropeptide, corticotropin-releasing factor (CRF) ( [Davis, 1998](#); [Davis et al., 1997](#)). CRF plays parallel regulatory roles at a hormonal level in HPA axis function, where it stimulates adrenocorticotropic hormone secretion from the pituitary, as well as at a local brain circuitry level, where it acts as a neuromodulator of brain states associated with aversive stimuli. For learned fears, as classically modeled by cue-specific fear conditioning, manipulations of CRF in amygdala nuclei produce less marked effects on fear-related behavior than they do for innate fears. For innate fears, manipulations of CRF in the basolateral nucleus of the amygdala, as well as the bed nucleus of the stria terminalis, produce relatively more robust changes in fear-related behaviors. To index fearfulness, [Davis et al. \(1997\)](#) rely on the degree to which a rat will startle when placed in a well-lit open field. High levels of fear, as induced either by an open field or a fear conditioning experiment, are reflected in potentiation of the startle reflex ( [Davis, 1998](#)). CRF infusions into relevant brain regions produce a further potentiation of this reflex in the open field test, although not in cue-specific fear conditioning experiments. There is evidence of an association between CRF and clinical anxiety, as well as measures of fear among nonhuman primates ( [Coplan et al., 1995b](#); [Pine and Grun, 1999](#); [Sapolsky, 1996](#)). As such, these data suggest a subset of fear behaviors in animals exhibit particularly close relationships with clinical anxiety.

Work on the heterogeneity of fear states also carries considerable psychopharmacologic implications. There is a rich tradition documenting parallels between effects of anxiolytic medications on anxiety in humans and animal models ( [Gray et al., 1996](#); [McNaughton, 1997](#)). For one set of phenomena, there are strong consistencies across species. For example, benzodiazepines exert robust effects on specific forms of acute anticipatory anxiety in humans and animals ( [Gray et al., 1996](#); [McNaughton, 1997](#)). Classically, these forms in animals have included approach-avoidance conflicts and fear learning paradigms, as modeled in fear conditioning. For another set of paradigms, there are less consistent cross-species parallels. For example, many antidepressants exert robust clinical effects on both acute panic and anticipatory anxiety in humans but minimal effects in animal fear paradigms, including fear conditioning experiments ( [Cassella and Davis, 1985](#); [Rodgers, 1997](#)). Closer parallels between animals and humans emerge in more recent studies that rely on ecologically informed animal models. For example, Blanchard et al. (1997) note close parallels in pharmacologic effects on panic disorder and rodents' reactions to select innate fear-provoking stimuli, such as the presence of a predator. Antidepressant medications, including selective serotonin reuptake inhibitors, exhibit parallel effects on such phenomena and on clinical anxiety disorders (Blanchard et al, 1997; [Rodgers, 1997](#)).

Because of the difficulties in conducting studies in nonhuman primates, neurochemical regulation of the circuitry underlying fear-related behaviors has been more extensively mapped in rodents than primates. Nevertheless, there is some lesion-based work examining the role of the amygdala in fear-related processes among nonhuman primates ( [Bachevalier et al., 1999](#); [Rolls, 1999](#); [Webster et al., 1991](#)). Studies have demonstrated involvement of the primate amygdala in socially relevant behaviors ( [Leonard et al., 1985](#); [Rolls, 1984, 1999](#)). Cells in the primate amygdala are sensitive to emotionally salient social cues, such as threat faces ( [Leonard et al., 1985](#)).

### Development and Basic Science Perspectives

Despite considerable advances in many basic science aspects of fear, neurodevelopmental aspects of anxiety remain relatively underexplored. The paucity of research in this area stands in contrast to a wealth of literature on developmental aspects of human fears. Most of the advances reviewed previously in neuroscience derive from the experimental psychology tradition, as illustrated by research on fear conditioning. In the area of developmental neurobiology, the advances that have emerged derive from both the experimental and ethologic traditions.

From the tradition of experimental psychology, most developmentally oriented research on fear states examines the organizational influences of early-life stress on the expression of fear-related behaviors and on the functioning of neural circuits associated with such behaviors. Early in the life of a rodent, stress can exert long-term, potentially permanent effects. [Levine et al. \(1967\)](#) initially noted the long-term effects on stress-reactivity of handling manipulations in the initial weeks of

life. [Meaney and colleagues 1988](#); ([Francis et al., 1999](#)) extended this work by demonstrating the full range of effects from handling and the underlying neural mechanism for the effects. For example, neonatal handling produces long-term increases in feedback sensitivity in the HPA axis, as well as decreases in anxiety on various standardized paradigms. Although relatively mild stressors, such as handling, do not exert such long-term effects in adult organisms, the precise developmental window for these effects has not been defined. It remains unclear if the HPA axis and related fear systems are susceptible to such environmental effects only during the neonatal period.

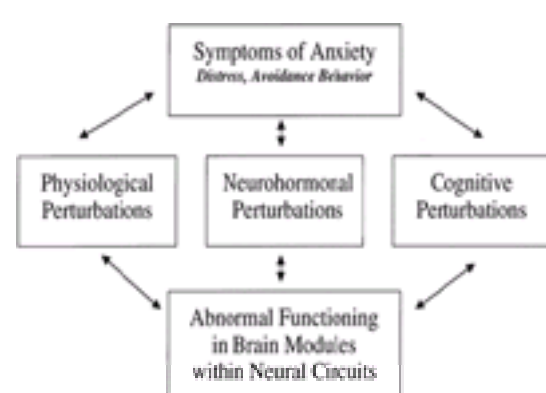

Other related work traces the development in nonhuman primates of neural pathways implicated in fear conditioning. Although the intrinsic connections of the primate amygdala mature very early in life, [Bachevalier and colleagues \(Bachevalier et al., 1999; Rolls, 1999; Webster et al., 1991\)](#) demonstrate considerable plasticity during childhood in the afferents from the inferior temporal region to the amygdala. Such plasticity may play a role in developmental variations in the effects of brain lesions on emotional behavior. Recent lesion studies among nonhuman primates primarily use adult animals, and the effects of amygdala lesions may vary as a function of developmental stage.

From the ethologic perspective, research among nonhuman primates establishes effects similar to those seen in rodents of early-life rearing manipulations on HPA axis function and fear-related behaviors. [Rosenblum, Coplan, and colleagues \(Coplan et al., 1995b, 1996; Smith et al., 1997\)](#) note such effects on infant bonnets in a variable foraging demand paradigm. In this experiment, mother bonnets are required to exert an unpredictable degree of effort to locate food, which affects the mother-child relationship. This produces increases in fear-related behaviors in the child and elevations in cisternal CRF when the former child bonnet is studied at maturity. Other work on nonhuman primates documents the effects of maternal separation on fear-related behaviors. [Suomi and colleagues \(Berman et al., 1994; Suomi, 1997\)](#) suggest that developmental experiences related to separation may interact with underlying genetic predispositions to produce fear states. Finally, work by [Kalin and Shelton \(1998\)](#) considers specificity in the developmental nature of fear responses shown by nonhuman primates. Much like work from Davis delineating differences between “fear” and “anxiety,” Kalin and Shelton find that immature primates show a range of responses to distinct threats, including isolation and social threat. Moreover, much like Davis' concepts of fear and anxiety, these responses in immature infant primates are dissociable in terms of their psychopharmacology.

## PARALLELS BETWEEN HUMAN AND ANIMAL FEAR

Through the mid-1990s, much of the clinical psychobiological research on human anxiety examined relationships between clinical factors and peripheral physiology or monoamine profiles. Underlying pathophysiologic processes were sought in measures of cardiovascular, respiratory, serotonin, or norepinephrine dysregulation. Such work remains an active area of investigation. For example, there is accumulating evidence, reviewed later, to link abnormalities in respiratory physiology to a family of disorders associated with spontaneous panic ([Coplan and Klein, 1996; Gorman et al., 1988; Klein, 1993, 1994; Papp et al., 1989, 1993](#)). Similarly, a wealth of research documents abnormalities in monoamine regulation in various disorders, particularly panic disorder ([Coplan and Klein, 1996](#)). Nevertheless, advances in basic science have provided the novel insights reviewed previously on the role for specific neural circuits in anxiety, and recent clinical studies have attempted explicitly to link such basic findings to clinical constructs.

Basic science conceptualizations of anxiety emphasize the role for neural circuits that involve an array of interconnected brain regions functioning as distinct modules ([Davis, 1998; Davis et al., 1997; Gray et al., 1996; LeDoux, 1996, 1998; Maren, 1999; McNaughton, 1997](#)). These include modules located in limbic structures, such as the amygdala and hippocampus, modules located in the frontal lobe, and modules located in the inferior posterior cortices. This conceptualization resonates with recent views on other brain processes, such as attention allocation, that emphasize the modularity of the brain. In basic science studies, knowledge of the relationship between functional aspects of brain modules and behavioral manifestations of fear states requires a careful delineation of the observable processes associated with fear states. Studies in humans delineate such components at multiple levels. The scheme for such work is illustrated in [Fig. 25.2](#).

**Figure 25.2.** Schematic of delineation of the observable processes associated with fear states.

At the grossest level, considerable research examines overt manifestations of anxiety and fear, considering the degree to which distinct fear states represent truly unique syndromes. Such overt expressions are manifest as avoidance behavior and subjective states of distress. At a slightly deeper level, such overt manifestations are associated with changes in cognitive functioning, autonomic regulation, and neurohormonal tone. Finally, these cognitive or physiologic alterations are, in turn, thought to arise from changes in brain function that may be detectable using modern neuroimaging techniques.

### Overt Manifestations of Fear and Anxiety in Humans

Clinical or behavioral manifestations of anxiety are categorized in the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition, revised; DSM-IV) based on the object of the anxiety and the form of the symptoms. As outlined elsewhere in this volume (see [Chapter 67](#)), distinct clinical disorders are defined based on their differential involvement of feared objects or situations, as well as their distinct constellations of symptoms. Phobias refer to excessive fear related to specific objects or situations; panic disorder involves recurrent episodes of spontaneous sudden increases in fear associated with autonomic symptoms (panic attacks); and generalized anxiety disorder involves a pattern of pervasive worry. Other anxiety disorders not discussed in the current chapter include posttraumatic stress disorder and obsessive-compulsive disorder.

Beyond these clinically defined syndromes, development is characterized by a pattern of normal fears and worries ([Evans et al., 1999; Fredrikson et al., 1996; King et al., 1989; Muris et al., 1998, 1999; Ollendick et al., 1989, 1991; Pine and Grun, 1999](#)). These include fears in toddlers related to separation and strangers, fears during the early school years related to small animals and bodily harm, as well as fears and worries during adolescence related to social concerns. Phenomenologically, behaviors exhibited during such normal fear states resemble those found in the anxiety disorders, both being characterized by avoidance or withdrawal and high levels of physiologic arousal. However, such early childhood fears are considered a normal aspect of development as long as they are not associated with excessive distress or impairment. The relationship between such normal fears and later, clinically significant anxiety disorder remains an area of active study. [Rosen and Schulkin \(1998\)](#) suggest that normal degrees of fear-related behavior during childhood, through effects on the CRF system in the amygdala, may alter the underlying substrate from which later anxiety disorders arise. Similarly, the behaviorally inhibited temperament represents a normal behavioral variant in toddlers that predicts anxiety disorders during childhood and adolescence ([Biederman et al., 1995; Kagan, 1995; Schwartz et al., 1999](#)). Nevertheless, the limited available longitudinal data suggest that high levels of developmentally appropriate fears during childhood show relatively weak associations with later clinical anxiety disorders ([Fyer, 1989; Pine, 1999; Pine et al., 1998a](#)).

Each of the developmentally appropriate and clinical fear states in humans share various similarities in terms of observable behavior with anxiety states in animals. This includes the tendency to avoid objects or situations associated with the fear, the tendency closely to monitor the feared object, and the tendency to experience changes in somatic activity associated with avoidance and monitoring.

Considerable disagreement remains on the degree to which specific fear states or anxiety syndromes described in DSM-IV represent truly distinct categories. Despite clear distinctions in terms of overt symptoms, there is some evidence to suggest that some supposedly distinct anxiety disorders in DSM-IV actually represent subtle variations on a single category of anxiety state. Such evidence includes extremely high comorbidity rates, particularly among children, and similarities in overt symptoms, as well as in demographic correlates of the various disorders ([Cooper and Eke, 1999; Costello and Angold, 1995; Fyer et al., 1995; Klein, 1995; Merikangas et al., 1999](#)). For other disorders, there is more evidence from longitudinal and family-based studies to suggest that the syndrome described in DSM-IV

depicts a relatively specific construct. The most convincing evidence of specificity probably exists for phobias. For both social and specific phobia, there is relatively good evidence to suggest that these syndromes, particularly among children and adolescents, are distinct from each other as well as from other anxiety disorders (Cooper et al., 1999; Fyer, 1989; Klein, 1995; Merikangas et al., 1999; Pine et al., 1998a). For separation anxiety disorder, there also is evidence of distinction from other anxiety disorders, although the evidence appears somewhat less convincing than for phobias. For example, relative to childhood phobias, separation anxiety disorder appears to show a closer longitudinal and family-based tie to adult panic disorder (Costello et al., 1995; Pine, 1999). Generalized anxiety disorder, in contrast, exhibits strong relationships with a range of anxiety disorders (Fyer et al., 1995; Pine, 1999; Pine et al., 1998a). Data on specificity of clinical disorders is consistent with basic science research emphasizing the heterogeneous nature of fear states in animals.

### Cognitive Correlates of Anxiety

Beyond similarities between animals and humans in overt symptomatic manifestations of fear and anxiety, anxiety in humans is associated with particular cognitive attributes that are reminiscent of attributes found in animals. The most consistent cognitive feature associated with fear and anxiety in humans represents an attention bias for stimuli associated with danger (Andrews et al., 1990; Barlow, 1988; Capps et al., 1996; Kendler et al., 1995; McNally, 1996, 1997; Mineka and Sutton, 1992). This bias resembles the high degree of vigilance animals show for feared scenarios or objects. Attention bias in human anxiety states typically is measured with one of two standardized paradigms, either the dot-probe (McNally, 1996; Mineka and Sutton, 1992) or the emotional Stroop task (Andrews et al., 1990). The Stroop task requires subjects to name the color of various potentially threatening words, such as *coronary* or *embarrass*. Individuals with high levels of anxiety show prolonged latency for naming such color-words. This effect presumably arises from interference, such that reactions elicited by a fear-word affects attention to the color of the word. In the dot-probe task, individuals monitor two boxes, one containing either a threatening word or picture and another containing a neutral word or picture, presented on either side of a computer screen. Subjects must press a button when a target appears in one of the boxes, and reaction times to these targets are influenced in individuals with high levels of anxiety by proximity between the threat cue and the target.

Both the results for the Stroop and the dot-probe tasks remain amazingly well replicated across a range of disorders (Andrews et al., 1990; Barlow, 1988; Capps et al., 1996; Kendler et al., 1995; McNally, 1996, 1997; Mineka and Sutton, 1992). Attention bias is found across development and across most anxiety disorders, including phobias, panic disorder, and generalized anxiety disorder. Similar degrees of attention bias are found across these disorders, although each disorder may show particular susceptibility to attention biases associated with words that are most explicitly linked to a particular disorder. For example, subjects with panic disorder may show particularly prolonged latency to panic-related words, such as *smother*, whereas subjects with social phobia may show particularly prolonged latency to phobia-relevant words, such as *embarrass*.

Disruptions in mnemonic functioning represent a second, albeit less well-replicated cognitive correlate of human anxiety (Capps et al., 1996; Mathews and MacLeod, 1994; McNaughton, 1997; Squire, 1992; Taghavi et al., 1999; Williams et al., 1996). Two aspects of memory have been examined. First, overall levels of memory performance are influenced by functional aspects of limbic structures, including the hippocampus, that are implicated in animal models of anxiety (Capps et al., 1996; McNaughton, 1997). As a result, a series of studies in humans consider relationships between clinical anxiety and memory performance. In general, most studies find relatively intact memory function across anxiety disorders, although there are some notable exceptions to these findings. Second, memory is influenced by the emotional salience of perceived stimuli (Pine and Grun, 1999; Roozendaal et al., 1999; Vasey et al., 1996). Both humans and lower animals display a tendency selectively to recall arousing or emotionally evocative stimuli. In anxiety disorders, particularly panic disorder, there is some limited evidence that fear-related words are selectively recalled (McNally, 1997). Nevertheless, the weight of the evidence more convincingly demonstrates mnemonic bias but not attention bias in depressive disorders and attention bias but not mnemonic bias in anxiety disorders. Given the influence of attention on encoding and the influence of anxiety on attention, the lack of a mnemonic bias in anxiety has led to the suggestion that some active cognitive process interferes with encoding or recall in anxiety.

Anxiety-related bias in cognitive functions is thought to index the underlying diathesis for anxiety (Kendler et al., 1995). These cognitive attributes are seen as elemental reflections of dysfunction in limbic brain circuits associated with animal models of anxiety. This conceptualization of cognitive functions may provide a key avenue for integrating basic and clinical science on anxiety. Despite the heuristic importance of these views, effective treatments have been shown to eliminate cognitive bias in anxiety (Andrews et al., 1990; Kendler et al., 1995), which suggests either that cognitive bias is more a reflection than a cause of anxiety or that effective treatments alter both symptoms and the underlying diathesis for anxiety. Longitudinal or high-risk studies documenting an association between prior cognitive bias and later anxiety are needed to clarify the nature of these associations. There is some evidence that self-reported cognitive bias, in the form of anxiety sensitivity, predicts later anxiety reactions to stress (Schmidt et al., 1999). However, such self-reported bias may be confounded with subtle clinical symptoms. No studies have used the Stroop or dot-probe task to predict changes in clinical anxiety over time.

From a neuroscience perspective, clinical work on cognitive biases provides a potentially important avenue for integrative research. Studies of mnemonic bias in animals precisely delineate the role for a neural circuit centering on the basolateral amygdala (Pine and Grun, 1999; Roozendaal et al., 1999; Vasey et al., 1996). Regulation of this circuit is understood in precise detail, involving monoamine and autonomic influences. For attention bias, more neuroscience research examines influences on attention for incentive, rewarding stimuli than for anxiety-related stimuli (Gallagher and Holland, 1994; LeDoux and Muller, 1997; Phelps and Anderson, 1997). Distinct amygdala nuclei influence distinct aspects of such bias for incentives. Nevertheless, given strong influences of the amygdala on attention for rewards, such research has piqued interest in the role of the amygdala in attention for punishments and other anxiety-related stimuli.

### Physiologic and Neurochemical Correlates of Anxiety

As in the area of cognition, research on physiologic and neurochemical correlates of anxiety may provide insights into underlying brain pathways for anxiety in humans, facilitating integration between basic and clinical studies. Changes in autonomic physiology represent key aspects of anxiety in animal models (Davis, 1998; Davis et al., 1997; LeDoux, 1996, 1998). Such changes are linked to specific anxiety-related constructs. For example, in animals, panic-like states associated with flight involve marked increases in both respiratory and cardiovascular arousal that facilitate escape from proximal danger. In contrast, vigilance or orienting responses associated with monitoring of a distal threat involve distinct changes in physiology associated with maximal intake of information from the external environment.

It remains unclear the degree to which research on human autonomic physiology can facilitate an integration of basic and clinical views of anxiety. Clearly, work in this area has established important parallels between anxiety states in humans and animals. For example, both flight reactions in animals and panic attacks in humans share similar autonomic hallmarks. Moreover, there is some evidence that distinct emotional states are each associated with a unique profile in terms of autonomic physiology. For Damasio (1994), distinct emotional states may reflect the evaluation of such unique peripheral physiologic profiles by ventral components of the frontal lobes. Nevertheless, at least for measures of cardiac autonomic function, there exists insufficient evidence of specific relationships between physiology and one or another specific disorder to support the notion that peripheral physiologic profiles provide labels for one or another emotion. Recent physiologic studies on respiration and on startle regulation do suggest that work in these areas may provide more direct insights on the underlying brain pathways involved in human disorders.

In animal models, respiratory changes are intimately connected with specific fear states involving innate, immediate threats. Flight reactions associated with immediate threat involve robust increases in respiration, possibly resulting from activation of regions in the brain stem involved in respiratory control (Pine and Grun, 1999). Separation reactions also are associated with brain stem activation and precise control of respiratory activity associated with distinct separation-related vocalizations. Moreover, both panic and separation anxiety reactions in animals are sensitive to manipulations of the opiate systems (Blanchard et al., 1997; Kalin, 1993; Kalin and Shelton, 1989, 1998; Pine and Grun, 1999). In humans, longitudinal and family-based studies note associations between separation anxiety and panic, suggesting parallels with animal fear states involving precise changes in respiration. Moreover, in humans, both panic disorder and separation anxiety disorder show unique associations with respiratory dysregulation (Klein, 1994; Papp et al., 1989; Pine et al., 1998b). Unlike for work on cognitive bias, respiratory dysregulation in panic disorder relates to the underlying risk for the condition (Gryell, 1997). Abnormalities in respiratory control are found in asymptomatic first-degree relatives of patients with panic disorder. Such abnormalities also characterize panic patients with particularly high family loadings for panic disorder.

In terms of startle regulation, the work by Davis and others reviewed previously relies on the startle reflex to delineate the role for precise neural structures in distinct fear states (Davis, 1998). The circuitry for this primitive reflex is preserved across phyla, and the magnitude of startle provides a conserved, reliable, easily quantifiable index of underlying neural activity. In humans, the effect of distinct manipulations on the startle reflex is thought to index the degree to which underlying brain circuits may place an individual at risk for specific learned or innate forms of fear associated with one or another anxiety disorder. In animals, startle is used during fear conditioning experiments to assess learned components of fear. Among humans, there is some evidence of abnormal fear learning both among adults with clinical anxiety disorders and among children of adults with clinical anxiety disorders (Grillon et al., 1991, 1997a, 1997b, 1998a, 1998b, 1999; Merikangas et al., 1999; Pine and Grun, 1999). In these groups of individuals, enhanced startle potentiation has been found in the context of a fear conditioning experiment. Similarly, in animals, startle also is used during an open-field test to index the degree of innate fear. Among humans (Merikangas et al., 1999), dark-potentiated startle provides an analogous index that also has been linked to both clinical anxiety disorders and to familial risk for anxiety.

Although research on startle, respiration, and autonomic physiology provides insights into underlying brain circuitry, work on neurochemical aspects of anxiety occupies a unique place in clinical research on anxiety. Extensive studies examine monoamine and GABA profiles in patients with various anxiety disorders. Although consistent abnormalities arise, this work provides no more compelling account than other psychobiological studies on the underlying physiology of clinical anxiety. However, unlike physiologic studies, neurochemical studies carry direct therapeutic implications. Various pharmacologic compounds exert parallel effects on anxiety states in humans and animals. These data strongly implicate regulatory dysfunction in brain monoamine and GABA systems in the pathophysiologic process of anxiety (Crestani et al., 1999; Malizia et al., 1998; Roy-Byrne, et al., 1996). As reviewed in chapters on therapeutics, there is consistent evidence that benzodiazepines, selective serotonin reuptake inhibitors (SSRIs), and tricyclic antidepressants alleviate many forms of clinical anxiety. As noted previously, such clinical effects show many parallels with human anxiety states. Research in this area may provide key insights into further integration between basic and clinical studies. Namely, recent basic science work has begun to distinguish different forms of fear among animals based on pharmacologic response profiles. This basic work shows interesting parallels with clinical syndromes. For example, both flight reactions to predators in rodents and spontaneous panic in humans are insensitive to diazepam, potentiated by acute SSRI treatment, and reduced by chronic SSRI treatment (Blanchard et al., 1997; Rodgers, 1997). As normal and pathologic fear states in animals are understood in increasingly precise detail, novel pharmacologic compounds may be uncovered that selectively alleviate specifically deranged components of one or another brain circuit. Documentation of pharmacologic parallels between fear states in animals and humans using existing compounds may facilitate the application of such novel agents to clinical syndromes.

## Imaging Studies

Neuroimaging studies provide one of the most exciting opportunities to document parallels in the underlying neurocircuitry associated with anxiety among humans and animals. Through imaging, structural and functional aspects of particular neural circuits can be evaluated across species, providing neuroanatomically informative research tools. A comprehensive review of neuroimaging studies in anxiety is beyond the scope of the current chapter. A brief summary of available techniques is provided, and findings are summarized that bear on research reviewed in other sections.

Neuroimaging techniques have been used primarily to evaluate three aspects of neural circuits implicated in anxiety: neurochemistry, brain structure, and functional activity. Neurochemistry has been evaluated using techniques that rely on radioactivity, including positron emission tomography (PET) and single-photon emission tomography (SPECT), as well as radiation-free techniques that rely on magnetic resonance spectroscopy (MRS). Although PET and SPECT techniques can assess a wide array of compounds, current MRS techniques are suitable only for evaluating relatively large compounds. GABA and glutamate emerge as two such potentially clinically relevant chemicals. Brain structure has been evaluated primarily with structural MRI (sMRI), and brain function has been evaluated either with PET or functional MRI (fMRI). For studies in children, the magnetic-based techniques of MRS, sMRI, and fMRI represent ideal research tools in that they are safe, relatively inexpensive, and reliable.

Many studies examining the relationship between neurochemistry and anxiety focus on GABA and monoamines. Despite some inconsistencies across studies, at least three groups find evidence in PET or SPECT studies of abnormalities in central nervous system GABA among patients with panic disorder (Kuikka et al., 1995; Malizia et al., 1998; Tiihonen et al., 1997). These findings are consistent with studies that examine behavioral effects of GABA manipulations, where there is evidence of an altered set-point in the GABA complex among patients with panic disorder (Roy-Byrne et al., 1992). Definitive PET/SPECT data on serotonin or norepinephrine are not available, although the availability of appropriate ligands should generate such data in the future. Studies examining brain structure in anxiety focus on limbic regions. There is some evidence of medial temporal lobe abnormalities in panic disorder, which may relate to studies among rodents implicating the amygdala and hippocampus in anxiety (Dantendorfer et al., 1996).

Perhaps the most extensive imaging data relevant to anxiety pertain to the relationship between acute anxiety and changes in brain activity. Initial research in this area demonstrated an inverted-“U”-shaped association between cerebral blood flow and levels of anxiety, reminiscent of the Yerkes-Dodson relationship between arousal and cognitive performance (Mathew et al., 1997). These findings may relate to more recent work from Dager et al. (1999) demonstrating elevated brain lactate in patients with panic disorder during lactate infusion. Elevations in brain lactate may reflect more extreme reductions in blood flow during panic, with effects on the balance between aerobic and anaerobic metabolism. Other studies using brain mapping techniques have detected one or another brain region that might be particularly susceptible to anxiety-associated changes in cerebral blood flow or glucose metabolism. These studies have used a range of techniques in various patient groups to induce anxiety, including fear conditioning experiments in healthy subjects (LaBar et al., 1998), lactate infusions in patients with panic disorder (Dager et al., 1999), and presentation of feared objects in patients with either specific phobias or obsessive-compulsive disorder (Mountz et al., 1989; Reiman, 1990). For these studies, changes in brain activity across diverse regions are correlated with changes in acute anxiety. Although these studies reveal considerable heterogeneity in the degree of activation across various brain regions, limbic structures in the temporal and frontal lobes are relatively consistently implicated. Finally, the most recent imaging studies focus on activation of neural structures implicated in fear among animals during procedures similar to those used in studies of fear among humans. Hence, a series of studies document amygdala activation during fear conditioning experiments in humans (LaBar et al., 1998). Similarly, basic science research implicates the amygdala in the processing of facial cues indicative of threat (Leonard et al., 1985; Rolls, 1984). Neuroimaging studies accordingly document amygdala activation in such processes (Fredrikson et al., 1995; Mountz et al., 1989; Rauch et al., 1997).

## HOW DO SYMPTOMS OF ANXIETY ARISE?

Studies reviewed previously document parallels in the behavioral, physiologic, and anatomic substrate of fear states in animals and humans. During acute fear states, humans and other animals exhibit similar behaviors, similar changes in physiology, and activation in similar brain systems. Moreover, specific and related forms of acute fear or anxiety states in humans and animals exhibit similar susceptibility to distinct pharmacologic manipulations. In clinical terms, anxiety disorders are conceptualized as abnormalities in the regulation of fear states. Such dysregulation might involve a low threshold for arousal of the brain systems involved in one or another form of fear, an inability to turn off these brain systems, or a failure of adaptive learning in these brain systems. This final section uses the parallels between anxiety states in animals and humans to summarize current views on the origins of human anxiety symptoms and disorders.

Anxiety disorders, like most common psychiatric disorders, represent complex conditions. This means that the disorders result from interactions among multiple risk factors and underlying predispositions. Although a comprehensive, accepted pathophysiologic model of anxiety does not exist, three conclusions have received relatively strong support. These conclusions most accurately summarize current views on the underlying origins of anxiety. These conclusions include the realization that (a) anxiety disorders develop against a back-drop of underlying preclinical vulnerability, (b) anxiety disorders are developmental conditions, and (c) environmental factors exert profound direct effects on the symptoms of anxiety. Data supporting these three conclusions are briefly summarized.

Evidence that anxiety disorders develop from an underlying vulnerability includes findings from studies reviewed previously documenting abnormal startle and respiration in healthy relatives of patients with anxiety disorders, as well as from studies on cognitive style or symptomatic precursors of anxiety, including anxiety sensitivity, negative affectivity, or neuroticism. The precise origin of such underlying predispositions remains unclear. Family studies consistently note a strong association between anxiety in parents and their children (Klein, 1995; Pine et al., 1999). Moreover, twin studies among both children and adults document a statistically significant genetic component to various forms of anxiety (Fyer et al., 1995; Klein, 1995; Morris et al., 1998). Finally, association studies for a polymorphism in the serotonin transporter gene provide some evidence of a genetic contribution to potential precursors of anxiety, such as neuroticism (Lesch and Mossner, 1998).

Despite such evidence of a genetic component, anxiety disorders in general involve a smaller genetic component but larger environmental component than typically observed in mood or psychotic disorders. From an environmental perspective, parents with anxiety disorders may use distinctive child-rearing practices that may affect risk for anxiety (Klein, 1995). As such, familial associations between parent and child anxiety could result either through direct effects from modeling of anxiety, effects of parent-child relationships on underlying predispositions for anxiety in children, or through interactions between parent-child relationships and a genetically predetermined diathesis.

A firm understanding of the diathesis for anxiety in humans of all ages requires studies focusing on children at risk for anxiety disorders. This requirement results from the second major tenet on the origins of clinical anxiety, concerning the developmental nature of anxiety in humans. Temperamental factors measurable during the first years of life, such as behavioral inhibition, predict later onset of anxiety disorders (Biederman et al., 1995; Kagan, 1995). Children with the temperamental construct of behavioral inhibition react to novel situations with signs of reticence or withdrawal. Based on peripheral physiologic data, behavioral inhibition is thought to result from an underlying hypersensitivity within amygdala-based neural circuits (Kagan, 1995). Behavioral inhibition is relatively common, found in approximately 15% of American children, and childhood anxiety disorders are even more common, with a general lifetime prevalence greater than 20%. Although most children with behavioral inhibition do not develop clinical anxiety disorders, behavioral inhibition does predict an elevated risk for childhood anxiety disorders, particularly social phobia (Schwartz et al., 1999). Similarly, although most children with anxiety disorders do not exhibit symptoms past adolescence, childhood anxiety disorders do predict adult disorders (Pine et al., 1998a). In fact, most adult anxiety disorders are preceded by an anxiety disorder during childhood. Taken together, such

developmental data suggest that childhood anxiety disorders or behavioral inhibition serve as constraining factors on adult outcomes. Children and adolescents who meet criteria for neither behavioral inhibition nor clinical anxiety disorders are unlikely to have an anxiety disorder as adults. A large proportion of children who do meet such criteria also are free of anxiety disorders as adults. However, among adults with anxiety disorders, most have met such criteria as children. This suggests that a key to understanding the origins of anxiety across the life span lies in gaining insights into factors that determine the degree to which childhood anxiety will remain chronic or transient.

The third major conclusion on the origins of anxiety relates to the role of environmental factors in anxiety disorders. Although compelling data suggest anxiety arises from an underlying diathesis, equally compelling data implicate environmental or contextual factors in anxiety. At an elemental level, fear conditioning experiments in animals demonstrate an effect of context on acute fear states (LeDoux, 1996, 1998). At a more complex level, many forms of stress, such as isolation or unpredictability in the stressor, affect the degree to which an organism reacts to punishment (LeDoux, 1996, 1998). For humans, as highly social organisms, social factors provide particularly compelling influences on fear states. Effects of social factors on fear states are found in both observational and experimental studies. For example, epidemiologic studies find that acute stress in the form of life events predicts an increase in anxiety symptoms over time, whereas twin studies document a large effect of the nonshared environment on risk for anxiety (Kendler et al., 1992). In experimental studies, manipulations of the social environment as well as of expectancies produce changes in acute anxiety reactions to stress (Francis et al., 1999). Moreover, clinical studies that rely on cognitive behavioral techniques document robust acute and long-term effects of experiential factors on anxiety symptoms. A central question to emerge from basic experimental research concerns developmental effects on associations between risk factors and overt manifestations of anxiety. As noted earlier, rearing manipulations in rodents and nonhuman primates can produce long-term alterations in behaviors and neurochemical factors related to anxiety. Although weaker, if any, effects usually result from environmental manipulations in adulthood, the precise shape of these associations across developmental epochs has not been determined. Moreover, clinical studies have only begun to consider the relevance of such basic science work to human anxiety disorders.

## CONCLUSIONS

This chapter reviews prior studies on the neurobiology of fear in animals and humans. Considerable parallels exist in these areas, possibly because of the strong selective pressure on organisms for development of brain circuits involved in perception of and reaction to danger. As modern neuroscience sheds light on the pathophysiologic processes of fear states in animals, the parallels with fear states in humans may ultimately provide important insights for predicting outcomes of anxiety and potential novel treatments.

Depressive syndromes in children and adolescents constitute a group of serious mental disorders with considerable risk for recurrence and subsequent psychosocial impairment with, in some cases, continuity into adult life ( [Birmaher et al., 1996](#); [Harrington and Dubicka, 2001](#) ). Using the American Psychiatric Association *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) clinical criteria ( [American Psychiatric Association, 1994](#) ) successfully identifies the same clinical syndromes in school-age children, adolescents, and adults. Most psychiatric studies have focused on two disorders, major depression and dysthymia, although there is an emerging literature on other affective syndromes, including depressive adjustment reaction, minor depressions, and, more recently, early-onset bipolar disorder ( [Geller et al., 2000](#); [Lewinsohn et al., 1995](#) ).

This chapter discusses the nature of clinical signs and symptoms that in combination result in detectable clinical syndromes. A developmental perspective is taken, examining the frequency, characteristics, and patterning of these symptoms at different ages in girls and boys in the first two decades of life.

### CLINICAL CONSTITUENTS OF DEPRESSION

All affective conditions, including the depressive component of bipolar disorder, share a core set of signs and symptoms that involve undesirable alterations of mood and feelings, thoughts, social behaviors, and physical functions. An essential feature is that of a change in mood from pleasant (euphoric) to unpleasant (dysphoric), even painful. This mood shift is experienced as relatively pervasive, persisting over time and place and sufficiently severe to interrupt everyday functioning. This negative mood state is accompanied by other sets of other features in varying combinations, including negative and distorted cognitions about the self, impaired concentration and attention, and an adverse alteration in a range of physical characteristics, eating, sleeping, energy, and activity. Symptoms usually are elicited at interview through direct questioning of the child or adolescent and his or her parents, with information occasionally obtained from other relatives, teachers, or close friends.

Signs are concurrent observations made by the interviewer about the respondent's general appearance and may include changes in facial expression, increases or decreases in physical activity, general care in dressing and personal hygiene, and diminished speed and fluency of speech. Interviewers also are expected to make a judgment about the subject's general awareness of his or her mental condition, recent and current behavior, and general personal care. This evaluation of the degree of insight a subject has into his or her well-being may have considerable implications for clinical management. For example, the ability of the patient to participate in voluntary treatment may be determined by the interviewer's evaluation of this feature. The extent to which parents, siblings, and the wider environment, such as peers and school personnel, are involved in clinical care also may be determined by the interviewer's judgment of insight and other person-specific characteristics such as motivation.

### DETECTING DEPRESSIVE SIGNS AND SYMPTOMS

The reliability and validity of diagnostic assessments have been the subjects of much investigation in university and research settings using instruments developed for research inquiries in both clinical and community populations ( [Hodges, 1993](#); [Kaufman et al., 1997](#) ). By contrast, little is known of the utility and efficacy of diagnostic procedures in routine clinical practice used throughout the world or the processes through which diagnoses are arrived at in different settings, such as private practice, health care clinics, multidisciplinary teams, or primary care. As a result, the sensitivity and specificity for the detection of mental disorders in child and adolescent health care settings by different professional groups are not known. Furthermore, the same language may be used to convey quite different things about the patient's current well-being. For example, the word *depression* may be used to describe a particular mood state only, a psychological dynamic or causal process, a syndrome of signs and symptoms, a categorical illness state, or even a disease with known pathophysiologic correlates or established etiologic mechanisms.

The focus of most research into affective disorders has been on the detection of syndromes obtained from interview procedures, often delivered by intensively trained research staff ( [Costello et al., 1996b](#); [Lewinsohn et al., 1993](#); [Verhulst and Koot, 1995](#) ). In large-scale epidemiologic studies, quantitative symptom counts of current low mood, negative thoughts, and physical changes obtained from self-report or parent questionnaires have been used as additional proxies for syndromes to improve the power of the investigation ( [Hewitt et al., 1997](#); [Silberg et al., 1999](#) ). In clinical studies where sample sizes of "real" cases are large enough (usually between 80 and 200), multivariate statistics have been applied to obtain distinctive factors or clusters of signs and symptoms as a test of the construct validity of depressive syndromes ( [Kolvin et al., 1991](#); [Ryan et al., 1987](#) ). Community and clinical studies also have paid considerable attention to the signs and symptoms reflecting other disorders accompanying the presence of major unipolar depression. The inclusion of comorbid syndromes has been used to delineate clinical subtypes of depression based on the pattern of diagnoses at presentation. Examples include double depression (dysthymia and subsequent major depression) ( [Kovacs, 1997](#) ), depressive conduct disorder ( [Harrington et al., 1991](#) ), and depressive obsessional disorder ( [Goodyer et al., 1997](#) ). For presenting depressive disorders in young people, comorbid syndromes are the rule rather than the exception, but their validity as clinical markers of etiologic differences within this group of conditions remains unclear ( [Angold et al., 1999](#) ).

### DEPRESSIVE SYNDROMES

The early work in adult populations was successful in delineating the characteristics of somatic (high levels of physical symptoms, weight loss, insomnia, early-morning waking, diurnal variation of mood, persistent feelings of guilt, hopelessness, and psychomotor retardation or agitation) as opposed to psychological depressions (anxious mood, initial insomnia, self-pity rather than self-blame, complaints of anorexia rather than weight loss). A series of criteria for the classification of depression was subsequently proposed by [Feighner and colleagues \(1972\)](#) at Saint Louis. Phenomenologic psychopathology remained the core construct guiding these criteria, with no dependency on putative causation. These suggestions formed the basis for subsequent refinements that led to Research Diagnostic Criteria for the diagnosis of depression ( [Spitzer et al., 1978](#) ). For these purposes, a diagnostic category had to be supported by two sets of mutually exclusive descriptive criteria: those that specify characteristics that lead toward making a diagnosis (inclusion criteria) and those that lead away from making the diagnosis (exclusion criteria). These principles form the basis of the current American Psychiatric Association's classification in the DSM-IV ( [American Psychiatric Association, 1994](#) ) and the International Classification of Diseases (ICD) sponsored by the World Health Organization ( [World Health Organization, 1994](#) ). The adoption of these systems has led to a method of classification that has satisfactory reliability between professional raters for signs, symptoms, and course of depressive disorder. The system has proven highly successful in generating a common language for the diagnosis of depressive disorders that makes findings comparable between investigations despite marked differences in the nature of the populations studied. This categorical approach to classification of depression is not without its detractors, however. For example, it is widely recognized that meeting inclusion criteria still allows for considerable variation in clinical presentation, including high levels of nondepressive symptoms, giving rise to marked individual differences in the descriptive psychopathology of depressions. With the main research emphasis on the quantity of depressive symptoms as predictors of subsequent onset of depression, little attention has been paid as yet to the relative importance of different types of symptoms or their salience to the subject for evolving a depressive disorder. In addition, many children and adolescents present with a range of symptoms that fall below inclusion

threshold for a diagnosis (too few or insufficient duration) but are of sufficient severity to cause personal impairment ( [Costello et al., 1996a](#)).

## Major Depression

According to the DSM-IV ( [American Psychiatric Association, 1994](#)), the diagnosis of major depressive disorder (MDD) requires establishing first the mandatory presence of lowered mood (dysphoria) together with four of eight other possible nonmandatory symptoms from the two broad domains of disordered cognitions and physical changes. These are shown in [Table 26.1](#).

Mood	Cognitive	Physical
Dysphoria or irritability in children	Anhedonia Feelings of worthlessness Inappropriate guilt Diminished ability to think or concentrate Recurrent thoughts of death or suicidal ideation	Weight change (includes a failure to make expected weight gains) Fatigue or loss of energy Psychomotor agitation or retardation

\*The diagnosis can be made only when five or more symptoms are present over a 2-week period. Dysphoric mood must be present.

**Table 26.1. Symptoms of Major Depression in Childhood Adolescence<sup>a</sup>**

It is essential that the five symptoms occur concurrently with each other over a minimum 2-week period. In children and adolescents, but not in adults, the entry criterion of lowered mood can be irritability. Young people often identify their own negative feelings with mood-valent words such as *gloomy*, *grumpy*, or *down*, and these should be used in interviews where there is uncertainty about the salience of the word *depressed*, such as with the prepubertal child. It is important to establish that these symptoms are not accounted for by the direct effects of substance misuse or a general medical condition, particularly one that involves known brain changes, because this reduces the likelihood of reliable and valid mental state assessments. In addition the symptoms should not be accounted for by recent bereavement.<sup>1</sup>

There are no requirements for a particular pattern of cognitions or physical symptoms. Despite the inference from adult studies that physical symptoms reflect a more sustained, severe, or even “biological” syndrome, there is no hierarchy or weighting in favor of these features in the DSM-IV classification system [but see the ICD-10 somatic depression subtype, which has been accorded special status because of the long-standing clinical belief that endogenous depression is a severe and potentially distinctive disorder ( [World Health Organization, 1994](#) )]. Equally, no distinction is made regarding the duration of these disorders, which, providing they have been present for at least 2 weeks, may vary in length for any period of time, even years. They also may differ in their severity or personal psychosocial impairment from mild, indicating only a modest deviation from normal behavioral functioning, to unable to care for oneself and requiring 24-hour intensive psychiatric care.

## Dysthymia

Dysthymia has been described as a chronic mood disturbance of young people characterized by long-standing gloom and dysphoria, brooding about feeling unloved, and affect dysregulation. The dominant negative cognition is self-deprecation or negative self-esteem. There are high rates of irritability and anger in everyday circumstances (i.e., occurring as a hyperemotional response to social hassles in the everyday environment) ( [Kovacs et al., 1994](#) ). According to the DSM-IV, dysthymia is a chronic depressive condition that in childhood or adolescence presents with the same general characteristic of lowered mood (dysphoria or irritability) as major depression but must have been present for at least 1 year or more. In addition to depressed mood, the subject must have two of a further six symptoms from the list shown in [Table 26.1](#) except that feelings of guilt and suicidal behavior are not included because they are for major depression. The implication is that the latter two symptoms are not found in dysthymic disorders and, if present, suggest that the patient is likely to be suffering from major depression.

The best clinical description comes from the work of [Kovacs and colleagues \(1994\)](#) based on children referred to mental health services. Compared with MDD, dysthymia is distinguished by the virtual absence and significantly lower prevalence of anhedonia and social withdrawal, and comparatively lower levels of guilt, morbid preoccupation, and impaired concentration. Practically none of the dysthymic children had reduced appetite, and few had hyposomnia or fatigue ( [Kovacs et al., 1994](#) ).

It is important to establish that the patient does not fulfill criteria for current major depression. If major depression has preceded the onset of dysthymia, then there must have been full remission of all depressive symptoms for at least 2 months before the development of dysthymia. By contrast, episodes of major depression can be superimposed on dysthymia disorder, in which circumstance both diagnoses can be given.

## Subthreshold and Minor Depressions

Aware of the limitations of coverage in the classification of mental disorders, both the DSM and ICD systems include criteria for a “not otherwise specified” category, for those cases not meeting full criteria for a specified syndrome. Despite this important caveat, there have been continual calls for the addition of new “disorders.” During the DSM process, over 150 different new disorders were proposed, with varying levels of evidence supporting their addition to the classification ( [Pincus et al., 1999](#) ). A review and synthesis of studies on minor depression and other “brand names” demonstrated that a myriad of names and definitions for subthreshold depression have been used in the literature, with varying duration, symptom thresholds, and exclusions. Of particular importance was the observation that to date little has been done to bridge the difference between clinical and primary care perceptions of what constitutes a mental disorder. There is little doubt that primary care physicians see individuals of all ages with distressing and dysfunctional mental states that are not well articulated in the psychiatric nosology and often are not a major consideration to mental health specialists ( [Pincus et al., 1999](#) ). Epidemiologic findings in childhood and adolescence also have shown that a significant number of young people between the ages of 6 and 18 years have current symptoms with psychosocial impairment that may warrant treatment, but do not meet criteria for a clinical diagnosis ( [Costello et al., 1996a](#) ). The natural history of these subthreshold conditions remains a matter for further research, ideally in longitudinal designs such that the temporal relationship between impairments and clinical status can be examined as an evolving rather than static process. What little has been done to date suggests that, from the public health perspective, it would be unwise to ignore subthreshold depressions (and indeed other subclinical syndromes) if they present with personal impairment ( [Costello et al., 1999](#) ). The evidence is that such young people are adding to the general burden of affective morbidity in the community at large and may continue to do so over time. Whether there are specific and particular continuities and discontinuities in signs and symptoms between subthreshold conditions and clinical disorders is not known.

## Somatic Depression

A second public health issue that impinges on the diagnostic status of depressions in young people are somatic complaints [not to be confused with the ICD-10 use of the term *somatic (endogenous) depression*, which is synonymous with physical depressogenic symptoms dominating the presenting picture]. In primary care settings, approximately 2% to 10% of children at any one time complain of aches and pains such as headaches, stomach aches, and limb pain, and, somewhat less frequently, tiredness or fatigue ( [Campo and Fritsch, 1994](#); [Garralda, 1996](#) ). In some of these children, this represents a physical presentation of psychiatric disorder. The prevalence of depressive illness in this somatic population is not known. There is no doubt, however, that in the 8- to 11-year-old age group in particular the main concurrent psychological features are internalizing emotional symptoms of anxiety and depression ( [Larson, 1991](#) ). These types of physical symptoms also are relatively common in children and adolescents presenting with depressive disorders, with prevalence estimates in clinical populations as high as 70% ( [McCauley et al., 1991](#) ). The current data are sparse, but it seems that physical symptoms such as abdominal pain, headache, limb pain, and malaise (which are not part of the diagnostic criteria for the depressions) may be an index of affective disorders in young people, even when comorbid anxiety disorders are taken into account. Whether they should be considered as potential components of a more developmentally sensitive set of diagnostic criteria is worth further consideration. In such circumstances, an adequate mental state examination often detects whether psychological or physical signs and symptoms of depression are present.

In the preschool child, for whom there are no really satisfactory criteria for mood disorders, somatic features may be particularly important indices of a current affective illness. The relation between somatic and depressive features deserves further inquiry in this younger population.

## DEPRESSIVE SYMPTOMS

### Patterning of Symptoms

When symptoms of depressive disorders obtained from psychiatric interview data of clinical populations have been subject to multivariate analysis, two components—negative cognitions, consisting of self-blame, hopelessness, low self-worth, and suicidal features, and biological “endogenous” features, consisting of dysphoria, anhedonia, fatigue, and psychomotor retardation—usually have been identified (Kolvin et al., 1991; Ryan et al., 1987). Anxious and conduct factors also have been obtained from these approaches, indicating the heterogeneity of affective disorder presentations. In the study by Ryan and colleagues (1987), suicidal ideation was associated with both negative cognitions and the conduct factor. Inspection of symptom frequency in depressed cases shows that whereas initial insomnia frequently is reported in childhood, terminal insomnia is less so (Carlson and Kashani, 1988; Kolvin et al., 1991; Ryan et al., 1987). Compared with adolescents, somatic symptoms are reported more frequently by younger depressed children, but loss of weight, diurnal variation of mood, and psychomotor retardation are less pronounced in youth than in adulthood (Cooper and Goodyer, 1993; Kolvin et al., 1991). Individual or combinations of symptoms that are rare or uncommon in the community but frequent in patients could be important indices of depressive conditions or those at risk for such conditions. By contrast, some symptoms may be so common in the community at large that they are unlikely to be specific enough to indicate at-risk populations. The importance of specific symptoms and their patterning for the detection of disorders thus depends on a knowledge of the base rates of signs and symptoms in the community in general.

In a community-based study of major depression in adolescent girls, a profile of depression, anxiety, and oppositional/conduct symptoms and disorders was obtained from 1,056 girls aged 11 to 16 years interviewed for the occurrence of one or more episodes of major depression (DSM-III-R criteria) over the previous 12 months (Cooper and Goodyer, 1993). Subjects were selected for interview on the basis of high scores (>80th percentile) on the mood and feelings questionnaire (MFQ), a self-report measure of depressive symptoms, together with a random sample of low and medium scorers. Three hundred sixty-eight girls (45 high scorers) were assessed within 2 weeks of completion of the self-report. A number of core clinical depressive features were estimated to have a prevalence of approximately 20% in this interviewed community sample, notably depressed mood, social withdrawal, and early insomnia. Depressive thoughts were estimated to be less common, with guilt and ideas of worthlessness found in less than 10%, but nihilistic ideas were found in 16%. Although the girls were selected for interview specifically on the sole basis of their self-reported depression scores, there also were anxious and behavioral symptoms. School phobia was particularly common (37%), as was anxiety associated with school attendance (20%). Other anxious symptoms were less common than depressive features with somatic symptoms (aches and pains), which occurred in 10% and were related in most cases to school attendance. A number of oppositional and conduct symptoms also were estimated and shown to be relatively common, with defiance to parents (29%) being markedly prevalent. Stealing, lying, vandalism, and defiance of school teachers all were found in just under 10% of this female sample.

The findings suggest that as many as one in four adolescent girls have differing types of depressive symptoms, some of which will be behavioral as well as anxious. Many of these would be deemed “in scope” for a clinical intervention based on DSM or ICD entry criteria, or reflect a cause for concern to primary care services. Estimates of the syndrome of (DSM-III-R) major depression in this sample showed that the 1-month prevalence was 3.6% and the 12-month prevalence 6.0%, very similar to other published reports (Angold and Costello, 2001). A further 8.9% and 20.7% were classified as subthreshold disorders at 1 and over 12 months, respectively, further demonstrating the potential public health difficulties regarding the targeting of the appropriate at-risk populations.

### Age Effects on Symptom Patterns

#### CHILDREN

Because the syndromes of major depression and dysthymia have been described in both prepubertal and in preschool children, high self-report depression scores may provide important clues regarding the detection or prediction of these disorders (Kovacs et al., 1994, 1997). In a study of 1,300 first-graders, the highest endorsed symptoms on a self-report measure were aches and pains (14.7% to 28.0%), followed by sad affect (13% to 17%) and then helplessness/hopelessness (12% to 25%) (Edelsohn et al., 1992). Although it is unclear if children of this age appraise all of these items with the same salience as adults, those with scores in the upper quartile showed considerable stability over a 4-month period. This stability of reporting included negative cognitions of the self and the future. Children as young as 5 years of age have a substantial set of emotions and can report the presence of both guilt (the belief that one has committed a wrongdoing leading to self-blame) and shame (the conscious feeling of humiliation brought about by actions of self or others) (Ferguson et al., 1999), and even preschoolers (especially girls) can manifest guilt-related beliefs and behaviors, including a heightened sense of empathy, a misplaced sense of responsibility, and unrealistic ideas about their own ability to produce or reduce another's plight (Zahn-Waxler and Kochanska, 1988). Stable high scorers also were more likely to show persistent difficulties in areas of personal and academic competence. This suggests that functional impairment and depressive symptoms can be both present and stable in childhood populations and in some cases may be “hidden from view” by somatic complaints (Kashani and Carlson, 1987; Kashani et al., 1983, 1986).

#### ADOLESCENTS

Somewhat similar concerns have been expressed about the nature of depressive symptoms in adolescence where, unlike childhood, persistent sad mood, especially with overt functional impairment, may be an indicator of an evolving depressive disorder (Compas et al., 1993). Increasing self-report depression scores occur across the adolescent age range, suggesting developmental influences on the occurrence of symptoms. For example, Fig. 26.1 shows the proportion of MDD at each MFQ decile point between 11 and 16 years in the community study described previously (Cooper and Goodyer, 1993).

**Figure 26.1.** The legend indicates three levels of mood and feelings (MFQ) self-report scores, 20, 30, and 50, from a possible range of 0 to 66, obtained from 1,056 girls aged 11 to 16 years. The estimated proportion of cases (y axis) is, as expected, greater for higher scores at each age. Importantly, the same level of symptom scores at each age estimates significantly different proportions of cases. This suggests developmentally sensitive differences in adolescent girls for the likelihood for detecting major depression from self-reports. (Data first published in Cooper PJ, Goodyer IM: A community study of depression in adolescent girls.1: Estimates of symptom and syndrome prevalence. *Br J Psychiatry*. 163:369–374, 1993.)

As age increases, high MFQ scores predict major depression with increasing specificity. For example, with an MFQ score of 30, 3.6% of 11-year-olds, 20.4% of 14-year-olds, and 42.9% of 16-year-olds would be cases of major depression (DSM-III-R criteria were used for this data set). With a score of 50 or more, 32.8% of 11-year-olds, 68.1% of 14-year-olds, and 84.1% of 16-year-olds would be such cases. The MFQ items reflect all symptoms that constitute depressive disorders, but there are at least three potentially crucial influences on the relation between scores and development:

1. It may be that some symptoms are consistently associated with major depression at different ages and developmentally insensitive. For example, taking an overview of all studies to date, negative mood (dysphoria and irritability), withdrawal from normal social activities, loss of energy, and early insomnia may be invariant features of current major depression across the school-age years.

2. Equally, because the same scores have such markedly different implications for the liability of depression at different ages, endorsement of some items may be highly dependent on individual differences in maturation in the child. Such items are likely to show increases in reporting with age. Here, the best candidate symptoms appear to be terminal insomnia, suicidal acts, and perhaps negative views about the world (but not necessarily negative thoughts about the self).
3. It also is likely that the salience of the same item is quite different for girls (and probably boys) of different ages. Thus, even if the symptom is endorsed to equal levels by girls between 11 and 16 years of age, the negative intensity and personal impairment of a given symptom may have different effects between ages. This more inferential assumption about salience rather than mere frequency of reporting, might refer particularly to making judgments about self-worth and self-efficacy (such as impaired scholastic and personal performance), impairments in attention and concentration, and also physical state such as motor agitation or retardation.

Although there is general agreement that development does influence endorsement of clinically relevant symptoms, these rather specific suggestions are speculative given the current knowledge base. Very little indeed is known about the interaction between maturation and the liability to endorsing particular symptoms on checklists in the school-age population at large. Such information would be most helpful in determining the base rate of symptoms at different ages for both sexes.

Might there also be developmentally sensitive issues regarding the reporting or endorsement of nondepressive symptoms in such populations? Returning again to the data from the previously mentioned study, one would conclude that this is likely, perhaps in much the same way as described previously for depressive symptoms. Thus, fears and phobias and oppositional behavior with parents look relatively invariant over this age range and may occur with broadly the same frequency and meaning between the ages of 6 and 19 years. With the increasing importance of peer group and school-based environments, both school reluctance and oppositional behavior in social circumstances may reflect a developmentally mediated set of symptoms increasing with age. Finally, endorsement of features such as lying, stealing, and argumentativeness may well have quite different meanings to the subject at different ages.

An interesting group of symptoms in community subjects are those regarding obsessional thinking and compulsive acts. Two percent of the aforementioned sample in the community study of girls reported obsessional thinking, and 8.2% obsessional acts. This makes the thinking relatively uncommon but actions relatively more common in this sample, particularly in relation to other nondepressive symptoms. Given that comorbid obsessive-compulsive disorder with major depression may index a somewhat more severe major depressive condition with decreased likelihood of short-term recovery, the relation between obsessional and depressive symptoms may be worth more detailed investigation ([Goodyer et al., 1997](#)).

Is it possible to use individual or particular combinations of symptoms in the community to identify evolving cases or young people at high risk for depressions? A preliminary multivariate examination of depressed cases among girls in the community suggests that three symptoms, hopelessness, insomnia, and mendacity, in combination are best predictors of current major depression compared with subthreshold cases ([Goodyer and Cooper, 1993](#)). Further examination to predict the presence of current major depression at different ages suggests that, at 11 to 12 years of age, depressed girls are particularly likely to report symptoms of hopelessness and reduced speech compared with age-matched control subjects; at 13 to 14 years, the best symptom predictors were depressed mood, concentration impairment, impaired school performance, guilt, and indecisiveness; and at 15 to 16 years, depressed mood and agitation were the best discriminators. These preliminary results demonstrate that there are developmentally sensitive patterns of symptoms associated with major depression in adolescent girls at different ages. Interestingly, even though hopelessness is a significant predictor of major depression, it appears most specifically associated with younger rather than older adolescent cases. Again, even though concentration impairment and agitation were equally endorsed by depressed girls across this age range, they appear specifically to predict depression only in cases older than 13 years of age. These findings are similar to those reported from the Oregon Adolescent Project, which noted considerable construct validity for the diagnosis of (DSM-III-R) major depression in adolescents, but also that symptom patterns may change across the adolescent age range and within subjects who report recurrent episodes of the disorder ([Roberts et al., 1995](#)).

Much remains to be done to confirm these early results that suggest that the current nosology, although necessary in many respects, is insufficient for detecting depressions in the younger adolescent and therefore even more possibly in the prepubertal child. There is, however, considerable core construct validity for the syndrome of major depression as currently constituted. The most frequent depressive symptoms are depressed mood, hopelessness, social withdrawal, agitation, and nihilistic ideas, all of which are likely to occur in greater than three-fourths of cases of major depressions at all ages across adolescents.

#### *Negative Cognitions, Suicidal Thoughts, And Actions*

A decrease in frequency with age for the self-reporting of the symptom of hopelessness, ranging from approximately 90% in 11- to 14-year-olds with major depression down to nearly 50% in 15- to 16-year-olds, is similar to the observation of [Kashani and colleagues \(1989\)](#) that there is no increase in the reporting of this core negative cognition between prepubertal childhood and adolescence. By contrast, in Cooper and Goodyer's community study, suicidal actions show an increase with age, with the handful ( $n = 5$ ) of depressive cases younger than 13 years of age exhibiting no suicidal acts, compared with 24% ( $n = 21$ ) of the 15- to 16-year-old depressives. The symptom of hopelessness also is a significant predictor of completed suicide among already depressed adults ([Brown et al., 2000](#)), although in younger populations this relationship remains unclear. Given the known correlation between suicidal intent and depression in adults and, to a lesser extent, in adolescents, the apparent inverse relationship between hopelessness and suicidal actions with age seems odd. Suicidal actions appear more likely in juveniles with a history of both dysthymia and major depression compared with depressive adjustment disorders and nondepressed cases ([Kovacs et al., 1994](#)). Whether this is because patients with these double depressions are specifically more likely to report greater levels of hopelessness compared with those with other affective disorders is not clear. Indeed, how negative views of the self evolve as cognitive schemas within a child, how they become translated into "symptoms," and the nature of their prospective relations with subsequent depressions with and without suicidal intentions and actions require much clearer understanding. This is not merely a theoretical issue but has practical implications for detecting young people at risk for suicide among those in the community predisposed to depressions.

A social cognitive model for depression has been proposed that postulates that dysphoric mood and dysfunctional thinking are more apparent among individuals with a previous history of depression, increasing the tendency to further episodes through biases in recall of negative thoughts about the self ([Teasdale and Barnard, 1993](#)). This notion suggests that memory is influenced by dysphoric moods in ways that increase the liability for negative self-referent material to be rehearsed and elaborated during subsequent depressive episodes ([Teasdale, 1999](#)). Using a prospective design, the Oregon Adolescent Depression Program reported that compared with adolescents with a history of first-episode depressions, those with a history of recurrent depression self-reported more depressive symptoms and higher levels of dysfunctional negative cognitions ([Lewinsohn et al., 1999](#)). This study provides the first evidence for the notion that depression is in reality "bad for the mind" through dysphoric effects in the long term on episodic memory and self-schema. The authors relied on self-report data to infer dysfunctional cognitions rather than establish if recurrent disordered subjects were more likely to recall negative views about themselves during induced negative mood. The findings therefore require replication using a similar longitudinal design but with the appropriate experimental procedures for mood induction and measures of self-description. Normal adolescents at risk for depression because of a more emotionally negative temperament also report increased negative cognitions about the self when in dysphoric mood compared with those not at risk in a similar negative mood state ([Kelvin et al., 1999](#)). This suggests that the pattern of negative cognitive symptoms in depressed adolescents may arise from vulnerabilities in emotion processing in a particular subgroup of adolescents. A prospective study of adolescents at risk for depression would determine if negative cognitive symptoms were, in fact, liable to precede the onset of first-episode depression. If so, then such symptoms would be potentially causal and not only the consequences of previous episodes of depression or dysthymia.

#### **Executive Functions, Physical Symptoms, and Depression**

A somewhat different model of recurrent disorder has been proposed by Post and colleagues which suggests that the role of physiologic processes inducing dysphoria and associated physical symptoms are more important in promoting recurrent than first episodes of depression ([Post, 1992](#); [Post et al., 1986](#)). The Oregon study did not contain sensitive measures of such symptoms over time, and therefore, it remains unclear whether there is a difference in the prevalence of physical and neuropsychological symptoms, such as impaired concentration, between first and recurrent episode depressions.

Indeed, although neuropsychological and physical symptoms, including impaired concentration, fatigue, agitation, and early insomnia, are reported as relatively frequent (>75% of cases) in both community and clinical studies, we know little of their origins or whether they carry specific effects for the natural history or treatment of major depression in young people. Although there is consistent evidence for various forms of memory difficulties in depressed patients ([Austin et al., 1999](#); [Kuyken and Dalgleish, 1995](#); [Teasdale, 1999](#)), it is not known whether specific neuropsychological deficits in working or declarative memory, or dysfunctions in attentional processing, are present before the onset of depressions, emerge as the nature of affective syndromes unfolds, or are direct consequences of attempts to deal with other existing prodromal depressive features. Part of the difficulty lies in merging two somewhat different research philosophies and strategies such that developmentally sensitive, experimentally based neuropsychological measures can be realistically applied to large enough samples of children and adolescents both in the community and in the clinic, preferably in longitudinal designs.

It also is unclear if subjects in whom depressive conditions develop have a greater liability for physical disruption of sleeping, eating, and energy before onset. No prospective studies have determined the attributable risk associated with a particular physical symptom or set of symptoms for the onset of juvenile forms of

depression. Thus, the relative contribution of the three domains of negative cognitions, executive dysfunction, and physical signs and symptoms to the onset of first-episode depression or the risk of recurrence for different forms of depression is unclear.

## SEX DIFFERENCES

Most research in affective disorders is on girls and women, and little in reality is known about depression in boys and men. Sex difference in rates of major depression from mid-adolescence through the seventh decade is one of the most robust findings in psychiatric epidemiology ( [Bebbington et al., 1998](#); [Piccinelli and Wilkinson, 2000](#)). Most clinical studies of sequential cases appear to have few or no sex differences in the size of their study populations or in the nature and characteristics of the disorders ( [Goodyer et al., 1997](#); [Mitchell et al., 1988](#)). This may reflect the impact of severity on the probability of referral, suggesting that the sex difference in prevalence in the community is due to there being a greater proportion of mild and moderate clinical depressions in women compared with men.

As yet, however, there is no concise explanation for the sex difference in childhood and adolescence, and little is known about the nature and characteristics of depressions between the sexes in young people.

In a prospective study of a group of 181 male (n = 68) and female (n = 103) adolescents aged 12 to 16 years at high psychosocial risk for psychopathology, there were 30 episodes of major depression (8 male and 23 female) over the 12-month follow-up period, giving a prevalence estimate of 17% overall for this population ( [Goodyer et al., 2000](#)). Determining if self-report MFQ scores at entry were associated with subsequent major depression for each sex revealed that of the 23 cases of major depression in girls, 14 (60%) were high scorers (>80th percentile of the MFQ, = 26 in this study from a range of 0 to 66); by contrast, for the 8 cases of major depression in boys, only 1 (12.5%) had a high MFQ score at entry. These findings suggest that sex, as well as age factors, influence the salience and validity of self-reported depressive symptoms as indicators of major depression. Compared with girls, boys' self-reports of depressive symptoms may be less sensitive in detecting or predicting major depression, at least in community adolescent populations.

## COVARIATION OF ANXIOUS AND BEHAVIORAL SYMPTOMS WITH DEPRESSIVE SYNDROMES

In a comprehensive review of 19 population studies of depressive disorders, [Angold and colleagues \(1999\)](#) reported high rates of comorbid anxiety disorders in nearly half of all such studies. Clinical studies of major depressions have invariably reported very high (up to 80%) estimates of concurrent nondepressive comorbid disorders, particularly anxiety syndromes ( [Birmaher et al., 1996](#); [Herbert et al., 1996](#)). School refusal is more strongly associated with depression than often is recognized ( [Kolvin, 2001](#)), whereas specific fears and phobias may be less so. Separation anxiety disorder appears more likely in younger depressive subjects, suggesting a potential developmental influence on the phenomenologic characteristics of clinical anxiety states accompanying depressive disorders. Anxiety disorders are not the only form of comorbid syndromes found in young people with major depression. Others include oppositional defiant disorder, conduct and dysthymic syndromes, and obsessive-compulsive disorder ( [Goodyer et al., 1997](#); [Kovacs, 1997](#); [Mitchell et al., 1988](#)).

A number of authorities have suggested that anxious states are likely to precede depressive disorders in school-age populations (e.g., [Compas et al., 1993](#); [Kovacs et al., 1989](#)). The cross-sectional findings reported to date cannot unravel the precedence of syndromes to each other. The notion that nondepressive syndromes of different types may precede the onset of depressive syndromes remains an important question in the natural history of the origins of affective illness in young people.

The nature and characteristics of nondepressive features may provide important clues concerning the etiology and outcome of depressive disorders that are clinically heterogeneous. Prospective community studies of the covariation between anxious and depressive symptoms in young people are beginning to appear in the literature, providing new insights into the natural history of emotional symptoms in the school-age years. For example, [Cole and colleagues 1996, \(1997\)](#) have monitored 330 elementary school children and their parents (n = 228) in a repeat-measures design over 3 years, examining the temporal relationship between anxiety and depressive symptoms. Individual differences in the measures of depression and anxiety proved remarkably stable ( [Cole et al., 1998](#)). The findings did not imply that individual levels of anxious and depressive symptoms did not change, but rather that each child's position remained stable in the ranking in relation to others in the sample. Importantly, high scores from self- and parent-reported anxiety scores predicted increases in self- and parent-reported depression scores over time. By contrast, high levels of self- and parent-reported depression scores did not predict increases in anxiety over time. These findings support the hypothesis that anxiety symptoms precede those of depression. Cole and colleagues also showed that high self- and parent-report scores in depression did not predict increases in anxiety and, as a consequence, suggested that increases in depressive symptoms was a precursor to reductions in subsequent anxiety symptoms.

Despite the well-described association between conduct symptoms and depression in child and adolescent populations, there are no reported studies of the nature of the covariation over time between these symptoms in the child or adolescent age range.

Prospective studies of both emotional and behavioral symptom profiles of children and adolescents at high risk for affective psychopathology followed through the adolescent period of risk for onset of major depression (13 to 16 years) would substantially contribute to our understanding of how symptom patterns evolve, organize, and relate to each other. They also would be able to delineate the symptom combinations in the childhood years that are most associated with the onset of subsequent affective psychopathologies in juveniles.

## HISTORICAL OVERVIEW

Impaired thinking or thought disorder has been regarded as the hallmark of schizophrenia since the first descriptions of this illness by [Bleuler \(1951\)](#). Bleuler regarded loosening of associations as a fundamental sign that represents the pathologic process of schizophrenia. In contrast, he regarded hallucinations and delusions as accessory signs that were secondary to the pathologic process of schizophrenia.

From the clinical perspective, earlier theories on thought disorder were all-encompassing and tried to explain thought disorder as a unitary concept ( [Holzman et al., 1986](#)). Since the late 1970s, several studies have demonstrated that thought disorder is not a unitary concept and does not occur specifically in schizophrenia ( [Andreasen and Grove, 1986](#); [Butler and Braff, 1991](#); [Grossman and Harrow, 1996](#); [Holzman et al., 1986](#); [Marengo and Harrow, 1997](#); [Sax et al., 1995](#); [Serper, 1993](#)).

Introduction of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) ( [American Psychiatric Association, 1980](#)) and DSM-III-R ( [American Psychiatric Association, 1987](#)) provided further clarification of terms by clearly differentiating between disturbances in the form and content of thought. Thus, formal thought disorder describes the clinical manifestations of the manner in which patients present their thoughts to the listener ( [Fish, 1962](#)) and the organization, control, and processing of thoughts ( [Holzman et al., 1986](#)). Delusions, a thought content disturbance, refer to firmly held personal beliefs that are based on incorrect inference about external reality in spite of obvious proof or evidence to the contrary ( [Butler and Braff, 1991](#)).

Unlike earlier studies, the clinical studies that have been conducted since the late 1970s have used reliable and valid instruments for the assessment of well-defined aspects of thought disorder ( [Aloia et al., 1998](#); [Andreasen and Grove, 1986](#); [Docherty and Gordinier, 1999](#); [Goldberg et al., 1998](#); [Harvey and Serper, 1990](#); [Holzman et al., 1986](#); [Mesure et al., 1998](#); [Nestor et al., 1998](#)). These studies have characterized the positive and negative dimensions of formal thought disorder in schizophrenic adults, as well as their relationship with clinical symptoms ( [Andreasen et al., 1990](#)), cognitive/attentional deficits ( [Braff et al., 1991](#); [Cornblatt et al., 1985](#); [Nestor et al., 1998](#); [Nuechterlein et al., 1986](#)), linguistic deficits (see review in [Kuperberg et al., 1998](#)), treatment responses ( [Spohn et al., 1986](#)), and biological measures ( [Fukuzako et al., 1996](#); [Holinger et al., 1999](#); [McGuire et al., 1998](#); [Menon et al., 1995](#); [Shenton et al., 1992](#); [Vita et al., 1995](#)).

In contrast, very few studies were conducted on thought disorder in childhood before the DSM-III. The DSM-III made two important contributions to this field of research. First, it put an end to the historical debate over the relationship between infantile autism and schizophrenia ( [Eisenberg and Kanner, 1956](#); [Fish and Ritvo, 1978](#); [Kanner, 1957](#); [Kolvin et al., 1971](#); [Makita, 1966](#); [Rutter, 1972](#); [Rutter and Lockyer, 1967](#); [Rutter et al., 1967](#)). Second, the DSM-III provided well-defined inclusionary and exclusionary criteria for schizophrenia. Use of these criteria stopped the practice of labeling a variety of clinical manifestations, such as impaired social relationships, language deviance, disturbed reality testing, delusions, and abnormal stream and form of thought as thought disorder. In addition, investigators have become cognizant of the impact of developmental factors on the methods for eliciting and coding thought disorder in childhood ( [Arboleda and Holzman, 1985](#); [Caplan et al., 1989, 1990a, 1992a, 2000](#); [Makowski et al., 1997](#); [Tompson et al., 1990, 1997](#)). As a result, research on schizophrenic children diagnosed based on DSM-III, DSM-III-R, and DSM-IV criteria followed a similar trajectory to that on schizophrenic adults, albeit at a slower pace.

This chapter includes three sections that describe three aspects of psychotic thinking in children: formal thought disorder, hallucinations, and delusions. Each of the chapter's three sections reviews studies on the clinical assessment, underlying mechanisms, and differential diagnosis of formal thought disorder, hallucinations, and delusions, respectively, in childhood-onset schizophrenia.

## FORMAL THOUGHT DISORDER

### Definition

Formal thought disorder represents clinical measures of the form or manner in which the patient presents his or her thoughts to the listener. Numerous clinical signs have been used to describe these communicative characteristics, such as illogical thinking, incoherence, loose associations, digressive speech, circumstantiality, tangentiality, vague speech, overelaborate speech, clanging, neologisms, poverty of speech, poverty of content of speech, echolalia, and others ( [Andreasen, 1979](#)).

The DSM-IV ( [American Psychiatric Association, 1994](#)) uses the term *disorganized speech* (e.g., frequent derailment or incoherence) rather than *formal thought disorder*. The DSM-III-R ( [American Psychiatric Association, 1987](#)) required the presence of loose associations or incoherence to diagnose formal thought disorder. The DSM-III ( [American Psychiatric Association, 1980](#)) included four formal thought disorder signs: illogical thinking, loose associations, incoherence, and poverty of content of speech.

### Clinical Assessment Studies of Formal Thought Disorder in Childhood

A review of the literature demonstrates a dearth of studies on formal thought disorder in childhood schizophrenia and schizophrenia spectrum disorders ( [Arboleda et al., 1985](#); [Cantor et al., 1982](#); [Caplan et al., 1989, 1990a, 1992a, 2000](#); [Caplan, 1994a](#) and [1994b](#); [Green et al., 1984](#); [Kolvin et al., 1971](#); [Russell et al., 1989](#); [Tompson et al., 1990, 1997](#)) and one study on children at risk for schizophrenia ( [Arboleda and Holzman, 1985](#)). Only three groups of researchers have used reliable and valid instruments for the clinical assessment of formal thought disorder in children ( [Arboleda and Holzman, 1985](#); [Caplan et al., 1989, 1990a](#); [Tompson et al., 1990, 1997](#)).

[Kolvin et al. \(1971\)](#) reported that 60% of children with late-onset psychosis had disorder of association, 45% had derailment of thought, and 51% had talking past the point as described by [F.J. Fish \(1962\)](#). The criteria for assessing formal thought disorder, however, were not operationalized for use with children. Cantor identified formal thought disorder signs, such as loose associations, neologisms, illogicality, clanging, poverty of speech, and poverty of content of speech, in both the early-onset and adolescent-onset groups of children with schizophrenia ( [Cantor et al., 1982](#)). Like Kolvin, Cantor did not use a reliable and valid instrument for assessing formal thought disorder in these children. In addition, she did not clarify how she operationalized these formal thought disorder signs for the younger group.

[Green et al. \(1984\)](#) reported that all the schizophrenic children in their sample fulfilled the DSM-III schizophrenic inclusionary criterion for formal thought disorder signs. Because the clinical characteristics of the schizophrenic children in this study were retrospectively obtained from medical charts, it is not clear how the DSM-III formal thought disorder signs were operationalized in this sample of children aged 6 years, 7 months to 11 years, 11 months.

[Russell et al. \(1989\)](#) made reliable global clinical ratings of the DSM-III criteria of formal thought disorder from the Interview for Childhood Disorders and Schizophrenia. These investigators reported that 40% of their schizophrenic sample exhibited incoherence or marked loosening of associations, illogical thinking, or poverty of content of speech accompanied by affect disturbance, delusions, hallucinations, or disorganized behavior ([Russell et al., 1989](#)).

From the developmental perspective, normal children learn to present the listener with their thoughts in a logical and coherent fashion from the toddler period through adolescence ([Shatz, 1982](#)). Formal thought disorder, a clinical measure of the way the child presents his or her thoughts to the listener, involves the maturation of cognitive, linguistic, and pragmatic skills ([Caplan, 1994a](#)). Two studies have addressed the relationship between age and formal thought disorder in childhood.

Using the Thought Disorder Index (TDI), [Arboleda and Holzman \(1985\)](#) conducted the first study that demonstrated the importance of controlling for the level of cognitive development when assessing thought disorder in normal children younger than 10 years of age. This also was the first study to use a formal psychological test with suitable control groups to assess thought disorder in psychotic and high-risk children.

The TDI has demonstrated reliability and validity in schizophrenic, manic, and depressed adults and in their first-degree relatives ([Holzman et al., 1986](#)). It codes 22 categories of verbal responses to the standardized percepts on the Rorschach cards as associative, combinatorial, disorganized, and unconventional verbalizations ([Holzman et al., 1986](#)). The TDI therefore examines a broader range of thought disturbance categories than the DSM-IV (i.e., derailment and incoherence), DSM-III-R (i.e., loosening of associations and incoherence), and DSM-III formal thought disorder signs (i.e., loose associations, illogical thinking, incoherence, and poverty of content of speech). [Arboleda and Holzman \(1985\)](#) found that children with psychosis and psychotic spectrum disorders and those at risk for schizophrenia and affective disorder had more severe thought disorder levels than normal children and children with nonpsychotic psychiatric diagnoses. Using the TDI and the Family Consensus Rorschach Task ([Loveland et al., 1963](#)), [Tompson et al. 1990](#), ([1997](#)) demonstrated that schizophrenic and schizotypal children had significantly more thought disorder and disturbed attention than depressed children and normal children.

In an earlier study, [Asarnow et al. \(1988\)](#) also described a relationship between low Wechsler Intelligence Scale for Children—Revised distractibility factor scores and communication deviance in the parents of children with schizophrenia and schizotypal personality disorder, but not with depression and dysthymia. From the developmental perspective, the findings of [Asarnow and colleagues \(1988\)](#) suggest that the thought disorder of schizophrenic children also might reflect an attentional impairment in both the parents and child, with difficulty establishing a shared focus of attention.

More recently, [Makowski et al. \(1997\)](#) found significantly more idiosyncratic word use, illogical reasoning, perceptual confusion, loss of realistic attunement to the task, and loosely related ideas in the TDI responses of 20 schizophrenic adolescents compared with 12 adolescents with psychotic depression, 34 nonpsychotic adolescents in an inpatient psychiatric unit, and 29 adolescents in a general hospital unit with nonlife-threatening medical illness. These findings highlight that thought disorder is found in both the adolescents with schizophrenia and those with psychosis and depression. The thought disorder of the two groups differed, however, with bizarre content characterizing the speech of the schizophrenic subjects.

[Caplan et al. \(1989\)](#) developed a play procedure, the Story Game, and a coding system, the Kiddie Formal Thought Disorder Scale (K-FTDS), for the assessment of formal thought disorder in middle childhood. Compared with a structured psychiatric interview, the Story Game elicited adequate speech samples that could be reliably rated for formal thought disorder in children ([Caplan et al., 1989](#)). The K-FTDS operationalized the four DSM-III signs of formal thought disorder—illogical thinking, loose associations, incoherence, and poverty of content of speech—so that they could be coded even if children spoke in small paragraphs of one to two utterances.

A study conducted on 88 schizophrenic and 190 normal children demonstrated that illogical thinking and loose associations are reliable, valid, sensitive, and specific measures ([Caplan et al., 2000](#)). Comparison of schizophrenic, schizotypal, and normal children indicates that loose associations occur almost specifically in the schizophrenic and schizotypal children ([Caplan, 1994a](#) and [1994b](#); [Caplan et al., 1989, 1990a, 2000](#)). There are no significant differences in the illogical thinking and loose associations scores of the schizophrenic and schizotypal children ([Caplan, 1994b](#); [Caplan et al., 1990a](#)).

From the developmental perspective, normal children younger than 7 years of age have illogical thinking and loose associations ([Caplan et al., 2000](#)). The young schizophrenic and normal children have significantly higher illogical thinking and loose association scores than the older children with these respective diagnoses ([Caplan et al., 2000](#)).

## Etiology and Pathogenesis

Examination of the relationship of well-defined clinical measures of thought disorder with attention/information processing ([Harvey and Serper, 1990](#); [Nestor et al., 1998](#); [Nuechterlein et al., 1986](#)), linguistic/pragmatic (see review in [Kuperberg et al., 1998](#)), and biological measures ([Fukuzako et al., 1996](#); [Holinger et al., 1999](#); [McGuire et al., 1998](#); [Menon et al., 1995](#); [Shenton et al., 1992](#); [Vita et al., 1995](#)) has been an important step in defining and delineating the components of thought disorder in schizophrenic children. The pathogenesis of formal thought disorder in adult schizophrenia nevertheless remains unclear.

In terms of attention/information processing, negative signs of formal thought disorder have been associated with poor performance on cognitive tasks that demand effortful recruitment of information processing ([Nuechterlein et al., 1986](#)), and working memory deficits ([Nestor et al., 1998](#)). Positive signs of formal thought disorder, however, are related to distractibility ([Cornblatt et al., 1985](#); [Harvey et al., 1986](#)).

Studies in schizophrenic adults with thought disorder highlight deficits in the use of linguistic context to process and produce speech (see review in [Kuperberg et al., 1998](#)), cohesive devices to refer to people, objects, and events ([Docherty and Gordinier, 1999](#); [Harvey et al., 1986](#); [Harvey and Serper, 1990](#)), semantic categorization ([Mesure et al., 1998](#)), and structure of semantic knowledge and network ([Paulsen et al., 1996](#)), as well as aberrant automatic spread of activation or facilitation in semantic networks ([Aloia et al., 1998](#); [Goldberg et al., 1998](#); [McCarley et al., 1999](#); [Weisbrod et al., 1998](#)). The findings of these studies suggest that schizophrenic adults have both receptive and expressive difficulties involving the ability to organize and monitor incoming and outgoing speech (i.e., higher-level linguistic functions). However, there is no evidence for impairment in linguistic functions, such as syntax, in adult schizophrenia (see review in [Kuperberg et al., 1998](#)).

From the biological perspective, several imaging studies have demonstrated involvement of the frontal ([Liddle et al., 1992](#); [Vita et al., 1995](#)), temporal ([Fukuzako et al., 1996](#); [Holinger et al., 1999](#); [Liddle et al., 1992](#); [Menon et al., 1995](#); [Shenton et al., 1992](#)), and anterior cingulate regions ([Liddle et al., 1992](#); [McGuire et al., 1998](#)) in the thought disorder of schizophrenic adults. [Andreasen and Grove \(1986\)](#) proposed that negative formal thought disorder signs of schizophrenic adults, such as poverty of content of speech, are akin to the alogia (i.e., difficulty generating organized speech) found in patients with frontal lobe disease.

Similar to the research on thought disorder in adult schizophrenia, research on the etiology and pathogenesis of formal thought disorder in childhood schizophrenia has included studies on attention/information processing ([Asarnow et al., 1994](#); [Karatekin and Asarnow, 1998](#)), linguistic/pragmatic deficits ([Caplan, 1994a](#) and [1994b](#); [Caplan et al., 1992a, 1996, 2000](#)), and possible biological correlates of thought disorder ([Caplan et al., 1992b, 1993, 1994, 1997](#), in press) in schizophrenic children.

From the *cognitive* perspective, [Caplan et al. \(1990a\)](#) found that illogical thinking and loose associations are related to different aspects of impaired attention/information processing in children with schizophrenia spectrum disorder. Illogical thinking appears to be related to a deficit in momentary processing capacity, measured by the partial report span of apprehension task ([Caplan et al., 1990b](#)), and to the schizophrenic child's difficulty with screening out extraneous stimuli and focusing on the task at hand ([Caplan et al., 1990c](#)). The requirement to present the listener with logical reasoning might tax these cognitive skills in the schizophrenic child ([Caplan, 1994a](#) and [1994b](#)).

In the case of loose associations, the child unpredictably changes the topic of conversation without preparing the listener for the topic change. Loose association is associated with distractibility ([Caplan et al., 1990b, 2000](#)). Thus, the cognitive demands of this situation appear to be different from those eliciting illogical thinking ([Caplan, 1994a](#)).

From the *linguistic/pragmatic* perspective, as demonstrated in schizophrenic adults ([Docherty and Gordinier, 1999](#); [Harvey, 1983](#); [Harvey and Serper, 1990](#)),

schizophrenic children underuse discourse devices that link clauses (sentences) and establish coreference, such as conjunctions and referential cohesion ( [Caplan et al., 1992a, 2000](#)). They make reference to people, objects, or events without previously identifying these referents (i.e., unclear and ambiguous reference). Schizophrenic children also repeatedly disrupt the ongoing conversation to refer to the immediate surroundings (i.e., exophora). This difficulty focusing on the conversational text is associated with illogical thinking and loose associations, unlike other aspects of the discourse deficits of these children ( [Caplan, 1994a](#) and [1994b](#); [Caplan et al., 2000](#)).

Schizophrenic children use fewer self-initiated strategies of repair for on-line correction of errors in conversation involving the organization of ideas or the connections between these ideas across sentences ( [Caplan et al., 1996](#)). In terms of the organization of ideas, they use fewer false starts (i.e., an incomplete clause that begins, but does not complete an idea) and fillers (i.e., words that fill pauses without changing the meaning) compared with normal children. Regarding links between ideas of contiguous sentences, they make fewer clarifications of the referents they use to identify people, objects, or events. Underuse of these repair strategies is associated with loose associations and distractibility ( [Caplan et al., 1996](#)). Thus, in addition to impaired organization and processing of thoughts captured by measures of formal thought disorder, the listener has difficulty following who and what the child is talking about because of abnormal use of linguistic devices that tie together ideas expressed across sentences and impaired correction of online errors in conversation.

Finally, from the *biological* perspective, as demonstrated in adults with complex partial seizure disorder ( [Csernansky et al., 1988](#); [Perez et al., 1985](#); [Slater and Beard, 1963](#); [Taylor and Marsh, 1979](#)), a schizophrenia-like psychosis is found in children with this form of epilepsy ( [Caplan et al., 1991, 1992b, 1997, 2000](#); [Lindsay et al., 1979](#)). In search of a possible biological model of formal thought disorder in childhood-onset schizophrenia ( [Caplan et al., 1992b, 1993, 1994](#)), this association has led to several studies of thought disorder (i.e., formal thought disorder and discourse deficits) in children with complex partial seizure disorder.

The following findings suggest that illogical thinking in middle childhood might reflect frontal lobe dysfunction ( [Caplan et al., 1993, 2001](#), in press b). First, children with complex partial seizure disorder and electroencephalographic evidence for frontotemporal involvement used significantly more illogical thinking and fewer cohesive ties and self-initiated strategies of repair than those without frontal lobe involvement ( [Caplan et al., 1992b, 1994, 1997, 2001](#), in press b). Second, follow-up of seven children who attained seizure control after temporal lobectomy for intractable complex partial seizures revealed postoperative normalization of their high illogical thinking scores ( [Caplan et al., 1993](#)). Seizure control after temporal lobectomy might therefore reduce frontal lobe dysfunction and the illogical thinking found in these children. This hypothesis is based on the propagation patterns of temporal lobe seizures with spread first to the ipsilateral and contralateral frontal lobes and then to the contralateral temporal lobe ( [Lieb et al., 1982](#)), and on intraoperative electrocorticography evidence for functional frontal abnormalities in more than half the patients who undergo temporal lobectomy ( [Mizrahi et al., 1990](#)).

In summary, illogical thinking and loose associations represent different attentional and linguistic impairments in childhood-onset schizophrenia. Preliminary evidence suggests that illogical thinking might reflect frontotemporal dysfunction in the child.

### **Differential Diagnosis of Formal Thought Disorder in Children**

#### *PSYCHOTIC DISORDERS*

Schizophrenic adolescents have both positive (loose associations) and negative formal (i.e., poverty of content of speech, illogical thinking) thought disorder signs. Although infrequent, incoherence sometimes is found in the severely ill adolescent patient. The formal thought disorder manifestations of adolescent manic patients include loose associations, distractibility, tangentiality, and digressiveness, together with pressure of speech. As previously mentioned, despite high levels of thought disorder, the formal thought disorder of adolescents with psychotic depression differs from that of schizophrenic adolescents in the absence of bizarre content ( [Makowski et al., 1997](#)). With the exception of brief episodes of disorganized thinking, children with dissociative disorder have no formal thought disorder ( [Hornstein and Putnam, 1992](#)).

In the child with organic psychosis, the severity of formal thought disorder is related to the severity of global cognitive impairment ( [Caplan et al., 1987, 1992b](#)). Severe incoherence and fragmentation of utterances usually are indicative of "organic" formal thought disorder. Whereas the clinical manifestations of formal thought disorder wax and wane in the child with nonorganic psychosis, they tend to be pervasive in the child with organic psychosis ( [Caplan et al., 1987](#)). Children with complex partial seizure disorder and a schizophrenia-like psychosis have illogical thinking, but no loose associations ( [Caplan et al., 1991](#), in press b).

#### *PERSONALITY DISORDERS*

According to the DSM-IV, patients with a diagnosis of schizotypal personality disorder meet criteria for odd speech, but not for formal thought disorder. However, a sensitive and specific instrument, such as the K-FTDS, can detect formal thought disorder not otherwise identified by structured psychiatric interviews in schizotypal children ( [Caplan et al., 1990a](#)). Although schizotypal children have lower illogical thinking and loose associations scores than schizophrenic children, these differences are not statistically significant ( [Caplan et al., 1990a](#)).

#### *DEVELOPMENTAL DISORDERS*

Children with these disorders might have formal thought disorder secondary to their cognitive or language delay. Because normal children with a mental age under 7 years have illogical thinking and loose associations ( [Caplan et al., 1989, 1990a, 2000](#)), children with mental retardation might exhibit illogical thinking or loose associations by virtue of their low mental age. Evidence for generalized cognitive and developmental delay and the absence of other signs of psychosis would suggest a diagnosis of mental retardation.

Children with specific expressive language disorders and with developmental aphasia have deficits in the social use of language (i.e., pragmatics). Clinically, therefore, their speech could meet criteria for formal thought disorder. The presence of a specific language disorder without other signs of psychosis would support a diagnosis of a specific expressive disorder.

Because of their impaired communication skills, children with pervasive developmental disorder not otherwise specified also could meet criteria for formal thought disorder ( [Van der Gaag, 1993](#)). The presence of a qualitative impairment in reciprocal social interaction and verbal and nonverbal communication, as well as a restricted repertoire of activities and interests, will guide the clinician toward the pervasive developmental disorder diagnosis.

### **Conclusions**

Illogical thinking and loose associations are reliable and valid measures of formal thought disorder in middle-childhood schizophrenia spectrum disorders. Reliable clinical assessment of formal thought disorder involves the use of specific instruments for eliciting speech samples from children (e.g., Rorschach cards, the Story Game) and for measuring formal thought disorder (e.g., the TDI, the K-FTDS). Based on developmental data, 7 years of age is the cutoff point for normal developmental changes in these measures. Different attention/information processing and linguistic/pragmatic deficits underlie illogical thinking and loose associations in schizophrenic children. Underlying pathogenetic mechanisms might involve the frontal/frontotemporal areas.

### **HALLUCINATIONS**

#### **Definition**

The hallucinatory experience has been defined variously as a "false sensory perception not associated with real external stimuli" ( [Kanner, 1957](#); [Kaplan and Sadock, 1985](#)) and as "an apparent perception of an external object when no such object is present." Hallucinations may involve any of the senses and are to be distinguished from vivid eidetic imagery, intensified images or sensory impressions, fantasy productions, and imaginary companions. Hallucinations that occur while falling asleep or waking (hypnagogic and hypnopompic hallucinations) often are categorized as distinct from hallucinations that occur in the fully awake state. Hallucinations may be more or less vivid.

#### *OCCURRENCE*

Hallucinations appear to be rare in children younger than 6 or 7 years of age. [Rothstein \(1981\)](#) reviewed 21 studies published between 1931 and 1975 of children

who experienced auditory or visual hallucinations. The definition of hallucinations and the quality of the behavioral observations varied across these studies. [Rothstein \(1981\)](#) concluded that hallucinations in children were not pathognomonic of psychosis. They were found in normal children suffering from anxiety states, in transient situational responses, in deprived children with personality disorders, and in schizophrenic children. The definition of "schizophrenia" in a number of the studies reviewed by [Rothstein \(1981\)](#) differed from that found in the DSM-III, DSM-III-R, and DSM-IV.

Additional studies of the prevalence of hallucinations in children treated in child and adolescent psychiatry services confirm that hallucinations are not pathognomonic for schizophrenia and that they are infrequent in the young child. [Garralda \(1984\)](#) reviewed the case records for 4,767 children seen at the Children's Department of the Maudsley Hospital between 1954 and 1966. None of the 1.1 % of the children noted to have hallucinations on admission were younger than 8 years of age.

[Kempf \(1987\)](#) examined the hospital records of 331 children admitted to a public psychiatric hospital and diagnosed psychotic. Of the 171 children with hallucinations, three were younger than 8 years of age, and none of the children were younger than 6 years of age. It is unclear if age 6 years was the cutoff age for admission to the hospital in this study.

[Egdell and Kolvin \(1972\)](#) reported hallucinations in only two of 40 inpatients between 5 and 15 years of age who had a variety of psychiatric disorders, excluding psychosomatic conditions. The ages of the two patients were not given. [Kotsopoulos et al. \(1987\)](#) also studied the nature of hallucinations in a population of child psychiatry outpatients. Eleven children (of an approximate sample of 100) were reported to hallucinate, all of them older than age 7 years.

[Kolvin et al. \(1971\)](#), [Green et al. \(1984\)](#), [Russell et al. \(1989\)](#), and [McKenna et al. \(1994\)](#) have all reported finding hallucinations in substantial portions of children having "late-onset psychosis" or DSM-III schizophrenia. The rate of hallucinations in these studies was similar, with 80% or more of the children having hallucinations. Even in this highly selected sample, very few children younger than 8 years of age could be identified as having hallucinations.

[Ulloa et al. \(2000\)](#) found psychotic symptoms in 4.5% of 2,031 children referred to a mood and anxiety disorder clinic. Among these children, 80% had hallucinations, mainly auditory, and there was a diagnosis of bipolar disorder in 24%, major depression in 41%, subsyndromal depression in 21%, and schizophrenia spectrum disorders (schizophrenia and schizoaffective disorders) in 14%.

## TYPES OF HALLUCINATIONS

Like adults, children have auditory, visual, olfactory, and tactile hallucinations. The rate of these different types of hallucinations is similar across studies, with auditory hallucinations in 80% to 100% ([Gordon et al., 1994](#); [Green et al., 1984](#); [Kolvin et al., 1971](#); [McKenna et al., 1994](#); [Russell et al., 1989](#)), visual hallucinations in 30.3% to 78.9% ([Gordon et al., 1994](#); [Green et al., 1984](#); [Kolvin et al., 1971](#); [McKenna et al., 1994](#); [Russell et al., 1989](#)), olfactory hallucinations in 21%, and tactile hallucinations in 37% ([Gordon et al., 1994](#); [McKenna et al., 1994](#)).

Hallucinations in children resemble hallucinations in adults. [Kempf \(1987\)](#) described children as reporting voices "ordering me to kill my sister," "telling me to run away," "calling my name," "telling me to do bad things," "telling me to steal," and "telling me to destroy." He also described children who heard voices calling them "faggot," "punk," and "prostitute." One child heard a voice telling him to do good things. Sometimes the voice was identified as that of a relative; sometimes it was not identifiable. The context of the visual hallucinations comprised people, but most children reported seeing monsters.

[Kotsopoulos et al. \(1987\)](#) described a child who believed he had "a bunch of kids in the head" or who heard voices talking of murder or lurking monsters, "a friendly man talking from the closet," or "the voice of a man urging disobedience."

[Burke et al. \(1985\)](#) reported mumbling voices and voices telling the child to hurt himself or others, for example, "a voice telling him to stab his sister" and "the voice of a man and a woman, one telling him to hurt other children, one telling him not to." Visual hallucinations varied from menacing figures to shapes and scenes.

## FOLLOW-UP

Few studies have provided diagnostic outcome data. [Garralda \(1984\)](#) followed up 20 subjects who had been identified in childhood as having hallucinations and compared them with a control group. After a mean follow-up period of 17 years, Garralda retested 16 of the 20 subjects whose mean age was then 30 years. Sixty-seven percent of the index subjects continued to have hallucinatory experiences. Garralda's findings indicate that continued hallucinations were not associated with an increased risk for later psychosis, depressive illness, organic brain damage, or other psychiatric disorder.

Like [Garralda \(1984\)](#), [Del Beccaro et al. \(1988\)](#) reported hallucinations in 50% of their adolescent sample (mean age, 17 years) after a 4-year follow-up. Eighty percent of these subjects had required further psychiatric care during the 4 years.

## Etiology and Pathogenesis

### NEUROBIOLOGICAL MECHANISMS

The findings of biochemical, imaging, and genetic studies in schizophrenia suggest that the hallucinations of schizophrenic patients might be associated with dysfunction of the primary auditory cortex in the anterior and middle superior temporal gyrus ([Rajarethinam et al., 2000](#)), increased cortical activity in Heschl's gyrus (i.e., transverse temporal gyrus) ([Dierks et al., 1999](#)), the glutamatergic N-methyl-D-aspartate receptor ([Vollenweider et al., 2000](#)), and the cholecystokinin type A receptor gene ([Wei and Hemmings, 1999](#)). Studies are needed on the interaction among hallucinations and neuroimaging, biochemical, and genetics findings to delineate the mechanisms underlying hallucinations.

### PSYCHOLOGICAL MODELS

At an empirical level, nonpsychotic forms of hallucinations would appear to be associated with states of extreme stress and altered consciousness. Illusions and fleeting pseudohallucinations have been reported in posttraumatic stress disorder in adults, although the phenomena have not been especially marked or vivid, even in severe cases ([Horowitz, 1987](#)). [Terr \(1985\)](#) has reported that, after a traumatic event that contributes to the death of someone close, a survivor may see or hear the dead friend or family member. Hallucinations of a more vivid type also have been reported in children who have lost close relatives ([Andrade and Srinath, 1986](#); [Yates and Bannard, 1988](#)). Children with other traumatic experiences, such as sexual and physical abuse, can present with hallucinations ([Hornstein and Putnam, 1991](#); [Read and Argyle, 1999](#)). Such effects might be mediated through increased cortical arousal secondary to emotional activation, although this is speculative.

Earlier psychoanalytic writers have suggested that hallucinations could be viewed as the breakthrough of preconscious or unconscious material into consciousness in response to psychological stress and conflict. As such, the material would be projected onto the world and then perceived as coming from outside. Although somewhat metaphorical in nature, these suggestions allow a bridging between the biological events that underlie hallucinations and the nature of the hallucinatory experience, reflecting as it must a person's prior experiences and current unconscious and preconscious fears, conflicts, defenses, and general mental state.

## Differential Diagnosis of Hallucinations in Children

### PSYCHOTIC DISORDERS

The hallucinations of schizophrenic children wax and wane, change in form and nature, cause subjective distress to the patient, are associated with poor reality testing, and are not mood congruent. In contrast, the hallucinations of children with an affective psychosis are mood congruent, associated with bizarre ideation, and variable. The hallucinations of children with dissociative psychosis, however, often involve a threatening voice and a protecting voice, usually of people known to the patient ([Hornstein and Putnam, 1992](#)). Children with organic psychoses have fixed hallucinations. The child with epilepsy and hallucinations does not remember the content of auditory hallucinations that are ictal.

### PERSONALITY DISORDERS

By definition ([American Psychiatric Association, 1994](#)), patients with schizotypal personality disorder (Russell, 1994) do not have hallucinations but might have

perceptual experiences, like illusions. Unlike schizophrenic children, these children vacillate as to the reality of their unusual perceptual experiences. Children with multidimensionally impaired disorder also have illusionary experiences ([Kumra et al., 1998](#))

#### ANXIETY DISORDERS

Children with anxiety might report that they see and hear monsters in the night, but not in the day. Their reality testing for the nature of these experiences is intact during the day, but not at night. Their hallucinatory experiences cause subjective distress.

Children with obsessive-compulsive disorder often present with mental images. When associated with auditory hallucinations, they are more akin to visual hallucinations. When the patient experiences repeated thoughts rather than voices associated with the mental images, they are most likely to be obsessive-compulsive phenomena.

#### DEVELOPMENTAL DISORDERS

Some children with high-functioning autism or Asperger's syndrome have hallucinatory experiences associated with their circumscribed interests. The children have poor reality testing regarding these experiences, act on the basis of their experiences, and do not experience subjective distress.

#### IATROGENIC CAUSES

Hallucinations in children have been reported as a side effect of promethazine hydrochloride ([Hickson et al., 1990](#); [Zametkin et al., 1986](#)), decongestants, such as pseudoephedrine and triprolidine ([Sills et al., 1984](#)), methylphenidate ([Bloom et al., 1988](#)), as well as anesthetic agents, such as ketamine ([Garcia-Velasco et al., 1998](#)) and isoflurane ([Kelsall et al., 1994](#)).

#### Conclusions

Hallucinations occur in children, although they appear to be rare before 7 years of age. They may be associated with a wide variety of diagnoses, ranging from response to stress and bereavement to more serious disorders, such as schizophrenia and affective disorders.

### DELUSIONS

#### Definition

A delusion is a belief that appears quite false (and sometimes bizarre) to others of the person's same cultural, social, and religious group and that cannot be changed by logical argument or evidence against it. [Mullen \(1979\)](#) has suggested that the characteristics of a delusion include that the belief (a) is held with total conviction, (b) may have great personal significance to the individual, and (c) is not amenable to reason or modifiable by experience. In adults, delusions often are of a persecutory or grandiose nature. Persecutory delusions include the idea that one is threatened with personal harm, one is being systematically robbed, or one's spouse is unfaithful. They may be simple beliefs or complex ideas with multiple false inferences.

#### OCCURRENCE

In contrast to studies of hallucinations, few studies have focused on the phenomenon of delusions in children. It is interesting that none of the studies that dealt with milder hallucinations or with hallucinations in "nonpsychotic" children mention delusions ([Andrade and Srinath, 1986](#); [Burke et al., 1985](#); [Edgell and Kolvin, 1972](#); [Kotsopoulos et al., 1987](#); [Yates and Bannard, 1988](#)). The studies that have focused on psychotic symptoms in childhood schizophrenia ([Gordon et al., 1994](#); [Greene et al., 1985](#); [Kolvin et al., 1971](#); [McKenna et al., 1994](#); [Russell et al., 1989](#); [Spence et al., 1994](#)) and affective disorder ([Chambers et al., 1982](#); [Ulloa et al., 2000](#)) all mention the presence of delusions in their results. [Garralda \(1984\)](#) found that paranoid and persecutory delusions were common in her 20 "late-onset" psychotic children. The children complained that they were being poisoned or that someone was following them. One boy claimed that people were shooting at him from under the floor.

[Kolvin et al. \(1971\)](#), [Green et al. \(1984\)](#), [Russell et al. \(1989\)](#), [Gordon et al. \(1994\)](#) and [McKenna et al. \(1994\)](#) all reported that prepubertal children with DSM-III schizophrenia had delusions similar to those seen in adult schizophrenia. [Bettes and Walker's \(1987\)](#) earlier findings suggested a low rate of positive symptoms, such as delusions and hallucinations, in schizophrenia during childhood and early adolescence. However, the incidence of delusions in most studies varied from 36% to 94% ([Gordon et al., 1994](#); [McKenna et al., 1994](#)), with similar base rates reported by [Kolvin et al. \(1971\)](#), [Green et al. \(1985\)](#), and [Russell et al. \(1989\)](#) of 57.6%, 54.2%, and 53%, respectively.

[Chambers et al. \(1982\)](#) reported delusions of control, persecution, or sin in children with major depressive disorder. Ideas of reference or thought insertion were not noted in these samples. Similarly, [Ulloa et al. \(2000\)](#) found delusions in 22% of the children who were seen at a mood disorder and anxiety disorder outpatient clinic and who met criteria for psychosis. As previously mentioned, 24% had bipolar disorder and 62% major or subsyndromic depression.

#### TYPES OF DELUSIONS IN CHILDHOOD

Like adults, children have bizarre, persecutory, somatic, grandiose delusions and ideas of reference ([Gordon et al., 1994](#); [Greene et al., 1984](#); [McKenna et al., 1994](#); [Russell et al., 1989](#)). Unlike adults, their delusions are unsystematized in the form of irrational fears and cosmic threats ([Russell et al., 1989](#)). The persecutory delusions found in schizophrenic adolescents are less elaborate and systematized than in adults, but more than in children ([Apter et al. 1991](#)).

Unlike adults and adolescents, children also have magical thinking and morbid fantasies ([Russell et al., 1989](#)). In our clinical experience, these are precursors to delusions if they are fixed and pervasive, the child acts on them, or the child does not accept the imaginary quality of these thoughts (i.e., poor reality testing).

#### Etiology and Pathogenesis

##### NEUROBIOLOGICAL FACTORS

Few hypotheses have been advanced to explain the neurobiological origin of delusions or to specify what brain mechanisms might be at their root. Imaging and cognitive studies shed some light on the underlying pathogenesis. In schizophrenic adults, delusions are associated with the relationship between volume of the orbital surface of the frontal lobe on the right and the anterior cingulate and superior frontal gyri ([Szeszko et al., 1999](#)). [Spence et al. \(1997\)](#) suggest that misattribution of significance to sensory information as indicated by hypoactivation of parietal and cingulate cortices in an H<sub>2</sub>[<sup>15</sup>O] positron emission tomography study might underlie delusions. [Andreassen et al. \(1997\)](#) have demonstrated decreased perfusion in lateral, orbital, and medial frontal lobe regions as well as in inferior temporal and parietal cortex, and increased perfusion in subcortical circuits, such as the thalamus, cerebellum, and retrosplenial cingulate gyrus. They suggest that these dysfunctional neural circuits might underlie cognitive impairment that prevents efficient processing of input and production of output, leading to symptoms such as delusions, hallucinations, and thought disorder

##### PSYCHOLOGICAL FACTORS

There have been no studies on psychological factors in the delusions of children.

#### Differential Diagnosis of Delusions in Children

##### PSYCHOTIC DISORDERS

As previously mentioned, the delusions of children with schizophrenia are bizarre, persecutory, somatic, and referential. Children with manic disorders have grandiose

delusions. Children with psychotic depression have mood-congruent delusions of guilt and nihilism that are not bizarre. Children with psychosis associated with epilepsy can have persecutory or mood-congruent delusions (i.e., grandiose, nihilistic). Children with an organic psychosis associated with a degenerative disorder have unsystematized and changing delusions.

#### PERSONALITY DISORDERS

Children with schizotypal personality disorder do not meet criteria for delusions. They have vacillating reality testing for unusual ideas (i.e., suspicious, grandiose ideas) that come and go.

#### ANXIETY DISORDERS

If children with obsessive-compulsive disorder present with bizarre ideation associated with their compulsions and poor reality testing for these thoughts, these most probably are delusions—for example, a child who coughs repeatedly to protect himself because he knows from the look in people's eye that their saliva will infect him.

#### DEVELOPMENTAL DISORDERS

Similarly, the circumscribed interests of children with high-functioning autism and Asperger's syndrome, such as preoccupations with dinosaurs, trains, numbers, road maps, and so forth, are not delusions. However, if associated with bizarre ideation and poor reality testing, they are delusions.

#### IATROGENIC CAUSES

Stimulant toxicity can cause delusions of persecution in children.

### CONCLUSIONS

From a cognitive viewpoint, children continue to develop their understanding of the world and of others well into their early school years. Despite “erroneous” notions about events, causes, and relationships between phenomena in their world, children rarely develop delusions in the absence of a more serious disorder, such as schizophrenia or affective disorder.

In this chapter, we examine the developmental, neurobiological, and psychosocial aspects of hyperactivity, impulsivity, and attention. These three symptoms are grouped together because, although they are distinct in many ways, there is a great deal of overlap among them. It is, thus, difficult, particularly in young children, to determine if the behavior one observes is purely a problem of attention, hyperactivity, or impulsivity, or a conglomerate of all three. This chapter presents a brief developmental description of how these symptoms can be expressed at various ages. This is followed by a summary of key neurobiological aspects that may underlie these symptoms and, finally, psychosocial factors that may contribute or complicate the symptoms are discussed.

## H3>DEVELOPMENTAL ASPECTS OF HYPERACTIVITY, IMPULSIVITY, AND ATTENTION

### Temperament

The developmental aspects of symptoms such as hyperactivity, impulsivity, and attention cannot be discussed without an appreciation of the role of temperament in these behavioral characteristics. One of the first researchers to investigate temperamental differences in young children was [Gesell \(1937\)](#). Using films and direct observation, he identified some 15 behavioral characteristics that could be identified in the first year and remained relatively stable until the fifth year. The work on temperament by Thomas and Chess and their coworkers ([Thomas et al., 1968](#)) is well known. They interviewed and observed parents and their infants periodically, beginning when the children were approximately 3 months of age and delineated various behavioral or temperamental profiles. These profiles were composed of the following behavioral aspects: activity level, rhythmicity of biological functions, approach or withdrawal to new situations, intensity of emotional reactions, threshold of sensory responsiveness, adaptability, quality of mood, distractibility, attention span, and persistence. We, thus, see that activity and attention are key elements in the temperamental profiles. It was further shown that children, even in the first few months, differ greatly on the aforementioned temperamental characteristics. In discussing the symptoms of hyperactivity, impulsivity, and attention, it is necessary to be aware of normal temperamental variability in these behaviors.

The individual variability of temperamental characteristics may have a number of different origins. Hereditary factors certainly play an important role. Several twin studies ([Freedman and Keller, 1963](#); [Rutter et al., 1963](#); [Torgersen and Kringlen, 1978](#); [Vandenberg, 1969](#)) have shown that monozygotic twins were significantly more alike than dizygotic twins on various behavioral and temperamental characteristics, including those delineated by [Thomas and colleagues \(1968\)](#). As [Dobzhansky \(1967\)](#) suggested, these behavioral aspects probably are polygenetically inherited and constitute patterns of growth and ways of responding to the environment rather than specific traits. There also is a suggestion that some minor congenital physical anomalies may be associated with behavioral differences (e.g., impulsivity and hyperactivity in boys) ([Quinn and Rapoport, 1974](#); [Waldrop et al., 1968, 1978](#)).

Organic brain damage, whether prenatal, perinatal, or postnatal, has a significant effect on behavioral development and may influence temperamental characteristics. The marked irritability, low frustration tolerance, and short attention span of the brain-injured child has been well documented.

Psychosocial factors such as parenting style, family and environmental stressors, and psychological intervention may influence and modify behavioral, developmental, and temperamental characteristics. This dynamic interplay among genetic, biological, and psychosocial influences on behavioral and temperamental profiles results in the individual variability seen clinically. An extreme expression of this variability gives rise to symptoms that prove problematic to the child and his or her family. A description of how the symptoms of hyperactivity, impulsivity, and inattention can be expressed at various ages follows.

### Hyperactivity, Impulsivity, and Inattention in Infancy

In infancy, the aforementioned symptoms often are expressed by sleep disturbance, feeding problems, increased fidgetiness (not cuddly), excessive irritability, and crying.

Sleep disturbance may take the form of sleeping very little or for very short periods with the result that the infant often is awake and demanding. Sleep, when it does occur, often is very restless. The infant also may wake with a startle reaction followed by screaming.

Feeding problems may include poor sucking or crying during feedings, needing to be fed for brief periods fairly often, and not being able to settle into a workable sucking or feeding rhythm. The infant may be irregular in his or her wish for food or easily distracted from feeding. Infants sometimes become picky eaters, and these problems may give rise to problems in the mother–infant relationship. Increased irritability, fidgetiness, crying, or colic make it difficult to soothe or cuddle the child or have him or her settle down for any length of time. Sometimes the child may develop self-soothing or self-stimulating behaviors such as excessive thumb sucking, head rolling, head banging, or rocking. Once the infant begins to crawl, he or she may be in constant motion with relative disregard to the mother's presence or absence, or other dangers. This makes the child extremely accident prone, requiring constant close supervision.

The infant may be hypertonic or may not enjoy being held. All these behaviors make it difficult to establish a harmony with the child and feel effective as a parent.

The constant activity, which is forever changing and often dangerous, is evident, but at this stage, it is difficult to delineate the relative contributions of impulsivity and

inattention to the observed behavior.

### Symptoms in the Toddler and Preschooler

Normal preschoolers are very active, have short attention spans, and are fairly impulsive. It therefore often is difficult to identify children whose behavior in these areas constitutes symptoms as opposed to normal variability. Two researchers who have looked at these problems in this age group in great detail are Weiss ([Schleifer et al., 1975](#)) and Campbell ([Campbell et al., 1982](#)).

#### HYPERACTIVITY

Direct observations ([Schleifer et al., 1975](#)) or actometer measures ([Campbell et al., 1982](#)) did not show “hyperactive” preschoolers to be more active than normal control subjects in free play situations. However, the two groups were significantly different in more structured settings. In general, in this age group, hyperactivity presents with the child always running, never walking, always being on the go, changing the focus of his or her activity frequently so it appears to be without purpose or goal. The child may have difficulty sitting still for any length of time. For example, he or she frequently leaves the table during meals, cannot sit through the reading of a story, or is in constant state of motion, even when watching television.. This inappropriate activity is particularly evident in structured situations.

Despite the marked gross motor activity, which sometimes is developmentally precocious, fine motor coordination and language often are delayed. The marked hyperactivity and inattention may contribute to these delays. The child may thus be very active but poorly coordinated and clumsy, making him or her quite accident-prone. Sleep disturbances may continue, with children sleeping little, restlessly, or for short periods.

#### IMPULSIVITY

In this age group, impulsivity (often referred to as *cognitive impulsivity*) has been measured directly by various laboratory tests and described by careful observations ([Campbell et al., 1982](#); [Schleifer et al., 1975](#)). Tests of impulsivity in this age group have included the Early Childhood Matching Familiar Figures Test, which measures dimensions of reflectivity–impulsivity, Draw a Line Slowly Test, which measures motor impulsivity, and the Cookie Delay Test, which measures more global impulsive responses. All these tests have shown that some preschoolers are much more impulsive than others. Observational ([Schleifer et al., 1975](#)) and descriptive data show that children with this symptom shift their activities unpredictably: They dash out into street for no apparent reason, grab toys, or hit other children without any discernible provocation. The impulsivity makes their behavior unpredictable, very disruptive, and often dangerous. It also presents problems in behavioral management, limit setting, and discipline. Parents frequently complain that children with these symptoms “do not listen,” do not learn from their mistakes because they seem to be unresponsive to praise or punishment, and continue to repeat behaviors parents try to curtail.

#### PROBLEMS OF ATTENTION

Attention also has been studied by laboratory means [e.g., Auditory Continuous Performance Test ([Schleifer et al., 1975](#))] and direct observations ([Campbell et al., 1982](#); [Schleifer et al., 1975](#)). Children in this age group with attention problems shift their activities frequently, are inattentive during structured tasks, do not complete activities they begin, cannot play alone, and are easily distracted.

### Symptoms in the Elementary School–Age Child

#### HYPERACTIVITY

Hyperactivity in this age group is measured by parents' and teachers' rating scales, direct observational measures, or direct mechanical measures using actometers, stabilimeters, electrical mats, wrist microcomputers, or ultrasonic or photoelectric systems. In general, these measures can identify some children who are significantly more active than age-matched control children. Perhaps the longest and most naturalistic study that focused on measuring activity in this age group was carried out by [Porino and coworkers \(1983\)](#). Children in this study wore an actometer with a memory continuously 24 hours a day for 7 days. The authors showed that hyperactive children were, in fact, more active in all situations, structured or free, even during sleep, than were matched control subjects.

However, overall activity levels tell only part of the story. The activity often is “off task,” disruptive, and random, with no apparent goal or purpose. Much of it may be fidgetiness and restlessness, which take the form of leaving one's seat in the classroom, walking around, or engaging in some other somewhat inappropriate activity.

Hyperactivity also may be expressed in being unable to sit through a meal, a story, a game, or a television program. The marked disruptive nature of the activity ([Klein and Young, 1979](#)) is what is often disturbing to parents and teachers and what distinguishes it from high normal activity, frequently resulting in referrals for professional help. In a free play environment, the increased activity may be expressed by disruptive physical contact with other children (running into them, pushing, hitting, disrupting their play). This may be done without any particular anger, hostility, or malicious intent but often results in quarrels and fights with other children.

#### IMPULSIVITY

As the child matures, there is the general expectation that he or she will acquire greater inhibiting control over his or her behavior and become progressively less impulsive. Impulsivity in this age group again can be divided into an impulsive, cognitive, or problem-solving style ([Kagan et al., 1964](#)) and general behavioral impulsivity. The Matching Familiar Figures Test ([Kagan et al., 1964](#)) is a frequently used measure for assessing an impulsive cognitive style. As [Weiss and Hechtman \(1993\)](#) have pointed out, any test (e.g., Continuous Performance Test) that requires some inhibition or delay in response also may measure an element of impulsivity. This impulsive cognitive style may be seen in poor, incomplete, or error-ridden schoolwork because the child rarely follows a careful, systematic, stepwise approach. It also may express itself in a variety of games, particularly those requiring some strategy or ones where moves that are impulsive and not well thought out result in failure (e.g., chess).

However, it is the impulsive behavior that often proves the most difficult and dangerous. The impulsivity often is characterized by uncontrolled behavior with no thought to the consequences. It may be dangerous, such as walking on a high ledge or leaning from a balcony, or not socially accepted, such as taking another child's toy or stealing a candy bar or comic on the spur of the moment. As the child matures, his or her impulsive behavior can become more dangerous and problematic. Some authors have linked this characteristic to adult antisocial personality characteristics ([Clouston, 1982](#); [Lewis, 1974](#); [Weiss and Hechtman, 1993](#)).

#### PROBLEMS OF ATTENTION

Attention is not a uniform dimension or a single cognitive process. As [Taylor \(1985\)](#) has pointed out, the many different functions involved in attention include “the ability to resist distraction; to maintain one's performance on a long task; to focus intensely on specific stimuli; and to explore complex stimuli in a planned and efficient way” (p. 427). The school-age child who has attentional problems may have difficulty in some or all of these aspects of attention.

Distractibility often is described in children with attentional problems, but several investigators ([Davidson and Prior, 1978](#); [Taylor, 1982](#)) have been unable to document this difficulty in a laboratory setting. However, [Radosh and Gittelman \(1981\)](#) found that a very distracting stimulus affected performance on a very boring arithmetic task in children with attentional problems.

It has been argued that the apparent distractibility of these children really is a problem of *sustained attention*. They cannot focus on anything for any extended time and so appear easily distractible. Developmentally, as the child matures, his or her attention span should lengthen, and he or she should be able to concentrate for progressively longer periods. This developmental task is not readily achieved in children with attentional problems. Their short attention span results in not completing tasks, games, or projects, frequently shifting from one activity to another, and in general doing poorly on any task requiring sustained attention (e.g., Continuous Performance Test).

Children with attentional problems often are very disorganized in problem-solving activities and cannot deal with complex stimuli or tasks in a planned and efficient way. Tests such as the Embedded Figures Test clearly show the deficits that exist in this area. Attempts to teach more organized and effective cognitive strategies to children with attentional difficulties have met with limited success ([Abikoff, 1987](#)).

## Symptoms in the Adolescent

In adolescence, symptoms such as hyperactivity, impulsivity, and inattention may change in presentation because of the child's developmental stage and because of psychosocial aspects of the child's life (e.g., school failure, social ostracism), which also affect how symptoms are expressed.

### HYPERACTIVITY

There clearly is a decrease in gross motor hyperactivity. The adolescent usually can sit through a meal and is not grossly running around all over the place like the younger child. However, he or she is still very restless and fidgety. Hyperactivity takes the form of a lot of small muscle versus large muscle movements (e.g., tapping one's fingers, shaking one's leg, shifting positions in one's chair), as opposed to getting up and running around. This change in gross motor hyperactivity has led some authors ([Eisenberg, 1966](#); [Laufer and Denhoff, 1957](#)) to suggest that the symptoms are limited to childhood and that, by adolescence, the child may "outgrow" the problem. This became a common belief perpetuated by clinicians to parents.

Prospective follow-up studies of hyperactive adolescents by [Gittelman-Klein \(1987\)](#) and [Lambert et al. \(1987\)](#) suggest that 20% to 30% of adolescents may no longer have problems; however, most (70%) ([Biederman et al., 1998](#); [Barkley et al., 1990](#)) continue to have difficulties. Their hyperactivity merely takes another form. In addition to the restlessness and fidgetiness already described, they may become involved in many sport activities (if coordination problems are not too severe) or ride their bikes for long periods. They seem always on the go, going to and from places and rarely staying put for any extended time. They may listen to music but are in almost constant motion while doing so. Thus, the hyperactivity persists but may have found more acceptable channels (e.g., sports), and more often involves small muscle movement expressed as restlessness or fidgetiness.

### IMPULSIVITY

As the child enters adolescence, persistent impulsivity may result in increasingly dangerous impulsive acts, leading to ever-greater problems for the adolescent and his or her family. Again, for 20% to 30% of adolescents who had problems with impulsivity in childhood, this difficulty is no longer significant ([Gittelman-Klein, 1987](#); [Lambert et al., 1987](#)). However, for most children ([Barkley et al., 1990](#); [Biederman et al., 1998](#); [Weiss et al., 1971](#)), the continued impulsivity makes them appear very immature and leads to ever greater problems. The impulsivity may be expressed in dangerous and at times socially maladaptive ways. For example, playing the class clown and impulsively calling out, making jokes, or otherwise disrupting the class is not uncommon.

The adolescent may impulsively take a car and go on a joy ride. He may blow up at teachers, peers, or parents. Sometimes these blowups may be physical. Impulsive, excessive drug or alcohol use may occur from time to time. Some of these impulsive behaviors are affected by the child's poor self-esteem arising from chronic school failure and social ostracism by parents, teachers, and peers. The impulsive cognitive style also persists into adolescence, with the result of decreased organized problem-solving capabilities and continuing poor academic achievement.

### ATTENTIONAL PROBLEMS

Attentional problems often persist into adolescence and are expressed in easy distractibility, failure to complete tasks, short attention span for a particular activity, and frequent shifting from one activity to another. Continued difficulties with tasks requiring sustained attention or organized problem-solving and planning capacities often are seen. Thus, the attentional problems continue to be experienced in adolescence, causing the same deficits as they did earlier. However, the continued difficulties and failures may lead to poor self-esteem and poor motivation with a sense of hopelessness and helplessness. An adolescent may then give up and make few attempts to tackle difficult tasks. This giving up, in turn, contributes to the adolescent falling further behind and experiencing a greater sense of failure.

## Symptoms in Adulthood

Symptoms of hyperactivity, impulsivity, and inattention in adulthood may present in a form different from that seen in previous age groups because of the person's developmental state, life circumstances, and psychosocial factors influencing his or her previous and current situation.

Our knowledge regarding the adult picture of these symptoms comes from very different data sources. These sources include (a) controlled, prospective follow-up studies, which follow children with these symptoms prospectively into adult life; (b) retrospective studies, which look at old records, try to reconstruct childhood diagnoses from them, and then attempt to contact these adults; (c) studies that look at adults with these or similar symptoms; and (d) family studies of parents and relatives of children with these symptoms.

Space does not permit a detailed description of the aforementioned studies, but a brief mention of some key ones in each category is made here.

### CONTROLLED, PROSPECTIVE STUDIES

[Weiss and Hechtman \(1993; Weiss et al., 1985\)](#) conducted one of the first controlled, prospective 10-, 12-, and 15-year follow-up studies on 75 young adults who had symptoms of hyperactivity, impulsivity, and inattention during childhood and 45 matched normal control subjects (mean age, 19 years at 10-year follow-up, 25 years at 15-year follow-up). The evaluations were comprehensive, assessing academic, work, psychiatric, social, physiologic, and psychological parameters. The psychological parameters addressed key symptoms of hyperactivity, impulsivity, and attention. In addition to interviews with subjects and parents, reports were obtained from schools, employers, and the court system.

[Gittelman and colleagues \(1985; Mannuzza et al., 1993\)](#) also conducted a controlled, prospective study of 101 subjects who had these symptoms in childhood and 100 matched normal control subjects (mean age at follow-ups, 18.3 and 26 years). Comprehensive evaluations included interviews with subjects and parents and various rating scales. Forty percent of the subjects continued to have two or more symptoms of hyperactivity, impulsivity, or inattention. It also appeared that those subjects who continued to have these symptoms were more likely to have conduct disorder and substance abuse.

[Barkley \(1998\)](#) in his 15-year, prospective follow-up study of 148 hyperactive and 76 matched control subjects (mean age, 21 years), found that although 3% met diagnostic criteria for attention deficit hyperactivity disorder (ADHD) by self-report, 43% met these criteria by parental report, suggesting continuation of the symptoms of inattention, impulsivity, and hyperactivity in many adults with similar childhood symptoms.

### RETROSPECTIVE STUDIES

Retrospective studies [e.g., [Borland and Heckman \(1976\)](#), [Feldman et al., \(1979\)](#)] usually have not focused on the key symptoms of hyperactivity, impulsivity, and inattention, instead focusing on overall educational, employment, social, and emotional outcomes of adults who had these symptoms in childhood.

[Wood and coworkers \(1976\)](#) selected 15 adults from a psychiatric outpatient clinic whose main presenting complaints were impulsivity, restlessness, irritability, inattentiveness, and emotional lability. Some of these patients also had childhood histories of these symptoms, and these subjects tended to respond to stimulant treatment for the symptoms outlined in adulthood.

Similarly, [Mattes and colleagues \(1984\)](#) selected 66 patients from an outpatient psychiatry clinic with symptoms of restlessness, excitability, impulsivity, and irritability. Twenty-nine of these subjects had similar symptoms in childhood, but unlike the study by [Wender et al. \(1981\)](#), this fact did not predict responsiveness to stimulant medication.

### FAMILY STUDIES

In general, studies of parents and other relatives of children with symptoms of hyperactivity, impulsivity, and inattention have looked at various diagnostic categories as opposed to these specific symptoms in the adult relatives under study. These family studies were comprehensively reviewed by [Hechtman \(1996\)](#). Because they did not focus particularly on the symptoms under discussion, they are not detailed here.

## HYPERACTIVITY

The significant gross motor hyperactivity described at younger ages usually is much less frequent and pronounced in adulthood. Prospective studies by [Weiss et al. \(1985\)](#), [Gittelman et al. \(1985\)](#), [Mannuzza et al. \(1993\)](#), and [Barkley \(1998\)](#) that have followed subjects into adulthood have shown that 35% to 40% no longer have these symptoms as adults. The symptoms of hyperactivity that are expressed usually take the form of restlessness and fidgetiness and always being “on the go.” Adults with these symptoms tend to gravitate toward jobs that require a good deal of physical activity ([Weiss et al., 1985](#)) (e.g., sales, construction, mechanics) as opposed to sitting at a desk. Their leisure time also is spent actively doing various sports or going from one place to another. These subjects have difficulty with any endeavor requiring long periods of inactivity, such as reading a long novel. During interviews, adults who continued to be hyperactive were observed to be more restless and fidgety, with many small muscle movements or frequent changes in their sitting positions ([Weiss et al., 1985](#)).

## IMPULSIVITY

In adulthood, impulsivity is expressed socially and cognitively. Socially, it may take the form of frequent, sudden changes of job or place of residence. The sudden job changes often follow some dispute with colleagues or supervisors in which the subject simply suddenly quits without warning. Changes of residence similarly are frequent and sudden, often following some dispute with family or roommates.

It is difficult to pinpoint if the increased number of car accidents reflects problems of impulsivity, inattention, or both. Characteristically, it is coupled with some aspects of poor judgment. Other, perhaps less significant, examples of impulsive actions these subjects are likely to engage in include suddenly leaving an interview, work, a movie, or a party for no apparent reason. Restlessness may be associated with this behavior, but impulsivity is a key factor. Cognitive impulsivity is reflected in a continuing cognitive style that is impulsive and somewhat disorganized. This affects problem-solving capabilities, which may then affect work performance.

The impulsivity in this age group has serious social and work consequences because it may result in changing unstable social relationships and a poorer work record ([Barkley, 1998](#); [Weiss and Hechtman, 1993](#)).

## PROBLEMS OF ATTENTION

In adulthood, attentional problems can be seen in leisure and work activities. In terms of leisure activity, these subjects do not enjoy anything that requires sustained concentration or attention, such as reading a long novel or playing chess. In the work setting, activities requiring sustained attention often are difficult or boring for these individuals. They can be easily distracted, and completing such tasks quickly and accurately may present problems. At university, subjects tend to study for short periods with frequent breaks to cope with the difficulties of sustained attention.

In general, these symptoms in adulthood continue to affect the person's work, social, and emotional adjustment. The problems result in poor self-esteem, hopelessness, depression, and anxiety and are at times accompanied by excessive drug or alcohol use. This causes the situation to deteriorate still further. Unraveling this complex picture of pain and problems to detect the key underlying symptoms often is difficult, and so these basic handicaps frequently remain undetected in adulthood.

## NEUROBIOLOGICAL ASPECTS OF HYPERACTIVITY, IMPULSIVITY, AND INATTENTION

In general, the neurobiological aspects of the symptoms outlined have not been worked out comprehensively. Several excellent recent reviews on the subject ([Biederman and Spencer, 1999](#); [Castellanos, 1997](#); [Faraone and Biederman, 1998, 1999](#); [Swanson et al., 1998a](#); [Zametkin and Liotta, 1998](#)) clearly illustrate the complexity of the area, the divergent findings, and the many questions yet to be resolved. The symptoms are not unidimensional and probably involve various interrelated neuroanatomic and neurochemical systems. This complexity and interrelatedness make it unlikely that any one area or neurochemical system will be found to be solely or primarily involved in any particular symptom. What follows is a brief summary of the current evidence suggesting involvement of various neuroanatomic and neurochemical systems in different aspects of these symptoms.

The neurobiological aspects of the symptoms outlined include the following areas:

1. Genetics
2. Neuroanatomic aspects
3. Neurochemical aspects, including:
  - Neuroanatomic aspects of neurotransmitters
  - Nonpharmacologic studies of neurotransmitters
  - Psychopharmacologic studies of neurotransmitters
  - Neurotransmitter theories and neuroendocrine studies
4. Neurophysiologic aspects, including data from computed tomography (CT), magnetic resonance imaging (MRI), single-photon emission tomography (SPECT), and positron emission tomography (PET) scans, electroencephalography (EEG), and evoked potential studies

## GENETIC STUDIES

Four types of studies suggest that genetic factors play a role in problems of attention, hyperactivity, and impulsivity: twin, siblings and half-siblings, adoption, and family studies.

### Twin Studies

Genetically based disorders should be concordant in twins, and more so in monozygotic (MZ) than in dizygotic (DZ) twins. A number of twin studies have looked at the concordance of symptoms of inattention, hyperactivity, and impulsivity in twins.

In an early study, [Rutter et al. \(1963\)](#) reported that MZ twins were more similar to each other than DZ twins in psychomotor activity. Similarly, [Willerman \(1973\)](#) reported the heritability of activity scores to be 0.77 for 54 MZ and DZ twin pairs. [Torgersen and Kringlen \(1978\)](#) also found evidence for a genetic component in both activity levels and distractibility.

[Stevenson \(1992\)](#), using multiple regression analysis on data obtained from 91 pairs of MZ twins and 105 pairs of same-sex DZ twins, concluded that results were consistent with a significant genetic contribution to individual differences in activity level and attention abilities. More recently, [Edelbrock and colleagues \(1995\)](#) evaluated 99 MZ and 82 same-sex DZ twin pairs aged 4 to 15 years using the Child Behavior Checklist completed by parents. They found correlations of 0.68 (MZ) and 0.29 (DZ) for attentional problems. In general, using multiple regression analysis, they found significant genetic influences on competence in school and on all areas of problem behavior. Significant shared environmental influences were detected for participation in activities, quality of social relationship, performance in school, anxiety/depression, and delinquent behavior.

Most recently, [Hudziak et al. \(2000\)](#), using parent ratings on the Child Behavior Checklist, evaluated 492 twin pairs aged 8 to 12 years on attention problems and aggressive and anxious/depressed behaviors. Estimates of genetic influences were 60% to 68% for attention problems, 70% to 77% for aggressive behaviors, and 61% to 65% for anxious/depressed behaviors.

[Goodman and Stevenson \(1989\)](#) studied 570 twins 13 years of age. These authors focused particular attention on 29 MZ and 45 same-sex DZ twin pairs in which at least one twin met criteria for pervasive hyperactivity. MZ twins were more alike than same-sex DZ pairs on objective measures of attentiveness and on parent and teacher ratings of hyperactivity (59% vs. 33%). In their careful study, these authors also explored the possible effects of stereotyping (i.e., the tendency to rate identical twins similarly); adverse family factors (e.g., marital discord, parental criticism, and malaise); and perinatal adversity (e.g., low birth weight). They concluded that genetic effects accounted for approximately half of the explainable variance in hyperactivity and inattentiveness.

In their extensive study of reading-disabled twins in the Colorado Reading Project, [Gillis et al. \(1992\)](#) and [Gilger et al. \(1992\)](#) attempted to diagnose ADHD in the

twins by parental responses on the Diagnostic Interview of Children and Adolescents [DICA ( [Herjanic et al., 1982](#))]. They examined 81 MZ and 52 same-sex DZ pairs of a reading-disabled sample of twins and found that for reading disability, the concordance rate was 84% for MZ twins and 66% for DZ twins. The concordance rate for both reading disability and ADHD was 44% for MZ twins and 30% for DZ twins. The data suggest that reading disability and ADHD may have strong although independent genetic components.

[Gillis et al. \(1992\)](#) examined the same group of subjects but focused particularly on 37 MZ and 37 same-sex DZ twin pairs in which one twin had been diagnosed with ADHD using the DICA. The authors used a basic regression model for analysis and found that 79% of MZ twins and 32% of DZ twins were concordant for ADHD ( $p < 0.001$ ). Furthermore, adjustment for IQ or reading performance differences did not substantially change the results. The authors, thus, conclude that the results of their analysis suggest that ADHD is highly heritable (0.91).

One of the largest twin studies is being carried out by [Levy et al. \(1997\)](#) in Australia. They evaluated 1,938 pairs of twins aged 4 to 12 years, and their siblings and determined the perinatal and developmental history, as well as the incidence and concordance of ADHD, conduct disorder, and separation anxiety disorder. Only same-sex twins were used in the analysis, and of these, 849 were classified as MZ and 555 as DZ. Concordance for ADHD for MZ twins was 82% compared with 38% for DZ twins, suggesting a heritability of 0.75 to 0.91 ( $p < 0.001$ ).

In another large twin study originated in Minnesota, [Sherman et al. \(1997\)](#) obtained mother (DICA, revised) and teacher ratings (Teacher Rating Form) of inattention and hyperactivity/impulsivity on 194 pairs of MZ twins and 94 pairs of DZ twins (all boys aged 11 to 12 years). Concordance rates for teacher ratings of inattention were 0.78 for MZ and 0.57 for DZ twins ( $p = 0.001$ ). For mother ratings of inattention, the concordance rates were 0.70 for MZ and .30 for DZ twins ( $p < 0.001$ ). For teacher ratings of hyperactivity and impulsivity, the concordance rates were 0.69 for MZ and 0.42 for DZ twins ( $p < 0.001$ ). For mother ratings of hyperactivity and impulsivity, the concordance rates were 0.92 for MZ and 0.32 for DZ twins ( $p < 0.001$ ). These ratings suggest a genetic effect of 0.39 to 0.69 for inattention and 0.69 to 0.91 for hyperactivity/impulsivity, with teachers reflecting a lower genetic rating than mothers.

Generally, the twin studies have shown that regardless of informant and method of assessment (questionnaires or interviews), there is a consistently and significantly higher rate of concordance for attentional, hyperactive/impulsive symptoms in MZ versus DZ twins. As pointed out by [Rutter et al. \(1999\)](#), their review estimates of heritability for these symptoms have ranged between 0.54 to 0.98, suggesting a strong genetic component.

### Sibling and Half-Sibling Studies

[Welner et al. \(1977\)](#) evaluated 53 hyperactive children and their siblings and compared them with 38 nonhyperactive control subjects and their siblings. The authors found that the hyperactive child syndrome was more common among the brothers of the hyperactive children than among brothers of control subjects (26% vs. 9%). Furthermore, the hyperactive children and their brothers presented with more symptoms of anxiety and depression than did the control subjects (16% vs. 6%). The probands, but not their siblings, also presented with more antisocial symptoms than control subjects. This lends support to a family–genetic risk in this condition and suggests that hyperactive children also may show comorbid conditions of depression and anxiety.

In another early study, [Safer \(1973\)](#) compared the incidence of ADHD in 19 full-sibling and 22 half-sibling pairs. Each pair had been raised together by a common mother. One member of each pair was known to have “minimal brain dysfunction,” now known as ADHD. Over half (10) of the full-sibling pairs were concordant for ADHD, compared with only two of the 22 half-sibling pairs. This significant difference between full and half-siblings further supports a genetic component of hyperactivity.

### Adoption Studies

Early studies by [Morrison and Stewart \(1973\)](#), [Cantwell \(1975\)](#), and [Alberts-Corush et al. \(1986\)](#), showed that adoptive relatives of ADHD children are less likely to have ADHD or associated disorders than are biological relatives of such children. In addition, biological relatives of ADHD children perform worse on standardized measures of attention than do adoptive relatives of ADHD children. In a study of international adoptees, age 10-15, [Van den Oord et al. \(1994\)](#) estimated that genes accounted for 47% of the variance of inattention scores on the Child Behavior Checklist.

In another adoption study, [Cadoret and Stewart \(1991\)](#) studied 283 adoptees aged 18 to 40 years. The adoptees were divided into two groups based on whether biological parents showed evidence (from adoption agency records) of psychiatric problems or behavioral disturbances. In addition to these evaluations, direct evaluations of adoptees and adoptive parents were performed. The authors concluded that adult adoptees had to have both a biological parent with a history of criminality/delinquency and a placement in a lower-socioeconomic–status adoptive home to have an increased likelihood for development of antisocial personality disorder. This suggests that although in general, adoptive studies support a genetic component in hyperactivity, there is always an important interplay between genetic and environmental factors. Thus, in general, adoption studies also support a genetic component in these symptoms.

### Family Studies

Family studies of children with symptoms of inattention and hyperactivity/impulsivity have been based on the assumption that a genetic component of these symptoms will be reflected in a higher familial rate of the disorder for probands. Thus, in an early study, [Morrison and Stewart \(1971\)](#) found that 20% of hyperactive children had a parent who could be (retrospectively) diagnosed as hyperactive, compared with 5% of their medical control subjects. Similarly, [Cantwell \(1972\)](#) reported that 20% of hyperactive boys in his sample had a parent who could be classified as being hyperactive/antisocial in childhood, as opposed to 2% of the pediatric clinic control subjects.

The most extensive family studies to date have been carried out by Biederman and colleagues ( [1990](#), [1992](#)). In the first of these studies, [Biederman et al. \(1990\)](#) compared 73 male ADHD probands and 264 of their first-degree relatives with 26 psychiatrically referred but not ADHD children and 101 of their first-degree relatives, as well as 26 normal pediatric clinic control subjects and 92 of their first-degree relatives. The authors used interviewers who were unaware of the children's diagnostic status, and employed structured psychiatric interviews; they also controlled for sex, generation of relative, age of proband, social class, and the intactness of the family. Relatives of ADHD probands had higher morbidity risks for ADHD (25.1% vs. 5.3% vs. 4.6%,  $p < 0.00001$ ), antisocial disorders (24.3% vs. 6.9% vs. 4.2%,  $p < 0.00001$ ), and mood disorders (27.1% vs. 13.9% vs. 3.6%) than did relatives of psychiatric and normal control subjects. These findings indicated the importance of family–genetic factors in ADHD.

In an expanded study of 140 probands, 120 normal control subjects, and 822 first-degree relatives, [Biederman et al. \(1992\)](#) found nearly half (49%) of the subjects with ADHD had no comorbidity with conduct disorder, major depression, or multiple anxiety disorders. However, compared with control subjects, ADHD probands were more likely to have these conditions. Similarly, relatives of ADHD probands had a higher risk for ADHD (25% vs. 8%), antisocial disorders, major depression (26% vs. 9%), substance dependence, and anxiety disorders. Biederman and colleagues suggest that ADHD and major depression may show common familial vulnerabilities, that ADHD and conduct disorder may be distinct subtypes, and that ADHD and anxiety disorders are transmitted independently in families. The authors conclude that these results extend previous findings indicating family–genetic influences.

In summary, twin, sibling, adoption, and family studies all suggest a strong genetic component in the development of hyperactivity, inattention, and impulsivity. [Figure 28.1](#) clearly shows that these studies suggest heritability ranging from 0.5 to 0.98. This still leaves questions regarding the role and importance of environmental factors and the mode of inheritance.

**Figure 28.1.** Estimates of heritability from twin and family genetic studies. (Modified from Faraone SV, Biederman J: Neurobiology of attention deficit hyperactivity disorder. *Biol Psychiatry* 44:951–958, 1998.)

### Mode of Inheritance

Given the strong evidence of genetic influence in ADHD, several hypotheses have been presented as to the possible mode of genetic transmission. [Omenn \(1973\)](#) examined the possibility of sex-linked transmission, given the male preponderance in the condition. However, the author concluded that this was unlikely because of the high frequency of father-to-son transmissions. Morrison and Stewart suggested a polygenic mode of transmission, but could not substantiate it because of limitations of their sample size. A polygenic multiple-threshold model was suggested by [Rhee et al. \(1999\)](#) after analyzing sex differences in the extensive Australian twin and sibling pair study. [Deutsch et al. \(1990\)](#), studying dysmorphic children with ADHD, stated that the dysmorphic changes were consistent with a single-gene autosomal dominant inheritance. Tests of this model would require larger samples and more definitive diagnoses of both ADHD and dysmorphic phenotypes.

[Faraone et al. \(1992\)](#), using the data obtained from subjects and relatives studied by [Biederman et al. \(1992\)](#), applied segregation analysis to these data and suggested the data were consistent with the effects of a single gene. Similar results have been reported in a twin study by [Eaves et al. \(1993\)](#), a pedigree study by [Hess et al. \(1995\)](#), and a family study by Bailey et al. (1997a). Despite these findings suggesting a single gene, as [Faraone and Biederman \(1998\)](#) pointed out, differences in fit between genetic models were modest. This was particularly true for the comparison of multifactorial and single-gene inheritance. This has raised the suggestion that symptoms of ADHD may be caused by several interacting genes of modest effect. Such an idea is consistent with ADHD's high population prevalence and high concordance in monozygotic twins but modest recurrence risk to first-degree relatives.

To date, a specific definitive mode of inheritance has not been established, but work in this area is proceeding. However, [Pauls \(1991\)](#) points out that diagnostic uncertainty impedes progress in developing genetic models that address the type of genetic transmission involved. He argues for the importance of longitudinal studies of prospectively identified subjects and careful observation of their offspring as the best way to resolve some of the thorny methodologic difficulties of family and genetic studies.

### MOLECULAR GENETIC STUDIES

There has been a growing focus on molecular genetic studies to discover or pinpoint the abnormal gene or genes that cause symptoms of inattention, hyperactivity, and impulsivity and, thus, are implicated in the etiology of ADHD.

The molecular genetic studies, in general, can be divided into two large groups, the human studies ( [Table 28.1](#) ) and the animal studies ( [Table 28.2](#) ).

**Table 28.1. Summary of Human Molecular Genetic Findings**

Study	Gene	Findings
Gao et al., 1996	Dopamine transporter gene (DAT)	Hyperactive mice
	Downregulation of mRNA for D1 and D2 receptors	
Jacob et al., 1998	Plasma membrane dopamine transporter gene (DAT)	Hyperactive mice
	50% increase in striatal dopamine	
	300% increase in striatal dopamine	
Schneiders et al., 1998	Plasma membrane transporter gene (DAT)	Hyperactive mice
	Impaired spatial cognitive function	
	Locomotor response to psychostimulants depends on autoregulatory feedback	
Ku et al., 1994	Dopamine 1 receptor gene (D1)	Hyperactive mice
Ishii et al., 1995	Dopamine 2 receptor gene (D2)	Hyperactive mice
Aceti et al., 1996	Dopamine 2 receptor gene (D2)	Hyperactive mice
Rubenstein et al., 1996	Dopamine 4 receptor gene (D4)	Hyperactive mice, better coordinated
	Increased synthesis of dopamine in caudate and putamen	

**Table 28.2. Summary of Animal Molecular Genetic Studies—Dopamine Knockout Models**

In one of the early molecular genetic studies, [Hauser et al. \(1993\)](#) showed that a mutation in the thyroid receptor- $\beta$  gene, which causes generalized resistance to thyroid hormone, was associated with a high rate (61%) of hyperactivity and impulsivity (but not inattention) in affected individuals. However, the thyroid receptor- $\beta$  gene cannot be a major cause of ADHD because the prevalence of generalized resistance to thyroid hormone is very low (1/2,500) in patients with ADHD ( [Weiss et al., 1993](#) ), and the association between ADHD and the thyroid receptor- $\beta$  gene has not been found consistently ( [Weiss et al., 1994](#) ). However, the study sparked a great deal of interest and may have opened the door to the identification of specific genetic abnormalities in this condition.

Many of the molecular genetic studies have focused on genes involving dopamine because this neurotransmitter has been implicated in ADHD and its symptoms, both in neuroanatomic and pharmacologic treatment studies.

### Dopamine D2 Receptor Gene

In an early population-based association study, [Comings et al. \(1991\)](#) found that a genetic variant of the dopamine D2 receptor gene (DRD2; D2-A1 allele) was significantly increased in patients with Tourette's syndrome (44%,  $n = 147$ ), ADHD (46.2%,  $n = 104$ ), autism (54.5%,  $n = 33$ ), alcoholism (42.3%,  $n = 104$ ), and posttraumatic stress disorder (45.7%,  $n = 33$ ) compared with normal control subjects (24.5%,  $n = 77$ ). The prevalence of this allele was not significantly increased in patients with depression, panic attacks, Parkinson's disease, or obesity. However, because the D2-A1 gene is present in fewer than half of the individuals affected, the gene is not thought to be the primary cause of these disorders. The authors suggest that the DRD2 gene acts to modify the expression (making the symptoms better or worse) of the major gene or genes (yet to be discovered) that cause the condition.

More recently, [Rowe et al. \(1999\)](#), exploring the same DRD2 gene and using parental genotypes as controls to control for population heterogeneity, found no significant association or linkage between subjects with ADHD and this gene.

[Winsberg and Comings \(1999\)](#) investigated different dopamine genes and their relationship to methylphenidate response in African-American children with ADHD.

There was no relationship between the DRD2 gene and methylphenidate response.

We thus see that the association of the DRD2 gene with ADHD is neither specific nor consistent and, at present, lacks the promise of other dopamine genes [e.g., dopamine transport gene (DAT1) and the dopamine 4 receptor gene (DRD4)].

### Dopamine Transport Gene

In an early family-based association study, using the haplotype relative risk (HRR) design, [Cook et al. \(1995\)](#) showed an association between ADHD and the 480-bp allele of DAT1. This finding was replicated in a population-based study by [Waldman et al. \(1996\)](#). However, the authors found that the gene was associated not only with ADHD but also with conduct disorder, Tourette's syndrome, and obsessions. In a subsequent family-based study, which examined association and linkage, [Waldman et al. \(1998\)](#) found strong associations and linkage of ADHD with DAT1 with the combined but not inattentive subtype. [Cook and colleagues' \(1995\)](#) findings were further confirmed by [Gill et al. \(1997\)](#) in a family-based study of 40 probands and their parents using the same HRR design. These authors also found an association between ADHD and the DAT1 gene. Confirmation of the association of the DAT1 gene with ADHD also came from [Daly et al. \(1999\)](#) in another family-based study originating in Ireland.

The importance of the DAT1 gene (10-repeat allele) in ADHD was demonstrated by [Winsberg and Comings \(1999\)](#), who showed that homozygosity of this allele characterized nonresponse to methylphenidate in a group of African-American children with ADHD.

However, not all molecular genetic studies involving the DAT1 gene have shown a positive association with ADHD. [Crowe and Vieland \(1998\)](#) failed to replicate an association between ADHD and DAT1 with the 480-bp allele. Similarly, [Palmer et al. \(1999\)](#) indicated that in their large sample, they found no evidence of linkage or linkage disequilibrium between DAT1 and ADHD.

The aforementioned studies clearly suggest that the DAT1 gene may have an important role in the etiology of symptoms of ADHD. However, it may need to interact with a number of other genes to exert its effects. This would account for some of the divergent findings to date.

### Dopamine 4 Receptor Gene

Early interest in the DRD4 gene came from a population study by [Ebstein et al. \(1996\)](#), in which the authors showed that the seven-repeat allele of DRD4 was associated with novelty seeking. People with this trait are described as impulsive, exploratory, excitable, and quick tempered, characteristics frequently seen in people with ADHD. The association between the DRD4 gene and novelty seeking was replicated in a study by [Benjamin et al. \(1996\)](#), where population- and family-based measures were combined. However, another population-based study by [Malhotra et al. \(1996\)](#) failed to confirm this association.

[LaHoste et al. \(1996\)](#), in a population study, found higher rates of the seven-repeat allele of the DRD4 gene among children with ADHD compared with control children matched for sex and ethnicity. These results were maintained when the sample was increased by 50% ([Sunohara et al., 1997](#)). In a family-based study of 52 families, using a HRR design, [Swanson et al. \(1998b\)](#) also found a significant association between ADHD and the DRD4 (seven-repeat allele) gene. Confirmation also came from a study by [Smalley et al. \(1998\)](#) using affected sibling pairs and singleton families and the transmission disequilibrium test (TDT) and mean level of identity descent sharing. The TDT showed the seven-repeat allele is differentially transmitted to children with ADHD. [Rowe et al. \(1998\)](#) found a significant association with the seven-repeat allele of the DRD4 gene for combined and inattentive subtypes, but not the hyperactive/impulsive subtype of ADHD. [Bailey et al. \(1997b\)](#) found a similar association between ADHD and the DRD4 gene. [Faraone et al. \(1999\)](#) studied triads composed of an adult subject with ADHD, his or her spouse, and their child with ADHD. Using a multiallele TDT, they also reported an association between the DRD4 gene and ADHD.

Here too, however, the findings are not all consistent and uniformly positive. [Comings et al. \(1999b\)](#), in a population study involving 737 individuals from four different groups of control subjects and 707 index subjects from four different groups with impulsive, compulsive, addictive, drug abuse, and pathologic gambling behaviors, Tourette's syndrome, and ADHD, found no difference regarding the seven-repeat alleles of DRD4 in any of the groups, although some differences in those carrying any of the five and eight alleles were associated with pathologic gambling and ADHD. [Castellanos et al. \(1998\)](#) also found no association between the DRD4 seven-repeat allele and the 41 children with ADHD and 56 control subjects matched for ethnicity and sex. Furthermore, behavioral and anatomic MRI measures that previously discriminated ADHD and control subjects showed no significant difference between those with and without the DRD4 seven-repeat allele. Thus, this study did not support the association between DRD4 and ADHD. Finally, [Winsberg and Comings \(1999\)](#) found no association between DRD4 receptors and methylphenidate response in a group of African-American children with ADHD.

All these findings suggest an important role for the DRD4 seven-repeat receptor in ADHD. However, as with the DAT gene, the DRD4 gene may exert its influence in ADHD in combination with other genes and in conjunction with other neurotransmitter systems. There have been relatively few molecular genetic studies that have explored other genes and other neurotransmitter systems. Some of these studies are described in the following sections.

### Other Genes

#### DOPAMINE B-HYDROXYLASE GENE

[Daly et al. \(1999\)](#) conducted a family-based study using both the TDT method and HRR analysis. The authors found an association between ADHD and the dopamine b-hydroxylase (DBH) gene.

#### DOPAMINE 5 RECEPTOR GENE

In the same study, [Daly et al. \(1999\)](#) also explored the connection between the dopamine 5 receptor gene (DRD5) and ADHD and found a significant association, particularly in nonfamilial cases.

#### DOPAMINE 1 RECEPTOR GENE

[Thompson et al. \(1998\)](#) explored the association between the dopamine 1 receptor gene (DRD1) and Tourette's syndrome (n = 50), Tourette's syndrome with comorbid ADHD (n = 35), obsessive-compulsive disorder (n = 30), and alcohol dependence (n = 72), with 50 normal control subjects. The authors found no significant association between the DRD1 gene and these disorders and concluded that this gene was unlikely to contribute to the inheritance of these disorders.

#### CATECHOL-O-METHYLTRANSFERASE GENE

[Eisenberg et al. \(1999\)](#) conducted a family-based study of 48 child/parent triads with ADHD using a HRR design and a parent-to-proband allele transmission test. The authors found an association between the catechol- O-methyltransferase (COMT) gene (high activity COMT val allele) and the ADHD.

It is suggested that the high enzyme activity of the COMT val allele increases central nervous system (CNS) clearance of dopamine (and norepinephrine), thus resulting in lower CNS dopamine/norepinephrine levels, which may be important in the pathogenesis of the disorder because methylphenidate, which increases dopamine and norepinephrine turnover, is used in the treatment of the condition.

However, [Barr et al. \(1999\)](#) tested for linkage in 77 ADHD families, using functional polymorphism at codon 158, which determines COMT activity. The authors analyzed the data with the TDT and found no evidence of linkage of this polymorphism in their ADHD sample.

Clearly, more studies are needed to clarify the role of the COMT gene in ADHD.

#### ANDROGEN RECEPTOR GENE

The male predominance of externalizing behaviors suggest that the X-linked androgen receptor (AR) gene might be involved. [Comings et al. \(1999a\)](#) evaluated 302 Tourette's syndrome and control subjects. There was a significant association between AR gene haplotypes and ADHD, conduct disorder, and oppositional defiant

disorder (ODD), suggesting that variation in the human AR gene plays a role in externalizing disorders, including ADHD.

#### IMMUNE FUNCTION AND REGULATION GENES

[Odell et al. \(1997\)](#) explored the association of ADHD with alleles of two genes, the null allele of the C4B gene and the b-1 allele of the DR gene, both coding for products involved in immune function and regulation. The family-based study evaluated 31 subjects with ADHD and their parents and 10 normal control subjects. DR and C4B typing were performed by serologic human leukocyte antigen typing techniques and the DNA method, polymerase chain reaction–restriction fragment length polymorphism. Each of the alleles was found to be significantly associated with ADHD. Approximately 55% of subjects with ADHD carried both these alleles on one of their chromosomes, compared with 8% of normal control subjects. The authors conclude that genes related to the immune system may be associated with development of the symptom of ADHD.

#### Animal Molecular Genetic Studies (Dopamine Knockout Model)

A series of molecular genetic studies that have focused on dopamine genes and ADHD have involved animals (mostly mice) using a gene knockout techniques (see [Table 28.2](#)). These studies have explored the role of dopamine transporter and five dopamine receptors. [Giros et al. \(1996\)](#) showed that knocking out the dopamine transport gene resulted in a hyperactive mouse with some evidence of downregulation of the messenger RNA for D1 and D2 receptors. Thus, a relationship between hyperactivity and the dopamine system is suggested. [Jaber et al. \(1998\)](#) knocked out the plasma membrane dopamine transport gene and produced a hyperactive mouse with a 5% increase in intracellular dopamine and a 300% increase in extracellular dopamine. The importance of this gene in regulation of intracellular and extracellular dopamine is clear. [Gainetdinov et al. \(1999\)](#) also knocked out the plasma membrane transporter gene and similarly produced hyperactive mice who also had impaired spatial cognitive function. These mice had decreased locomotion in response to psychostimulants. However, the authors postulate that this response depended on serotonergic transmission. Thus, the interaction of dopamine and serotonin systems is suggested.

[Xu et al. \(1994\)](#) and [Accili et al. \(1996\)](#) knocked out the D1 and D3 receptor genes, respectively, and produced hyperactive mice, whereas [Baik et al. \(1995\)](#) and [Rubenstein et al. \(1996\)](#) knocked out the D2 and D4 receptor genes and produced hypoactive mice. However, D4 knockout mice were better coordinated and had increased synthesis of dopamine in the caudate and putamen.

These studies clearly show that the dopamine genes are part of an integrated system wherein dysfunction in one area results in compensatory mechanisms in other areas. The dopamine genes also undoubtedly are linked and integrated with genes involving other neurotransmitters. More detailed and extensive studies involving both animal models and human subjects will be needed to identify these complex interrelationships.

#### Summary of Molecular Genetic Studies

Most of the molecular genetic studies to date have focused on dopamine-related genes (e.g., DRD2, DAT1, DRD4, DBH, DRD5, DRD1). Replications of positive associations with ADHD have been seen most frequently with the DAT1 gene and the DRD4 seven-repeat allele. However, often these positive associations are not limited to ADHD but occur with other conditions as well, and so are not specific for ADHD. Furthermore, for each of these genes, there are some studies that have shown negative results that do not support the association. Clearly, more research is needed to clarify the role of these genes in ADHD.

#### Neuroanatomic Aspects

The complexity of trying to pinpoint particular neuroanatomic areas that might be involved in symptoms such as hyperactivity, impulsivity, and inattention can best be illustrated in the following example. [Mirsky \(1987\)](#), in his review entitled “Behavioral and Psychophysiological Markers of Disordered Attention,” makes the case that attention is not a single function but has various distinct and separate aspects such as focusing, executing, sustaining, and shifting attention. He further suggests that these different functions involve different brain regions that are interconnected and organized into a system. This attentional system is so widespread that it is very vulnerable to damage and dysfunction. Depending on where the damage or dysfunction occurs, different aspects of attention may be affected ([Fig. 28.2](#)).

**Figure 28.2.** Semischematic representation of brain regions involved in attention. **Left:** Some interconnections among the regions are shown. The connections are conceivably sufficient to support the concept of an attention system. **right:** Tentative assignment of functional specializations. (Reproduced with permission from Mirsky A: Behavioral and psychophysiological markers of disordered attention. *Environ Health Perspect* 74:191–199, 1987.)

Specifically, [Mirsky \(1987\)](#) suggests

the functions of focusing on environmental events are shared by superior temporal and inferior parietal cortices, as well as by structures that comprise the corpus striatum, including caudate, putamen, and globus pallidus. The inferior parietal and corpus striatal regions have strong motor executive functions. Considerable amounts of encoding of stimuli are accomplished by the hippocampus, an essential mnemonic function that seems to be required for some aspects of attention. The capacity to shift from one salient aspect of the environment to another is supported by the prefrontal cortex. Sustaining a focus on some environmental event is the major responsibility of rostral structures, including the tectum, mesopontine reticular formation and midline, and reticular thalamic nuclei (p. 197).

In a similar recent outline, [Faraone and Biederman \(1999\)](#) suggested

It is likely that a network of interrelated brain areas is involved in the attentional-executive impairments of ADHD children. The cingulate cortex plays a role in motivational aspects of attention and in response selection and inhibition. A system mainly involving right prefrontal and parietal cortex is activated during sustained and directed attention across sensory modalities. The inferior parietal lobule and superior temporal sulcus are polymodal sensory convergence areas that provide a representation of extrapersonal space which plays an important role in focusing on and selecting a target stimulus. The brainstem reticular activating system and reticular thalamic nuclei regulate attentional tone and filter interference, respectively. Working memory deficits implicate a distributed network including anterior hippocampus, ventral anterior and dorsolateral thalamus, anterior cingulate, parietal cortex, and dorsolateral prefrontal cortex (p. 795).

Thus, there is a consistent suggestion that problems of attention, impulsivity, and hyperactivity involve abnormalities in the frontocortical and subcortical systems, particularly prefrontal and basal ganglia areas ([Casey et al., 1997](#); [Castellanos, 1997](#); [Faraone and Biederman, 1999](#); [Swanson et al., 1998a](#); [Zametkin et al., 1998](#)).

It therefore is not surprising that, in their early review of the literature, [Zametkin and Rapoport \(1987\)](#) showed that over the years a wide variety of brain areas have been implicated in these symptoms by various authors.

More recently, neuroimaging studies have provided more direct evidence of possible areas of brain abnormalities in subjects with symptoms of inattention, hyperactivity, and impulsivity. These studies involve either structured or functional imaging. CT and MRI provide structured images, whereas SPECT and PET

produce functional images. These latter studies require ionizing radiation and have thus been associated with ethical concerns regarding the study of children and normal control subjects. Functional MRI (fMRI) studies hold promise because they do not require ionizing radiation and combine both types, allowing structural and functional views by measuring blood flow.

Table 28.3 summarizes various types of neuroimaging studies involving subjects with problems of attention, impulsivity, and hyperactivity. As can be seen from the table, studies vary in methods used (e.g., CT, MRI, fMRI, PET, SPECT), subjects studied (e.g., male and female; children, adolescents, adults; medicated, unmedicated; control subjects used—normal control subjects, matched on various parameters, sibling controls), and areas of the brain investigated (e.g., cortical, subcortical). Therefore, it is not surprising that findings of the various studies vary considerably. However, a certain consistency does emerge. Many studies (Amen et al., 1993; Casey et al., 1997; Castellanos et al., 1996; Ernst et al., 1994; Filipek et al., 1997; Hynd et al., 1990; Lou et al., 1984; Rubia et al., 1999; Semrud-Clikeman et al., 2000; Sunshine et al., 1997; Zametkin et al., 1990, 1993) have found a decrease in function (blood flow or glucose metabolism) in the frontal lobes, particularly the prefrontal cortex. Some found this abnormality only on the right (Castellanos et al., 1996; Filipek et al., 1997), whereas others did not. Another consistent finding involving the cerebral cortex is a smaller cerebellum (Berquin et al., 1998; Castellanos et al., 1996; Mostofsky et al., 1998; Nasrallah et al., 1986). Mostofsky et al. (1998) and Berquin et al. (1998) indicated that the decrease was specifically in the posterior vermis of the cerebellum. The anterior cingulate cortex has been shown to have decreased activity in subjects with ADHD (Bush et al., 1999; Zametkin et al., 1990), as has the temporal lobe (Ernst et al., 1994).

**Table 28.3. Neuroimaging Studies**

Several studies have shown a smaller corpus callosum in subjects with ADHD (Giedd et al., 1994; Hynd et al., 1991; Semrud-Clikeman et al., 1994). The findings in other cortical areas appear less consistent. The parietal lobe was found to be smaller in subjects with ADHD by Filipek et al. (1997), but had more activation according to Sunshine et al. (1997) and was found to be hyperperfused by Lou et al. (1989). Similarly, the occipital lobe was found to be smaller in subjects with ADHD by Filipek et al. (1997) but hyperperfused by Lou et al. (1984, 1989, 1990) and Schweitzer et al. (2000). The suggestion is that the increased activity in the parietal and occipital areas during tasks may, in fact, contribute to the distraction and inattention of the subjects with ADHD.

The other area of the brain that has been consistently implicated in ADHD is the striatal area, consisting of the basal ganglia with its caudate nuclei, nucleus accumbens, globus pallidus, and putamen. Specifically, decreased activation and right hyperperfusion were noted by Vaidya et al. (1998) and Lou et al. (1989), respectively.

A smaller globus pallidus was noted in three studies, although Singer et al. (1993) and Aylward et al. (1996) both stipulated a smaller left globus pallidus, whereas Castellanos et al. (1996) pinpointed a smaller right one.

Similarly, a smaller caudate nucleus was suggested in several studies, with a smaller left caudate nucleus identified by Filipek et al. (1997), Casey et al. (1997), and Semrud-Clikeman et al. (2000), whereas Castellanos et al. (1996) and Zametkin et al. (1990) both pointed to a smaller right caudate nucleus. These differences may be associated with the larger number of female subjects in the studies by Castellanos et al. (1996) and Zametkin et al. (1993). Decreased functioning of the caudate nucleus was documented through hypoperfusion by Teicher et al. (1996), and decreased response by Rubia et al. (1999). Only one study (Mataro et al. 1997), involving adolescents with ADHD, showed a larger right caudate nucleus and suggested this was evidence of immature development in this area with decreased reabsorption.

Although few studies have documented any abnormalities in the putamen, Ernst et al. (1994) suggested decreased activity in the right and left posterior putamen in girls with ADHD.

Substriatal structures such as the thalamus and the hippocampus also have been shown to be less active in subjects with ADHD. Specifically, Zametkin et al. (1990) showed the right thalamus to be less active. Subsequently, Zametkin et al. (1993) and Ernst et al. (1994) showed that the left thalamus was smaller. These later studies had more female subjects. Decreased activity of the hippocampus was consistently shown to be on the right by Zametkin et al. (1990, 1993) and Ernst et al. (1994).

In summary, neuroimaging studies suggest decreased size and activity in the frontal lobes, particularly the prefrontal area. A smaller corpus callosum and cerebellum and decreased activity in the anterior cingulate also have been consistently found.

Decreased activity in the striatal area also has been shown. A smaller and less active globus pallidus and caudate nucleus have both been documented, although in some studies this is on the right, in others on the left. Decreased activity in substriatal structures (e.g., thalamus and hippocampus) also has been documented.

These findings have led to the hypothesized interconnecting cortico-thalamic-cortical system with a reciprocal excitatory and inhibition network of these areas as illustrated by Swanson et al. (1998a) and described by Castellanos (1997).

## NEUROCHEMICAL ASPECTS OF ADHD

### Neuroanatomic Studies of Neurotransmitters

Even though some areas of the brain have been clearly associated with certain neurotransmitters, such as the caudate nucleus and corpus striatum with dopamine (Mattes, 1980) and the median raphe area with serotonin (Wirtshafter et al., 1986), neuroanatomic studies of neurotransmitters have proven very complex. The complexity comes from the fact that any particular area can be involved with several different neurotransmitters or receive projections from various neurotransmitter pathways or nuclei. Thus, there rarely is a one-to-one correspondence between a particular area and a sole neurotransmitter that exerts exclusive influence on this area.

Hence, we see that the frontosubcortical systems (identified previously) that control attention and motor behavior are rich in catecholamines. The catecholamine hypothesis therefore has been popular as an explanation for the abnormalities of attention, hyperactivity, and impulsivity seen in subjects with ADHD (Oades, 1987; Pliszka et al., 1996). This hypothesis emphasizes the central role of dopamine (Castellanos, 1997) and norepinephrine (Arnsten et al., 1996; Mefford and Potter, 1989).

### NONPHARMACOLOGIC STUDIES OF NEUROTRANSMITTERS AND THEIR METABOLITES

These types of studies have compared subjects with symptoms of hyperactivity, impulsivity, and inattention and normal control subjects with respect to monoamines and their metabolites in urine, plasma, platelets, and, rarely, cerebrospinal fluid (CSF). The limitations of such peripheral measures in reflecting an accurate CNS neurotransmitter picture are well outlined by Zametkin and Rapoport (1986). A comprehensive review and outline of these types of studies was carried out by Zametkin and Rapoport (1987) and is summarized in Table 28.4. In general, no consistent differences in any of the peripheral measures of monoamines and their metabolites were found between children with these symptoms and normal control subjects. However, in a series of studies conducted at the National Institute of

Mental Health, Castellanos et al. (1994, 1996) showed a positive correlation between levels of hyperactivity and the CSF concentration of homovanillic acid (HVA; the peripheral dopamine metabolite) in boys diagnosed with ADHD. Furthermore, the HVA concentration in CSF was a good predictor of the therapeutic response to methylphenidate, dextroamphetamine, and pemoline. The boy with the greatest CSF HVA concentration had the best responses to treatment. These findings were consistent with an earlier study (Shetty, 1973) showing that postamphetamine decreases in CSF HVA were highly correlated with behavioral improvement.

Investigator	ADHD	Control	Age	Method	Findings
Boyd and Chubb, 1975	28	18	10-12	CSF	No differences in HVA
Boyd et al., 1977	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1981	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1982	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1983	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1984	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1985	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1986	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1987	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1988	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1989	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1990	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1991	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1992	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1993	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1994	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1995	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1996	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1997	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1998	15	15	10-12	CSF	No differences in HVA
Boyd et al., 1999	15	15	10-12	CSF	No differences in HVA
Boyd et al., 2000	15	15	10-12	CSF	No differences in HVA

### PSYCHOPHARMACOLOGIC STUDIES OF NEUROTRANSMITTERS

These types of studies look at the particular psychopharmacologic agent, its possible relationship to one or more neurotransmitters, and its clinical effect. From such analysis, it is then postulated how the drug may work and what the possible underlying problem in the neurotransmitter system may be.

Again, [Zametkin and Rapoport \(1987\)](#) provide an excellent review and summary of such studies. More recently, [Biederman and Spencer \(1999\)](#) reviewed various types of psychopharmacologic agents, including stimulants; noradrenergic agents (e.g., tricyclic antidepressants, bupropion, monoamine oxidase inhibitors, tomoxetine);  $\alpha_2$ -noradrenergic agonists (clonidine and guanfacine); as well as serotonergic and mixed serotonergic-noradrenergic agents.

The authors concluded that agents effective in ADHD tend to have adrenergic/dopaminergic activity. Thus, stimulants are thought to be involved in blocking the reuptake of dopamine and norepinephrine into the presynaptic neuron and increasing the release of these monoamines into the extraneuronal space by altering monoaminergic transmission. [Wang et al. \(1995\)](#) used PET scans with [ $^{11}\text{C}$ ]-methylphenidate to show its binding to dopamine transporter after intravenous administration to normal adults. Methylphenidate binding localized to the basal ganglia (putamen, caudate, and ventrostriatum) and the cortex (temporal insula and cingulate gyri). [Volkow et al. \(1998\)](#), using similar techniques, showed that the transport binding and clearance times corresponded to clinical effect, and the degree of blocking of dopamine transport was dose dependent. [Ding et al. \(1997\)](#) showed that the D-threo isomer and not the L-threo isomer, which comprises 50% of commercially available methylphenidate, binds selectively to the dopamine transporter.

In general, the tricyclic antidepressants are thought to be less effective than the stimulants. The tricyclic antidepressants, particularly the secondary amines (desipramine, nortriptyline, and protriptyline), are thought to be involved in the transport and reuptake of norepinephrine. Bupropion, also shown to be effective in ADHD, is thought to possess both indirect dopamine agonist and noradrenergic effects. Tomoxetine, an experimental noradrenergic-specific compound, has shown some promising results for adults ([Spencer et al. 1998](#)) and children ([Spencer et al., 1999](#)) with ADHD. Controlled studies with  $\alpha_2$ -adrenergic agonists are limited.

Serotonergic and mixed serotonergic/noradrenergic agents appear to be less effective in ADHD than stimulants, suggesting a lesser role of serotonin in ADHD. Clinically, selective serotonin reuptake inhibitors have not been found to be effective for ADHD symptoms ( [National Institute of Mental Health, 1996](#)). [Ernst et al. \(1997\)](#) evaluated the effect of selegiline, a selective monoamine oxidase type B inhibitor, which is thought to affect serotonin metabolism; selegiline affected monoamine metabolites and dopamine plasma levels, as well as producing clinical changes, suggesting the involvement of several neurotransmitter systems.

However, findings for the mixed serotonergic/noradrenergic atypical antidepressant venlafaxine are unclear. Although response rates of 77% in adults with ADHD ([Adler et al., 1995](#); [Findling et al., 1996](#); [Hornig-Rohen and Amsterdam, 1995](#); [Reinherr et al., 1995](#).) and 50% in children with ADHD ([Luh et al., 1995](#)) have been reported, dropout rates due to side effects (particularly increased hyperactivity) have been high at 21% and 25%, respectively.

In general, pharmacologic studies support the importance of the catecholamines, dopamine, and norepinephrine in ADHD, with a less prominent role for serotonin.

#### Dopamine

There is much evidence to support the importance of dopamine in ADHD. The neuroanatomic areas implicated in this condition (cortical-striatal-thalamic-cortical network) are known to be areas of dopamine concentration. Molecular genetic studies have suggested the involvement of a dopamine transport gene and various dopamine receptor genes, particularly the DRD4 and DRD2 genes. Stimulant agents, which are very effective for ADHD symptoms, are known to be involved in binding the dopamine transporter and thus preventing reuptake of dopamine into presynaptic nuclei.

[Ernst et al. \(1999\)](#), using PET and the tracer [ $^{18}\text{F}$ ]-fluorodopa, showed that the accumulation of [ $^{18}\text{F}$ ]-fluorodopa in the right midbrain was 48% higher in 10 children with ADHD compared with 10 normal control subjects and was correlated with symptom severity. Finally, various studies using animal models ([Boix et al., 1998](#); [Fahlke and Hansen, 1999](#); [Russell et al., 1998](#)) also have implicated dopamine and its associated structures.

#### Noradrenergic Hypothesis

The noradrenergic system also has been implicated in a number of ways. [Mefford and Pothier \(1989\)](#) hypothesized that an imbalance in tonic epinephrine formation would disrupt the normal inhibition of locus ceruleus neurons, resulting in inattention, distractibility, sleeping difficulties, and some cognitive deficits. The authors suggested that this may be the underlying problem in ADHD.

[Oades et al. \(1998\)](#) showed that plasma levels of norepinephrine and epinephrine were slightly elevated, but urinary levels of norepinephrine and serotonin metabolites were markedly elevated in children with ADHD versus healthy control subjects. Similarly, [Halperin et al. \(1997\)](#) showed that plasma levels of the noradrenergic metabolite 3-methoxy-4 hydroxyphenylglycol were higher in children with ADHD and reading disabilities compared with such children without reading disabilities. [Pliszka et al. \(1996\)](#) reviewed a large number of studies involving plasma and urinary levels of epinephrine and concluded that children with ADHD may show higher levels of norepinephrine activity and lower levels of epinephrine activity.

[Biederman and Spencer \(1999\)](#) clearly reviewed the studies showing the efficacy of noradrenergic agents, such as tricyclic antidepressants, bupropion, monoamine oxidase inhibitors, novel adrenergic agents, tomoxetine, and a  $\alpha_2$ -noradrenergic agonist (clonidine and guanfacine) in subjects with ADHD. The efficacy of these noradrenergic agents suggests the importance of the noradrenergic system in this condition.

#### Serotonergic Hypothesis

This hypothesis is based on the fact that serotonin-depleted animals show increased aggression and hyperactivity. In addition, hyperactive subjects have shown inconsistent changes in platelet and blood 5-hydroxytryptamine (serotonin). The hypothesis was supported by results of drug studies involving tricyclic antidepressants and monoamine oxidase inhibitors, which affect serotonin metabolism and are moderately effective for the symptoms of hyperactivity, impulsivity, and inattention. However, pharmacologic studies involving L-tryptophan, a serotonin precursor ([Nemzer et al., 1986](#)), and fenfluramine, which acutely increases and then depletes brain serotonin, showed no consistent results.

Similarly, in a small open study, [Barrickman et al. \(1991\)](#) suggested fluoxetine (a selective serotonin reuptake inhibitor) may be beneficial in treating children with ADHD. Most clinical experience ([National Institute of Mental Health, 1996](#)) did not support this finding. However, [Spivak et al. \(1999\)](#) showed that children with severe ADHD tended to have lower blood levels of serotonin compared with children with mild ADHD.

[Roffman and Raskin \(1997\)](#) also implicated the serotonergic system when they showed in an animal study that the serotonin synthesis inhibitor p-chlorophenylalanine significantly affected stimulant-induced stereotypic behavior in these animals. However, it can be concluded that if serotonin plays a role in ADHD, it is not a central but rather an adjunctive role to one or more of the other neurotransmitters.

#### *Nonspecific Catecholamine Hypothesis*

It is clear from the foregoing discussion of specific neurotransmitter systems that not one but several neurotransmitter systems are involved in ADHD. In an early review, [Zametkin and Rapoport \(1987\)](#) concluded that there is no basis to believe that a single neurotransmitter abnormality is responsible for symptoms of ADHD. Subsequently, [Rogeness et al. \(1992\)](#) reviewed the three main neurotransmitters that may influence behavior problems in children: dopamine, norepinephrine, and serotonin. They suggested that ADHD is best understood by the *interaction* of multiple neurotransmitters. Specifically, they stressed that the *balance* between the norepinephrine and dopamine systems is critical, rather than variations in the individual systems. Furthermore, the authors stated that the development of individual systems from infancy to adulthood is influential on behavior because this process affects the relative activity of the systems based on neuronal maturation. Hence, results of past studies may have been confusing because multiple neurotransmitters were not studied at once and narrow age ranges were not used.

[Pliszka et al. \(1996\)](#) also presented a multistage hypothesis, which emphasized the interaction of norepinephrine, epinephrine, and dopamine in the modulation of attention and impulsivity.

[McCracken \(1991\)](#) was more specific in his hypothesis and stated that for a drug to be effective in treating ADHD, it needed to increase both dopamine release and adrenergic inhibition in the locus ceruleus.

Similarly, [Mercugliano \(1995\)](#) stressed that the most effective drugs in the treatment of ADHD are those that increase transmission of dopamine and norepinephrine.

[Arnsten et al. \(1999\)](#) also stressed the importance of optimal levels of norepinephrine and dopamine receptor stimulation. The authors suggest that too little or too much receptor stimulation in response to stress impairs neuronal activity in the prefrontal cortex and subsequent cognitive function, such as working memory. Further support for the interrelation and importance of norepinephrine and dopamine has been provided by [Lanau et al. \(1997\)](#), who showed that both transmitters are potent agonists at the dopamine D4 receptor.

#### *Other Neurotransmitters*

Other neurotransmitters, such as g-aminobutyric acid (GABA), which is thought to be a predominantly inhibiting neurotransmitter in the CNS, and histamine, which acts centrally and peripherally, have not been studied in relation to the symptoms outlined, but may be implicated in the future.

[Mrzljak et al. \(1996\)](#), however, pointed out that dopamine D4 receptors are abundant in GABAergic interneurons in prefrontal cortex. Furthermore, [Prosser et al. \(1997\)](#) showed that plasma GABA levels were elevated in nonmedicated behaviorally disordered children. These levels were seen to be lower after medical treatment.

[Passani et al. \(2000\)](#), in an extensive review of the neurotransmitter histamine, suggest that although the neurotransmitter is found in the tuberomammillary nuclei of the hypothalamus, these cells' widespread projections to the cerebral cortex, thalamus, and pontomesencephalic tegmentum extend its effect to many functions. The histaminergic system is thought to act as a regulatory center for whole-brain activity. It also is thought to be involved in the regulation of physiologic functions and behavior, including learning and memory. Histamine's effects on cognition might be explained by its modulation of the cholinergic system.

Clearly, little research has involved these other neurotransmitter systems that also may play a role in the symptoms of inattention, hyperactivity, and impulsivity.

In summary, much work remains to be done in trying to untangle the role and relative importance of the various neurotransmitter systems, their interaction, the regulation of an optimal balance, and all the factors that may disrupt this interaction and balance.

#### *NEUROENDOCRINE ASPECTS*

The interest in neuroendocrine aspects in children with symptoms of hyperactivity, impulsivity, and inattention comes from two main but interrelated areas. The preceding discussion suggested that norepinephrine, dopamine, and serotonin may be involved in the symptoms described. However, these same neurotransmitters are known to affect hormone production and release in the anterior pituitary and thus affect the hypothalamic–pituitary–adrenal axis and the hypothalamic–pituitary–growth hormone axis. Reports of possible growth suppression in children given stimulants to treat symptoms of hyperactivity, impulsivity, and inattention have resulted in considerable interest in the growth hormone axis in these children. A number of studies investigated growth hormone levels in children with these symptoms on and off stimulant medication and in matched, normal control subjects. In a series of studies, [Greenhill and colleagues \(1981\)](#) showed no change in the sleep-related pattern of human growth hormone secretion before or after treatment with dextroamphetamine. An insulin tolerance test also showed no differences in growth hormone response. However, boys who received long-term methylphenidate treatment for their symptoms showed elevations of sleep-related growth hormone compared with normal control subjects ([Greenhill et al., 1984](#)). [Shaywitz et al. \(1982\)](#) studied hyperactive children treated with methylphenidate and found that growth hormone levels increased with plasma levels of methylphenidate, both peaking at the same time. [Garfinkel et al. \(1986\)](#), exploring the effect of dextroamphetamine in hyperactive adolescents, found that the growth hormone response in these subjects was greater than that of normal control subjects and that it peaked at the point of maximal absorption and clinical effect of the amphetamine. [Weizman et al. \(1987\)](#) studied the effects of acute and chronic methylphenidate administration on b-endorphin, growth hormone, prolactin, and cortisol levels in children with these symptoms. They found that with chronic use of methylphenidate, the results of growth hormone challenge tests were augmented. [Hunt and colleagues \(1984\)](#) demonstrated growth hormone response to clonidine administration in a similar group of children.

The complexity of the neuroendocrine issue has been well illustrated by [Jensen and Garfinkel \(1988\)](#), who looked at prepubescent and pubertal hyperactive and control children and measured their growth hormone response to L-dopa and clonidine challenges. They found that the growth hormone response was lower in the prepubescent children, and also lower to the L-dopa than to the clonidine challenge. In addition, the response in the hyperactive children was lower than that in control subjects. This clearly suggests that both the dopamine and norepinephrine systems are involved in growth hormone release and that this process is affected by pubertal development and stimulant medication.

The interest in thyroid hormone and its association with symptoms of hyperactivity and impulsivity was first sparked by [Hauser et al. \(1993\)](#) when they reported high rates of these symptoms in people affected by a genetic disorder that causes generalized resistance to thyroid hormone. However, this is a very rare condition, and subsequent studies (e.g., [Toren et al., 1997](#)) that have explored thyroid function in children with ADHD showed no thyroid abnormalities in these children. [Sawada et al. \(2000\)](#) suggested that given the significant sex difference in ADHD prevalence, estrogen may exert a neuroprotective role and thus prevent the development of the condition. Possible mechanisms for the neuroprotective effects of estrogen suggested by the authors included protection of estrogens as transcription factors and protection against oxidative stress by estrogens acting as antioxidants.

Conversely, [King et al. \(2000\)](#) found that in an animal model involving spontaneously hypertensive rats (SHR), which have been used as an animal model for ADHD, early testosterone treatment of SHR resulted in additional deficits in spatial memory in the water maze. In addition, the SHR had high basal adrenocorticotropic hormone and low corticosterone levels, suggesting a dysfunctional stress axis similar to that in humans with persistent ADHD (for review, see [Ryan, 1998](#)). Finally, there also was a further suppression of tyrosine hydroxylase immunoreactivity in the frontal cortex of androgen-treated SHR. The authors thus suggest that early androgen treatment may enhance the expression of hyperactivity and inattention in genetically predisposed animals and subjects.

In summary, neuroendocrine systems, particularly the hypothalamic–pituitary–adrenal axis, may be involved in ADHD. Involvement of growth hormone, cortical estrogen, and androgen have all been suggested. However, to date, the few studies that have been done had small, diverse populations. Clearly, more well-controlled

research is needed on young, prepubertal and pubertal populations to help clarify the role of neuroendocrine systems in this condition.

## NEUROPHYSIOLOGIC ASPECTS

In an effort to determine whether neuronal responses differ significantly in children with symptoms of hyperactivity, impulsivity, and inattention, researchers have examined the central and peripheral neural conducting responses in children with these symptoms. Centrally, these studies have involved EEGs and evoked potential recordings, and peripherally they have focused on motoneuron excitability. In reviewing many of these neurophysiologic studies ( [Weiss and Hechtman, 1993](#)), one is struck by the variability of the findings and the difficulty in coming to firm conclusions.

It has been estimated ( [Cantwell, 1980](#)) that 35% to 50% of children with ADHD symptoms may have abnormal EEGs. The most common abnormality reported involves diffuse, nonspecific changes and extensive slow EEG activity ( [Grunwald-Zuberbier et al., 1975](#); [Satterfield, 1973](#)). [Shetty \(1973\)](#), in his series of 75 hyperactive subjects, indicated that the most consistent abnormality was the absence of an appropriate amount of well-organized alpha waves for age.

Another EEG abnormality that has been described in hyperactive children involves difficulties with attenuation of alpha waves, which presumably reflects the decreased capacity of these children to stop attending to redundant events ( [Fuller, 1977](#)).

All of the aforementioned abnormalities have been described as immature patterns and interpreted as representing delayed CNS maturation in these children. Some support for this hypothesis was provided by [Hechtman and colleagues \(1978\)](#) when they compared sequential EEGs of hyperactive children, adolescents, and young adults and found increasing normalization of EEGs with increasing age, particularly in late adolescence.

Evoked potential studies have been inconclusive, giving conflicting results. [Satterfield \(1973\)](#) reported that the auditory evoked potentials in hyperactive subjects had longer latencies and lower amplitudes compared with age-matched control subjects. On the other hand, [Buchsbau and Wender \(1973\)](#), studying visual and auditory average evoked responses, showed increased latencies and higher amplitudes with increases in intensity of visual stimuli. Age- and sex-matched control subjects showed lesser increases in amplitude and decreases in latency. [Hall et al. \(1976\)](#), recording evoked potentials in response in four stimulus intensities under conditions of attention and inattention, found no differences in stability, amplitude, or latency between hyperactive children and control children. Most of these studies recorded evoked potentials at one or, at most, a few electrode sites.

[Satterfield et al. \(1988b\)](#) conducted a study on 20 6-year-old children with attentional problems and 20 matched, normal control subjects, using 19 recording sites and 2 choice discrimination tasks. They concluded that the children with attentional problems had abnormalities in the mismatch process, resulting in poor discrimination of salient stimuli. This is an automatic process not under voluntary control. It is thought to be a component of a basic orienting response that is mediated by the reticular activating system in unanesthetized animals ( [Aston-Jones, 1985](#)). A second abnormality found by [Satterfield et al. \(1988a\)](#) involved frontal processing negativity, reflecting additional processing (e.g., rehearsing of the standard in memory) of the attended stimulus. This activity is thought to be under voluntary control. Thus, the multisite recording studies illustrate the great complexity of these functions.

More recently, [Baving et al. \(1999\)](#) obtained baseline EEG recordings in 117 children (66 aged 4 years, 51 aged 8 years) with ADHD. The recordings were subjected to power spectral analysis and laterality scores were obtained. Boys with ADHD exhibited less right-lateralized frontal activity pattern than normal control boys. Girls with ADHD displayed more right-lateralized frontal activity pattern than normal control girls. This finding applied to children in both the age groups. The authors point out that this pattern of frontal brain activation is consistent with MRI studies of ADHD.

[Halliday and colleagues \(1983\)](#) investigated the effect of methylphenidate on visual evoked potentials in hyperactive children and concluded that the evoked response potential measures were more sensitive to age and attention conditions and less to methylphenidate dose. Peripheral studies that have looked at motoneuron excitability also give conflicting results. Thus, [Pivik and colleagues \(1986\)](#) showed that some hyperactive children had significantly elevated, whereas others had significantly depressed responses compared with matched control subjects.

The divergent, inconsistent, and inconclusive findings of these neurophysiologic studies may be related to the fact that we are attempting to understand complex, multifaceted central processes using fairly gross and perhaps nonspecific peripheral measures. Recent technological advances, which include measures of cerebral blood flow and glucose utilization, and positron-emitting liquids that can label and quantitate specific neurotransmitter receptors, will enable researchers to examine the functions of hyperactivity, impulsivity, and inattention with much greater precision centrally and peripherally, and may shed light on the many questions that remain.

## CONTRIBUTING PSYCHOSOCIAL FACTORS

In this section, we discuss possible psychosocial factors that can give rise to or complicate symptoms of hyperactivity, impulsivity, and inattention. Furthermore, these symptoms can significantly affect the person's emotional, social, and academic development. It is clear that relationships with parents, teachers, and peers, academic success, and self-esteem are all directly or indirectly influenced by these symptoms. Needless to say, these social and emotional parameters may in turn affect self-esteem and motivation and further augment the handicaps associated with the primary symptoms. Thus, the biological, social, academic, and emotional spheres all are interrelated and significantly and continually influence each other.

### Environmental Factors

It has been suggested that the physical environment may significantly contribute to the development or worsening of symptoms of hyperactivity, impulsivity, and inattention. Some authors (e.g., [Needleman, 1983](#)) have suggested that children living in environments where they are exposed to high lead levels are more likely to develop such symptoms. Lead, however, cannot account for the bulk of ADHD cases. Many children with ADHD symptoms show no lead contamination, and many children with high lead exposure do not acquire ADHD.

The idea that certain foods may contribute to the development of ADHD received attention when it was claimed that ADHD could be cured by eliminating food additives from the diet ( [Feingold, 1975](#)). However, systematic studies showed that diet was not effective and concluded that food additives do not cause ADHD ( [Conners, 1980](#)). Another dietary theory suggested that excessive sugar intake can lead to symptoms of hyperactivity, impulsivity, and inattention. Although some studies seemed to support this hypothesis, most systematic, controlled studies did not ( [Wolraich et al., 1995](#)).

The association between ADHD symptoms and pregnancy and delivery complications is not consistently positive, but on balance, the literature supports the idea that pregnancy and delivery complications can predispose children to ADHD ( [Sprich-Buckminster et al., 1993](#)). The specific pregnancy and delivery complications that have been implicated include toxemia or eclampsia, poor maternal health, maternal age, fetal postmaturity, long duration of labor, fetal distress, low birth weight, and antepartum hemorrhage.

Maternal smoking during pregnancy has been shown to increase the risk of antepartum hemorrhage, low maternal weight, low fetal weight, and abruptio placentae ( [Kline et al., 1989](#)). Maternal smoking also increases carboxyhemoglobin levels in both maternal and fetal blood, thus increasing the risk of fetal hypoxia ( [Fielding, 1985](#)). Both low birth weight and fetal hypoxia have been implicated in the etiology of ADHD. Maternal smoking also exposes the fetus to nicotine, which can damage the brain at critical times in the developmental process. Animal studies of pregnant mice and rats have shown a positive association between chronic exposure to nicotine and hyperactive offspring ( [Johns et al., 1982](#); [Slotkin et al., 1993](#); [Van de Kamp and Collins, 1994](#)).

It is unclear how significant a physically chaotic environment may be in contributing to the development of symptoms of hyperactivity, impulsivity, and inattention, although such an environment certainly is important in maintaining and augmenting these difficulties.

The prevalence of children with hyperactivity, impulsivity, and inattention is greater in disadvantaged, larger inner city environments. However, such settings also have more poverty, malnutrition, poor prenatal, perinatal, and neonatal health care, and more family violence. Any combination of these factors also may play a significant contributory role in the development and perpetuation of these symptoms.

Similarly, a school or classroom setting that is very unstructured or disorganized has a detrimental effect on children with these symptoms, causing their behavior to

deteriorate and their learning and academic achievement to be significantly impaired.

[Taylor \(1985\)](#) has pointed out the importance of cultural, social, and family variables in learning to focus attention and control impulsivity and hyperactivity. This process of socialization may be influenced by characteristics of the parents, the child, and the reciprocal interactions that develop between them. Increased psychopathology has been reported in parents of children with hyperactivity, impulsivity, and inattention ([Morrison, 1980](#); [Stewart et al., 1980](#)). This may suggest the genetic vulnerability of these children, but it also may result in problematic parenting, which can contribute to the development or perpetuation of these symptoms in the child. Parenting styles of parents whose children have symptoms of hyperactivity, impulsivity, and inattention have been looked at by a number of authors ([Campbell, 1973](#); [Humphries et al., 1978](#); [Mash and Johnston, 1982](#)). In general, these researchers found that parenting styles tended to more intrusive, controlling, and disapproving (particularly in structured tasks as opposed to free play) compared with parents of age-matched, normal control subjects. This negative parenting style improved significantly when the child's behavior improved because of stimulant medication treatment ([Humphries et al., 1978](#)). It therefore was concluded by [Humphries et al. \(1978\)](#) that the parents were responding to the child's behavior and not causing it. [Mash and Johnston \(1983\)](#) showed that having a child with these difficulties affects the parents' confidence in their parenting skills and results in more reported stress, social isolation, self-blame, and depression in the parents. We can, thus, clearly see the effects of this negative parenting style on the child's emotional development, competence, and self-esteem. Similarly, the child's problems affect the parents' sense of effectiveness and emotional well-being, which, in turn, reverberates in their interactions and relationship with their child. The same vicious cycle of negative interactions, stress, and sense of failure for both child and teacher can become established in the school, with similar detrimental effects.

It has been suggested that the symptoms of hyperactivity, impulsivity, and inattention may be expressions of underlying anxiety or depression. [Tizard and Hodges \(1978\)](#) showed that overactivity and inattention were prominent in children growing up in institutions. It is hypothesized that the underlying anxiety resulting from a lack of secure and stable relationships is expressed through these symptoms. Similarly, children raised in a disturbed family environment may experience similar insecurities and anxieties and express these feelings in a similar way. Children can show symptoms of hyperactivity, impulsivity, and inattention during acute periods of stress. However, these periods usually are of short duration (a few days or weeks), and the stress usually is readily identifiable (e.g., parental separation, a new sibling).

For children who live in chronically stressful, multiproblem circumstances, it is difficult to determine whether the symptoms reflect expression of underlying anxiety or depression, a problem in parenting and socialization, a genetically influenced biological problem, or some interaction of a number of these factors.

Relatively little research has addressed the psychosocial versus the biological aspects of these symptoms. The combination and interrelationship of both of these aspects has received even less attention. It is hoped that with current technological advances and our greater ability to look at such problems in a multifaceted way, we will gain a clearer, more comprehensive understanding of the possible etiology, development, and treatment of symptoms of hyperactivity, impulsivity, and inattention.

## 29 DEVELOPMENT OF THE SYMPTOMS OF VIOLENCE

Dorothy Otnow Lewis, M.D.

What do we know about human violence? Are human beings aggressive by nature? Must we be tamed to treat each other properly? And, if so, how should we go about that task? If we spare the rod, will we spoil the child? Was Wordsworth right—do we come into the world in a state of innocence, “trailing clouds of glory,” only to be corrupted by society? Rousseau thought so. Was Locke correct? Do we enter this world blank slates on which our environments and experiences will scrawl our course? Are “all men created equal,” or are some of us innately more aggressive than others? These questions, which for millennia have dominated literature, religion, and philosophy, are finally being tackled by science. And, as will become clear, there is something to be said for each of the foregoing points of view. We enter the world with certain innate but not inevitable potentials for behavior. What happens to us makes the difference.

The nature of human behavior is so complex that it is hard to agree on the very meaning of human aggression. Are we talking about the battles between Microsoft and Netscape or Serbia and Bosnia? Are we considering the behaviors of Lucretia Borgia or Lizzie Borden? John D. Rockefeller or Jack the Ripper?

The behaviors of other animals are more stereotyped than those of human beings and are therefore more easily classified. For example, [Moyer \(1971\)](#) has categorized animal aggressive behaviors as follows: predatory, intramale, fear induced, irritable, territorial, maternal, and instrumental. [Flynn and colleagues \(1970\)](#) have condensed these aspects of aggression into two categories, affective and predatory. Affective aggression, which includes intramale, fear-induced, irritable, territorial, and maternal types, involves intense activation of the sympathetic nervous system. There is an increase in blood pressure, piloerection, pupillary dilation, and threatening behaviors. Predatory aggression, on the other hand, evokes little autonomic activation and is accomplished by silently stalking the prey and expeditiously subduing it in the interest of providing a meal. Others have divided animal behaviors into offensive and defensive ([Blanchard and Blanchard, 1977](#)) and spontaneous versus conditioned aggression ([Thompson, 1969](#)). For the purposes of this chapter, the term *human aggression* is used simply to denote behaviors by one person intended to cause pain, damage, or destruction to another. It is not used as a synonym for assertiveness or ambitiousness.

[Volavka \(1999\)](#) suggests that most human violence can be categorized as impulsive or premeditated. Others have conceptualized two kinds of aggression: defensive, characterized by fear and high plasma cortisol levels, and offensive, characterized by impulsiveness and low serotonergic brain activity, high testosterone levels, and low cortisol levels ([Kalin, 1999](#)). The Federal Bureau of Investigation classifies murderers as organized and disorganized ([Douglas and Olshaker, 1995](#)), categories roughly similar to Volavka's. Although some investigators report apparent physiologic and cognitive differences between impulsive offenders and those who premeditate their acts ([Barratt, et al., 1997a, 1997b](#)), it would be a mistake to assume that those who premeditate their violence are necessarily healthier or more neuropsychiatrically intact than impulsive offenders (current insanity statutes to the contrary notwithstanding). Some of the most violent, diabolical, psychotic acts are planned over months and even years. Copious writings of the Unibomber attest to this truth.

But what about wars? Surely, the attacks on Pearl Harbor and Hiroshima cannot be discounted as the products of madmen. Some of the canniest (if not best) minds were behind them. Clearly, violence does not always bespeak “insanity.”

### EVOLUTION AND VIOLENCE

Before “attacking” the question of whether within the human species some of us are innately more aggressive than others, it would be wise to take distance and examine ourselves as a species. Does it matter that we *Homo sapiens sapiens* are, in essence, a variety of ape? It does. [Wrangham and Peterson \(1996\)](#) note that of 4,000 mammals, only chimpanzees and humans live in patrilineal, male-bonded communities in which males form “aggressive coalitions with each other in mutual support against others” (p. 24). For centuries, it was assumed that humans were the only animals that actually made war on each other. Jane Goodall's observation of raiding parties of male chimpanzees and of their gratuitous violence toward already subjugated members of other chimpanzee communities put that misconception to rest, while taking us humans down a peg ([Goodall, 1986, 1991](#)).

Since Darwin, we have had some inkling of our primate origins. However, not until the discovery of the structure of deoxyribonucleic acid (DNA) and the ability to type its variations could we appreciate our evolutionary closeness to the “other” great apes, especially to the chimpanzee. In 1904, [Nuttall \(1904\)](#) reported that human blood did not react with rodent antisera, precipitated moderately in the presence of monkey antisera, and formed the thickest precipitant of all when mixed with ape antisera. Thus, began the biochemical documentation of our closeness to apes. Subsequent studies comparing the structure of gorilla, orangutan, chimpanzee, and human DNA indicated not only that humans are genetically more closely related to chimpanzees than we are to any other known species, but that the DNA of chimpanzees themselves is more similar to our DNA than it is to that of the other great apes (e.g., gorillas) ([Sibley, et al., 1990](#)). Given our biological and behavioral similarities to the great apes, particularly to the chimpanzee, it is not unreasonable to assume that at least some of our human aggressiveness can be explained in terms of evolution. Such aggressiveness must, at some time, have had survival value. Whether this large brain of ours, with its potential for destruction as well as reflection, will continue to serve us well remains to be seen.

### SEX AND AGGRESSION

Are all humans equally aggressive? Clearly not. The males of our species, like male chimpanzees, are more violent than females—no doubt about it. Whether measured in childhood in terms of roughness of play ([Maccoby and Jacklin 1974](#)) or in adulthood in terms of violent crime ([Federal Bureau of Investigation, 1998](#)), the male human behaves in demonstrably more aggressive ways than the female. These differences are not peculiar to a particular society but have been observed cross-culturally in societies as different from each other as Ethiopia and Switzerland ([Omark et al., 1973; Whiting and Edwards, 1973](#)). In the United States, men are approximately eight times as likely to commit murder, nine times as likely to commit armed robbery, and four to five times as likely to commit aggravated assault as women ([Federal Bureau of Investigation, 1998](#)). Men also are many times more likely than women to commit nonviolent crimes such as burglary, car theft, drunken driving, and even fraud.

The greater inherent aggressiveness of the male human also is reflected in the patriarchal nature of almost all human societies ([Wrangham and Peterson, 1996](#), p. 118). In fact, a 1971 survey of 93 societies around the world revealed that men retained all important political positions in 88% of them and that in most societies men tended to hold all significant leadership roles in kinship groups as well. Most surprising is the finding that maltreatment of women by men (i.e., wife beating) is more the rule than the exception in societies the world over ([Heise et al., 1994; Levinson, 1989](#)). Among mammals, rape reportedly is common in but two nonhuman mammals (orangutans and elephant seals), and occurs occasionally in chimpanzees, gorillas, and howler monkeys ([Galdikas, 1995; Palmer, 1989; Wrangham and Peterson, 1996](#)). Thus, in addition to human beings, four of the five mammals known to rape are primates; three are apes. Needless to say, men are many times as likely to commit rape as women. The human male is, in short, the predominant maker and breaker of the rules in human society.

Given the overwhelming evidence that human males are more violent than females in nearly all societies, before considering the cultural or environmental contributions to human violence, it makes sense to examine what we know about our own biology. What factors seem to contribute to greater male violence?

Much as we may wish to attribute most, if not all, of the differences between human male and female aggressiveness to cultural influences, overwhelming evidence exists that, long before birth, the die is cast; male and female brains develop differently *in utero*. The architectural and functional differences between male and female brains are, to this day, “areas” of controversy. Whereas some investigators have noted marked differences in what are referred to as the *sexually dimorphic* areas of the hypothalamus and corpus callosum (Allen et al., 1989, 1991; Arai et al., 1985), others have highlighted the similarities between male and female brains. Nopoulos and colleagues (2000), in their magnetic resonance imaging (MRI) study, stressed the similarities between male and female brains. However, they found that human males have larger brains than females and, what is more, the greatest size discrepancies are in the cerebrum, that alleged repository of reason and impulse control. The male cerebrum is reportedly 8% larger than the female.

Gonadal hormones play important roles in the development of aggressive behaviors. Gonadal hormones are especially critical during fetal and neonatal development (Goy and McEwen, 1980). These hormones have been shown to affect sexually dimorphic areas of the brain, and their early presence has been reported to be important to the normal development of aggressive behaviors in many animals. The importance of androgens to fighting behaviors or dominance has been demonstrated in such diverse species as fish, lizards, birds, and chimpanzees (Floody and Pfaff, 1972). However, when severely threatened, even castrated animals have been able to fight fiercely (Barfield, 1984). Estrogens have been observed to have varying behavioral effects, depending on the state of the recipient. On the other hand, in some species, when given prenatally, estrogen has been associated with masculine brain development and aggressive behavior (Gorski, 1986; Paup et al., 1972; Ruppert and Clemens, 1981). Androgens such as testosterone are metabolized in the brain to form estrogens (Reddy et al., 1974).

It is now well recognized that estrogens influence the sexual differentiation of the male and female brain and thus influence behavior (Hutchison et al., 1999). Estrogens have been found to influence dendrite formation and the formation of synapses (Garcia-Segura et al., 1986; Woolley and McEwen, 1994). They have permanent organizing effects on the structure and function of the brain during critical prenatal periods. The transformation of testosterone to the estradiol essential to brain differentiation requires activation of the cytochrome P-450 aromatase enzyme (Kelly et al., 1999; Reznikov et al., 1999). *In vitro* studies of neurons indicate that neurons from the male fetal hypothalamus have higher aromatase activity than neurons from the female fetal hypothalamus. Furthermore, a greater number of neurons from male brains contain aromatase than do neurons from female brains (Hutchison et al., 1999). Testosterone, in turn, increases aromatase activity and greatly increases estradiol formation. However, cells containing aromatase reportedly respond only during critical developmental phases. The actual molecular mechanisms that are activated in response to estradiol and masculinize the fetal brain are not yet understood. What we do know is that testosterone activates the aromatase in the brain; it is converted to estradiol; estradiol further masculinizes the brain; and these changes, in turn, affect postnatal behavior. The relationship of the masculinization of the fetal brain to the production of neurotransmitters and receptors in the brain is not yet well understood (Reznikov et al., 1999), however, differences in the amount, turnover, and localization of catecholamines have been documented in the brains of male and female rats. The effects on behavior of sex differences in the central nervous system (CNS) are extremely complex. “Steroid derivatives progesterone, testosterone, and glucocorticoids, referred to as neuroactive steroids or neurosteroids, can also alter behavioral responses through nongenomic actions, and supports their potential role in mediating sex-related differences” (Kelly et al., 1999, p. 659). The behavioral effects of neurosteroids are numerous and include sedative, anesthetic, and anxiety-reducing properties. They are thought to play important roles in mediating sex-related differences in behavior responses (Kelly et al., 1999). Exactly how biochemical events are translated into behaviors is not known.

In summary, a plethora of data from such diverse sources as archeology, anthropology, genetics, and biochemistry tell us that we are a potentially aggressive species, and that the males among us are, by nature, more aggressive than the females. But is that the whole story? Is biology destiny? Not necessarily. After all, most men are not murderously violent, and not all women are “shrinking violets.” Why, then, within our species, are some of us more violent than others?

## FROM THE SOCIOLOGIC TO THE BIOCHEMICAL—A TREND

In the middle of the 20th century, at least in part in reaction to Lombroso's earlier theories that criminals represented a degenerate biological phenomenon (Alexander and Selesnick, 1966), investigators looked almost exclusively to society for explanations of criminality. Merton (1938, 1957), one of the most influential social scientists of the time, noting that criminality and violence were considerably more prevalent in the disadvantaged sectors of society than the well-to-do, theorized that antisocial behavior was a manifestation of the efforts of the socioeconomically deprived to attain, by hook or by crook, the wealth and status that the more successful and dominant sectors of society could obtain legitimately. Other social scientists hypothesized that deviance was basically a reflection of society, and that subcultures of violence encouraged criminality (Cohen, 1955). Children became delinquent and violent because of their exposure to deviant behaviors (Cloward and Ohlin, 1960). Criminality was, in essence, an alternative lifestyle.

The past quarter century has seen an almost 180-degree about-face in the study of violence and criminality, as investigators have turned back to biology to try to explain deviance, especially to explain violence. Advances in the so-called hard sciences (e.g., genetics, biochemistry, cellular biology, neuroanatomy, neurophysiology), increasing our ability to identify, measure, and even visualize biological similarities and differences among us macroscopically and microscopically, have undoubtedly encouraged this research direction. Studies of the relationship of such neurochemicals as serotonin (Sahakian, 1981), norepinephrine (Stolk et al., 1984), dopamine (McKenzie, 1971), vasopressin (Coccaro et al., 1998), and nitric oxide (Nelson et al., 1995) to aggressive behavior in animals (Alpert et al., 1981; Lal et al., 1968; Lycke et al., 1969; Randrup and Munkvad, 1966; Reis, 1972) encouraged similar studies in humans. Initially, the finding of a relationship between low cerebrospinal fluid (CSF) levels of 5-hydroxyindole acetic acid (5-HIAA; a metabolite of serotonin) and impulsiveness and aggressiveness in humans (Brown et al., 1979; Brunner, 1996; Linnoila et al., 1983; Virkkunen et al., 1989) seemed to shed light on the question of why some individuals were more aggressive than others. Studies of men depleted of tryptophan, the amino acid precursor of serotonin, indicated that they become more aggressive in a laboratory setting than do men not so deprived (Bjork et al., 1999). Of note, those men with a tendency toward hostility as measured on an aggression questionnaire reportedly responded more aggressively to tryptophan depletion than did nonhostile men.

However, the relationship of serotonin levels and serotonin system responsiveness to degrees of aggression is not simple. A study of young (7- to 11-year-old) aggressive boys with attention deficit/hyperactivity disorder revealed a *greater* prolactin response to fenfluramine (i.e., greater serotonergic responsivity) in aggressive than in nonaggressive boys (Halperin et al., 1996). A study of blood serotonin [5-hydroxytryptamine (5-HT)] levels in adolescents diagnosed with conduct disorder reported that those with early-onset maladaptive behaviors had *higher* blood 5-HT levels than later offenders and that blood 5-HT correlated positively with ratings of aggressiveness (Unis et al., 1997).

In a sophisticated study of the relationship of brain 5-HIAA levels in infants to subsequent behavioral characteristics, Clarke and colleagues (1999) followed a sample of children from their first weeks of life to 30 months of age. They found but a modest correlation between low CSF 5-HIAA levels and aggressive behaviors. In contrast, environmental factors such as poverty, as reflected in Medicaid insurance, and poor family cohesiveness were strongly associated with behavior problems at 30 months of age. Another recent study documented a relationship between low socioeconomic status, low prolactin response, and increased aggression (Matthews et al., 2000). Finally, a metaanalysis of 39 studies linking 5-HIAA levels to violence in humans found that psychiatric patients as a group, whether violent or nonviolent, had similar 5-HIAA levels. The mean 5-HIAA level in both violent and nonviolent patient groups was lower than the mean level in groups of normal, healthy volunteers (Balaban et al., 1996). Thus, serotonin levels may prove to be indicators of overall psychopathology that only at times is manifested by aggressiveness.

## MENTAL ILLNESS AND AGGRESSION

Does mental illness itself predispose an individual to violence? For years, psychiatrists promoted the notion that mental illness is no different from any other kind of physical illness in terms of aggressiveness. That is not so. Studies from around the globe, including studies from more and less developed nations, indicate that violence is more common among seriously mentally ill individuals than it is among the general population. In a study of patients with schizophrenia from 10 different countries around the world, the occurrence rate of assault was extremely high (20.6%), especially in “developing countries” (31.5%) compared with “developed countries” (10.5%) (Volavka, 1997). The study of a Danish birth cohort revealed that hospitalized patients diagnosed with schizophrenia had higher arrest rates for violent crime than did nonpatients (Brennan et al., 2000). Monahan (1997) reported that, in a study of psychiatric patients from three U.S. cities, those diagnosed with affective disorders had the highest rates of violence postdischarge. In a study of 812 psychiatric patients, within 6 months after discharge, almost half of the patients behaved violently. Of those who became violent, 16% of the men and 31% of the women had an affective disorder (Newhill et al., 1995). In a much smaller follow-up study of male psychiatric patients, those with major affective disorder were significantly more likely to commit violent crimes than were those diagnosed with schizophrenia (Hodgins et al., 1999). Hodgins et al. distinguished between those with early antisocial behaviors and those whose antisocial behaviors started concomitant with the onset of affective disorder (Hodgins et al., 1998). We have found in our own clinical work that many manic-depressive, delinquent adolescents, whose hypomanic, problematic behaviors started in childhood, were dismissed then as having conduct disorders and only later identified as suffering from bipolar

disorders. When a careful history of the periodicity of antisocial behaviors was obtained, as well as a family psychiatric history, it became evident that many of the adolescents had experienced extremes and fluctuations of mood since childhood that contributed to their social maladaptation. It is vital that some child psychiatrists, confronted with a child's repeated misbehavior, consider the possibility that the child may be manic or hypomanic.

Another psychiatric disorder associated with episodic extreme violence is posttraumatic stress disorder (PTSD) ([McFall et al., 1999](#)). The more serious the symptomatology, the greater the violence. Child abuse seems to intensify PTSD symptoms in subsequently traumatized individuals ([Bremner et al., 1993](#)). Homicidal violence has been perpetrated by individuals with severe dissociative disorders, especially by men with dissociative identity disorder ([Lewis et al., 1997](#); [Loewenstein and Putnam, 1990](#)). This disorder comes into being as a result of early, ongoing, extreme maltreatment, the psychobiological effects of which are discussed later.

One of the rarest and therefore most overlooked causes of episodic recurrent violence in children is the acute confusional state that is sometimes associated with the development of migraines. During these attacks, children may appear confused, agitated, hyperactive, and even violent. These states, considered to be auras associated with migraines, can last from minutes to hours. They may occur before, during, after or independent of the migraine headaches themselves ([Eggers, 2001](#)). During these episodes, children may destroy objects and even attack others who attempt to restrain them. Children may experience trance-like or dreamlike states, macropsias, or micropsias, olfactory, visual, and auditory hallucinations, déjà vu, and just about all of the symptoms associated with complex partial seizures ([Ardila and Sanchez, 1978](#)). Sometimes the episodic, agitated, aggressive auras precede by years the development of migraine headaches, making the diagnosis difficult. Often the diagnosis must be made retrospectively, after onset of the headaches ([Ehyai and Fenichel, 1978](#); [Steifel and Ruttner, 1995](#)).

Granted, mental illness is associated with violence. Nevertheless, most mentally ill individuals are not violent. They are, rather, more vulnerable to the stressors in their immediate and extended environments.

## GENES AND AGGRESSION

Scientists have identified specific genes controlling the synthesis and breakdown of specific neurotransmitters in animals ([Cases et al., 1995](#); [Nelson et al., 1995](#)) and humans ([Brunner et al., 1993](#); [New et al., 1998](#)). The genes controlling the breakdown of monoamine oxidase ([Belfrage et al., 1992](#); [Cases et al., 1995](#)) and catechol-O-methyltransferase ([Gogos et al., 1998](#)) have been identified, as has the gene for tryptophan hydroxylase, important in serotonin synthesis ([Nelson et al., 1994, 1997](#)). Scientists now are able to manipulate genes in animals and thereby modify behaviors. Some scientists have gone so far as to suggest that such manipulations (or machinations) might have applications for the management of human aggression ([Tecott and Barondes, 1996](#)). Twin studies as well as studies of adopted-away children of criminal biological parents have been interpreted as showing a genetic contribution to violent, antisocial behavior ([Cadoret et al., 1997](#)). However, no study to date has demonstrated a genetic predisposition specifically to violence. [Gjone and Stevenson \(1997\)](#), in a study of a large sample of twin pairs, using parent report data, showed an association between early temperament and subsequent aggression. Most closely associated with subsequent aggression were the characteristics of emotionality and high activity, especially in boys.

Estimates of the genetic contribution to aggression depend in great measure on the methods used to measure aggression. Observational measurements of aggressive behavior yield lower heritability statistics than do report and questionnaire studies ([Cadoret et al., 1997](#)). Whatever the study, scientists agree that genetic predispositions *alone* do not account for complex human behaviors. It would seem, rather, that adverse home environments, and their interactions with biological temperamental characteristics, may increase the likelihood of a maladaptive, aggressive behavioral outcome ([Cadoret et al., 1995](#)).

The bottom line is that the ways we are treated *in utero*, at birth, during infancy, and in childhood and adolescence are the most important influences on our adaptation and, hence, on our aggressiveness.

## ENVIRONMENTAL INFLUENCES ON AGGRESSION

### Intrauterine and Perinatal Factors

The very position *in utero* of animals in a litter has been found to influence behavior. Female mice that develop *in utero* between two males are more aggressive after birth than those positioned between other females ([vom Saal, 1984](#)). Thus, animals from the same litter who have shared the same uterus at the same time have not had identical prenatal environments. Maternal stress during pregnancy also has been shown to affect the behavior of offspring long after delivery ([vom Saal, 1984](#)).

In humans, there is strong evidence that different kinds of noxious prenatal influences, ranging from minor viral infections to maternal anxiety and psychological stress, have been associated with childhood maladaptation ([Pasamanick, 1956](#); [Rutter, 1970](#); [Stott, 1973](#); [Stott and Latchford, 1976](#)). The adverse effects of maternal alcoholism and other substances on fetal development and subsequent postnatal social and intellectual functioning are well documented. The exposure of the fetus to abnormal levels of certain gonadal hormones also has been associated with behavioral sequelae ([Ehrhardt and Money, 1967](#); [Ehrhardt et al., 1968](#)). Our own studies ([Lewis and Shanok, 1977](#); [Lewis et al., 1979, 1985](#)) and those of others ([Levine et al., 1985](#)) have documented the higher prevalence rate of histories of perinatal problems in the delinquent versus nondelinquent populations.

Given the vicissitudes of life *in utero* and at birth, we should not conclude that even temperamental styles such as "emotionality" and early activity levels necessarily reflect genetic endowment. Similarly, it would be an error to take for granted that the relationship between an adoptee's aggressiveness and a biological parent's antisocial history is necessarily genetic. Parents who have been in and out of prisons are not likely to have been well nourished nor are they likely to have received the best medical care. The lives of mothers who release their children for adoption cannot have been easy. There is now evidence that heightened maternal cortisol as a result of stress affects the fetus and increases aggressiveness postnatally. Furthermore, the partners with whom offenders link up frequently suffer from mental illness and have been psychiatrically hospitalized ([Lewis et al., 1976, 1981](#)). Thus, the adopted-away children of criminal parents in all likelihood had stressful *in utero* experiences. Moreover, the genes they inherited may well have predisposed them to a variety of different kinds of mental disorders other than antisocial personality disorder that compromised normal adaptation. In other words, behaviors that at first appear to be genetic may not be. As Buttercup in Gilbert and Sullivan's *H.M.S. Pinafore* so aptly put it, "Things are seldom what they seem."

### Nurturing

Nurturing affects temperament. Animals bred to have an especially gentle nature, if cross-fostered by adult females of a violent strain, will become more aggressive than is their usual nature ([Southwick, 1968](#)). There is evidence that mice reared in the company of their fathers as well as their mothers grow up to be more aggressive than those raised only by mothers ([Mugford and Nowell, 1972](#)). On the other hand, the effects of cross-fostering aggressive mice by less aggressive females are more variable. Certain strains retain their aggressiveness ([Southwick, 1968](#)), whereas others become less aggressive ([McCarthy and Southwick, 1979](#)). In another study, mice from an aggressive strain reared by males and females of their own strain were more aggressive than those raised either by two females or a male and a female of a less aggressive strain ([Smith and Simmel, 1977](#)). Isolation during critical developmental periods can engender aggression in otherwise gentle animals ([Brain and Nowell, 1971](#); [Goldsmith et al., 1976](#); [Luciano and Lore, 1976](#)). Thus, there is evidence from animal studies that innate temperament can be modified and that the quality of parenting and environment influences adult behaviors.

Very early experiences have especially powerful and enduring effects on physiologic and psychological development and, therefore, on behavior. In animals, qualities of parenting during the first days and weeks of life are particularly important to subsequent social adaptation. Although many reptiles are equipped to defend themselves shortly after birth, most mammals require parental protection for varying periods.

In humans, the first months and years of life are periods of extreme vulnerability, emotionally and biologically. Although the auspicious neuropsychiatric and emotional cards a person is dealt at birth may seem to predict a successful game, experience can reverse what under other circumstances would have been a winning hand. Adversity during the earliest periods of development can change the relationship of a child to the environment from a gentle give-and-take to a rough-and-tumble struggle. For example, research on attachment has shown that the ways that mothers and infants interact during the earliest weeks and months of life affect subsequent aggression in the child ([Lyons-Ruth, 1996](#)). Attachment behaviors, which are evoked in the infant by stress, especially by separation, have the goal of reducing anxiety and restoring a sense of security. At times of stress, securely attached infants turn unambivalently to their mothers for comfort. Adequate mothers sense their children's needs and respond appropriately. Mothers who lack tenderness, are inappropriately intrusive, and harbor suppressed anger toward their babies seem to engender insecure, avoidant attachments. Avoidant attachment has, in turn, been associated with subsequent aggressive behavior in boys ([Renken et al., 1989](#)).

Researchers have noted more seriously pathologic, "disorganized" patterns of attachment in certain infants. The mothers of these infants are especially disturbed and

distressed, and are more likely than the mothers of securely attached infants to have experienced abuse or abandonment themselves. They also are more likely to have been psychiatrically hospitalized ([Lyons-Ruth et al., 1991](#)). Their children seem to lack consistent strategies for reducing stress. These children's behaviors are hard to categorize but tend to include apprehension, helpless or depressed behaviors, unpredictable alterations between approach and avoidance, and apparent "freezing" or stilled, slowed movements ([Main and Soloman, 1990](#)). Several studies have shown a relationship between disorganized attachment and early childhood aggression ([Lyons-Ruth and Block, 1993](#)). Looking retrospectively, preschoolers manifesting extremely hostile behaviors were found to be six times more likely than normal children to have been classified in infancy as having had disorganized attachments to their mothers.

Poor mothering takes its toll intellectually as well as behaviorally. Infants with disorganized attachments lag in their mental development regardless of maternal IQ ([Lyons-Ruth, 1991](#)). [Lyons-Ruth and colleagues \(1996\)](#) found that the combination of early disorganized attachment and lags in cognitive development were associated with aggressive behaviors at 7 years of age. Thus, it would appear that poor mothering affects brain function itself.

The period during which attachment forms is crucial developmentally. During the first year of life, the human brain increases in weight from an average of 400 g to an average of 1,000 g, and this growth spurt continues through the second year of life ([Glaser, 2000](#); [Schore, 1994](#)). The brain develops in a genetically determined sequence from brain stem to cortex ([Nelson and Bloom, 1997](#)), and myelination of the frontal lobes is not complete until early in the third decade of life ([Benes, 1998](#); [Pincus, 2000](#)). However, with few exceptions ([Gould et al., 1997, 1999](#)), the brain's neurons form and migrate to their genetically determined positions during embryonic and early postnatal life. The degree to which new neurons are created later in development is an active area of research. During the first 2 years of life, an enormous proliferation of brain cells, axons, dendrites, and synapses occurs, with more synapses created than eventually will be used. Which brain cells and synapses will survive and which, by virtue of disuse, will be pruned and ultimately disappear depends to a great extent on experience ([Singer, 1995](#)). In short, the ways in which infants are treated, the kinds of attachments they are fortunate or unfortunate enough to make, affect the very structure and function of their brains and thus influence their behaviors. Studies of animals ([Hubel and Wiesel, 1979](#)) and humans ([Scarr, 1993](#)) support the concept of sensitive periods in brain development during which particular kinds of stimulation must occur if development is to proceed normally. Human beings have evolved in such a way that certain types of mothering experiences are requisite for brain and behavior to develop normally. Good parenting has survival value. In the second year of life, the frontal lobes are still growing. These are the areas of the cerebrum involved not only in reasoning and judgment but in the regulation of goal-directed behavior and the control of affects and impulses ([de Haan et al., 1994](#); [Glaser, 2000](#); [Thatcher, 1994](#)). During this crucial period of brain growth, infants cannot modulate their own arousal. The caregiver therefore must respond to the infant's stress and restore a sense of safety and well-being. There is good reason to believe that these early lessons in affect and impulse control, which seem to leave indelible impressions on the infant brain and mind, affect adaptation throughout life ([Sroufe et al., 1999](#)).

Although the earliest experiences may have special adaptational consequences because of the young child's extreme vulnerability, behavioral adaptation is the result of the ongoing interaction of the child with his or her environment. Attachment itself is not fixed and can change in response to levels of maternal stress ([Vaughn et al., 1979](#)). The usual adverse behavioral consequences of compromised early attachment also may be modified by improved social supports for the caregiver ([Erickson et al., 1985](#)). There is something about early, nurturant mothering, fostering secure bonds, however, that enables securely attached children to withstand subsequent adverse environments better than children who have not experienced secure attachment. School-age experiences and the quality of care during early adolescence do affect adaptation. However, all things considered, a major, if not *the* major, influence on behavioral outcome seems to be the nature of early mothering.

## Abuse

A copious literature attests to the association of maltreatment in childhood and aggression in adolescence and adulthood ([Cicchetti and Carlson, 1989](#)); the extent to which the category of "abused" children overlaps with that of children who have suffered attachment disorders and the independent influences of each are difficult if not impossible to measure. Whereas complete emotional deprivation of infants leads to severe depression and even to death ([Bowlby, 1969, 1975](#); [Spitz, 1946](#)), lesser degrees of neglect have been associated with poor peer relationships and aggressive behaviors ([Mueller and Silverman, 1989](#)). [Widom's \(1989\)](#) research suggests that neglect can be as powerful an influence on the development of aggression as physical abuse. Severe physical abuse has been associated with subsequent extremely violent behaviors ([Feldman et al., 1986](#); [Lewis et al., 1986, 1988a, 1988b, 1989, 1997](#)).

Early, repeated sexual abuse seems to have especially devastating consequences. There is evidence that a disproportionate percentage of sexually assaultive adults have histories of having been sexually abused as children ([Groth, 1979](#); [Rubenstein et al., 1993](#)). In the author's experience, the most grotesque sexual crimes have been committed by men who, as children, experienced extraordinary sexual abuse.

How do severe abuse and neglect engender aggression? The answer is not simple and must be gleaned from a variety of different kinds of studies and observations. What is clear is that the human organism is so constructed that maltreatment affects every aspect of functioning—cognitive, emotional, and physiologic.

## NEUROCHEMICAL EFFECTS OF ABUSE

From a biological standpoint, we do know that stressors of various kinds affect us physiologically, activating the hypothalamic–pituitary–adrenal axis and causing the release of catecholamines from the brain and the adrenal medulla and the release of cortisol from the adrenal cortex ([Le Doux, 1996](#)). Animal studies have shown a relationship among stress, hypersecretion of cortisol, and damage to the brain ([Sapolsky et al., 1990](#); [Uno et al., 1989, 1990](#)). Studies indicate that excessive exposure to glucocorticoids results in a loss of neurons in the hippocampus as well as a decrease in dendritic branching of the remaining neurons ([Sapolsky et al., 1985](#); [Wooley et al., 1990](#)). It is thought that damage occurs because of cellular vulnerability to the neurotoxic effects of the excessive release of excitatory amino acids such as glutamates ([Armanini et al., 1990](#); [Virgin et al., 1991](#)). Glucocorticoids also reportedly inhibit neurogenesis. Neurogenesis has been reported to occur even in mature animals ([Gould et al., 1999](#); [Reagen and McEwen, 1997](#)). Support for the toxic effects of glucocorticoids on the human brain come from computed tomography and MRI studies of individuals treated with glucocorticoids ([Bentson et al., 1978](#); [Okuno et al., 1980](#)) and of patients with Cushing's syndrome ([Starkman et al., 1992](#)). MRI studies of subjects with PTSD after combat trauma or child abuse ([Bremner et al., 1995, 1997](#); [Stein et al., 1997](#)) reported diminished hippocampal volume ranging from 5% to 26%. Although it has been assumed that these volume changes reflect the damaging effects of excessive cortisol secretion resulting from stress, other neurobiological mechanisms also may be operating. In his critical review of the literature on glucocorticoids and hippocampal atrophy, [Sapolsky \(2000\)](#) observes, "stress decreases the levels of brain-derived neurotrophic factor messenger ribonucleic acid (RNA) in the hippocampus" (p. 392), and some of this inhibition is thought to be independent of glucocorticoids ([Smith et al., 1995](#)). Whatever the underlying mechanism, abusive treatment and severe emotional stressors actually affect brain structure and function.

## NEUROANATOMIC CONSEQUENCES OF ABUSE

More recently, [De Bellis and colleagues \(1999\)](#), using MRI scans, compared the brains of 44 maltreated children with PTSD with a healthy, matched comparison sample. The cerebral volumes of the abused children were reportedly 7% smaller than in the control subjects; the corpus callosum was smaller, and the volumes of CSF in the lateral ventricles and cortical and prefrontal cortical areas were larger in the abused sample. Whether these cerebral abnormalities were reflections of the effects of increased catecholamine concentrations, high cortisol levels, lack of early stimulation, or other developmental catastrophes could not be ascertained. Whatever the psychobiological explanations, this degree of brain pathology cannot help but impair intellectual and behavioral functioning. As [Glaser \(2000\)](#) so cogently observes in his review of the literature on child abuse and neglect and the brain, "The neurobiological findings shed some light on the many emotional and behavioral difficulties which children who have been abused and neglected show. Hyperarousal, aggressive responses, dissociative reactions, difficulties with aspects of executive functions, and educational underachievement thus begin to be better understood" (p. 110).

Another common result of abuse or neglect is direct injury to the CNS. Almost any CNS trauma may be associated with hyperactivity, emotional lability, diminished intelligence, poor judgment, and impulsiveness. Children with these kinds of deficits and vulnerabilities are less able to think ahead and understand the consequences of their behavior. They are more likely than normal children to respond aggressively to provocative stimuli, be they in the form of violent television programs and movies or interpersonal conflicts. In our own studies of violent juveniles and adults, medical histories were so replete with evidence of CNS insults that it usually was impossible to ascertain the exact cause of brain dysfunction. It is known that injuries to the CNS, even apparently mild concussions, can have a cumulative effect neurologically and cognitively ([McCrea et al., 1997](#)). Extremely violent juveniles often have experienced multiple accidents and injuries, many of them inflicted by those entrusted with their care ([Ewing-Cobb et al., 1998](#); [Hatzitaskos et al., 1994](#); [Lewis et al., 1979, 1988b, 1989](#)).

The temporal and frontal poles of the brain, especially the undersurfaces of the frontal lobes, are the most vulnerable to contusions after injury ([Pincus, 2000](#)). Numerous studies have documented a relationship between frontal lobe dysfunction and aggressiveness. Several investigators, using different neuropsychological test protocols, have demonstrated evidence of greater frontal lobe dysfunction in delinquents than nondelinquents ([Berman and Siegal, 1976](#); [Wolff et al., 1982](#); [Yeudall et al., 1982](#)). Frontal lobe dysfunction has been associated with especially aggressive behaviors, as measured neuropsychologically ([Brickman et al., 1984](#)). Studies also have documented the association of aggression with frontal lobe injury ([Grafman et al., 1996](#)) and frontal lobe dysfunction ([Raine et al., 1994, 1997](#)).

These findings are not surprising, given the importance of the frontal lobes in modulating emotions and impulses.

Our overall adaptation as a species, our ability to overcome obstacles, defend ourselves when threatened, procreate and cooperate to raise our young, and by and large not kill each other when angered, is a reflection of the balance in our brains between appetites and drives and reflection and control. Animal studies have shown us that the part of the CNS most involved in sexual and aggressive feelings lies deep in our brains, in a complex central area commonly referred to as the *limbic system*. The most important areas of the limbic system associated with aggression are thought to be the hypothalamus, the septal area, and the amygdala. In animals, activating and inhibiting areas are very near each other. Ablation and stimulation of these parts of the brain results in an increase in or a diminution of aggressive behaviors, depending on the areas stimulated and the kinds of animals studied.

Some of the most fascinating animal research regarding limbic function and aggression involves the amygdala, the area of the brain located medially, deep within the temporal lobes. Experiments on animals suggest that the amygdala is especially involved in aggression in response to fear ( [Egger and Flynn, 1963](#); [Siegel and Flynn, 1968](#)). Damage to the amygdala has been reported to result in a diminution of aggressive behaviors in response to novel stimuli.

Studies in which electrodes have been implanted in the brains of human subjects indicate that the limbic system also is involved in human aggression ( [Mark and Ervin, 1970](#)). Abnormal electrical activity in parts of the limbic system, as occurs in some psychomotor/complex partial seizures, has been reported to be associated with aggressive behaviors ( [Mark and Ervin, 1970](#)), although debate continues regarding whether directed aggression can occur during a seizure itself ( [Delgado-Escueta et al., 1981](#)). Reports of aggressive behavioral changes in patients with brain tumors localized to parts of the limbic system also are consistent with findings of an association between limbic activity and aggression ( [Malamud, 1957, 1965](#)).

Damage to the medial portion of the temporal lobes has been associated with poor impulse control and aggression ( [Poston et al., 1994](#)). Our own studies ( [Lewis et al., 1982](#)) and those of others ( [Devinsky and Bear, 1984](#); [Fenwick, 1989](#); [Spiers et al., 1985](#)) suggest that certain patients with temporal lobe/complex partial seizures may behave in episodically aggressive ways. Although directed violence toward another person during a seizure is relatively rare, such violence does occur postictally, and several investigators have suggested that personality changes occur in some patients with seizures that include periods of intense anger ( [Devinsky and Bear, 1984](#); [Fenwick, 1989](#)). However, most patients with epilepsy are not violent. Usually the frontal lobes, those sentinels of social adaptation, inhibit violent impulses arising in the limbic system. When, however, there is abnormal limbic activity and defective frontal lobe control (as is the case in some extremely aggressive juvenile and adult offenders), the stage is set for violence to break through. One of the most repetitively homicidal serial killers we have seen had a cyst in the right anterior temporal lobe, scarring in both frontal lobes, and spiking on electroencephalography in the frontal and temporal regions. In his case, violence was preceded by an aura and followed by deep sleep. On awakening, his memory of his violent acts was clouded. This kind of case is rare, but it illustrates the difficulties in adaptation when the limbic system and frontal lobes are both severely damaged. This patient also had been the victim of early, ongoing sexual abuse, a fact that raised the question of whether the disequilibrium in his brain would have expressed itself as violence had his upbringing been less deviant and more nurturing.

#### PSYCHOLOGICAL AND COGNITIVE EFFECTS OF ABUSE

The effects of abuse are not simply physical. Maltreatment has psychological consequences as well. Abuse actually changes the way in which the environment is perceived. Studies of animals as well as children have shown that one of the consequences of maltreatment is the development of hypervigilance. It has been demonstrated that defeat increases defensiveness in laboratory mice ( [Flannelly et al., 1984](#)). What is more, this conditioned defensiveness is generalized to other situations and other opponents ( [Leshner, 1981](#); [Seward, 1946](#)). Likewise, abused children seem to become hypervigilant, repeatedly misinterpreting their surroundings, and perceiving ambiguous stimuli as threatening ( [Dodge et al., 1984](#); [Rieder and Cicchetti, 1989](#)). These observations regarding young children are consistent with the author's clinical observations of violent juvenile delinquents. In fact, the symptom that the author and others (e.g., [Myers et al., 1995, 1997](#); [Ulzen and Hamilton, 1998](#)) have found distinguishes violent delinquents from their less aggressive peers most clearly is episodic paranoid ideation and misperceptions ( [Lewis et al., 1989](#)). Similarly, paranoia is the most important symptom shown to distinguish violent psychiatric patients from other patients (Yesavage, 1983a, 1983b).

Paranoia is a symptom common to numerous mental disorders (e.g., mania, depression, schizophrenia, Alzheimer's disease) and seems to have a certain survival value. Fearfulness keeps us on our toes. Fear in numerous species, from crocodiles to humans, is processed in the amygdala. Stimulation of the amygdala elicits defensive responses in such diverse species as lizards, dogs, and monkeys ( [Le Doux, 1996](#)). In human beings, when the amygdala is stimulated in the course of surgical procedures, the most commonly reported experience is a sense of fear and foreboding ( [Halgren, 1992](#)). Unlike lizards and other animals, human beings, by virtue of their large cerebral cortex, usually can process the experience intellectually and act rather than simply react. The prefrontal cortex exercises some control over the kinds of automatic defensive reactions engendered in the amygdala. However, as noted previously, recent data suggest that violence often is associated with frontal lobe dysfunction. It is reasonable to suspect that the paranoid misperceptions and consequent violent responses of many repeatedly violent juveniles and adults result, at least in part, from the reactions of a fear-primed amygdala, absent the controls of normally functioning frontal lobes.

We know that once a response has been established or conditioned (e.g., a hormonal or neurophysiologic response to fear-inducing stimuli), it is easily reevoked by exposure to similar stressors. Such recurrent, maladaptive physiologic responses probably play important roles in the hypervigilance and retaliatory aggression of many severely abused, violent children and adults.

Child abuse also contributes to violence by diminishing a child's expressive skills. Severely abused children manifest specific kinds of deficits in verbalization. For example, toddlers who have been abused are less able than normal children to use words that reflect their inner states or feelings ( [Cicchetti and Beeghly, 1987](#)). Ironically, these truly tortured souls speak less about their negative feelings than do children from nonabusive backgrounds. The abused child's inability to identify, much less verbalize his or her own feelings of distress is paralleled by an inability to appreciate the distress of others. Toddlers who have been physically abused show less empathy than their peers to the distress of other children ( [Main and George, 1985](#)). The extent to which this empathic deficiency is primarily psychodynamic or is related to frontal lobe dysfunction has not been determined. Whatever its cause, it undoubtedly contributes to the abused, violent child's imperviousness to the pain of others.

The tendency of abused children to repress or deny their own painful feelings as well as the pain of others, their inability to articulate emotions, their emotional lability and impulsiveness, their tendency to distort reality and perceive threats where they do not exist, and their resultant tendency to put angry feelings into actions rather than words can become a relatively enduring adaptational style. This constellation of characteristics accounts in great measure for the tendency of clinicians to dismiss severely abused, aggressive children, adolescents, and adults as simply conduct disordered or sociopathic.

#### Modeling of Abusive Behaviors

Aggression also is learned. There is sound experimental evidence that modeling plays an important role in the development of aggressive behaviors in animals ( [Hamburg, 1971](#)), as well as children ( [Bandura, 1973](#)). We also know that aggressive behaviors (like more adaptive behaviors) can be learned through reinforcement. One of the most important contributions to our understanding of the role of reinforcement in the genesis of aggression is [Patterson's \(1977\)](#) observation that when children's aggressive behaviors are punished severely by parents, they tend to continue. [Farrington \(1978\)](#) also found severe physical punishment to be a major antecedent of aggressive delinquency. Probably the most powerful generator of aggression in animals and possibly in humans is the repeated infliction of pain ( [Berkowitz, 1984](#)). So strong is this response in animals that a conventional experimental method for inducing murderous behaviors in mice and rats involves administering painful shocks to their feet (an ethically questionable practice). Physical torment also is an effective means of engendering viciousness in fighting dogs (e.g., pit bulls). The consequences of maltreatment in animals include the development of hypervigilance. Defeat in animals tends to engender defensiveness ( [Flannelly et al., 1984](#)), which, in turn, is generalized to other situations and other opponents ( [Leshner, 1981](#); [Seward, 1946](#)). It therefore is no surprise that children who have been painfully physically abused tend to behave in more aggressive ways than their nonabused peers ( [Cicchetti and Carlson, 1989](#); [Widom, 1989](#)).

To summarize, child abuse contributes to violence in several ways:

1. It provides a model of behavior.
2. It teaches aggression through reinforcement.
3. It inflicts pain, a known powerful stimulus to violence.
4. It creates neurophysiologic responses in the brain that both damage the brain and affect its functioning.
5. It damages parts of the brain related to impulses and their control.
6. It increases paranoia.
7. It impairs cognition and the ability to make judgments and foresee consequences.
8. It diminishes the ability to verbalize feelings.

9. It interferes with the child's ability to empathize with the feelings of others.

In short, child abuse is the most powerful generator of child, adolescent, and adult violence that we know. The earlier, the more pervasive, and the more enduring the abuse, the more likely it will engender aggressive adaptational styles. Furthermore, the more neuropsychiatrically impaired the child is to begin with, the more likely the abuse will result in a repetitively violent individual. Boys are especially vulnerable. Psychotic symptoms, especially paranoia, brain damage or dysfunction, and abuse are a deadly combination ([Lewis et al., 1988a, 1988b, 1989](#)).

## SOCIAL FACTORS AND VIOLENCE

### Cultural and Socioeconomic Influences

It is obvious from the differences in the rates of violent crime in different societies and in different sectors within societies that social factors influence aggressive behaviors. The mortality rates alone of young men in different parts of the world attest to the importance of social forces. For example, in 1995, only 38 young men between 15 and 24 years of age in both England and Wales combined died of homicide, compared with 6,224 such deaths in the United States ([Currie, 2000](#)). Although murder rates throughout much of the world increased markedly in the 1990s, the rate in the United States stands out in comparison with most European countries, Japan, and India. ([Grossman, 1996](#)). The rate of serious juvenile violence in the United States rose dramatically between 1987 and 1994 and since then (i.e., between 1994 and 1999) has decreased ([Farrington and Loeber, 2000](#)). True, the overall homicide rate in the late 1990s had diminished to 1960s levels; however, as [Currie \(2000\)](#) observed, the decline in overall violent deaths was more a reflection of lower mortality rates for adults older than 25 years of age. Whereas in 1998 the homicide death rate of Americans 25 years of age and older was approximately half what it was in 1970, the death rate by homicide of children 14 to 17 years of age was almost 50% higher than in 1970, and for young adults between 18 and 24 years of age it had almost doubled. To quote [Currie \(2000\)](#), "Lethal violence in the United States, in short, has increasingly become a young person's game" (p. 749). Some have hypothesized that the dramatic rise in juvenile violence in the early 1990s was a reflection of increases in gang membership, gun use, drug dealing, and drug use, especially the use of crack cocaine ([Farrington and Loeber, 2000](#)). Whatever the causes of the previous increase and the more recent decrease in violent crime, the fact remains that the United States still stands out among other developed countries in terms of its violence, especially its high rate of juvenile homicide. Juvenile violence also has increased in other advanced countries, but, in Western European countries, the increase has been predominantly in less serious forms of assault ([Currie, 2000](#)).

[Courtwright \(1998\)](#), in his trenchant analysis of the sociocultural characteristics of our country that contribute to its excessive violence, observes, "...other things being equal, the total amount of violence and disorder in society is negatively related to the percentage of males in intact families of origin or procreation..." (p. 247). He goes on to say, "Families rather than governments are the first best defense against violent and disordered behavior" (p. 279). He points out that the particular mixture of demographic, cultural, and social characteristics of our frontier, its surplus of young, unparented, unmarried men, its code of honor, its racist attitudes, its heavy alcohol consumption, its lack of religious convictions or practices, its devotion to guns, and its lack of an effective system of law enforcement formed a matrix for violence. Moreover, the closing of the frontier did not eliminate the "national self-image" in that, to this day, Americans continue "to think a manly man is someone with a gun and an attitude" (p. 4). Courtwright points out that, after World War II, when marriage rates went up and families focused on childrearing, social stability, and financial security, church attendance rose and violent crime diminished. However, between the 1960s and the 1980s, with the sexual revolution and the increasing divorce rate, the overall number of American men living alone roughly doubled and, in spite of increased use of contraception and abortion, the American population saw "a huge increase in the percentage of children who were illegitimate and raised in fatherless families" (p. 5). Courtwright stresses the civilizing influences of early upbringing in stable families and draws a cogent analogy between the violence-inducing frontier society and today's urban ghettos. He states, "Indeed, it is possible to think of the urban ghettos as artificial, unusually violent frontier societies—vice-ridden combat zones in which groups of armed, unparented, and reputation-conscious young bachelors, high on alcohol, cocaine, and other drugs, menace one another and the local citizenry, undeterred, if not untouched, by an entropic justice system" (p. 272). He concludes that in environments in which stable, intact families and adequate parental guidance are lacking (e.g., frontier towns, ghettos, urban areas during the early morning hours), violence will flourish. Therefore, it is not surprising that at this time our country is more violent than most Western European countries.

Juvenile violence is not spread uniformly across our country. Juvenile violence is far more prevalent in urban than rural settings. According to [Farrington and Loeber \(2000\)](#), in 1977, there were 56 known juvenile homicide offenders per million juveniles in the United States, and more than one-fourth of these homicidal juveniles came from just 8 of the 3,139 counties in the United States. The cities in these counties were Chicago, Illinois; Los Angeles, California; Houston, Texas; New York, New York; Baltimore, Maryland; Detroit, Michigan; Philadelphia, Pennsylvania; and Dallas, Texas. Most homicides were committed with firearms. Much juvenile and adult violence would not be lethal were access to guns more difficult.

In addition to the availability of guns, what promotes violence? [Currie \(2000\)](#) reminds us that violence in general, and youth violence in particular, is linked to "the experience of growing up toward the bottom of the U.S. social and economic ladder" (p. 752). He notes that material poverty and extreme economic inequality are associated with high homicide rates; this is true if one compares violence in states, cities, or neighborhoods within cities. He points out that efforts to determine whether the major contributing factor is socioeconomic inequality or racial subordination are academic because all three, violence, poverty, and racial subordination, cluster together in the same populations. Being relatively low on the socioeconomic totem pole is not associated with violence so much as is living in grinding poverty. In their study of violent crime in Columbus, Ohio, [Krivov and Peterson \(1996\)](#) found an especially high rate of violent crime in the poorest of poor neighborhoods. According to Currie, "It is this strong link between extreme deprivation and violence that accounts for the tragic association between violence and race in America." Bolstering this contention was the finding that in Columbus, Ohio, extremely deprived white neighborhoods had nearly as high violent crime rates as extremely deprived African-American neighborhoods.

Poverty alone does not seem to account for violence. Sociologists believe that a strong influence on criminality springs from "social disorganization," the lack of extended families to support youngsters whose families lack the stability to nurture them properly ([Currie, 1998](#)). Children in these communities often are shifted from caretaker to caretaker. Proper nutrition and safety, much less the establishment of secure attachment, fall by the wayside. The challenge often is just staying alive. One of the most convincing and thought-provoking theories of the linkage of violence and social deprivation was proposed by [Landau \(1984\)](#). He hypothesized that violence and aggression would increase in societies when social support systems malfunctioned or totally failed. Using inflation rates and the ratio between marriage rates and divorce rates as measures of social stress and family instability, Landau found an association to exist between these indices of societal malfunction and rates of violent crime in 11 of 12 countries studied in the 1960s and 1970s. The only country in which this association was not found was Japan, a country, as Landau noted, in which there are strong behavioral controls outside the family (e.g., in schools and workplaces). The Japanese culture itself instills strong feelings of shame for moral transgressions. The societal stressors associated with violence in other countries are associated with suicide rates rather than murder rates in Japan.

In impoverished societies, the determination of which children will succumb to violence as an adaptational style depends on a multiplicity of other variables, including biological, family, peer, school, and community factors ([Farrington and Loeber, 2000](#)). Among short-term precipitants of violence, Farrington and Loeber cite "being bored, angry, drunk, or frustrated" as well as "situational opportunities, including the availability of potential victims" (p. 744). Among the individual characteristics conducive to violence, [Farrington and Loeber \(2000\)](#) stress impulsivity or low IQ. Numerous studies from various parts of the world have documented an association between low or low-normal IQ and violence ([Teichner et al., 2000](#)). It is important to stress that neither impulsivity nor low IQ is necessarily inherited. The wealth of data cited in the foregoing discussion attests to the potentially adverse effects on intelligence, temperament, and behavior of impaired attachment, child abuse, neglect, and neurologic insults. In summary, the kinds of external stressors and intrinsic vulnerabilities that play roles in individual violence (e.g., physical discomfort, lack of nurturance and stability, CNS dysfunction, increased rates of mental illness, child abuse) are more pervasive in disadvantaged communities and contribute significantly to the disproportional rate of violence in the most impoverished sectors of society. Whether mental illness, cognitive impairment, and intellectual limitations cause individuals to sink into these impoverished environments, or whether the environments themselves give rise to these kinds of disabilities is not easily determined. It is reasonable to infer that interactions among vulnerabilities and adverse environments create matrices for violence.

### Media Influences

Evidence regarding the influence of violent entertainment on children and adolescents is not conclusive. Nevertheless, many studies of violence and the media suggest a link between the two, especially in the case of very vulnerable children ([Lagerspetz, 1989](#)). Clearly, the media affect different individuals differently, and violent children tend to gravitate more toward aggressive films than do better-functioning children. Children from violent homes are reportedly affected differently from those growing up in nurturing households ([Brown and Pennell, 2000](#)). Thus, causality is hard to prove. Some studies suggest that exposure to violent material increases violent fantasy (and, perhaps, by extension, violent behavior), especially in men ([Hess et al., 1999](#)). A study of the effects of violent video games found a relationship between playing or viewing violent video games and subsequent aggression, especially in men. The authors reported that men in general had a more hostile view of the world than women. Although academic achievement reportedly is inversely proportional to time spent playing video games, causality would be difficult to prove ([Anderson and Dill, 2000](#)).

A major vulnerability to the effects of exposure to violent materials is youth. Small children, to begin with, react differently from older children to the effects of aggression on others. For example, small children often continue to act aggressively in spite of a victim's expressions of pain, whereas older children and adults are more likely to be inhibited by the victim's suffering ( [Patterson et al., 1967](#)). In an experiment in which children of different ages were shown the beginning of a series of aggressive films and asked to choose among endings for them, younger children tended to choose violent outcomes for violent films, whereas older children were more likely to take into consideration whether the violence observed was justified or unjustified when choosing an outcome ( [Leifer and Roberts, 1972](#)). It would seem that emotional and cognitive maturity are important factors influencing choice.

A study of the content of a random sample of music videos aired at selected times of high adolescent viewership revealed that 14.7% of videos contained overt interpersonal violence, with an average of 6.1 violent acts per violent video ( [Rich et al., 1998](#)). Attractive role models were aggressors in over 80% of these videos. African Americans were overrepresented as aggressors and white women were the most frequently depicted victims. The authors suggested that such depictions reinforced false stereotypes. Ways in which media may affect behavior include modeling, disinhibition, desensitization, the arousal of aggressive feelings, and the encouragement of risk-taking ( [Derksen and Strasberger, 1996](#); [Huesman et al., 1997](#)).

The extent to which media contribute to violence not only by producing violent films but by transmitting news of violence from all over the globe deserves attention. [Groebel and Hinde \(1989\)](#) capture the interaction among biological and psychological vulnerabilities and the influence of the media in their statement, "The most likely link between the media and aggression is a reciprocal one. News media reflect societal aggressiveness but also create the image of a violent world. Viewers with aggressive predispositions prefer violent programs which in turn reinforce their aggressive tendencies" (p. 139). Thus, in a free society, in which all news can be reported and there are few restrictions on the aggressive content of programming, so that for the majority of individuals have unlimited access to information, we accept the risks inherent in exposing more vulnerable individuals, young and old, to violent stimuli.

### Gangs and Crowds

A word should be said about the tendency of relatively nonviolent youngsters to act aggressively when in gangs or crowds. People have a tendency to look with suspicion on others they perceive to be different from themselves ( [Grossman, 1996](#)). What is more, it is easier to stereotype and ultimately dehumanize a group we do not know than it is an individual with whom we have a relationship. This tendency to regard people who are different from us with suspicion accounts to some extent for the greater amount of violence in a heterogeneous society such as the United States, compared with a more homogeneous society like Japan. In a crowd, we also tend to lose our own individuality. With anonymity we act as if we are less responsible for our own behaviors and thus permit ourselves a greater expression of aggression than we would were we acting alone.

### REEXAMINING HUMAN NATURE

This chapter opened with a question: What kind of animal are we? From the data presented, it might be inferred that we are essentially violent. That is not so—not even in the United States. After all, in 1997, in the United States, there were only 4.1 arrests per 1,000 juveniles for seriously violent crimes (e.g., homicide, rape, robbery, aggravated assault). The rate ranged from a high of 10.2 per 1,000 in Illinois to 0.8 per 1,000 in West Virginia ( [Snyder and Sickmund, 1999](#)). Thus, we are a relatively nonviolent beast, considering our evolutionary origins.

What other evidence have we of our essentially peaceful nature? When the World War II historian S.L.A. Marshall and his team of interviewers spoke with thousands of soldiers in more than 400 infantry companies in Europe and the Pacific right after combat, the researchers found that only 15% to 20% of American riflemen had fired on the enemy ( [Marshall, 1978](#)). Soldiers in World War II were not unique in their reluctance to kill their fellow men. Studies of Civil War battles and of European battles of the late 19th century suggest that our forebears were similarly reluctant to kill each other, even in battle ( [Ardant du Picq, 1946](#); [Griffith, 1989](#)). There also is evidence that intense interpersonal combat takes an enormous psychological toll on soldiers. We do not like to kill each other. Historians have estimated that a third of all Israeli and Egyptian casualties in the 1973 Arab-Israeli war were psychiatric in nature ( [Shalit, 1988](#)). The overwhelming majority of soldiers kept in continuous battle for extended periods (e.g., 2 months) succumb to a variety of different psychiatric conditions that impair their ability to function in the field ( [Swank and Marchand, 1946](#)). War—killing each other—does that to us. [Grossman \(1996\)](#), in his summary of the literature on the effects of mortal combat, concludes, "There can be no doubt that this resistance to killing one's fellow man is there and that it exists as a result of a powerful combination of instinctive, rational, environmental, hereditary, cultural and social factors" (p. 39).

Given our apparently innate reluctance to kill each other, what is it that enables or even causes some of us to override these inhibitions? The Army has learned that to get ordinary human beings to kill each other, they must be trained to do so. Normal people must be conditioned to kill each other. Whereas during World War II, soldiers were trained to fire at targets in a field, modern training simulates battle, with human-shaped targets popping up and, if hit, immediately falling down. This instantaneous and repeated reinforcement of behavior has been credited in part with American soldiers' rise in firing rates from 15% to 95% between World War II and the Vietnam War. To get soldiers to overcome their inhibition to kill, every effort is made to dehumanize the enemy and desensitize the soldier to the act of killing ( [Grossman, 1996](#)). Soldiers also are taught to obey orders of their superior officers without question. In short, it takes a lot to get a normal human being to kill another human being.

One must ask, therefore, What about those four juveniles per thousand who are arrested for seriously violent acts? Some would dismiss the recurrently violent among us as simply inherently antisocial or sociopathic ( [Grossman, 1996](#)). To bolster such theories, they turn to studies reporting apparently inherent autonomic hyporeactivity in antisocial youngsters ( [Hare, 1970](#); [Mednick, 1981](#); [Raine et al., 1990](#)). Others point to the twin and adoption studies as evidence of innate predispositions to violence ( [Cadoret et al., 1995, 1997](#)).

Clearly, temperaments differ, and they differ from birth ( [Chess and Thomas, 1984](#)). But temperament is not synonymous with behavior. The ways in which temperamental predispositions manifest themselves depends on experience. Violent individuals are made, not born. Even autonomic arousal, a characteristic that may at first seem inherent, can be modified by experience (e.g., prefrontal cortical damage diminishes autonomic responsiveness to social stimuli) ( [Damasio, 1998](#)). Some of the factors that influence aggression are the timing, duration, and intensity of stimuli, with early stimuli having an especially strong impact. These influences cannot really be separated into psychological and biological, environmental and intrinsic because, as we have seen, there is a constantly changing dynamic interaction between the two. In human beings, we know that when intrinsic vulnerabilities such as brain dysfunction or a predisposition to mental illness are coupled with an abusive upbringing, violence often follows. A useful way to conceptualize the influences on aggression is as follows: Anything that increases irritability, discomfort, fearfulness, suspiciousness, and impulsivity lowers the threshold for aggression and increases the likelihood of violent behavior. Anything that impairs reality testing, judgment, foresight, self-esteem, empathy, self-control, and the ability to verbalize feelings rather than act on them also lowers the threshold for violence and enhances aggressiveness.

In contrast, anything that increases self-control, enhances judgment and foresight, increases self-esteem and a sense of security, increases the ability to recognize one's own feelings and the feelings of others, and increases the ability to express these feelings verbally rather than behaviorally raises the threshold for aggression and diminishes the likelihood of violent behavior.

Our understanding of human nature, of our aggressive evolutionary origins and yet innate disinclination to murder each other, suggests that much human violence can be prevented. The simple act of nurturing our young adequately would be a good place to start. Once a child has been damaged psychologically, emotionally, and neurophysiologically and has adopted an aggressive adaptational style, the degree to which that course can be reversed remains a question. Although the first 2 years of life are critical to normal brain development, "The process of neural plasticity in response to learning and the acquisition of new memories continues throughout childhood and into adulthood" ( [Glaser, 2000](#), p. 101) There is reason to believe that even in late childhood and adolescence, with appropriate intervention, change for the better can occur ( [Kazdin, 2000](#)).

We may not know exactly what works to diminish violence once it has developed, but we have excellent indicators of what does not work. As this review of violence illustrates, we know that isolation and neglect often lead to aggressive behaviors. We know that responding punitively to aggressive behaviors reinforces these behaviors. We know that physical discomfort and frustration increase violence. We know that physical brutality engenders violence. And we know that witnessing the violence of others is conducive to the development of an aggressive adaptational style. Given the fact that at this time in our history our correctional systems incorporate all of the factors known to enhance violent behaviors, and that younger and younger children are being incarcerated, it is not surprising that the rate of recidivism for violent offenders, children and adults, is so high. However, knowing what we already know about human nature, with a little ingenuity we could use this knowledge to devise effective prevention and treatment programs.

[Conclusions](#)  
[Chapter References](#)

In recent years, psychiatrists have been rediscovering the clinical importance of their historical roots in medicine in general and in neurology in particular. The proliferating volume of clinical research data has generated a growing awareness of important biological influences in psychiatric disorders, which in some circles, for some time, had been viewed almost exclusively in terms of their psychological and environmental determinants. This contemporary reintegrated neuropsychiatric perspective has, in turn, been associated with an increased concern by psychiatrists with the psychiatric manifestations of and complications of primary neurologic disorders ([Brumback and Coffey, 1998](#)).

In this context, clinicians evaluating children and adolescents with neurologic dysfunction must also be prepared to integrate developmental considerations in evaluating and treating these patients ([Kagan, 1998](#)). Syndromes that affect the central nervous system (CNS) tend to have particularly augmented cognitive, emotional, and behavioral effects if they begin and persist during these early periods of development. In this regard, a syndrome that is static in its neurologic sequelae (e.g., cerebral palsy) is quite different in its psychiatric implications from a progressive disorder, such as one of the neurodegenerative disorders, commonly diagnosed initially in childhood. Furthermore, the area and extent of neurologic involvement is crucial to determining the impact on development. Thus, a CNS lesion that generates intellectual impairment in the form of learning disabilities or frank mental retardation will make a substantial difference in the patient's coping capacities, quite apart from other focal neurologic or psychiatric impairments.

The Isle of Wight study demonstrated that children with brain injury suffer a significantly greater rate of psychiatric impairment than children with comparable degrees of physical disability not involving the CNS ([Goodman, 1994](#); [Rutter, 1989](#)). Beyond the psychological sequelae of impaired physical functioning, the clinician must consider the potential direct neurophysiologic impact of CNS dysfunction on emotional, cognitive, and behavioral capacities ([Howe et al., 1993](#); [Pine et al., 1993](#)).

Not all CNS dysfunction meriting differential diagnostic consideration by child psychiatrists is as evident as that following a well documented brain injury. Indeed, one of the crucial tasks of the clinician in evaluating a youngster manifesting signs or symptoms of dysfunctional behavior or emotion is to assess the patient multidimensionally. This precludes the simplistic assumption that the dysfunction can be understood as deriving exclusively from either neurogenic or psychogenic origins. The multi-axial diagnostic format of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV and DSM-IV-TR) encourages clinician consideration of psychopathology in this multidimensional manner ([American Psychiatric Association, 2000](#)).

With a growing level of sophistication, we have come to appreciate important neurogenic substrates of the CNS dysfunction central to a growing number of traditional psychiatric disorders, including the schizophrenias, pervasive developmental disorders, tic and Tourette's disorders, attention deficit/hyperactivity disorder, affective disorders, and anxiety disorders, to name just a few. Because we now recognize that every behavior and subjective experience has a neurophysiologic correlate (which most often currently is not identifiable), the neurogenic versus psychogenic distinction is ultimately a semantic one, determined by our current level of neurophysiologic sophistication.

For purposes of this chapter, the neuropsychiatric signs, symptoms, and syndromes considered are those relevant to definable or presumed brain lesions. *Signs* are objective, observable deviations from normal behavior, performance, or neurophysiology. The mental status examination and more formal psychological testing assess both spontaneous behaviors and responses to standard cognitive queries. These often are usefully supplemented by formal neurologic evaluation, with its associated assessment of other areas of CNS function. *Symptoms* are the subjective observations by the patient of some deviation of experience or behavior from the norm. It is important in the case of children and adolescents to ascertain independently, from parents, to what extent such subjective complaints by the patient represent a change from the youngster's preexisting state and over what time frame.

[Table 30.1](#) delineates a variety of diagnostic parameters, together with relevant signs and symptoms important to the diagnosis of neuropsychiatric syndromes ([Horvath et al., 1989](#)). It must be emphasized that, in assessing children and adolescents, the clinician needs to have a sense of the relative range of normal vis-à-vis an individual patient's age. This makes more complicated an assessment that, for adults, by contrast, can be gauged against a relatively unimodal standard normal range.

Consciousness and arousal	Is there a reduced state of awareness (clouding)? Is there a disturbance in levels of the sleep-wake cycle? Is there a marked change in customary activity level? Is the capacity to shift focus and sustain attention impaired?
Motion	Are there any inappropriateness, flaccid, or hyperactive?
Reaction	Is the ability to process information reduced?
Cognitive processing	Is there an impairment of content? (e.g., concrete versus poor abstract/concept-forming ability?) Is there a loss of general intellectual content?
Cognitive content	Are there any delusions or paranoid ideas, hallucinations?
High cortical functions	Is there evidence of aphasia, hemiparesis, or incoherent speech, apraxia, or constructional difficulty, apraxia?
Memory	Is there difficulty to learn new information and to transfer it from short- to long-term memory? Is there difficulty to remember if familiar event in the past? Is there difficulty with recall or recognition? Is there difficulty with verbal or visual memory?
Mood	Is the mood consistently depressed, elated, irritable, aggressive, or anxious? Is the mood labile, apathetic, indifferent?
Judgment	Is social judgment impaired? Is there any "magical" thought?
Time course	Do the symptoms fluctuate? Do the symptoms progress steadily or in a stepwise manner? Is there a discrete decline in function or a discrete increase in symptoms?

**Table 30.1. Diagnostic Parameter Signs and Symptoms**

Many of these signs and symptoms can be adequately evaluated by a clinician in the course of a routine office evaluation. Nevertheless, the general clinical impression thus generated often can be usefully supplemented by formal psychological and neuropsychological testing. Although specific discussion of such testing is beyond the scope of this chapter, it behooves the clinician to be aware of the special techniques available for the assessment of the infant and young child ([Neuper et al., 1998](#)); some of the tools available to aid in clinical evaluation of cognitive and behavioral function ([Weinberg et al., 1998](#)); and the potential benefits of formal neuropsychological testing ([Boll et al., 1998](#)).

This chapter follows the DSM-IV and DSM-IV-TR format of replacing the DSM-III-R category of "Organic Mental Syndromes and Disorders" because this designation incorrectly implies that "nonorganic" mental disorders do not have a biological basis ([American Psychiatric Association 2000](#)). Instead, DSM-IV and DSM-IV-TR use two categories for what have traditionally been regarded as neuropsychiatric syndromes:

1. Delirium, Dementia, and Amnesic and Other Cognitive Disorders
2. Mental Disorders Due to a General Medical Condition

The essential ingredient in both of these broad diagnostic groups is an experiential or behavioral abnormality associated with transient or permanent documentable dysfunction of the brain. In this chapter, several of the aforementioned DSM-IV and DSM-IV-TR categories of mental disorder are addressed as they pertain to children and adolescents. Mental disorders associated with intoxication and withdrawal are discussed in [Chapter 73](#). Mental disorders associated with acquired brain injury are addressed in [Chapter 33](#). Mental disorders associated with brain tumors, neurodegenerative disorders, epilepsy, and cerebral palsy are addressed in [Chapter 61](#).

## DELIRIUM

Delirium may be defined as a transient and usually reversible dysfunction in cerebral metabolism that has an acute or subacute onset, that is caused by the direct physiologic consequences of a general medical condition, and that is manifest clinically by a wide array of neuropsychiatric abnormalities ( [American Psychiatric Association, 2000](#)). Although the term has been used with differing connotations over the years and has many synonyms in the neurologic and psychiatric literature, it seems best for current purposes to use the preceding definition of delirium corresponding to that outlined in DSM-IV and DSM-IV-TR. Because, as noted earlier, disorders associated with intoxication and withdrawal are discussed in another chapter, [Table 30.2](#) outlines diagnostic criteria for delirium due to general medical conditions.

- 
- A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
- B. A change in cognition (e.g., memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
- C. The disturbance develops over a short time (usually hours to days) and tends to fluctuate during the course of the day.
- D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiologic consequences of a general medical condition.
-

**Table 30.2. Diagnostic Criteria for Delirium Due to General Medical Conditions**

### Predisposing Factors and Clinical Features

Aside from the factor of age (children and the elderly reportedly have a higher risk), polypharmacy and multiple medical problems are probably the most common risk factors to delirium ([Trzepacz and Wise, 1997](#)). In addition, the following factors predispose to the development of delirium: postcardiotomy status, severe burns, preexisting brain damage, drug addiction, and acquired immunodeficiency syndrome ([Pontrelli et al., 1999](#)). Although formal epidemiologic studies are lacking, there is a consensus of reported clinical impressions regarding the vulnerability of children to delirium ([Amit, 1988](#); [Platt et al., 1994](#); [Prugh et al., 1980](#)). Because of the general acceptance of a tendency for children to regress under stressful circumstances, milder forms of delirium may be mistaken for simply regressive or provocative behavior. As with adults, however, undetected delirium may proceed to the point of self-injury or serious interference with medical treatment.

A clinical consensus suggests that, as the severity of a pathophysiologic stress increases, so does the probability of development of a delirium ([Wise and Brandt, 1992](#)). This is particularly true for burn patients, as well as for postoperative patients. Additional factors that are considered to foster the development of delirium include sleep deprivation, sensory deprivation, and sensory overload.

In addition to those clinical features outlined in [Table 30.2](#), the clinician also should note the possible presence of a prodromal period, characterized by restlessness, anxiety, sleep disturbance, and irritability. Also noteworthy and frequently present is a rapidly fluctuating and usually reversible course, which may include either hypoactivity or hyperactivity. Emotional lability often is observed, as is disorientation, dysgraphia (difficulty writing), constructional apraxia (difficulty drawing), and dysnomic aphasia (difficulty naming objects). Motor abnormalities that may be observed include tremor, asterixis (hand flap on extension), myoclonus (clonic muscle spasm), and symmetric reflex and muscle tone changes ([Lipowski, 1990](#)).

Although [Trzepacz \(1994\)](#) has reviewed the relative merits of 12 different assessment instruments that have been used for delirium with adults, there do not appear to be comparable instruments available for children. This probably reflects the greater difficulty in standardizing such instruments for children at various developmental levels. Therefore, currently, the clinician must integrate the diagnostic criteria for delirium with a cogent sense of age-appropriate developmental norms.

### Differential Diagnosis

Insofar as the basic etiology of delirium is conceptualized as a derangement in the functional metabolism of the brain, it is clear that a vast array of medical conditions originating within as well as outside the CNS can engender such a derangement. Because these numerous medical conditions cannot be reviewed here, an outline of more common causes is provided in [Table 30.3](#). As [Wise and Brandt \(1992\)](#) note, the catchy mnemonic “I WATCH DEATH” serves to remind the clinician of the potentially severe morbidity and mortality that can ensue from untreated or undertreated delirium. A more comprehensive list for consideration is outlined by [Trzepacz and Wise \(1997\)](#).

Infection	Encephalitis, meningitis, abscess, acquired immunodeficiency syndrome
Withdrawal	Alcohol, barbiturates, sedative-hypnotics
Acute metabolic	Acidosis, alkalosis, electrolyte disturbance, hepatic failure, renal failure
Trauma	Head trauma, postoperative stress, burns
Drug pathology	Alcohol, benzodiazepines, narcotics, hydrocephalus, seizures, stroke, tumor, vasculitis
Hypoxia	Anemia, carbon monoxide poisoning, hypotension, pulmonary embolism, cyanosis
Deficiencies	Vitamin B <sub>12</sub> , hypovitaminosis, niacin, thiamine
Endocrinopathies	Hypothyroidism, hyperthyroidism, hyperparathyroidism, hypoparathyroidism
Acute vascular	Hypertensive encephalopathy, stroke, migraine
Toxic/drug	Medications, pesticides, solvents
Heavy metals	Lead, manganese, mercury

DE, central nervous system.

**Table 30.3. Causes of Delirium (“I WATCH DEATH”)**

Ordinarily, a psychiatrist confronted by a delirious patient promptly involves a neurologic colleague in clarifying the differential diagnosis. It behooves the child psychiatrist, nevertheless, to be familiar with the neuropsychiatric evaluation of the patient with delirium. A summary of this process is outlined in [Table 30.4](#). It is most important to recall that more than one etiologic factor may be simultaneously at work in any patient.

1. Mental status  
 History: presence of consciousness, orientation, affect, mood, insight, thought, thought process, performance (memory, concentration, writing, motor and construction, apraxia, agnosia, speech)

2. Physical status  
 Neurologic: examination (head, eye, strength, lateral eye, cerebellum, meningeal signs, gait)  
 Review of systems: EKG, pulse, temperature, blood pressure, respiratory rate  
 Review of laboratory tests: serum electrolytes, renal and liver function tests, hematology, urinalysis, toxicology, thyroid function tests, serum ammonia, serum lactate, serum glucose, serum calcium, serum magnesium, serum phosphorus, serum uric acid, serum ferritin, serum vitamin B<sub>12</sub>, serum folate, serum vitamin D, serum parathyroid hormone-related protein, serum prolactin, serum cortisol, serum growth hormone, serum insulin, serum C-peptide, serum insulin-like growth factor-1, serum insulin-like growth factor-1 binding protein-3, serum insulin-like growth factor-1/2, serum insulin-like growth factor-1/2 binding protein-3, serum insulin-like growth factor-1/2 binding protein-3, serum insulin-like growth factor-1/2 binding protein-3

3. Laboratory examination: toxic  
 Blood chemistry: electrolytes, glucose, Ca, albumin, blood urea nitrogen, creatinine, liver function, blood count (hemoglobin, white count and differential, platelet count), serum ammonia, serum lactate, serum glucose, serum calcium, serum magnesium, serum phosphorus, serum uric acid, serum ferritin, serum vitamin B<sub>12</sub>, serum folate, serum vitamin D, serum parathyroid hormone-related protein, serum prolactin, serum cortisol, serum growth hormone, serum insulin, serum C-peptide, serum insulin-like growth factor-1, serum insulin-like growth factor-1 binding protein-3, serum insulin-like growth factor-1/2, serum insulin-like growth factor-1/2 binding protein-3, serum insulin-like growth factor-1/2 binding protein-3

4. Laboratory: based on clinical judgment  
 Electroencephalogram (EEG): focal abnormalities (Corbin defined by voltage slowing or low voltage fast activity) Computerized tomography (CT scan) Magnetic resonance imaging (MRI) (with contrast) Lumbar puncture (indicator of infection or increased intracranial pressure)

**Table 30.4. Neuropsychiatric Evaluation of the Patient with Delirium**

Clearly, the prognosis for a given patient with delirium varies with the etiology and, most important, with whether irreversible damage to the CNS is sustained. Hence, the outcome, depending on the timeliness and effectiveness of treatment, may vary from full recovery through progression to stupor and coma, to seizures, to chronic brain syndromes, or to death.

**Treatment**

If the clinician's differential diagnostic assessment has elucidated an etiology for the delirium, then specific treatments that can lead to resolution of the delirium often may be initiated. Specific treatments for identified causes of delirium are beyond the scope of this chapter and would be dictated by the tenets of accepted medical practice. In those situations where the etiology is unknown, even after a thorough initial evaluation, some interim supportive measures may well be helpful while diagnostic efforts continue. These are outlined under the following headings.

*MEDICAL MEASURES*

A patient with delirium should not only be in a hospital setting, but should be under close observation by nursing staff who are familiar with the management of delirium. This should involve frequent monitoring of not only vital signs but mental status, especially with a view to preventing self-injurious behavior.

*PHARMACOLOGIC MEASURES*

In the absence of double-blind trials, clinical experience has led to the advocacy of haloperidol administration in patients with delirium, based on numerous clinical reports of efficacy. Haloperidol also is favored in delirium because of its negligible anticholinergic and hypotensive properties and because it can be given parenterally ([Lipowski, 1990](#)). Although the use of haloperidol in pediatric patients with delirium is not well documented, its efficacy in children with a broad spectrum of more commonly encountered psychiatric disorders ([Teicher and Gold, 1990](#)) suggests that it may have a useful role in pediatric delirium ([Trzepacz and Wise, 1997](#)). Clinical titration with close monitoring, beginning with small doses and repeating every 30 to 60 minutes until the patient is calm, is common clinical practice. As with other psychiatric disorders, pediatric haloperidol doses may range from 0.25 to 10 mg/day, or from 0.05 to 0.15 mg/kg/day.

Benzodiazepines have the disadvantage of engendering sedation, which may further impair the delirious patient's cognition and may exacerbate the delirium. Small doses of intravenous lorazepam have been reported to be of some benefit, however, for patients who have not responded to high doses of haloperidol alone ([Lipowski, 1990](#)).

The use of risperidone in delirium has, thus far, been the subject of only isolated case reports in adults and adolescents ([Sipahimalani and Masand, 1997](#)). The use of this and other atypical neuroleptics in this domain awaits further systematic reports of clinical experience.

*PSYCHOSOCIAL MEASURES*

The presence of a calm family member or nursing attendant to provide reality testing, orientation, and reassurance can be very helpful in diminishing anxiety and allaying fears.

**DEMENTIA**

Dementia is a disorder of significant decline in multiple cognitive functions from the individual's previous intellectual level. In terms of the DSM-IV-TR definition, the essential feature of dementia is impairment of memory, associated with at least one of the following cognitive disturbances: (a) aphasia (language disturbance); (b) apraxia (impaired ability to carry out motor activities despite intact motor function); (c) agnosia (failure to recognize or identify objects despite intact sensory function); and (d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting) ([American Psychiatric Association, 2000](#)). The disturbance is severe enough to interfere with work and school, usual social activities, and relationships with others. The diagnosis of dementia is not made if these symptoms occur only in the presence of reduced ability to maintain or shift attention to external stimuli, as in delirium; however, delirium and dementia may coexist.

Although dementia is found predominantly in the elderly, some neuropsychiatric disorders described later in this volume, such as traumatic brain injury or degenerative brain disorders, may cause dementia in childhood and adolescence. In terms of DSM-IV-TR criteria, the diagnosis of dementia may be made at any time after the IQ is fairly stable (usually by age 4 to 6 years). Examples of medical conditions that may induce dementia in children or adolescents would include head injury, brain tumors, human immunodeficiency virus infection, cerebrovascular accidents, or neurodegenerative disorders ([Lerner et al., 1997](#)). Dementia in children may present as a deterioration in functioning, such as in school performance, or as a significant delay or deviation in normal development.

The mode of onset, subsequent course, and clinical management of dementia depend substantially on the underlying etiology. For this reason, such clinical features are addressed with reference to both dementia and other organic mental syndromes in the subsequent chapters of this volume dealing with acquired brain disorders and neurologic syndromes (see [Chapter 33](#) and [Chapter 61](#)).

**AMNESTIC DISORDERS**

Amnesic disorders are characterized by an impairment of memory that is attributable to a specific organic factor, such as a general medical condition (e.g., brain injury, vitamin deficiency), a substance of abuse, a toxin, or a medication side effect. The diagnosis requires the absence of the clouded sensorium associated with delirium or the more pervasive cognitive impairments associated with dementia. The syndrome, more commonly encountered as the Wernicke-Korsakoff syndrome among adult chronic alcoholics and attributed to thiamine deficiency, is relatively uncommon in children. It may be associated in children, however, with head trauma, hypoxia, lead or carbon monoxide poisoning, and herpes simplex encephalitis ([Mikkelsen, 1991](#)). Temporal lobectomy for intractable complex partial seizures may result in memory deficits, but this usually is of major significance only when surgery is bilateral ([Shimanura and Gershberg, 1992](#)).

**OTHER ALTERED STATES OF CONSCIOUSNESS**

Not all altered states of consciousness encountered clinically by child psychiatrists are subsumed by the neuropsychiatric syndromes outlined previously. Indeed, on a broad basis, most of the diagnostic categories encountered clinically, ranging from anxiety disorders and affective disorders to the schizophrenias, involve subtle or not so subtle alterations of attention, perception, cognitive processing, consciousness, and the like, subsuming all the diagnostic parameters delineated in [Table 30.1](#). A critical diagnostic task therefore is that of distinguishing those constellations of signs and symptoms associated with "traditional" psychiatric disorders from those associated with "neuropsychiatric" syndromes. The general current presumption is that the traditional psychiatric disorders are byproducts of particular constitutional or genetically based vulnerabilities, interacting with the individual's life experiences. In neuropsychiatric disorders, by contrast, the CNS abnormality is viewed as the overriding determinant of the presenting psychopathologic process. As reflected in our previous discussion, there are many instances where such distinctions are not

absolute. Thus, a *de novo* organic brain injury is likely to generate new psychopathology that interacts with a patient's preexisting vulnerabilities and personality structure. Alternatively, for example, a patient with a long-standing epileptic seizure disorder may develop secondary psychogenic seizures as a result of developmental adversities or intervening life stresses. The clinician's task, therefore, is to draw on all available sources of information to formulate as comprehensive a diagnostic assessment as possible, as the prerequisite for an effective treatment plan. Implicit in the foregoing is the premise of the multivariate etiology of any psychopathologic picture and an intent to give adequate consideration to both psychogenic and neurogenic factors. With these considerations in mind, three additional syndromes presenting as altered states of consciousness and presenting potential challenges to neuropsychiatric assessment are briefly noted; two others are discussed in some detail.

Altered states of consciousness associated with alcohol and drug use are addressed in [Chapter 73](#), those associated with dissociative disorders are addressed in [Chapter 70](#), and those associated with seizure disorders are addressed in [Chapter 61](#).

## STUPOR AND CATATONIA

Stupor has been defined differently by different authors. For most neurologists, stupor connotes a condition of behavioral nonresponsiveness, including loss of speech (mutism), markedly reduced movement (hypokinesia), and a reduced level of consciousness, from which the subject can be aroused only by vigorous and repeated stimulation. Stuporous patients are, thus, seen by most neurologists as having diffuse organic cerebral dysfunction of greater severity than that encountered in delirium, representing usually the next stage along a neurophysiologic continuum between clear consciousness and coma ( [Cutting, 1992](#); [Plum and Posner, 1980](#)). For many psychiatrists, on the other hand, stupor descriptively has connoted a relative preservation of consciousness in conjunction with mutism and hypokinesia ([Roberts, 1984](#); [Rogers, 1991](#)). As such, stupor has been associated in the psychiatric literature with traditional psychiatric conditions characterized by catatonia.

One of the most reasonable ways of reconciling this disparity in perspectives regarding stupor is to observe that both neurologists and psychiatrists see patients to whom they apply the symptomatic designation of stupor, but that the samples of patients they see, although overlapping somewhat, are significantly divergent. This becomes important in the differential diagnosis of stupor, regarding the need to separate organic from psychogenic stupors. Thus, [Plum and Posner \(1980\)](#) found psychogenic unresponsiveness to occur in only four of 386 unresponsive patients they saw on a neurology service. The predominant "psychogenic" diagnoses in their series of patients were catatonic schizophrenia and hysterical conversion, the latter usually associated with depression. By contrast, [Joyston-Bechal \(1966\)](#) found that in a psychiatric population, 69% of 100 "stuporous" patients had nonorganic disorders only. Of these 100 patients, 25% had depression, 34% schizophrenia, 23% organic disorders (mainly dementia), and 10% hysterical features. Nearly all the patients in both of the aforementioned and other studies ( [Cutting, 1992](#)) were adults, with no comparable series being available for children and adolescents.

[Cutting \(1992\)](#) proposes a classification in which catatonia is designated as a subtype of stupor, referring primarily to psychiatric symptoms traditionally associated with mood disorders, schizophrenia, and, less commonly, somatoform disorder. By contrast, the DSM-IV and DSM-IV-TR ( [American Psychiatric Association, 2000](#)), in addition to the previously noted traditional categories for catatonia, have added the category of "catatonic disorder due to a general medical condition," presumably as a way of reminding the psychiatrist to consider possible underlying organic factors rather than jumping to a premature diagnostic conclusion premised on the more familiar, traditional psychiatric diagnoses. In this regard, DSM-IV-TR defines catatonia as being characterized by any of the following: motoric immobility (hypokinesia or akinesia), excessive motor activity, extreme negativism or mutism, peculiarities of voluntary movement (e.g., waxy flexibility), echolalia, or echopraxia. The diagnosis of catatonic disorder due to a general medical condition is not given if the catatonia occurs exclusively during the course of a delirium.

Clarification of the cause of stupor or catatonia clearly is crucial in light of the potentially serious morbidity and mortality involved if the underlying condition is not effectively treated. Furthermore, inappropriate treatment, such as the use of additional neuroleptics in patients with neuroleptic-induced catatonic stupor ( [Philbrick and Rummans, 1994](#)) or other mismanagement of organic stupor, can cause further deterioration. Because by definition the patient is unable to give a history, securing other reliable informants becomes important. The history may disclose previous physical or mental illness or recent insults that may help clarify etiology. An illustrative example is a report of seven cases of posttraumatic mutism in children after severe head injury ( [Dayer et al., 1998](#)).

One report ( [Cohen et al., 1999](#)) reviewed all published reports on catatonia in adolescents from 1977 to 1997 (42 cases) and reviewed the authors' experience with 9 additional cases seen over 6 years at the authors' medical center. The authors note that, in contrast to its more common occurrence in adult affective disorder and schizophrenia, catatonia appears to occur rarely in adolescence (0.6% of psychiatric inpatients). The diagnoses of affective disorder and schizophrenia still predominated in the adolescent group, with representation also of pervasive developmental disorders and primary neurologic conditions. While maintaining that therapeutic management should be individually and diagnostically based, the authors emphasized (a) the frequency of neuroleptic-induced adverse effects, (b) the potential effectiveness of sedative drugs on motor signs, (c) the potential merits of electroconvulsive therapy for life-threatening or pharmacologically unresponsive conditions, and (d) the necessity to manage supportively family reactions and fears.

[Wing and Shah \(2000\)](#) lend additional evidence for viewing catatonia as a developmental complication emerging in later adolescence and young adulthood in neuropsychiatrically vulnerable patients. They surveyed 506 referrals to a center for autistic spectrum disorders and found that 17% of referrals aged 15 years and older had severe exacerbation of catatonic features. Further, they were significantly more likely than the comparison group to have had, before the exacerbation of these features, impaired language and passivity in social interaction.

On physical examination, a psychogenic catatonic disorder is suggested by closed eyes that resist opening and that close rapidly when the force used to open them is released. Although fixation of the eyes on objects in the patient's field of vision suggests alertness and awareness of the environment, this also may be seen in some organic disorders. Random roving eye movements, however, strongly suggest an organic disorder. On the other hand, voluntary deviation of eyes to the ground, no matter which side the patient is lying on, points to a psychogenic stupor ( [Roberts, 1984](#)).

The alert patient in psychogenic stupor usually attempts to protect himself or herself from injury ( [Rogers, 1991](#)). Thus, if the physician lifts the patient's arm and allows it to fall toward the patient's face, the patient usually will modify its path to avoid its striking him or her. Alertness also is suggested by a blink response to visual threat and purposeful, directed attempts by the patient to deflect a painful stimulus. Autonomic hyperarousal usually is present, with tachycardia, hypertension, and pupils that are equal, dilated, and responsive briskly and symmetrically to light.

The use of intravenous orazepam may be helpful when there is a strong index of suspicion that a patient's stupor or catatonia may be of psychogenic etiology ( [Clark and Rickards, 1999](#)). Careful neurologic evaluation of the patient should precede the use of this procedure, however, because the drug may confuse the monitoring of the patient's level of consciousness, which is vital when a progressive neurologic lesion is suspected. Similarly, it may interfere with interpretation of the electroencephalogram. In organic brain disorders, amobarbital sodium tends to cause cognitive deterioration: If this occurs, its use must be immediately stopped and the patient examined for any neurologic signs that may have been revealed. In the psychogenic patient, underlying psychopathology, such as positive symptoms of psychosis, may be revealed. The unresponsiveness of psychogenic patients tends to diminish with amobarbital sodium, but this may require a high dose of the drug. This is in contrast to the relatively low dose that often causes sedation and confusion in patients with organic brain disorders.

Further aspects of differential diagnosis and treatment would follow similar channels of consideration as those outlined previously in the section on [Delirium](#). Certainly, involvement of a neurologic colleague in the assessment to rule out pertinent neurologic etiology is essential before proceeding to treatment intervention for presumed psychogenic etiology. Furthermore, positive evidence for an underlying psychiatric diagnosis should be delineated before a specific psychiatric treatment plan can reasonably be initiated.

## CONCLUSIONS

Being cognizant of the diagnostic significance of neuropsychiatric signs, symptoms, and syndromes is essential for the well trained child and adolescent psychiatrist. Implicit in this is the psychiatrist's developing a multidimensional perspective that carefully attends to both the neurogenic and psychogenic influences that each patient brings to his or her interactions with the outside world. Only with such an adequately broad-based perspective on diagnosis can effective treatment planning for patients ensue.

There has been a dramatic change in the approach to pain in children since the mid-1980s. New research has provided a better understanding of the neurobiology and psychology of pain, as well as techniques to treat it more effectively. This new information has effectively counteracted the prevailing myths that had implied that children did not experience pain, or if they did, its impact was relatively insignificant. This chapter reviews some of the newer insights regarding the treatment of pain, focusing on our better neurologic understanding, on improved assessment techniques, and on the basic principles of pain management that apply to both acute and chronic pain situations.

## HISTORY OF UNDERTREATMENT

In 1974, Jo Ann Eland ([Eland, 1977](#)) examined the charts of 25 children who had undergone surgery at a large teaching hospital and found in total only 24 doses of analgesics had been prescribed for them throughout their entire hospital stay. Half of these doses were opioids and half were nonopioids. The average child who received any analgesia got approximately two doses. Children who had traumatic amputations, nephrectomies, and other painful surgeries were given essentially no analgesia. A number of other studies in this period documented this phenomenon. Work by [Mather and Mackie \(1983\)](#), [Beyer et al. \(1983\)](#), and [Schechter et al. \(1986\)](#) all revealed that children's pain in general was minimally treated, that PRN orders would typically be interpreted to mean "as little as possible," and that adults with similar pain problems received significantly more doses of analgesia than did children. The seminal and simultaneously most horrifying research of this era was the work of Anand, who examined the impact of surgery on infants for patent ductus without anesthesia, which was the standard of care in many institutions. Anand reported that preterm and term infants operated on without anesthesia had an enormous outpouring of stress hormones and clinically did much more poorly than did infants who received adequate anesthesia ([Anand et al., 1987](#)). The combination of these studies led to a significant change in the approach to postoperative pain management. By the late 1980s, editorials in most major journals demanded adequate anesthesia and postoperative analgesia ([Berry and Gregory, 1987](#); [Fletcher, 1987](#); [Hatch, 1987](#)). More research emerged on the use of patient-controlled analgesia for children ([Rodgers et al., 1988](#); [Tyler, 1990](#)), as well as on other approaches, and clinical practice guidelines were developed by a number of scientific and governmental agencies to help medical professionals treat pain more effectively ([Acute Pain Management Guideline Panel, 1992](#); [American Pain Society, 1989](#)). These responses clearly had an impact on pain management, and more recent studies of postoperative pain suggest a change both in practice and attitude.

In addition to postoperative pain management, another area that has seen a dramatic change is the management of procedure pain. Throughout the 1980s, it was not uncommon for children to undergo painful procedures such as bone marrow aspirations and laceration repairs with minimal or no sedation ([Bernstein et al., 1991](#); [Hockenberry and Bologna-Vaughn, 1985](#)). Often, when sedation was used, inappropriate agents were administered. Most poignantly, for many children with cancer, the painful procedures that they were forced to undergo as part of their diagnosis and treatment often were rated as worse than the disease from which they were suffering ([McGrath et al., 1990](#)). Frustratingly little research was focused on procedure pain management, and most oncologic research tended to focus on cure and not on symptom control. Again, in the past few years, with the growth of the palliative care movement in adults ([World Health Organization Expert Committee, 1990](#)), a simultaneous focus has occurred in children, and guidelines for procedure pain management in children have been developed by a number of professional societies ([American Academy of Pediatrics, Committee on Drugs, 1992](#); [American Society of Anesthesiologists, 1996](#)). Although there remain differences among the guidelines, it is quite clear that subjecting children to painful procedures without sedation no longer is considered acceptable. Pediatricians had come to accept children's fearfulness about pending procedures as implicit in pediatric care. Such assumptions are no longer valid.

Other pain problems have finally been subjected to examination, as well. Cancer pain ([Schechter et al., 1990](#)), sickle cell pain ([Shapiro, 1993](#)), pain associated with human immunodeficiency virus infection and acquired immunodeficiency syndrome ([Wishnie and Weisman, 1997](#)), and cystic fibrosis pain ([Ravilly et al., 1996](#)) have all received significant attention in the pediatric literature. Common pain problems also have begun to be scrutinized ([Schechter, 1995](#)). The pain associated with pharyngitis, otitis media, and immunizations, which historically had been ignored and thought to be an unfortunate but necessary component of pediatric medicine, is now being studied.

There continue to be significant areas where improvement is necessary, however. Children with chronic diseases whose pain problems are intermittent and unpredictable clearly are less well treated than those who have acute pain episodes that can be predicted, such as after surgery ([Johnston et al., 1992](#)). Even postoperative pain, however, continues to be problematic. The enormous increase in day-case surgery has left most pain management to be done at home by parents who may be anxious and inexperienced about using analgesia. Recent surveys have suggested a considerable amount of untreated pain after ambulatory surgery ([Nikanne et al., 1999](#)). Newborn pain also remains an area that requires attention. Although there have been great strides made in many settings, procedures such as circumcisions often are done without adequate analgesia or anesthesia, and postoperative care remains far less optimal than in older children and adults ([Anand et al., 1996](#); [Porter et al., 1997](#)). Finally, pain problems associated with no obvious pathologic process (recurrent abdominal pain, "growing pains," headache, fibromyalgia) continue to be challenging and require new thinking and approaches.

In summary, then, we have seen essentially a revolution in attitude and approach to pain in children. In the 1970s and early 1980s, there was almost no literature on pain management except for those documenting its inadequacy. Since that time, there has been an outpouring of research in major journals and of reviews available in the key textbooks, which allows practitioners easy access to this information. Assessment techniques have been standardized and subjected to more rigorous psychometric scrutiny. Children and their families are demanding more humane and compassionate care, and these factors all have combined to improve dramatically the management of pain in children.

## DEFINITION

Pain is defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" ([Merskey et al., 1979](#)). The definition goes on to state that pain is always subjective and is learned through experiences related to injury early in life.

Although this well accepted definition represents a significant advance in our understanding of pain, it also creates a number of potential problems. The definition

states clearly that pain results from sensory stimulation as interpreted through the broader lens of the individual's experience. Thus, the same painful stimulus can be interpreted in very different ways depending on modifying factors that may serve to magnify or dampen its magnitude. Modifying factors are discussed subsequently, but include age, sex, culture, context or meaning of the pain, as well as a child's temperament and affective state. The combination of the neurophysiologic stimulus and a composite of these variables serves to define the pain experience caused by a specific stimulus in an individual.

This definition has come under increasing scrutiny, however, by people who work with children in pain. It states that pain is learned through experiences with pain early in life, which implies therefore that newborns *cannot* experience pain because they have not had previous experience with injury. The definition also implies that the person must be capable of describing or reporting his or her pain, thus eliminating individuals such as newborns or developmentally disabled children and adults who are not capable of describing their discomfort. [Anand and Craig \(1996\)](#) have expressed concerns about this long-accepted definition and have proposed instead that pain perception is an inherent quality of life that appears early in development and serves as a signaling system for tissue damage. The signaling may occur not only through verbal description, but through a variety of behavioral and physiologic responses that are described later. They have called for a change in the accepted definition, and this issue is under review.

## NEUROPHYSIOLOGY OF PAIN

The basic concept of nociception is that pain messages emerge in the peripheral nervous system and are transmitted to the central nervous system, where they are interpreted.

Mechanical, thermal, or chemical stimuli excite various types of nociceptors in the periphery that give rise to either unmyelinated C fibers (small and slow conducting) or thinly myelinated A-delta fibers (larger and fast conducting). These primary afferents have their cell bodies in the dorsal root ganglion and project to the dorsal horn of spinal cord. Tissue injury in the periphery can result in the release of mediators (bradykinin, cytokines, prostaglandins) that sensitize A-delta and C fibers and increase pain sensation. Repeated injury to these fibers in the newborn period may lead to a surge in nerve growth factor and sprouting of nerves in inappropriate locations, leading to aberrant innervation, lowered pain thresholds, and a permanent effect on development of nerves in the injured region. Therefore, tissue injury in the newborn period may have permanent effects on the development of the pain system.

Nociceptive impulses are transmitted by these afferents to the dorsal horn of the spinal cord, where messages are amplified or attenuated in the complex layers of the dorsal horn and by interaction with surrounding neurons peripherally or centrally. In the spinal cord, a variety of neurotransmitters further modify nociceptive information. Substance P and calcitonin magnify transmission, whereas other neurotransmitters such as endogenous opioids may dampen transmission. The pain stimulus then proceeds up the nervous system through spinothalamic, spinoreticular, and spinomesencephalic tracts. Thalamic projections distribute the pain message throughout the brain because there is no single pain center in the brain. Projections to the cortex account for the impact of past experience on pain, whereas projections to the limbic system allow for the impact of emotions.

In addition, there are a host of descending projections that might inhibit and dampen the pain message. Descending inhibitory pathways arise from a number of different regions, such as the periaqueductal gray matter, the inferior olivary nucleus, and a number of other foci. These tend to become functional later in life, and therefore it is believed that excitatory mechanisms are in place significantly before inhibitory mechanisms. The complex interplay of all of these systems and the involvement of multiple dimensions creates each individual's unique response to painful stimuli.

It has become clear that the pain systems are in place relatively early in the life of the individual and, as a result, infants have the ability to perceive pain before birth. [Anand and Hickey \(1987\)](#) have made the case, in fact, that infants are hyperalgesic because distances traveled by nerve impulses are shorter, there are more nociceptors per surface area than at any time in life, there are no inhibitory mechanisms in place, the cutaneous flexor reflex has a lower threshold in younger infants, and it takes higher levels of analgesia to achieve pain relief.

Finally, as has been mentioned, it is clear that untreated pain may have long-term consequences. Data from rat pups and human newborns who undergo repeated procedures suggest a change in their nervous system, yielding hyperalgesia ([Fitzgerald et al., 1989](#)). Studies of boys undergoing circumcision without anesthesia suggest a different response to immunizations at 4 and 6 months ([Taddio et al., 1997](#)). [Grunau et al. \(1994\)](#) and [Johnston and Stevens \(1996\)](#) and others have looked at the impact of multiple procedures that occur in the neonatal intensive care unit and found predictable effects later in infancy. [Anand et al. \(1999\)](#) even have suggested that pain and stress in the newborn period stemming from unanesthetized ventilation or inadequate analgesia for painful procedures may be responsible for an increase in intraventricular hemorrhage.

## MODIFYING FACTORS

As is evident from the previous discussion, the amount of pain that a person experiences from a specific amount of trauma depends not solely on the extent of the tissue damage, but on a host of modifying factors that potentiate or diminish suffering. Different individuals clearly experience different amounts of pain from the same noxious stimulus, and the same noxious stimulus can cause varying amounts of pain in the same individual at different times in his or her life. Although many factors have been identified that have a role in the pain experience, some of the key modifiers for children are the context or meaning of the pain, the age of the child, the sex of the child, culture, and, finally, affect state. Extensive work has been done in each of these areas, and a thorough discussion is beyond the scope of this review.

### Meaning of the Pain

Early studies of pain suggested a fixed relationship between the intensity of the stimulus and the magnitude of the pain. This theory, known as *specificity theory*, was eventually rejected because it was not in concert with clinical observation.

One of the first investigators to notice a difference in pain responsiveness was Beecher, an anesthesiologist. Beecher's work highlighted the differences in pain perception between soldiers and civilians ([Beecher, 1956](#)). He found that only 25% of the 215 wounded soldiers he cared for requested opioids, whereas 82% of civilians with similar injuries requested pain relief. Beecher identified the fact that for the soldiers, the pain had a meaning that was very different from that of the civilians. For them, it was an expected part of their responsibility and often was seen as a sign of valor. For the civilians, however, the pain was not expected and represented a personal catastrophe and an uncertain future. Since Beecher's initial work on the context and meaning of pain, many other studies have identified similar disparities. For example, cancer surgery usually is reported as more painful than similar surgeries in which concern about cancer is not an issue. Cesarean sections reportedly hurt less than similar uterine surgery ([Bruegel, 1971](#)). In general, when the pain seems to have little benefit and to represent potential disfigurement or disability, it is perceived as more painful than in situations where this is not the case.

### Age

A number of studies have examined the relationship of children's response to pain as a function of their age. This literature seems to imply quite strongly that younger children experience more pain from a given stimulus than do older children. This has been a consistent finding in the literature. It is possible it represents a reporting bias of the child, a cognitive lack of understanding of the potential value of the procedure, or an actual difference in the experience. Regardless, in the overwhelming majority of research which has investigated bone marrow aspiration, venous cannulation, and blood sampling, younger age has been associated with greater pain.

### Culture

It is self-evident that both culture and ethnicity may have a role in the pain experience. These factors provide the framework through which a child sees the world and form the basis of shared attitudes, values, goals, and practices. How much pain expression is acceptable, the level of pain to which one should respond, strategies used to soothe and comfort, and how one responds to pain, all have strong cultural roots.

Many studies have attempted to identify unique patterns of response to pain among different cultures. [Zborowski's \(1962\)](#) seminal work in this field in the 1950s and 1960s continues to be cited today, primarily because of a lack of subsequent research. When comparing Italian, Jewish, "old American," and Irish people's response to a standardized pain stimulus, Zborowski found significant differences that could be explained by the individuals' cultural beliefs. Subsequent work has been done on many other ethnic groups ([Aun et al., 1986](#); [Gaston-Johansson et al., 1990](#)), as well on as the impact of acculturation ([Pfefferbaum et al., 1990](#)), that is, as one group becomes more and more like the mainstream culture.

Despite this conventional wisdom, few studies of adults and even fewer studies of children have examined the cultural contribution to pain perception. It is important to recognize that although there may well be intergroup differences in pain response, there are enormous intragroup differences, as well. Treating children's pain in a "culturally sensitive" way emphasizes the avoidance of stereotypes, while simultaneously considering culturally unique beliefs about causes of illness and implications of pain, the use of folk cures and alternative remedies, and the awareness of interactional styles.

## Psychological Variables

### ANXIETY

It is quite clear that a number of psychological factors can affect pain perception. There is extensive literature on the role of anxiety in promoting pain. This seems to occur in both individuals who are chronically anxious, as well as in those in whom anxiety is situationally induced. Newer studies have examined the benefit of preparation and education in reducing anxiety. In patients who are prepared in a developmentally appropriate way and who can anticipate the type of pain that they will experience, pain often is reported as decreased ([O'Byrne et al., 1997](#)).

Other factors, however, affect the value of preparation. There clearly are patients who are information seeking, and there are those who are information avoidant. These personality characteristics have a role in the value and style of preparation.

### DEPRESSION

Depression, likewise, appears to promote pain. In people who are depressed, pain is experienced more intensely. For example, patients who have recently sustained the loss of a loved one have, on average, four times the number of physical symptoms than in age-matched control subjects who have not had a similar loss ([Klerman and Izen, 1977](#)). Depression also may be a response to chronic pain. [Heiligenstein and Jacobsen \(1988\)](#), in evaluating children with cancer pain who were thought to be depressed, found that alleviation of pain often eliminated the depression without the need for antidepressants or other types of therapy.

Regardless, it is clear that the person's emotional state plays a role in the interpretation of a noxious stimulus.

## Personality Characteristics and Individual Differences

It has long been postulated that individuals with different personality styles react to or experience pain differently. There have been many studies that have looked at personality inventories and identified the fact that people with certain particular personality patterns were more prone to experience acute and chronic pain. Certainly, the adult literature is replete with suggestions that particular personality patterns on the Minnesota Multiphasic Personality Inventory tend to be associated with chronic pain states ([Blumetti and Modesti, 1976](#)). Typically, the studies report that people with elevations on the hypochondriasis, hysteria, and depression subscales are more likely to have chronic pain. Studies using other inventories such as the Maudsley suggest that patients classified as "introverts" have lower tolerance for laboratory-induced pain ([Haslam, 1967](#)). Specific pain problems, such as complex regional pain syndrome 1 (formerly, reflex sympathetic dystrophy), fibromyalgia, and chronic fatigue syndrome, all have been vaguely associated with specific emotional states and personality styles, and recent work by [Varni et al. \(1996\)](#) has suggested that decreased self-esteem may be associated with chronic pain conditions.

This literature is not nearly as clear as it once was thought to be, however. Other studies suggest these associations are more limited than initially thought and may even be artifactual. The traditional notion, for example, of the child with recurrent abdominal pain being shy, perfectionist, and compliant has been seriously questioned by investigators such as [McGrath et al. \(1983\)](#), who found no relationship between recurrent abdominal pain and a host of psychological variables or personality styles.

Another aspect of personality that has been investigated is the style of sensory processing. [Petrie \(1967\)](#), in a classic study, blindfolded subjects and asked them to estimate the size of wooden blocks. He found that some individuals tended to increase the size of what they perceived, others tended to decrease the size, and others report on it more accurately. He reported that in laboratory-induced pain, subjects who increased the size of the block tended to have the lowest tolerance for pain and therefore experienced the most pain, whereas those who reduced the size of the block tended to have the most tolerance for pain.

Another formulation about personality uses the construct of temperament, theoretically a biologically based, often inherited, set of behavioral characteristics (the "how" of behavior). Temperament is present early, and although it evolves over time, certain temperamental characteristics remain relatively stable throughout childhood. Temperamental characteristics include attention span, adaptability, threshold of responsiveness, intensity, and approach/withdrawal ([Chess and Thomas, 1996](#)). These dimensions have been clustered into three types—easy, slow to warm up, and difficult. In a variety of studies, it has been shown that the child's temperamental characteristics clearly have a role in response to pain. Adaptability, the temperamental characteristic that describes how an individual responds to new situations, has been shown to be the strongest predictor of how an individual responds to an injection ([Schechter et al., 1991](#)). [Oberklaid et al. \(1997\)](#) identified the fact that children with growing pains were more likely to be more intense and to be rated as more difficult temperamentally than control subjects. Across the studies on temperament and pain, characteristics associated with increased "difficultness" (increased reactivity, decreased adaptability, lower threshold, more negative mood, and greater intensity) were clearly correlated with increased pain behavior.

Many of these personality studies reported are problematic. They often suffer from inadequate controls, and the construct validity of some of the instruments used remains in question. It is by no means clear that pain problems will automatically develop in individuals with particular personality characteristics. It is likely, however, that psychological styles are important modifiers in the interpretation of painful stimuli.

## Summary

In summary, then, it is clear that pain is a composite of the noxious stimulus and its interpretation. That interpretation, or "lens" through which that noxious stimulus is viewed, is affected by the child's cognitive state, age, sex, culture, personality style, temperament, and emotional state, as well as family modeling and culture. The relative contribution that each of these factors makes varies from individual to individual, but it should be evident that the same noxious stimulus does not cause the same pain in different people.

## ASSESSMENT OF PAIN IN CHILDREN

Developmentally appropriate assessment is the cornerstone of pain treatment. Lack of adequate assessment techniques has significantly handicapped progress in pain management in children. Without adequate assessment and documentation, appropriate treatment is impossible and the impact of an intervention cannot be adequately determined. It also is possible to dismiss and ignore pain if its extent and intensity are not clearly documented.

Unfortunately, for younger children, direct reporting of pain is not always feasible, nor will they alert their care providers when they are in pain. As a result, this group was most vulnerable to undertreatment before adequate assessment techniques were developed. At this juncture, however, many unidimensional as well as multidimensional pain assessment techniques are available for children of all ages. It now is imperative that they be used, and the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) has incorporated documentation of pain management into their survey of hospital adequacy.

Because pain is an inherently subjective experience, the individual's report of his or her discomfort has been assumed to be the gold standard by which pain is assessed. In adults and children older than 8 years of age, pain intensity traditionally is assessed by use of a visual analog scale, typically a 10-cm line with anchors of "no pain" on one end and "the most pain imaginable" on the other end. The child or adult is then asked to rate pain on that line. Variations of this approach involve a line with numbered increments. The child is then asked to select the number that correlates with his or her discomfort. Most children older than 8 years of age have an internal symbolic representation of their discomfort and, thus, the ability to quantify their pain, which they can translate into a specific number. Children younger than 8 years of age, however, although able to report pain, often cannot offer specific numerical ratings. As a result, since the mid-1980s, a variety of modified self-report scales have been developed for children older than 3 years of age. These may involve the use of colors ([Eland, 1982](#)), the use of cartoon faces expressing varying degrees of discomfort ([McGrath et al., 1985](#)), the use of photographs of other children who are experiencing various degrees of discomfort ([Beyer and Aradine, 1988](#)), the use of a "pain thermometer," and the use of poker chips or other manipulatives ([Hester et al., 1990](#)). What they have in common is that children are asked to quantify in a ways that are developmentally appropriate the intensity of their discomfort. Although children do have a tendency to select higher numbers

than adults might select for the same pain problems, in general, many of these instruments have reasonable psychometric properties, and they allow the pediatric provider at least a gross estimate of the magnitude of the discomfort the child is experiencing. These instruments have been a major advance in caring for children in pain. Most institutions select a specific modified self-report scale, which should be available on all flow charts near the child's bedside table. In that way, children in all domains of the hospital and across all shifts receive a similar assessment technique whose results should be reasonably reliable.

For children younger than 3 years of age, or for children or adults who are developmentally delayed, these measures are not appropriate. As a result, nonspecific proxy measures of pain (pain behaviors and physiologic variations) must be used. Composite measures incorporating both of these types of markers have been developed that appear to have clinical utility.

Traditionally, a number of behaviors are associated with discomfort. These behaviors include position, crying, lack of appetite, as well as facial expression. The area of facial expression has received significant investigation, particularly in infant pain ([Grunau and Craig, 1987](#)). Specific patterns that involve closed eyes, furrowed brows, nasolabial flattening, and a taut tongue have been associated with pain. A specific technique for evaluating facial expression (the Neonatal Facial Action Coding System) has been developed and offers results that are thought to be reliable and reproducible ([Grunau et al., 1998](#)). Other research has examined the use of primarily physiologic parameters to assess pain. Increased heart rate, respiratory rate, and blood pressure have all been associated with acute pain ([Franck et al., 2000](#)). Increased cortisol (although not an instantaneous marker), likewise is associated with distress ([Sweet and McGrath, 1998](#)). Increased palmar sweating ([Harpin and Rutter, 1982](#)), decreased vagal tone ([Porges, 1992](#)), as well as decreased oxygen concentration in the blood have all been associated with increased pain.

A number of investigators have developed composite measures, using facial expression, other behaviors, and physiologic parameters. There are many measures that have been developed, including the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS), the Observational Pain Scale (OPS), the Neonatal Infant Pain Scale (NIPS), and the Premature Infant Pain Profile (PIPP). All of these have in common some composite of behaviors and physiologic parameters that yield a theoretically clinically usable score to make judgments about the child's level of pain. These are reviewed extensively elsewhere ([Finley and McGrath, 1998](#); [Stevens, 1997](#)).

Although no one instrument is universally accepted, at this juncture it does appear that there are adequate scales available to clinicians. What is most important is that each institution select scales that make sense within the logistical constraints of that institution, and use them in a routine, standardized, and uniform manner.

## **PAIN MANAGEMENT**

### **General Principles**

Although there clearly are significant differences in the way that acute and chronic pain in children is approached, there are many principles that apply to pain management in general. First and foremost is the use of a preventative approach. When pain can be anticipated, such as after surgery or in the midst of a chronic illness that is associated with pain, it should be treated prophylactically. This is the seminal principle that has emerged from the study of pain over the past 20 years. It makes no pharmacologic or humanitarian sense to require an individual to experience discomfort before treating it if that pain can be predicted. Lower doses of analgesics are necessary to prevent pain from occurring than to eliminate it once it has occurred. This principle is responsible for the general change in analgesic prescribing from PRN, which was the standard of care 20 years ago, to scheduled analgesics for predictable pain problems, which is the standard of care today.

Another key element of the war on pain is the use of adequate assessment. As previously mentioned, assessment is the cornerstone of pain therapy. It is necessary to develop a system that supports and expects the routine assessment of pain and in which that information yields appropriate interventions. Without assessment, adequate interventions cannot take place. Pain should be reassessed after the intervention has taken place to determine if the intervention was adequate and to determine whether additional interventions are necessary. Pain documentation should be done in a uniform manner and specific protocols and algorithms that flow from the documentation should be decided on in each institution. Hospital-wide quality assurance mechanisms should monitor the adequacy of pain documentation, and its importance has been recognized by its incorporation into recent JCAHO expectations.

Another key principle in pain management in children is the importance of the simultaneous use of pharmacologic and nonpharmacologic strategies. No matter what the level of pain, both of these general approaches should be part of the overall treatment plan. Preparation, parental presence, self-control, distraction, massage, hypnosis, transcutaneous electrical nerve stimulation, all potentiate the efficacy of analgesic therapy.

Parents should be involved in all decisions about their child's treatment, as well as their child's pain management. When pain can be expected after a procedure, parents should be queried regarding their opinion as to how the child will respond. That information should be factored into any treatment plan. In studies, parent opinion has been shown to be the variable that is most predictive of children's response to noxious stimuli ([Schechter et al., 1991](#)). Parents should be present during painful procedures, if at all possible, to help provide comfort ([Bauchner et al., 1996](#); [Shaw and Routh, 1983](#)). They can be taught specific strategies or use other methods, such as stroking, swaddling, and cuddling the child. All of these approaches, as is discussed later, have demonstrated effects on pain.

Another principle of pain management that is somewhat unique to children is the notion that analgesia should be provided in as pain-free a way as possible. Children are fearful of needles, and if pain relief is offered through the use of a needle, children often will not report subsequent discomfort for fear of receiving another injection. If at all possible, nonnoxious routes, such as oral and intravenous routes, should be used for analgesic administration.

Pain associated with diagnostic procedures is for many children the worst part of having a chronic disease. This pain should be aggressively treated, especially early on, so that it does not set in motion a cascade of fear and anxiety about subsequent procedures that colors the child's hospital experience and negatively affects all of his or her encounters with health care providers.

Finally, as much as possible, normative development should be promoted despite the difficulties the child is encountering. School attendance should be emphasized as well as maintaining the child's involvement in social and athletic activities. Pain should be treated aggressively, but secondary gain from it should be minimized. Children should be encouraged to participate in school and social events, so that increased vulnerability and social isolation do not occur.

### **Pharmacologic Treatment of Pain**

A number of drugs from many different categories have a role in the treatment of pain. In general, the administration of pharmacologic agents is part of an overall plan for pain management. The choice of agents is determined by the type and severity of the pain. Some of the agents described are in and of themselves analgesic, whereas others have properties that potentiate analgesia. Categories that are discussed include local anesthetics, which should be used for all needle procedures; nonsteroidal antiinflammatory drugs (NSAIDs), which are used for mild to moderate pain; opioids, which are used for moderate to severe pain; and a variety of adjuvant agents that potentiate analgesia and are more effective for opioid-resistant pain.

#### **LOCAL ANESTHETICS**

Local anesthetics should be used for all needle procedures. There have been significant advances in the availability of local anesthetics and a number of new agents hold enormous promise. A eutectic mixture of local anesthetics (EMLA) combines lidocaine and prilocaine in a cream that when placed under an occlusive dressing produces anesthesia through intact skin. EMLA causes some vasoconstriction and requires approximately an hour to work. It provides anesthesia to a depth of 2 to 4 mm, and is therefore beneficial for venous cannulation, phlebotomy, and other injection-related pain when adequate time is available ([Halperin et al., 1989](#); [Robieux et al., 1991](#)). Lidocaine can be administered through injection or through iontophoresis, in which an electric current drives it through the skin. Because lidocaine burns when injected, it can be buffered with sodium bicarbonate to reduce burning significantly. Amethocaine can be applied as a gel or cream. It works far more rapidly than EMLA and penetrates intact skin in approximately one-half hour. It causes vasodilation instead of vasoconstriction, which may offer advantages over EMLA ([Lawson et al., 1995](#)). Finally, vapocoolant spray also has been used to reduce injection pain. This has the advantage of rapid onset, but the disadvantage of lasting only approximately 10 seconds, with minimal depth of penetration ([Reis and Holobukov, 1997](#)).

Other local anesthetics that are longer acting are beyond the scope of this discussion. Also, discussion regarding drugs used for laceration repair can be found in alternative sources ([Ernst et al., 1995](#)). On the horizon is a long-acting local anesthetic that may last up to 1 week. Such an agent would significantly reduce the need for systemic analgesia after surgery.

## NONOPIOID ANALGESICS

This category contains two drug families, acetaminophen and the NSAIDs. Both categories of drugs have a ceiling effect, that is, a dose beyond which no additional analgesic efficacy is obtained.

Acetaminophen has certain advantages over the NSAIDs, and as a result, it is used more commonly. It seems to have limited effect on the gastrointestinal tract, platelet aggregation, or on the genitourinary tract, all of which are affected by many of the NSAIDs. Unfortunately, acetaminophen overdose has a significant impact on the liver. Its major disadvantage is its lack of antiinflammatory activity compared with NSAIDs.

The NSAIDs appear to work by inhibiting cyclooxygenase (COX), which blocks the synthesis and release of prostaglandins and leukotrienes. Prostaglandins mediate the inflammatory response, which can lead to additional pain in traumatized tissue. NSAIDs have a ceiling effect and their chronic use is limited by their effect on gastric mucosa, platelets, and renal parenchyma. Despite this, drugs such as ibuprofen and naproxen appear to have opioid-sparing and antiinflammatory effects and are an excellent choice for mild to moderate pain. They often are used individually or in conjunction with a “weak” opioid.

Recently, NSAIDs have been developed that have more selective effects. The COX-2 inhibitors work by inhibiting the COX-2 that is released in association with tissue in injury, while sparing COX-1, which has a protective effect on the gastric mucosa ([Peterson and Cryer, 1999](#)). As a result, these agents have antiinflammatory activity without some of the side effects that hamper many of the other NSAIDs.

## OPIOIDS

Opioids are centrally acting analgesics that function by mimicking the actions of endogenous opioids in the central nervous system. These agents are the drugs of choice for moderate to severe pain, and they have a long history of safe use and efficacy in children.

Opioids can be categorized in a number of different ways. One method of categorization is by the potency of analgesia they provide. Traditionally, there have been agents that have been considered “weak” (codeine and oxycodone) that are used for more moderate pain, often in conjunction with a NSAID or acetaminophen. There also are opioids that are considered “strong,” such as morphine and fentanyl. Opioids also can be categorized by their half-life, with the shorter-acting agents being fentanyl, morphine, and meperidine and the long-acting opioids being methadone, morphine sulfate (MS Contin; Purdue Frederick, Norwalk, CT), and oxycodone (OxyContin; Purdue Frederick). They also can be categorized as to their chemical derivation. Morphine, codeine, and hydromorphone are phenanthrene derivatives, whereas fentanyl and meperidine are phenylpiperidine derivatives. This has particular relevance when dealing with opioid side effects or allergy. Finally, they can be categorized by receptor type. Morphine, fentanyl, and codeine are mu receptor agonists, whereas drugs like nalbuphine and butorphanol are mixed agonist–antagonist drugs.

Regardless of which agent is used, a number of basic principles apply:

1. As with other agents, whenever possible, opioids should be used in a scheduled manner as opposed to an as-needed manner.
2. Opioids have no ceiling effect. The right dose is the one that eliminates pain. The doses typically suggested in most tables are the starting doses in opioid-naïve patients.
3. Opioids have a number of predictable dose-related side effects. Constipation and itching are quite frequent. Sedation, respiratory slowing, and respiratory arrest can occur as well. Therefore, when these drugs are used, appropriate monitoring should be put in place.
4. The blood–brain barrier is immature at birth and as a result the central nervous system is more permeable to morphine. Certain enzyme systems that metabolize opioids also are immature at birth. Newborns have a greater unbound fraction of morphine, slower clearance, and more vulnerability to its effects. Therefore, in children younger than 3 months of age, starting doses of morphine should be significantly reduced (one-fourth of the traditional dose for older children) and used only in a carefully monitored setting.

### Specific Opioids

Morphine is the gold standard and the classic mu receptor agonist. Morphine may be administered intravenously, rectally, intrathecally, subcutaneously, as well as by a number of other routes.

Fentanyl is 100 times more potent than morphine. It can be administered intravenously, intramuscularly, subcutaneously, transmucosally, and transdermally. It is used most commonly for short, painful procedures, but can be used for postsurgical pain as well as in continuous infusions or by frequent boluses. When used transdermally, it requires multiple half-lives to achieve efficacy and has prolonged activity after removal of the patch owing to fat storage.

Meperidine is a synthetic opioid that at one time was thought to offer advantages over morphine because it was thought to have less effect on the sphincter of Oddi and on bowel motility. This has been disputed in recent literature, however. More significantly, meperidine has a metabolite, normeperidine, that can cause hallucinations, agitation, and even seizures ([Armstrong and Berston, 1986](#)). As a result, meperidine has become far less popular and is no longer a drug of choice for acute or chronic pain.

Methadone is a long-acting opioid with a half-life of 19 hours, which has significant variability among individuals. It can be used as an alternative to continuous-infusion opioids because of its long half-life. Methadone has historically been used as a drug to maintain opioid-addicted patients and, as a result, carries an unfortunate stigma, but it remains a valuable drug in many acute and chronic pain situations.

Codeine usually is administered by the oral route, typically for mild to moderate pain, and often in conjunction with acetaminophen or NSAIDs. Although equal potency to morphine can be obtained with large doses of codeine, there is a concomitant increase in side effects that make it an inappropriate choice for severe pain. A number of other similar agents (hydrocodone and oxycodone) also are available. It is important when using codeine preparations to be aware of the possibility of acetaminophen toxicity. For example, patients taking 10 acetaminophen plus codeine tablets daily are ingesting over 3 g of acetaminophen, which is above the recommended dose and may cause toxicity.

As previously mentioned, opioids can be administered through a variety of routes, including oral, subcutaneous, intrathecal, epidural, intravenous, subcutaneous, and transmucosal, as well as by patient-controlled analgesia with or without a continuous infusion. They are an excellent choice for severe pain. Although there is significant concern about side effects, in reality, when monitored appropriately, these agents can be used safely. Issues of addiction and dependency have historically constrained opioid use ([Weissman and Haddox, 1989](#)). Most experts agree, however, that the treatment of pain in patients with medical illnesses rarely is associated with subsequent addiction, and that the likelihood of addiction in children is essentially negligible ([Kanner and Foley, 1981](#); [Porter and Jick, 1980](#)). Addiction itself is a psychological disorder reflected in obsessive attention to the drug and the paraphernalia associated with it. Dependency, however, is a physiologic phenomenon that occurs in any individual who uses these agents for over 7 days and can be addressed merely by weaning the child at a rate of 10% to 20% per day.

## ADJUVANT MEDICATIONS

A number of other agents have gained currency in the treatment of pain. In particular, certain antidepressants and anticonvulsants may have activity in opioid-resistant pain, such as neuropathic pain associated with nerve injury. Gabapentin has shown significant efficacy for diabetic neuropathy ([Rowbotham et al., 1998](#)). Tricyclic antidepressants such as nortriptyline and amitriptyline also have shown efficacy in this traditionally opioid-resistant type of pain ([Heiligenstein and Steif, 1990](#)).

Another category of adjuvant medication is the stimulants. These agents by themselves may not have analgesic properties, but they seem to counteract some of the sedation associated with opioids, and seem to have antidepressant qualities as well. They are increasingly used in chronic pain and palliative care medicine ([Bruera et al., 1992](#); [Yee and Berde, 1991](#)).

## Nonpharmacologic Approaches

A number of strategies that do not involve drugs are critical to the comprehensive management of pain. In particular, in chronic pain situations where children may have to cope with some degree of pain for the foreseeable future, strategies that facilitate coping are extremely beneficial. In addition, during painful procedures, a number of strategies in conjunction with pharmacologic approaches have emerged that help children through these trying times

### *PSYCHOLOGICAL/BEHAVIORAL STRATEGIES*

Because children tend to be more suggestible and more trusting than adults, they often respond well to psychological strategies that divert attention from their pain or reframe it.

Preparation of the child for pending procedures has been shown clearly significantly to ameliorate anxiety, which decreases discomfort. Preparation must be done in a developmentally appropriate way, and include both descriptions of the procedure itself, as well as how the procedure will feel ( [Zeltzer et al., 1989](#)). Different children with different personality styles react differently to preparation, and child health professionals need to individualize the approach based on the child's unique temperament and personality. Age-appropriate discussion about procedures has been shown clearly to lessen pain of procedures.

Another nonpharmacologic approach involves the active participation of parents during medical procedures. Although this now seems intuitive, it was not always so, and parents in other eras often were banished from treatment rooms because they were thought to increase the child's anxiety, to become anxious themselves during the procedure, and to increase anxiety in the operator. Overwhelmingly, however, studies that have looked at the role of parents during painful procedures have suggested strongly that children value their parents' presence in the treatment room during procedures ( [Bauchner et al., 1996](#)). Parents themselves, when involved as "coaches" providing comfort to their children during the procedure, feel less helpless and have more control during times that often are threatening and anxiety filled for both parents and children ( [Broome and Endsley, 1989](#)). Parental presence provides comfort for the child because there is a familiar person in the room, which often allows the procedure to be accomplished more effectively. Parents can quickly be taught a number of simple techniques that can help divert a child's attention from the procedure, or they can use other strategies that they have developed while helping their child through difficult times in the past.

Breathing techniques, distraction, and hypnosis are all strategies that help reduce anxiety during procedures. Distraction often involves the use of a breathing technique, counting, or using party blowers ( [Manne et al., 1994](#)) and bubble solutions. Other techniques involve having the parent read with the child or tell the child a favorite story ( [Kuttner, 1989](#)). Visual imagery techniques, where a child imagines that he or she is in a more pleasant place than the treatment room, also have been shown to be quite effective. Hypnosis is the more intense use of fantasy and suggestion ( [Katz et al., 1987](#); [Zeltzer and LeBaron, 1982](#)). Here, the parent involves the child in a fantasy, such as taking a magic carpet ride. Other hypnotic techniques may involve reframing the situation using techniques such as a "pain switch" or a "magic glove," in which children are told that using a particular technique will change the way a painful procedure feels. Although distraction techniques require essentially no training, hypnosis is slightly more complex. There are a number of courses available administered by professional societies to teach hypnosis for pain management in children.

Another nonpharmacologic approach to pain management is through the use of rehearsal. With this technique, children may watch the procedure they are about to undergo on a videotape, speak to someone who has undergone the procedure, and perform some version of the procedure on a stuffed animal ( [Jay et al., 1985](#)). This increased familiarity with what will happen to them gives children some sense of mastery over the upcoming event, and has been clearly associated with reduced pain after the procedure. Finally, there is literature that suggests that increasing one's control over the illness and its treatment can reduce pain ( [Kavanagh, 1983](#)). The ultimate example of this is the use of patient-controlled analgesia, where the child can administer his or her own medication with the use of a specially designed pump. Children older than 7 years of age can use this device, but other strategies to enhance self-control, such as giving the children some sense of control over the site for venous sampling, having them help with bandage removal, or selecting the time of day that something will occur, can be beneficial. All of these techniques clearly reduce significantly the pain associated with procedures and the effects of chronic hospitalization as well.

### *PHYSICAL APPROACHES*

There are a number of physical approaches to pain reduction. They work essentially at the level of the dorsal horn by stimulating larger afferents that carry less noxious messages. Cold, heat, and vibration can be used to reduce pain. Transcutaneous electrical nerve stimulation is a technique that uses a specifically designed instrument that generates various patterns of electrical sensations ( [Lander and Fowler-Kerry, 1993](#)). When a person has pain in an isolated area, such as a limb, electrodes can be placed in an appropriate location and a variety of different patterns of electrical impulses can be tried to dampen the pain messages. This technique has demonstrated efficacy in highly localized pain problems such as complex regional pain syndrome 1 and certain types of postoperative pain. It has less efficacy in more generalized pain problems, such as the pain associated with sickle cell disease.

## **SPECIFIC PAIN PROBLEMS**

### **Postoperative Pain**

Although postoperative pain management is not in the purview of most readers of this text, it is important to discuss it because in many ways it epitomizes the evolution of both attitudes and thinking about pediatric pain. As mentioned earlier in this chapter, inadequate postoperative pain management was the standard of care in the 1970s and 1980s. More recent surveys clearly suggest that there has been a dramatic improvement in pain management in children, although other investigators continue to question the actual degree of change ( [Hamers et al., 1998](#)). Earlier on, essentially no institutions had protocols in place to provide a uniform standard of care for children, but now most institutions that care for children have developed standardized approaches. In surveys of hospitalized patients, postoperative pain management was the one area in which there was general agreement that significant improvement had occurred ( [Johnston et al., 1992](#)). The predictability of postoperative pain has helped to foster the development of plans to ameliorate it. Unfortunately, with the escalation of day-case surgery, postoperative pain management once again is a problem because most of it must be done at home by parents, many of whom are uncomfortable medicating their child ( [Finley et al., 1996](#)). Another change that has occurred in the area of postoperative pain management is the increased use of regional techniques, such as epidurals. These approaches allow for better postoperative pain control without the use of systemic opioids.

In general, however, when regional techniques are not used, most clinicians order either continuous infusions or boluses of morphine every 2 hours for postoperative pain. For children older than 7 years of age, patient-controlled analgesia is available and often a desirable option. For infants younger than 6 months of age, a significant reduction in opioid dose is required, and administration needs to occur in a carefully monitored setting such as an intensive care unit.

What is most critical is that the general principles that have been mentioned are put in place. Good assessment is absolutely essential. It should naturally be assumed that what would hurt an adult would hurt a child, and therefore children who undergo painful surgeries should have scheduled postoperative analgesics given that predictable pain will ensue. Noxious routes should be avoided and the doses traditionally listed should be viewed only as suggested starting doses.

### **Procedure Pain**

For many children, the necessary medical procedures associated with diagnosis and treatment of disease are by far the worst part of their illness. For example, work by [McGrath et al. \(1990\)](#) and [Miser et al. \(1987\)](#) clearly suggests that for children with cancer, bone marrow aspirations and lumbar punctures are perceived by the children as worse than the disease itself. If inadequate analgesia is provided during the initial procedures, a cycle of fear and dread of future procedures may occur and subsequent procedures may be considered more painful than if adequate anesthesia was initially offered ( [Weisman et al., 1998](#)). Therefore, significant attention must be paid to pain management during procedures, especially at the outset of an illness.

A number of general principles have evolved that attempt to minimize pain and distress associated with procedures. Obviously, the intervention should be tailored to the child's own personality characteristics. Some children may require general anesthesia because of overwhelming anxiety and worry, whereas others may be far less responsive to the procedure. If at all possible, procedures should be performed in a treatment room and not in the child's room, which should function as a refuge from painful events. The people performing the procedures should be as skilled as possible. Because of the potential for negative imprinting that can occur, trainees should perform procedures only if a child has had a significant anesthesia/analgesia. Behavioral and pharmacologic techniques should be used jointly, as has been suggested for all pain problems. Local anesthetics should be used for all needle procedures, and parents should be present and involved as coaches. If the pain associated with the procedure is considered moderate or severe, sedation should be used. If sedation is used, many professional societies have developed specific guidelines that involve monitoring criteria, eating before the anesthesia, availability of resuscitative drugs and equipment, and the presence of appropriately trained personnel ( [American Academy of Pediatrics, Committee on Drugs, 1992](#); [American Society of Anesthesiologists, 1996](#)). Behavioral-cognitive strategies, such as

distraction and visual imagery, should be used even if pharmacologic sedation is scheduled. As was previously mentioned, if a series of painful procedures is necessary, aggressive pharmacologic approaches should be used during the first procedure so that a negative cycle of fear and anxiety does not occur.

### **Pain Associated with Chronic Disease**

Chronic diseases that affect children often are associated with pain. The pain may be secondary to the disease itself, to the procedures that are necessary to evaluate the disease, or to the treatment associated with the disease, such as radiation or chemotherapy for children with cancer. Because it is less predictable than other types of pain, such as postoperative pain, pain associated with chronic disease often is less well treated. In a survey of hospitalized children done in the mid-1990s, most of the children with less well treated pain problems were those with chronic disease, compared with those who were postoperative ( [Johnston et al., 1992](#)).

A number of general principles have emerged in the treatment of chronic pain in children. Because there can be multiple sources of pain, a pain problem list often is helpful so that the clinician can monitor pain from various sources and be sure that each is adequately addressed. Often, asking children to keep a pain diary is a valuable way of gathering this information, as well as empowering children by involving them in the diagnostic and treatment process. Analgesics should be administered in a scheduled way when pain is predictable. It often is helpful to use a long-acting medication with a short-acting medication for breakthrough pain. If frequent use of the short-acting medication is necessary, the dose of the long-acting medication should be increased. Once children are on stable therapy, if a dramatic dose escalation is necessary for pain relief, initially the clinician should consider disease extension before tolerance is considered and a thorough search for it should be undertaken.

There is a growing literature on the use of opioids for nonmalignant pain ( [Portenoy, 1996](#); [Zenz et al., 1992](#)). In the past, obsessive preoccupation with diversion and addiction was the norm, but now it is believed that these concerns should not restrict the humane use of opioids for individuals with chronic pain that interferes with their life. As much as possible, normal behavior should be encouraged and pain should not be allowed to become the major focus of the child's life. Normal development should be encouraged; school attendance should be demanded whenever possible. Physical activity has multiple benefits, and should be dictated by the child's level of impairment. Whatever that level is, however, some physical therapy or physical activity should be built into the child's schedule. Not only does this help with normative development in maintaining adequate muscle tone, but it helps with increased appetite and promotes restorative sleep at night.

Children with pain associated with chronic disease often benefit from nonpharmacologic strategies because they will have to live with pain for the foreseeable future and strategies that help them cope are extremely beneficial. Relaxation, self-hypnosis, and breathing techniques allow them to have some role in controlling their own pain. Depression often accompanies chronic pain and should be dealt with psychotherapeutically and pharmacologically, if necessary.

### **CHRONIC PAIN WITHOUT PATHOLOGY**

A number of chronic pain conditions exist in which there is no obvious alteration of physiology or anatomy. Recurrent abdominal pain, headache, "growing pains," fibromyalgia, and chronic fatigue syndrome are all situations in which a diagnostic process often yields no specific answers. Such conditions, however, should be handled using approaches similar to those used in pain associated with chronic disease. These include encouraging normative behavior and development, active involvement of the child in assessment through use of pain diaries, emphasis on nonpharmacologic techniques, pharmacologic control of pain, and therapy for depression or other psychological contributions to the child's discomfort.

### **SUMMARY**

The management of pain in children has undergone remarkable changes in a short time. The available literature has escalated exponentially, and attitudes have undergone significant revision as well. Practice patterns also have changed in many areas. Certainly, for predictable pain problems, we have made dramatic strides, but for less predictable pain patterns, we still have a way to go.

As emphasized throughout this chapter, the treatment of pain is essential to the humane care of children. Assessment is the cornerstone of that treatment, and needs to be undertaken in a uniform, developmentally appropriate manner. A number of pharmacologic and nonpharmacologic strategies are available, and most should be used jointly. Most important, pain should be anticipated and treated in a preventative manner if at all possible.

The multidisciplinary management of pain is one of the genuine advances in medical science in the past 20 years and should be considered an essential part of the compassionate medical care of children.

[Summary](#)

[Chapter References](#)

In child psychiatry, interest in genetic factors is at an all-time high. Psychiatric disorders often are transmitted within families, and research has implicated genetic factors in a variety of mental, developmental, and behavioral disorders of childhood onset ( [Lombroso et al., 1994](#)). Specific genetic mutations have been characterized in some developmental neuropsychiatric disorders (e.g., fragile X syndrome and Prader-Willi syndrome) although, thus far, identification of etiologic gene mutations in psychiatric illness has been unsuccessful.

Psychiatric disorders are examples of complex traits. As such, the transmission within families does not follow classic mendelian inheritance patterns, and it is presumed that a number of factors contribute to the ultimate expression of clinical psychiatric symptoms. These factors may include environmental variables, such as gestational and psychosocial conditions, biological variables such as comorbid medical conditions, and genetic factors. The genetic factors could be single loci, or as is more likely, psychiatric disorders could result from the expression of more than one gene (oligogenic or polygenic) in a larger context of potentially numerous environmental influences. It is quite likely that none of these etiologic factors is necessary or sufficient for the expression of any psychiatric disorder.

Although vital contributions come from research on environmental influences in psychiatric disorders, genetic study of disease yields evidence about the underlying biology and transmission of the illness, two important areas related to treatment and prevention. It is expected that early identification of vulnerability to psychiatric illness would allow for the development of early intervention and prevention strategies.

Considerable work has been done since the early 1990s to develop valid and reliable assessment instruments for the diagnosis and measurement of child psychiatric disorders. These instruments have made it more feasible to undertake genetic studies of childhood disorders. Concurrently, the development of more sophisticated genetic methods and successful genetic studies of other complex human diseases (e.g., colon cancer, diabetes, hypercholesterolemia) has led to an overall increased interest in the importance of genetic factors for the manifestation and expression of human disease.

Interest in the genetics of child psychiatric disorders is a part of a substantial increase in basic research in child psychiatry since the early 1980s. The purpose of this chapter is to summarize the methods suitable for the genetic study of child psychiatric conditions and to provide a brief review of the current understanding of the genetics of several of these disorders.

### METHODS SUITABLE FOR THE GENETIC STUDY OF CHILDHOOD DISORDERS

Historically, the approach taken in human genetics to determine if an illness has a genetic basis was to search for an aberrant or missing protein that would result in some observable structural or biochemical change. Emphasis has now shifted to the direct detection of altered deoxyribonucleic acid (DNA) sequences. Although this approach has been successful for many human diseases, it has not been effective in the study of psychiatric/behavioral disorders of childhood. In the absence of such data, other methods are useful to help establish the importance of genetic factors in the expression of an illness. Those methods include (a) studies of twins, (b) studies of adopted children, and (c) studies of families.

#### Twin Studies

Twin studies are quite useful in establishing that genetic factors are important in the manifestation and expression of a disorder ( [LaBuda et al., 1993](#); [Spector et al., 2000](#)). Historically, this approach came into use to estimate the relative contribution of genetic and environmental influences. The underlying genetic theory is straightforward. Monozygotic (MZ) twins are genetically identical. If a trait is completely determined by genetic factors, then MZ twins should have exactly the same phenotype. In contrast to MZ twins, dizygotic (DZ) twins share, on average, only 50% of their genetic material. Thus, if there is no unique contribution of twin environments, DZ twins should be no more similar than singleton siblings. For example, if a trait is determined by a fully penetrant autosomal dominant gene, then the concordance rate for DZ twins should be 0.50, compared with 1.0 for MZ twins. If a trait is determined by an autosomal recessive gene, then the expected concordance for DZ twins would be 0.25.

When inheritance is complex, mendelian patterns are not observed, and the concordance rates for MZ and DZ twins are not expected to approximate mendelian segregation ratios. In these circumstances, a significantly greater concordance for MZ twins compared with DZ twins is taken as evidence for the involvement of genetic factors in the phenotype being studied.

One of the advantages of the twin methodology is that it is possible to study the contribution of genetic factors to traits that may not present a stable phenotype throughout the course of development. A major complication of research designs that require assessment of children and adults in families is the determination of the "childhood affected status" of adults in the family units under study. Although various attempts have been made both to establish methods to assess adult phenotypes of childhood disorders and to develop methods to make retrospective diagnoses of childhood conditions, major questions remain concerning their reliability and validity. Twin studies can surmount these difficulties because twin pairs can be studied in the appropriate development epoch, so that reliable assessments can be made.

As has been pointed out ( [Pauls, 1985](#)), one of the most interesting applications of the twin study paradigm is the examination of discordant MZ twin pairs. Assuming a genetic etiology for a behavioral disturbance, MZ twins should show full concordance rates. The fact that they do not implies that environmental factors also are of etiologic importance. A closer examination of discordant twins should help to identify important nonheritable factors that mediate the expression of the underlying genetic vulnerability.

Another potentially important use of twin studies has been illustrated by [Plomin and Daniels \(1987\)](#). These investigators have demonstrated the ability for twin studies to estimate the nonshared environmental variance important for the manifestation of a phenotype. As these investigators have pointed out, nonshared environment may be the most influential factor in contributing to the phenotypes of children within families.

The greatest weakness mentioned by critics of the twin studies is the assumption that the environments for MZ and DZ twins are comparable. The assumption has been examined ( [Cohen et al., 1975](#)), and no relevant differences have been found. In addition, as [Rowe \(1983\)](#) has indicated, it is not enough to show that DZ twins differ from MZ twins or that singletons differ from twins and use this to condemn twin studies in general. It must be demonstrated that such differences in biology or environment are etiologically important for the particular disturbance under investigation.

## Adoption/Separation Studies

If there is a substantial environmental component important for the manifestation of a disorder, the twin study design cannot completely separate its effect from the genetic factors that also may influence the trait. Adoption or separation studies provide a method to examine more closely the extent to which environmental factors influence the phenotype being studied. If a trait is genetic, then children should resemble their biological relatives to a greater degree than they resemble their adoptive relatives. Thus, the extent to which adopted children resemble their biological parents is taken as evidence of a genetic contribution. If children resemble their unrelated adoptive relatives to any degree, then that resemblance is, at least in theory, due to shared environments. Separation studies therefore provide a potentially powerful method of separating the effects of genes and environment.

Although quite useful, adoption studies have some significant drawbacks in the study of childhood disorders. In fact, it is noteworthy that few adoption studies of childhood psychiatric disorders have been reported. One reason for this could be that it is critical to obtain reliable diagnostic assessments of the parents as children. Because much of the information about the biological parents comes from obstetric records, it often is impossible to retrieve the necessary information for reliable and valid assessment of the parents. A further complication is that data about the biological father often are completely missing. Therefore, it is not possible to evaluate the phenotype of the child in light of the phenotype of the father. As pointed out ( [Pauls, 1985](#); [Rutter et al., 1990](#) ), missing or incomplete data regarding one or both biological parents can seriously compromise the usefulness of adoption studies. One way to overcome this limitation is through the use of prospective longitudinal study designs ( [Plomin and DeFries, 1985](#); [Plomin et al., 1988](#) ).

## Family Studies

As discussed, twin and adoption/separation studies provide data useful in establishing that genetic factors are important for the expression of a disorder. However, both approaches are limited in that it is not possible to test hypotheses about specific genetic mechanisms of transmission. Studies of biological families yield data that allow examination of specific genetic hypotheses. However, as with twin studies, if there is a major environmental component important for the manifestation of the phenotype under investigation, then data from family studies will not prove the existence of genetic factors. Genetic and family environmental factors can interact in determining similarities and differences among relatives and cannot be unambiguously quantified without prior specific identification. Thus, it is important to distinguish between shared and nonshared familial and nonfamilial environmental factors. It also is important to keep in mind the possibility of confounding familial environmental similarity and genetic similarity within a given family.

Family studies have been helpful in establishing that most major adult psychiatric disorders are inherited. A major limitation of family studies for childhood psychiatric disorders is related to assessment and diagnosis, the same limitation as was discussed for adoption studies. It is essential that all relatives in a family study be reliably and validly assessed. Because there always are at least two adults (i.e., the parents) in every nuclear family, it is essential that methods be available to obtain the necessary information to assess the childhood phenotype of those adults. Retrospective data may be unreliable or unavailable. Information regarding current symptomatology is useful only if there is a one-to-one correspondence between the childhood phenotype and adult phenotype. Clearly, more longitudinal studies need to be completed to learn more about the adult phenotypic outcomes of child psychiatric disorders.

## Molecular Genetic Studies

Although results from twin, adoption/separation, and family studies can provide convincing evidence that genetic factors contribute significantly to the expression of childhood psychiatric disorders, none of these methods can prove the existence of specific genetic etiologic factors. One of the strongest forms of evidence for a genetic etiology is the demonstration of a molecular abnormality or the existence of a linked genetic marker. The search for specific molecular abnormalities or biochemical markers so far has not been fruitful in child psychiatry. A potentially more promising approach is the use of genetic linkage information.

Genetic linkage occurs when two different loci are sufficiently close on the same chromosome that they are transmitted together from parent to child. The demonstration of linkage in humans requires family studies to establish that alleles at the two loci cosegregate in families. Family data are used to estimate how frequently alleles at two loci are transmitted in combinations different from those occurring in the parents. If new combinations occur with equal frequency to parental combinations, then the two loci are not linked. If the frequency of parental combinations is relatively greater than that of new recombinants, the two loci are linked, and the frequency of new recombinants can be used to estimate the strength of linkage. The degree of linkage is measured as the recombination fraction and can range from 0.0 (complete linkage) to 0.5 (independent assortment). The minimum recombination frequency of 0.0 is found when alleles at two separate loci always are transmitted together. The maximum recombination frequency of 0.5 is found for alleles that have the same likelihood of being transmitted in new combinations as in the old combinations, from generation to generation. The maximum recombination occurs for loci far apart on the same chromosome and for loci on different chromosomes.

The statistical significance for a particular recombination fraction is determined by measuring the difference in the probability of observing linkage and comparing it with the probability of observing independent assortment in a given family. Finding statistically significant deviation from independent assortment for alleles at a known marker locus and at a hypothesized locus for a complex trait provides convincing evidence that there is a major gene contributing to the expression of the disorder. It is highly unlikely that any other explanation could mimic linkage with a marker locus.

Some problems in detecting linkage in human data include small family size, the inability to control matings, and the small prior probability that two loci are linked. The linkage method has had limited applicability until recently because of the paucity of available marker loci in humans. With the advent of recombinant DNA technology, this has changed dramatically. As part of the advance in genetics brought about by recombinant DNA techniques, there are now tens of thousands of DNA polymorphisms available for use in genetic linkage and association studies.

The current inventory of marker loci now spans the entire human genome at a remarkably fine level. In fact, the completion of the human genome sequence ( [International Human Genome Sequencing Consortium, 2001](#); [Venter et al., 2001](#) ) gives promise that in the not-distant future all human genes will be mapped and characterized. In parallel with that accomplishment, efforts are underway to identify and validate all segments of the genome that comprise functional genes. As the total human catalog of approximately 35,000 genes is annotated, it will be necessary to elucidate the sequence variations that are associated with functional differences.

Microsatellite polymorphisms (also referred to as *short tandem repeats*, or STRs) were the preferred markers of variation throughout the 1990s ( [Weber and May, 1989](#) ), and many thousands of these were identified. Because these markers are characterized by high levels of heterozygosity and large numbers of alleles, they provide a very useful tool for pedigree-based linkage analysis. The use of these markers has led to the mapping of a respectable number of monogenic and a few polygenic diseases. More recently, however, a new generation of markers has emerged based on a class of polymorphisms that results from single nucleotide changes. Such single-nucleotide polymorphisms (SNPs) will be extremely important in cataloging the variation within genes that is responsible for increased risk of or protection from disease. SNPs usually are biallelic and consequently less polymorphic than microsatellites, but their great abundance and accessibility to high-throughput, low-cost automated genotyping technologies eventually may lead to the replacement of microsatellites in gene mapping and positional cloning.

Given the phenotypic and apparent genetic complexity of child psychiatric disorders, traditional linkage methodologies may not be well suited for identifying genes of etiologic significance. In fact, most of the current studies involve approaches that do not require specification of the underlying genetic mechanism. In addition, given the availability of tens of thousands of polymorphic markers, an alternative approach that involves looking for population associations between known genes or markers and disorders has been suggested ( [Risch and Merikangas, 1996](#) ), although many difficulties remain ( [Chakravarti, 1998](#) ).

It is clear that a great deal of effort remains to identify rigorously susceptibility genes for child psychiatric disorders. One of the most difficult problems with linkage and association studies of psychiatric disorders has to do with understanding the precise nature of the inherited phenotype. All mental disorders have variable expression, and the data from twin studies usually have demonstrated the importance of nongenetic factors in their etiology. Nongenetic (or environmental) factors, along with variable expressivity and variable age of onset, reduce the power of the statistical methods available for the detection of linkage and association. Although an increase in the size of the sample being studied often helps to increase statistical power, a better understanding of the inherited phenotype is critical to the eventual identification of susceptibility genes for child psychiatric disorders. It is becoming increasingly clear that *Diagnostic and Statistical Manual of Mental Disorders* (DSM) diagnostic categories may not be optimal phenotypes for genetic studies that are designed to find and characterize genes for psychiatric disorders.

In the absence of a well understood etiology, demonstration of the presence of genetic factors usually does not resolve questions about the nature of the genes involved and how they interact with environmental factors. Is a particular gene necessary for the disease to develop? Will a certain genotype always lead to illness?

Are there ameliorating environments that prevent illness in people otherwise genetically susceptible? These questions need to be addressed. The full scope of gene–environment interactions can be understood only after the full disease process is understood.

Establishing that a disease locus is linked to a specific marker will be a major step in understanding the pathophysiology of child psychiatric disorders. However, before this methodology can be used successfully, there needs to be fairly strong evidence that at least some forms of a specific illness have an underlying genetic mechanism that is relatively simple (i.e., one or two major genes contributing significantly to the expression of the phenotype). As is discussed in the following section, there is considerable evidence that childhood psychiatric/behavioral disorders are influenced by genetic factors. However, the specific mode of transmission is not understood for most disorders of childhood; thus, the pursuit of genetic linkages needs to occur in the context of other studies examining specific genetic hypotheses of transmission.

## REVIEW OF THE GENETICS OF CHILDHOOD NEUROPSYCHIATRIC DISORDERS

In this section, the evidence that genetic factors are important for some of the more extensively studied childhood disorders is reviewed. A comprehensive review of all childhood disorders is beyond the scope of this chapter; for the current presentation, disorders were chosen that provide examples of the application of the approaches discussed previously.

### Attention Deficit/Hyperactivity Disorder

Attention deficit/hyperactivity disorder (ADHD) is a common neuropsychiatric and behavioral disorder of childhood onset ( [Barkley, 1998](#)). The prevalence of ADHD is high; it is the most frequently observed neurobehavioral problem in the pediatric age group. Prevalence rates have been estimated to range between 2% and 15% ( [Rutter, 1983](#)), and boys are affected approximately four times as often as girls ( [Shaywitz et al., 1983](#)). Although a variety of etiologies have been identified for some cases (infection—[Shaywitz and Shaywitz, 1982](#); head trauma—[Rutter, 1981](#); pregnancy and birth complications—[Whittaker et al., 1997](#); and intrauterine exposure to toxins—[Shaywitz et al., 1983](#)); in most individuals, no single etiologic factor is evident.

Cumulative results from several lines of investigation yield evidence that genetic factors play an important etiologic role in the expression of hyperactive and inattentive behaviors and ADHD. Results of several twin studies suggest that genetic factors are important for the expression of normal activity levels ( [Scarr, 1966](#); [Vandenberg, 1962](#); [Willerman, 1973](#)). However, many ADHD studies are weakened by uncertain validity of diagnosis and rating scales, small sample sizes, and ascertainment bias.

In an early study, [Lopez \(1965\)](#) examined 10 twin pairs (4 MZ, 6 DZ) in which one twin had “clinical hyperactivity.” He found 100% concordance in the MZ pairs, compared with 17% concordance in the DZ pairs. However, in light of several methodologic weaknesses in this study (four of the DZ twins were opposite-sex pairs), these results could not be considered definitive. In a large study of 13-year-old twin pairs (102 MZ and 111 same-sex DZ twin pairs), [Goodman and Stevenson \(1989\)](#) found that MZ twins had higher concordance on objective measures of inattentiveness and hyperactivity than same-sex DZ twins. Family environment measures and perinatal adversity did not significantly relate to hyperactivity measures. The researchers concluded that heritability accounted for 30% to 50% of the explainable variance in inattention and hyperactivity in this twin population. The common environmental effects accounted for less than 30% of the variance. [Stevenson \(1992\)](#) performed multiple regression analysis on data from a sample of 91 MZ twins and 105 same-sex DZ twins. These results also showed a significant genetic contribution to individual differences in activity levels (those measured through maternal ratings but not teacher ratings) and attention abilities. An important consideration is that the degree of heritability for hyperactivity and inattention is higher when estimated in a sample of relatives of severely affected ADHD probands, suggesting that the more deviant ADHD symptoms are linked to higher amounts of genetic influence (e.g., [Edelbrock et al., 1995](#); [Gillis et al., 1992](#)). More recent twin studies have supported this conclusion, indicating that most of the phenotypic hyperactivity-impulsivity variance (70% to 91%) is attributable to the genetic variance and that the amount of variance increases with the increased severity of the phenotype (e.g., [Faraone, 1996](#); [Gjone et al., 1996](#); [Levy et al., 1997](#); [Sherman et al., 1997](#); [van der Oord et al., 1996](#)).

Family history studies also provide support for the hypothesis that hyperactivity (and, by implication, ADHD) is familial. [Morrison and Stewart \(1971\)](#) surveyed first- and second-degree relatives of 59 hyperactive children and 41 control children. Twenty percent of parents of children with ADHD were retrospectively diagnosed as hyperactive, compared with 5% of parents of the control group. When data from first- and second-degree relatives were combined, the rates of hyperactivity were significantly higher in the relatives of the hyperactive children. [Cantwell \(1972\)](#) also showed that the frequency of hyperactivity was higher among relatives of hyperactive children than among relatives of control children. In a clinic sample of children (n = 72), [Pauls et al. \(1983\)](#) demonstrated that ADHD is familial and that it is vertically transmitted in families. Logistic regression analyses of family history data incorporating sex of the proband, parental affected status, and family history most adequately explained the patterns of ADHD in these families.

In addition, families of ADHD probands are characterized by higher overall rates of psychopathology, including higher rates of ADHD, conduct problems, substance abuse, and depression (e.g., [Barkley et al., 1990](#)). Conduct problems, substance abuse, and depression in the parents, however, is related more to the presence of conduct disorder in the children with ADHD than to ADHD itself ( [Barkley, 1998](#)).

Separation studies also suggest a genetic component in ADHD. [Morrison and Stewart \(1973\)](#) compiled self-report data from the adoptive parents of 35 hyperactive children. The adoptive parents reported lower levels of childhood hyperactivity among their biological relatives than the control group of biological parents raising their own hyperactive children. Because no information was obtained from the biological parents of the adopted children, no direct comparisons could be made between the adoptive and biological parents of the 35 adopted hyperactive children. In a separate study of adopted children, [Cantwell \(1975\)](#) reported results similar to those of [Morrison and Stewart \(1973\)](#). A weakness of both studies is bias resulting from the selection process permitting families to adopt and the inability to compare the families of the biological parents of adopted hyperactive children with the families of the adoptive parents of these same children. Nevertheless, these studies show that children may more closely resemble the families of their biological parents than those of their adoptive parents. One large study, however, studied biological parents of adoptees and found that if one of the biological parents had been judged delinquent or had an adult criminal conviction, the adopted-away son had a higher likelihood of having ADHD ( [Cadoret and Stewart, 1991](#)). A study of international adoptees revealed a significant genetic contribution (47%) to the variability on the Attention Problems Scale of the Child Behavior Checklist that is highly correlated with the ADHD diagnosis ( [van den Oord et al., 1994](#)). Hence, these results suggest that some genetic component is important for the manifestation of hyperactivity and inattention.

Another line of evidence for a genetic component of ADHD comes from a study comparing full- and half-sibling pairs ( [Safer, 1973](#)). In a comparison of the concordance of such sibling pairs for the diagnosis of minimal brain dysfunction, significantly higher concordance levels were found among the full-sibling pairs than among the half-sibling pairs.

In more recent family studies of patients with ADHD, [Biederman and coworkers \(1986, 1987a, 1987b\)](#) reported a higher frequency of ADHD among first-degree relatives of affected probands. These investigators interviewed all family members of 22 male subjects with ADHD and 20 unaffected control subjects. The morbidity ratio for ADHD was 31.5% among relatives of subjects with ADHD, compared with 5.7% for relatives of control subjects. In addition, rates of major affective disorder, conduct disorder, and oppositional disorder were significantly increased in the relatives of the ADHD probands. This study was the first to assess directly all first-degree relatives using structured interviews. The results give strong support to the hypothesis that ADHD is familial. However, because of comorbidity in the probands, it is not clear whether ADHD is a primary or secondary phenomenon. It appears that the increased rates of conduct and oppositional disorders occurred only in those families where the ADHD proband also had conduct disorder ( [Biederman et al., 1987a](#)). Although this suggests some specificity of transmission, the sample was too small to obtain definitive results. In addition, the considerable comorbidity (affective disorders and anxiety disorders) in first-degree relatives of children with ADHD complicates genetic interpretations of these findings ( [Biederman et al., 1991a, 1991b](#)). More recent analyses of ADHD probands (n = 140) and first-degree relatives explored the validity of subgrouping probands by comorbid status and demonstrated evidence for family-genetic risk factors in ADHD ( [Biederman et al., 1992](#)). Between 10% to 35% of the immediate family members of children with ADHD also were likely to have the disorder, with the risk of ADHD to siblings of affected children at approximately 32% ( [Biederman et al., 1992](#)), and the risk to children of parents with ADHD at approximately 57% ( [Biederman et al., 1995](#)).

Although all of these studies lend support to a hypothesis that some heritable component is important in the expression of ADHD, no clear mode of transmission has been determined. Because of the male preponderance, [Omenn \(1973\)](#) examined a sex-linked hypothesis. He concluded that it was unlikely because of the frequency of father-to-son transmission. [Morrison and Stewart \(1974\)](#) suggested a polygenic mode of transmission, but the report was based on a small number of families of hyperactive children. In a genetic latent structure analysis of dysmorphology in children with ADHD, an autosomal dominant model emerged when dysmorphology and ADHD were compiled into a single factor ( [Deutsch et al., 1990](#)). However, the validity of this model has not yet been tested.

Quantitative genetic analyses of the Boston familial dataset suggests a single-gene mode of ADHD inheritance ( [Faraone et al., 1992](#)). This finding started a string of

studies looking for genes involved in the expression of the disorder. The first candidate gene was the dopamine type 2 receptor (DRD2), with some researchers indicating the association between DRD2 and ADHD ([Blum et al., 1996](#); [Comings et al., 1991](#)) and others failing to replicate the association ([Gelernter et al., 1991](#)). The second candidate gene is the dopamine transporter (DAT1); the evidence for the involvement of DAT1 also is controversial, both supporting ([Cook et al., 1995, 1998](#); [Gill et al., 1997](#)) and dismissing ([Swanson et al., 1998](#)) the association. Yet another interesting candidate gene is DRD4. Similar to other candidate genes, some researchers reported the association ([LaHoste et al., 1996](#); [Muglia et al., 2000](#)), whereas others could not replicate its presence (e.g., [Hawi et al., 2000](#); [Kotler et al., 2000](#)).

In an interesting study of 18 families by [Hauser et al. \(1993\)](#), ADHD was strongly associated with a generalized resistance to thyroid hormone (RTH). This thyroid disorder is caused by mutations in the thyroid receptor beta gene and characterized by reduced responsiveness of peripheral and pituitary tissues to the actions of thyroid hormone. This study showed that, among the affected children, 70% met criteria for ADHD, whereas 20% of those who were unaffected met ADHD criteria. Among the affected adults, 50% met criteria for ADHD as children, compared with 2% of the unaffected subjects. Although there is no (converse) increased incidence of RTH in children with ADHD ([Weiss et al., 1993](#)), this finding should help guide future genetic and biological/hormonal studies of ADHD. For example, in a later study, researchers found approximately 50% comorbidity between RTH and ADHD in a group of RTH probands ([Stein et al., 1995](#)). However, given that RTH is rare in children with ADHD (approximately 1:2,500) ([Elia et al., 1994](#)), thyroid dysfunction appears unlikely to be a major cause of ADHD in the general population.

Thus far, no clear understanding of the genetics or the pattern of transmission of ADHD has emerged. Early studies were limited because (a) only families of male subjects were examined, (b) only parents of subjects were included, or (c) sample sizes were too small. More recent studies have used diverse ascertainment schemes and are characterized by larger sample sizes. In summary, this research has indicated an etiologic complexity underlying ADHD, with a number of areas where advances might enhance our understanding of the nature of the disorder. Specifically, the phenotype of ADHD needs clarification; a scientific unification of the nosologic classification of ADHD (e.g., inattention and hyperactivity-impulsivity subtypes) needs to be developed; and the effect of comorbid illness on ADHD classification needs to be explored.

## Autism

Evidence for a genetic contribution to the syndrome of autism comes from twin studies and family studies. Several reports of twins appeared in the literature before 1977. [Rutter \(1967\)](#) reviewed all twin studies reported before 1967 and concluded that no valid inferences about a genetic contribution to autism could be drawn from them. Additional reports appeared during the next 10 years ([Kean, 1975](#); [Kotsopoulos, 1976](#); [McQuaid, 1975](#)), but the conclusion remained unchanged ([Hanson and Gottesman, 1976](#)).

The results of another twin study were reported by [Ritvo et al. \(1985a\)](#). Their sample included 40 twin pairs ascertained through a registry established to identify high-density families and twin pairs. Individuals were included in the registry as a result of response to an advertisement published in a newsletter of the National Society for Autistic Children. The sample, thus, does not represent a random ascertainment of twin pairs. There were 23 MZ and 17 DZ twin pairs. The concordance rate was 95.7% for the MZ twins, compared with 23.5% for the DZ twins. These rates were significantly different and seem to present striking evidence for genetic factors. It is difficult to interpret these results, however, because the sample relied on voluntary participation. It also included opposite-sex twins in the DZ sample, which, as explained later, skews results. Thus, although the concordance rate evidence is impressive, it is of limited value because it is not clear what biases were operating in the selection of the sample.

The twin studies reported before 1977 and the study by [Ritvo et al. \(1985a\)](#) are difficult to interpret because of their methods of ascertainment. Most of the studies before 1977 appeared as case reports in the literature, and as such represented a biased sample of twins. [Folstein and Rutter \(1977\)](#), in summarizing the reports of 32 twin pairs that appeared before 1977, suggested two problems in the interpretation of the existing data. First, the sample of 32 pairs contained approximately twice as many MZ as DZ twin pairs (22 vs. 10). The frequency of DZ twins is approximately twofold that of MZ twins in the general population, and therefore, these 32 pairs are not a representative sample of twins. The same can be said for the [Ritvo et al. sample \(1985a\)](#), which contained 23 MZ and 17 DZ twin pairs. Second, in all of these studies, many of the twin pairs were opposite-sex pairs. With the reported sex difference in the frequency of autism, opposite-sex twin pairs are of limited value because their inclusion would tend to decrease the DZ concordance rate. In addition, few reports of same-sex twin pairs contained adequate clinical description and evidence of zygosity to allow confident interpretation of the data.

In response to the problems of ascertainment bias, [Folstein and Rutter \(1977\)](#) sought to obtain a complete and unbiased sample of same-sex twin pairs that included at least one autistic child. They reported on a study of 21 pairs of same-sex twins that were systematically collected through schools, hospital twin registries, and the National Society for Autistic Children in England. Of the 21 pairs, 11 were MZ twins. The diagnosis of autism was based on the criteria developed by [Kanner \(1943\)](#) and [Rutter \(1971\)](#). In all, the 21 twin pairs gave rise to 25 autistic children. Four of the MZ co-twins were diagnosed as having autism, whereas none of the DZ co-twins met the criteria for the syndrome. This difference is significant ( $p = 0.055$ ).

Another twin study using a similar ascertainment strategy was reported by [Steffenburg et al. \(1989\)](#). These investigators screened all Nordic countries for the occurrence of cases of autism with a same-sex twin younger than 25 years of age. Twenty-one pairs (11 MZ and 10 DZ) of twins and one set of MZ triplets were ascertained. Zygosity testing was completed for 18 of the twin pairs. In the remaining four pairs, zygosity was determined on the basis of placental evidence and physical appearance. The pairwise concordance for autism was 91% for MZ twins and 0% for DZ twins.

Both of these studies suggest that genetic factors are important in the expression of autism. However, because the MZ twins were not always fully concordant, they also suggest that nongenetic factors exist that may be of etiologic importance. Discordance for autism among twins could be explained if autism represents only the most severe expression of some other cognitive disorder. Presumably, several factors could interact to produce the severe phenotype, but the underlying genetic liability would be for a milder cognitive impairment. [Folstein and Rutter \(1977\)](#) developed this hypothesis. They proposed that if it was correct, the co-twins might exhibit some cognitive impairment without necessarily manifesting the full syndrome of autism. When Folstein and Rutter examined the co-twins in their study for some cognitive deficit, they found that in addition to the four autistic MZ co-twins, five other MZ co-twins showed some cognitive impairment. Hence, 9 of 11 MZ twin pairs were concordant for a cognitive deficit, whereas only 1 of 10 DZ twin pairs was concordant for a cognitive impairment. This difference is highly significant ( $p = 0.0015$ ). Further evidence for this hypothesis comes from a subsequent twin study ([Bailey et al., 1995](#)) that found 60% of MZ twins concordant for autism versus 0% for DZ pairs. Most of the nonautistic MZ twins were beset by social difficulties when examined at follow-up; using a combined broad phenotype of cognitive/social difficulties, the concordance rate in MZ pairs was 92%, versus 10% in DZ pairs.

These results suggest that there are genetic factors that may contribute to the expression of autism in some individuals. In addition, they support the hypothesis that these genetic factors also may be responsible for a different, possibly milder, manifestation in the relatives of autistic individuals. If this hypothesis is true, there should be a higher-than-expected frequency of this milder disorder in the relatives of autistic patients compared with the frequency in the general population.

[August et al. \(1981\)](#) attempted to test the hypothesis proposed by [Folstein and Rutter \(1977\)](#) by examining the siblings of autistic children. They used a case-control study design. The experimental group consisted of the siblings of 41 autistic individuals ascertained from the records of the autism program at the University of Iowa child psychiatry service. These 41 probands had a total of 71 siblings. The control group consisted of the 38 siblings of 15 individuals with Down's syndrome. Only Down's syndrome with the standard trisomy 21 was included in the study, to ensure that this type of cognitive deficit would not be transmitted within these families. The families of patients with Down's syndrome were chosen because August and coworkers wanted to compare the rates of cognitive impairment in two types of families in which at least one individual was impaired. The rationale was that if having an impaired child in the family was detrimental for nongenetic reasons, the rates of cognitive impairment should be similar in the two types of families. If, on the other hand, there were some factors specific to autism that could cause other cognitive deficits, the rates of disabilities should be higher in the siblings of autistic children. The subjects with Down's syndrome were selected, so that the ages of the siblings were in the same range as the ages of the siblings of the autistic children.

Only two siblings (2.8%) of autistic children in this study ([August et al., 1981](#)) met [Rutter's \(1971\)](#) criteria for autism. None of the siblings of the Down's syndrome probands was autistic. This rate is similar to the rates of 2% for sibling of autistic individuals reported by [Rutter \(1968\)](#) and the rate of 2.8% for the siblings of twins reported by [Folstein and Rutter \(1977\)](#). Although this is a very small recurrence risk, Rutter has pointed out that it represents at least a 50-fold increase over the general population prevalence.

Additional evidence for the familiarity of autism comes from a report by [Ritvo et al. \(1989b\)](#) of the recurrence risk estimates obtained from families identified through an epidemiologic study of autism in Utah. Two hundred seven families of autistic individuals were ascertained. The recurrence risk for autism in these families was estimated to be 8.6%. There was a suggestion of a sex difference in that if the first autistic child was male, the rate among siblings was 7%, compared with 14.5% when the first autistic child was female, although these differences were not significantly different. The overall risk of 8.6% represents a 215-fold increase over the

population prevalence estimate in the state ([Ritvo et al., 1989a](#)).

Although these findings considerably strengthen the evidence that autism is inherited, data for the familial nature of autism are even more convincing when the information on cognitive impairment is examined. In the study of [August and coworkers \(1981\)](#) discussed previously, a separate diagnosis of cognitive disability was made if at least one of the following criteria was met: (a) delay in spoken language persisting beyond the age of 30 months; (b) gross abnormality in language (either expressive or receptive); (c) verbal, or full-scale IQ score less than 80; (d) specific learning disability in the areas of reading, spelling, or arithmetic as assessed by a standard score of less than 80 on the Wide-Range Achievement Test; and (e) scholastic performance deficits of such severity as to require special educational remediation. One criterion omitted by August and coworkers but included in the Folstein and Rutter twin study was the symptom of grossly abnormal articulation persisting to 5 years of age. Thus, although the two sets of criteria were not exactly the same, there was a substantial overlap, so that a meaningful comparison could be made. Moreover, most of the nonautistic MZ co-twins were socially reticent, and this disability was even more striking when the twins were reexamined in adulthood ([Bailey et al., 1995](#)).

[August and colleagues \(1981\)](#) showed that the rate of cognitive impairment in the siblings of autistic children was considerably higher than the rate among the siblings of patients with Down's syndrome. Of the siblings of autistic patients, 11 (15.5%) showed some cognitive impairment, whereas only one (2.6%) of the siblings of patients with Down's syndrome was cognitively impaired. The difference is statistically significant. These results are consistent with those of [Folstein and Rutter \(1977\)](#) and suggest that autism may be etiologically related to these disorders of cognition, at least within families of autistic individuals. Autism, thus, may be the most severe expression of a disorder of cognition, and there may be genetic factors important for the manifestation of this spectrum of disabilities.

In a more recent study, [Freeman et al. \(1989\)](#) present data that they conclude do not support this hypothesis. Wechsler Intelligence Scales, Wide-Range Achievement Tests, and the Shipley-Hartford Tests were administered to 122 parents and 153 siblings of 62 autistic probands who were part of the Utah study discussed earlier ([Ritvo et al., 1989a, 1989b](#)). All of these studies of cognitive difficulties need to be interpreted with care. In all studies, learning problems were defined as being below some score on some cognitive or achievement test. Learning problems usually are defined as a discrepancy between IQ and achievement, so it is difficult to determine just what the frequency of learning problems was in the families of autistic probands.

The hypothesis of the etiologic relationship between autism and specific cognitive and social developmental disorders (e.g., language impairment and social deficit) has been tested in a number of family studies of broader autism phenotypes ([Bolton et al., 1994](#); [Landa et al., 1992](#); [Pickles et al., 1995](#); [Piven et al., 1991, 1994](#); [Santangelo and Folstein, 1999](#)). Indeed, parent and adult siblings of probands with autism described themselves more often, compared with families of control individuals, as aloof, unctuous, and emotionally detached ([Piven et al., 1994](#)). Moreover, relatives of individuals with autism reported significantly fewer friendships and informal social contacts than did relatives of control subjects ([Santangelo and Folstein, 1999](#)) and were less skilled in carrying out socially oriented narrative discourse ([Landa et al., 1992](#)). In addition, there were higher rates of anxiety disorders and major depression in autism relatives ([Piven et al., 1991](#)). However, relatives of autistic individuals did not show consistent elevation of mental retardation or reading and spelling problems ([Santangelo and Folstein, 1999](#)).

Although most of the autism studies presented here suggest the importance of genetic factors, most of the data do not allow specific genetic hypotheses about mode of inheritance to be tested. Genetic hypotheses were examined in a study by [Ritvo et al. \(1985b\)](#). The authors limited themselves to families in which at least two children met DSM-III criteria for autism. The families were ascertained through several sources, including medical records, referral from other clinicians, and response to an advertisement for "high-density" families. After attempting to correct for the bias introduced by this ascertainment scheme, the researchers used two methods to test several genetic hypotheses. Using a method developed by [Gladstein et al. \(1978\)](#), they tested the multifactorial-polygenic hypothesis and were able to reject it. They also tested the autosomal dominant and autosomal recessive hypotheses with classic segregation analysis. They were able to reject the dominant hypothesis but not the recessive hypothesis.

These results need to be interpreted with caution. First, as Ritvo and colleagues point out, their findings do not generalize to all patients with autism. These multiple-incidence families are a highly selected group and are not representative of all families. Second, the particular ascertainment scheme used makes it difficult to estimate accurately the ascertainment probability. As the authors point out, the estimates of the segregation frequency are fairly robust if the estimate of the ascertainment probability is reasonably close. However, it is not clear how misspecification of the ascertainment probability affected the estimate of the segregation ratio in these families. Thus, these results should be viewed as preliminary. Additional work is needed with a sample selected through conventional ascertainment procedures.

An important point to keep in mind when studying the genetics of autism is that it is likely to be a heterogeneous disorder. It is known that the syndrome has multiple etiologies ([Rutter, 1974](#)). It can develop in association with (and presumably as a result of) conditions as pathologically diverse as congenital rubella ([Chess et al., 1971](#)) and infantile spasms ([Taft and Cohen, 1971](#)). In addition, [Folstein and Rutter \(1977\)](#) suggested other possible nongenetic etiologic factors. They found that the autistic twin in a discordant twin pair was more likely to have experienced events that could have resulted in brain damage than were the autistic twins in a concordant twin pair. In all of the concordant MZ twin pairs, neither twin had experienced any trauma that could be interpreted as contributing to the development of their autistic behavior. These findings suggest etiologic heterogeneity.

Certainly, autism can (and does) develop after an environmental insult. However, it also can develop in the absence of any identifiable environmental agents. Any genetic factors that might exist for autism almost certainly will be more easily identifiable in the group of patients who do not experience any major environmental trauma. Thus, in future studies, a sufficient number of patients should be included, so that the data can be divided into groups based on presumed environmental insult to the proband. If the recurrence risks differ between the groups, this would provide additional evidence for specific etiologic subtypes and suggest which types were most likely to be genetic.

However, even the subset of patients with no known environmental risk factors could be heterogeneous. Nearly all inherited disorders in which the genetic mechanism is clearly understood have been shown to be genetically heterogeneous. The mucopolysaccharide storage diseases provide an excellent example. Initially, all affected children were considered to have "gargoylism." The clinical characteristics were quite uniform, and it was thought to represent a single disorder that showed a familial tendency. It has been shown subsequently that the mucopolysaccharidoses encompass defects of many different enzymes, each with a different underlying genetic mechanism.

Often, the multiple etiologies of a "single disease" become easily identifiable as new phenotypic levels are defined: What is apparently homogeneous at the level of gross symptomatology becomes obviously heterogeneous as physiologic or biochemical aberrations are used to redefine the phenotype. In future studies of the genetics of autism, care needs to be taken to obtain a homogeneous sample of autistic patients. A level of homogeneity can be achieved by using very strict diagnostic rules or by studying only those patients with a specific biochemical abnormality or genetic marker. For example, it has been shown that some autistic people also have the marker X syndrome ([August, 1983](#); [Brown et al., 1982](#); [Gillberg, 1983](#); [Meryash et al., 1982](#)). Certainly not all autistic patients have the mar(X) chromosome ([Watson et al., 1984](#)), but those who do may represent a subtype of autism with unique etiologic factors. By studying the families of a group of patients positive for the mar(X) chromosome, it might be possible to identify unique factors associated with this subset of autistic patients. Explorations of the link between the X chromosome and autism continues. (For review, see [Folstein and Piven, 1991](#).)

In addition to the X chromosome, current research on the genetic etiology of autism is focusing on regions of chromosome 15 ([Cook et al., 1998](#); [Maestrini et al., 1999](#); [Smith et al., 2000](#); [Wolpert et al., 2000](#)), chromosome 7 ([Ashley-Koch et al., 1999](#); [Ingram et al., 2000](#)), and several other genomic locations ([Auranen et al., 2000](#); [Philippe et al., 1999](#); [Risch et al., 1999](#)). Similar to the situation with ADHD research, the results are controversial, characterized by both replications and failures to replicate.

Although the results from these types of studies will not generalize to all autistic individuals, this should not be a deterrent to special ascertainment strategies. If it is possible to identify a specific etiology for a homogeneous group selected with a unique ascertainment, the residual cases will then be more homogeneous than the original population. Thus, the chances of determining the important etiologic factors for them are enhanced.

### Specific Reading Disability

Specific reading disability (RD), or dyslexia, is characterized by the presence of a discrepancy between predicted reading ability and actual reading achievement. Poor reading skills are present despite conventional instruction and adequate intelligence and sociocultural opportunity. The prevalence of RD among school-age children has been estimated to be between 6% and 9% ([Shaywitz et al., 1990](#)). These investigators found an equal sex ratio for RD in their sample. This is in contrast to many other identified samples, in which the rates of RD are two to four times higher in boys than in girls. These differences could be due to differing ascertainment

strategies or possibly different diagnostic criteria for RD.

Over the years, the definition and diagnosis of RD have not been uniform. It is not always clear that the results from various studies can be easily compared. Attempts have been made to identify more homogenous subtypes. [Johnson and Myklebust \(1967\)](#) and [Boder \(1971\)](#) observed that the spelling errors made by dyslexic persons could be categorized into several types: (a) auditory predominant, (b) visual predominant, and (c) a mixed subtype. [Mattis et al. \(1975\)](#) also suggested three distinct subtypes of RD. They used neuropsychological tests to define each of the three categories: (a) language disorder, (b) articulatory and graphomotor dyscoordination, and (c) visual-spatial perceptual disorder. The Colorado Family Reading Study (CFRS) ([Decker and DeFries, 1980](#); [DeFries and Decker, 1981](#); [DeFries et al., 1978](#); [Foch et al., 1977](#); [Lewitter et al., 1980](#)) identified four dyslexia subtypes in probands: (a) a spatial/reasoning deficit; (b) a coding/speed deficit; (c) a relatively specific reading disability subtype, with a deficit only in reading; and (d) a mixed or global subtype. These subtypes accounted for 91% of the CFRS proband sample. It is difficult to say whether the relatively specific reading-disabled subtype found by these investigators has been identified by others. Unfortunately, most classifications used slightly different diagnostic schemes for patient identification, and few attempts have been made at cross-validation.

In the 1990s, componential models of dyslexia were developed. These models are based on a number of general and specific linguistic cognitive processes (often referred to as reading- or dyslexia-spectrum processes). Despite considerable differences in clinical definitions of dyslexia, there is significant agreement among researchers regarding its cognitive spectrum. (For review, see [Sternberg and Spear-Swerling, 1998](#).) There is general consensus that single-word reading (ability to pronounce printed real words) is the best single criterion for the type of deficit typically referred to as specific reading disability. There also is general agreement that the spectrum of disability includes at least two major procedural deficits: one in phonologic skills and one in automatized lexical retrieval. Finally, the acquisition of reading is related to the acquisition of vocabulary; therefore, some investigators include vocabulary measures in their analyses of cognitive profiles of individuals with reading disability.

The phonologic processing deficiency usually is described as a two-component process: (a) an inability to segment words into phonemes (the so-called phonologic awareness deficit) and (b) an inability to decode written symbols (the so-called phonologic decoding deficit). Even though these two processes are substantially correlated, their developmental and etiological relationship are not fully understood. The automatized retrieval deficiency is operationalized as a rapid automatized naming deficit, wherein an individual is required to name from a printed page colors, objects, digits, or letters as quickly as possible. The relationship between deficits in rapid naming and in phonologic processing, and the contributions of each deficiency to dyslexia, are not straightforward. Current opinions span a continuum, from the concept that these processes are distinct entities to the concept that they are different manifestations of the same underlying latent process. Finally, a number of investigators have used measures of vocabulary in their investigation of normal and disabled reading. The nature of the relationship between vocabulary and single-word reading is complex and, most likely, reciprocal, with reading ability/disability both being influenced by and influencing vocabulary development.

Specific reading disability is familial. As early as 1905, studies were reported in which children with dyslexia often had affected relatives ([Fisher, 1905](#); [Hinshelwood, 1907, 1911](#); [Stephenson, 1907](#); [Thomas, 1905](#)). [Later, Orton \(1937\)](#) and [Eustis \(1947\)](#) also reported the familial nature of RD and, in addition, noted that affected individuals usually had normal intelligence. In 1950, Hallgren published the results of one of the largest family studies of RD, with 116 probands and 391 first-degree relatives. Hallgren reported a male excess among affected probands and affected first-degree relatives. Overall, 160 of the 391 (41%) first-degree relatives had RD. Hallgren calculated segregation ratios based on several mendelian models and proposed that RD was an autosomal dominant trait with sex-modified expression. Other studies confirm the familial nature of RD and that boys have higher prevalence rates than girls, but no specific genetic model were tested ([DeFries et al., 1978](#); [Finucci et al., 1976](#); [McGlannon, 1968](#); [Owen et al., 1971](#); [Walker and Cole, 1965](#)).

Further attempts to examine specific genetic hypotheses have resulted in inconsistent findings. [Symmes and Rapaport \(1972\)](#) proposed sex-linked recessive inheritance after studying the families of 54 children with RD. [Zahalkova and coworkers \(1972\)](#) studied the families of 65 dyslexic children, calculated a segregation ratio of  $0.42 \pm 0.06$ , and concluded that inheritance was autosomal dominant, with partial sex limitation. [Lewitter et al. \(1980\)](#) performed segregation analyses on families collected through 133 children with RD to test the hypotheses proposed by previous investigators. They also analyzed three subsets of the total data: families of male probands, families of female probands, and families of severely affected probands. No one hypothesis was supported in all the analyses. The researchers concluded that the results suggested that RD was genetically heterogeneous; however, when the analysis was restricted to children only, they were unable to reject the hypothesis of a single major locus. In 1991, Pennington et al. examined four independently ascertained samples (204 RD families) and found evidence for the hypothesis of major locus transmission in three samples and polygenic transmission in one sample.

Although RD clusters in families and appears to be transmitted, the data do not prove that the transmission is genetic. Additional evidence for a genetic contribution to the manifestation of RD has come from at least two other sources. The first is twin studies. In a 1967 literature review, Zerbini-Rudin found that of 17 MZ twin pairs, 100% were concordant for RD, compared with 35% (12/34) of DZ twin pairs. [Bakwin \(1973\)](#) examined 338 pairs of same-sex twins and found 14% (97/676) affected with RD. In the MZ twin pairs in which at least one twin had RD, 84% of the co-twins were also affected. In contrast, only 29% of the DZ twin pairs were concordant.

More recent twin studies continue to support a genetic hypothesis for RD. [DeFries et al. \(1987\)](#) estimated heritability for RD to be 30%. [Stevenson et al. \(1987\)](#) also found a low heritability for reading accuracy, but a substantially higher estimate (73%) for spelling. [Ho et al. \(1988\)](#), using a small sample of twins with the Bannatyne Cognitive Profile, reported that the MZ concordance for the profile was 67%, compared with 30% for DZ twins. However, these results may be compromised by the fact that reading problems are significantly more common in twins than in singletons ([Hay et al., 1984](#)). This finding suggests that there may be a major environmental component important for the expression of RD in twins and therefore, the estimates of heritabilities from twin data could be grossly inaccurate.

A second source of evidence for a genetic contribution to RD comes from linkage studies. As discussed earlier, the demonstration of linkage of a purported locus for a trait with a known genetic marker locus is strong evidence that a genetic component is important in the etiology of the trait.

Using current molecular techniques of linkage analysis, investigators have carefully studied selected pedigrees of dyslexic individuals in which developmental dyslexia recurs in different generations. The results of one early study suggested that a major gene for dyslexia was located on the short arm of chromosome 15 ([Pennington et al., 1991](#); [Smith et al., 1983, 1990](#)). [Fulker and colleagues \(1991\)](#) followed up these findings by selecting from the original extended-family study a sample of siblings who represented lower (i.e., more extreme) levels of reading ability. They applied multiple regression techniques, and their results also pointed to chromosome 15. However, subsequent molecular linkage studies, which included the same dyslexia pedigrees, refuted the original findings ([Cardon et al., 1994](#); [Lubs et al., 1991](#); [Rabin et al., 1993](#)). Furthermore, independent investigators who examined Danish families with an autosomal dominant pattern of transmission for dyslexia also were unable to replicate the chromosome 15 finding ([Bisgaard et al., 1987](#)). Later, however, [Grigorenko et al. \(1997\)](#) also found linkage evidence for deficits in word recognition on the long arm of chromosome 15q, and [Schulte-Körne et al. \(1997\)](#) and [Morris et al. \(2000\)](#) reported an association between a marker and reading disability in the same area.

Subsequent linkage studies were based on a possible association between dyslexia and immune system function. Of interest is that the region identified on chromosome 15 by [Smith et al. \(1983\)](#) as linked to dyslexia is near the b<sub>2</sub>-microglobulin gene, which has been implicated in the human autoimmune system ([Lazarus and Owen, 1994](#)). Although the causal basis of the association between autoimmune disturbances and dyslexia has not yet been demonstrated, the evidence of association has suggested a number of chromosomal regions as candidates.

In 1987, Pennington et al. advanced human leukocyte antigen (HLA) as a candidate region for dyslexia susceptibility loci. [Later, Cardon et al. \(1994\)](#) reported findings from an affected sibling-pair study that provided evidence for linkage between reading disability and DNA markers in the HLA region on chromosome 6. These investigators used a quantitative multitrait phenotype of reading by combining several reading and phonologic test scores and weighting them according to a system derived from previous research. A number of research groups have replicated these findings successfully ([Fisher et al., 1999](#); [Gayán et al., 1999](#); [Grigorenko et al., 1997, 2000](#)), although one has not ([Field and Kaplan 1998](#); [Petryshen et al., 2000](#)). Differences in phenotype definitions may account for these variations in replicability ([Grigorenko et al., 2000](#)).

Another region suggested by the association with immunologic functioning is the area around the Rh locus on chromosome 1. [Rabin et al. \(1993\)](#) reported suggestive evidence for the linkage of dyslexia to Rh and other markers on the short arm of chromosome 1. Linkage analyses with the Rh protein marker and two other DNA markers in the region (1p34-p36) yielded a lod score of 1.95 at  $q \leq 0.2$  for all families. Coincidentally, a German family was identified in which dyslexia and delayed speech development cosegregated with a balanced translocation involving chromosomes 1 and 2—t(1;2)(p22;q31) ([Froster et al., 1993](#)). Both [Smith et al. \(1991\)](#) and [Grigorenko et al. \(1998\)](#) have provided supporting evidence for a dyslexia locus on chromosome 1.

[Lubs and colleagues \(1991\)](#) identified a family with a translocation and fusion of chromosomes 13 and 14. Six of the seven family members with the translocation also have dyslexia; however, there is one dyslexic family member who does not have the translocation. Thus, this family provides a clue suggesting that there might be another gene associated with dyslexia on chromosome 13 or 14. These researchers also conducted a random genome testing that included selected markers on

chromosomes 1 to 4, 6, 8, 9, 11, 13, 14 to 16, and 18 to 21 ([Lubs et al., 1991](#)). No significant results were obtained.

Using a large extended Norwegian family in which developmental dyslexia was inherited as an autosomal dominant trait, [Fagerheim et al. \(1999\)](#) conducted a genome-wide search for linkage. This search resulted in the identification of a region on the short arm of chromosome 2 as a dyslexia susceptibility region. These results, however, have not been confirmed by any other group.

To summarize the linkage studies, multiple regions of interest have been identified throughout the human genome. None of these findings can be considered definite, and more research in those same regions is needed. However, a number of observations can be made on the basis of these results. First, various groups of researchers have identified overlapping but differential linkages to different reading-related processes. These semidifferential linkages of different phenotypes to different chromosomal regions might be either indicative of the genetic heterogeneity of developmental dyslexia or, if there are many genes involved in the manifestation of each separate process, suggestive of partial, but not complete overlap of these process-specific sets of genes. Second, because that clustering of different reading-related deficiencies often is observed in a single family, similar remedial efforts within a given family might have differential success. These individual differences (even within a single family) in reception of and response to remedial help are questions for special investigation. Third, it is possible that the observed variation in linkage results is related to the degree of severity of developmental dyslexia, even within one family. Fourth, it is possible that the observed variation within a family is due to the developmental differentiation of what dyslexia is—what is viewed as indicative of dyslexia in an adult in the family might be quite different from what is viewed as indicative of dyslexia in a child in the same family. Thus, the search for genes might be carried out not under the assumption that there is a single phenotype that breeds through multiple generations (e.g., the phenotype of single-word reading), but under the assumption that there are developmentally appropriate forms of the transmitted phenotype (e.g., rhyming in early childhood, phonemic segmentation during early stages of reading mastery, phonologic decoding during adolescence).

Specific reading disability is a complex disorder that is clinically heterogeneous and probably heterogeneous in etiology and pathogenesis. As noted earlier, several attempts have been made to identify different subtypes. Two studies ([Omenn and Weber, 1978](#); [Pennington and Smith, 1983](#)) have used the classification schemes of [Boder \(1971\)](#) to determine if the defined subtypes would “breed true” within families.

[Omenn and Weber \(1978\)](#) studied 21 families with multiple members with RD. Following criteria proposed by [Boder \(1971\)](#), individuals were classified as auditory-predominant subtypes if their history and test results showed dysphonetic spelling errors, striking mispronunciation, and greater difficulty in learning from oral presentation; individuals were classified as visual-predominant subtypes if their history and test results showed phonetic spelling errors, no mispronunciation, and greater difficulty in learning from written or visually presented material. Individuals were classified as mixed if they had characteristics of both previous subtypes. Eleven probands were classified visual predominant, seven as auditory predominant, and three as mixed. Most of the affected relatives who could be diagnosed had the same subtype as the proband, giving support for the hypothesis that the phenotypic subtypes reflect independent familial predispositions.

Of the four groups identified by [Decker and DeFries \(1980\)](#), the relatively specific reading-disabled subtype showed the most significant concordance between probands and other family members, specifically siblings. Thus, this subtype gave strong evidence for genetic factors contributing to a specific form of RD. However, as indicated previously, it is difficult to know whether this group identifies the same group as the Boder scheme.

[Pennington and Smith \(1983\)](#) indicated that there appears to be some evidence for specific subtypes to cluster in the same families in the study reported by [Smith and colleagues \(1983\)](#). The families giving evidence for linkage tended to have dyslexia due to subtle language processing deficits but appeared to have good visual-spatial skills. However, individuals in the family that did not give evidence for linkage appeared to have a visual-spatial dyslexia.

Although all of the aforementioned reports suggest some specificity, there have been no reports of specific tests of genetic hypotheses for these subtypes. The analyses done by [Lewitter et al. \(1980\)](#) divided the sample into age- and sex-defined groups but not into groups of clinically defined subtypes.

As noted, many studies show a male preponderance for RD. Using these data, several authors have suggested that RD may be a trait with a sex-modified threshold important for its expression ([Childs and Finucci, 1979](#); [Herschel, 1978](#)). If the genetic mechanism for the trait also is related to its differential expression in the sexes, then the risk to relatives should differ depending on the sex of the proband. That is, because girls are affected less frequently, the risk to the relatives of female probands should be greater than the risk to relatives of male probands. This is not the case for RD. [Childs and Finucci \(1979\)](#) state that the risk to the relatives of female probands is not significantly greater than the risk to the relatives of male probands. [Omenn and Weber \(1978\)](#) show that the risk is greater for relatives of female probands, but not significantly so. When the data presented by [Finucci et al. \(1976\)](#) are separated by sex of proband, the risks are not different for the two classes of relatives ([Pauls and Kidd, 1981](#)). These results could mean that (a) in each of these studies, the sample size is too small to obtain significance or (b) the sex difference observed is not related to the transmission of the trait. These ideas are supported by the work of [Shaywitz and colleagues \(1990\)](#) that distinguishes between school-identified RD sex ratios and research-identified sex ratios.

If the sex difference is not related to the transmission of RD, then it could be explained in several ways. First, the social or educational environment could be sufficiently different—favorable to girls, so that they would express the trait less often, even when they were genetically predisposed. If that were the case, one would expect a slightly different concordance rate for male and female MZ twins. If, in fact, boys were more apt to experience or be identified as having RD because of a detrimental, and biased, social or educational environment, then their concordance rate should be somewhat lower than that for girls. [Bakwin \(1973\)](#) reported concordance rates for male and female MZ twins to be 84% and 83%, respectively.

Another explanation for the observed difference could be that the male and female developmental processes interact differently with the genetic predisposition for RD and that the interaction produces more severe effects in boys than it does in girls. If that is the case, one also would expect boys to be more severely affected than girls.

In summary, it is clear that much work remains to be done to gain a better understanding of RD and its etiology. It is known that RD is familial and that part of the reason for the familial clustering is an underlying genetic mechanism. At present, it is not known what that genetic mechanism is, but a number of interesting candidate genes are being closely investigated. A variety of genetic models have been proposed; the most frequently mentioned one is a quantitative trait locus model. However, few if any of the alternative hypotheses have been rigorously excluded. Diagnostic uncertainty and probable etiologic and phenotypic heterogeneity cloud the picture. Work is needed to establish useful and unified criteria for all age ranges and to determine if there are phenotypic differences that tend to cluster in families. Yet, in spite of these complications, the field of RD is arguably the one where both theoretical models of the disability and its underlying genetic mechanisms are comparatively better understood than those in other areas of childhood neuropsychiatry.

### Gilles de la Tourette's Syndrome

Gilles de la Tourette's syndrome (TS) is a familial neuropsychiatric disorder with onset in childhood, characterized by chronic intermittent motor and vocal tics. The familial nature of TS was first described by Gilles de la Tourette in 1885. However, it was not until the 1970s ([Eldridge et al., 1977](#); [Shapiro et al., 1978](#)) that studies demonstrated an increased frequency of positive family history for tics in families of patients with TS. The family history study of [Kidd et al. \(1980\)](#) was the first to present frequencies of TS and chronic tics (CT) among relatives. That early study combined TS and CT into a single category and showed that the risk to relatives was significantly elevated over what would be expected by chance. In 1981, Pauls and colleagues analyzed the data collected by Kidd and coworkers, as well as family history data collected from TS clinic patients, to demonstrate that (a) the increased risk for TS and CT was consistent across the two samples and higher than expected by chance, (b) CT appeared to represent a variant expression of the syndrome, and (c) the patterns of occurrence of TS and CT were consistent with vertical transmission in families.

Subsequent to these studies, six groups ([Baron et al., 1981](#); [Comings et al., 1984](#); [Curtis et al., 1992](#); [Devor, 1984](#); [Kidd and Pauls, 1982](#); [Price et al., 1987](#)) reported results of genetic analyses of family history data in which specific transmission hypotheses were examined. All groups concluded that the pattern of transmission in families was consistent with a genetic hypothesis that postulated a single major locus to be responsible for susceptibility to TS or CT. However, this was not the only hypothesis supported. [Kidd and Pauls \(1982\)](#) were unable to reject the hypothesis that transmission of the syndrome was consistent with the contribution of many genes, each with equal and additive effect to the expression of the disorder (the so-called multifactorial-polygenic model). Likewise, [Comings et al. \(1984\)](#) could not reject the multifactorial-polygenic model unless extended relatives were included and the population prevalence for TS and CT was restricted to be less than 0.0075. However, the consistent conclusion of authors in all of the studies was that the mode of inheritance that gave the best fit to the data was one that postulated an underlying single major locus with two alleles. Although all studies supported a single-locus model, not all studies suggested an identical mode of inheritance. Three of the studies ([Baron et al., 1981](#); [Comings et al., 1984](#); [Price et al., 1987](#)) concluded that the most likely mode of inheritance for TS or CT was autosomal dominant with sex-specific penetrances. [Curtis et al. \(1992\)](#) did not detect the excess of male cases of TS that is commonly described. Results from the remaining two studies

suggested an additive model.

As indicated, all of these studies relied on family history data for the analyses. That is, the diagnoses of relatives were based on information given by one or at most two informants per family. It has been demonstrated in studies of other neuropsychiatric disorders that family history data underestimate the "true" rates of illness as determined by direct assessment ([Andreason et al., 1977](#); [Orvaschel et al., 1982](#)). This was demonstrated to be true for TS and CT as well ([Pauls et al., 1984](#)). Thus, the results of the genetic analyses summarized previously should be interpreted with caution. This is particularly true if the underestimation of rates does not occur uniformly across all classes of relatives. For example, if the rate of illness is consistently underestimated in the parents of the patients, then the pattern of illness will more closely resemble the pattern for a recessive or partially dominant condition. If there is a consistent underestimate of the illness in the relatives of a particular type of proband (e.g., relatives of male probands), the resulting patterns could lead to spurious conclusions.

[Pauls and coworkers \(1984\)](#) demonstrated that there appeared to be consistent underestimation of rates in the parents of TS probands in the family history studies of [Kidd et al. \(1980\)](#) and [Pauls et al. \(1981\)](#). Thus, the penetrances reported by [Kidd and Pauls \(1982\)](#) would be expected to be underestimates. This also could be true for the results reported by [Devor \(1984\)](#) because he analyzed only pedigrees reported in the literature.

Biases resulting from consistent underreporting of illness in relatives of a specific type of proband could also occur when it is generally believed by the informant that the illness is more common in one type of relative than another. This appears to have happened in the data collected by [Kidd et al. \(1980\)](#) and [Pauls et al. \(1981\)](#). These investigators reported an apparent increased risk to relatives of female probands in the family history they collected. However, data collected in the Yale Family Study of TS ([Pauls and Leckman, 1988](#)) suggest that the sex of the proband has no effect on the rates among relatives. Therefore, the analyses of Kidd and Pauls that incorporated a sex difference need to be reevaluated.

The results presented by [Baron et al. \(1981\)](#), although appearing to be consistent with a dominant mode of inheritance, predicted that approximately 70% of male and 50% of female patients would be phenocopies (individuals with the disorder but without the gene.) This high phenocopy rate could have resulted from a combination of underreporting for parents or underreporting for female relatives. Because fewer parents and female relatives would have been identified as affected, there would have been more families with isolated cases and, thus, a higher estimate of phenocopies.

Therefore, because of a variety of reporting biases, each of the aforementioned studies has some potential difficulties. Because these reporting biases can affect patterns within pedigrees, it is not surprising that the specific estimates of gene frequency and penetrances vary considerably from study to study. Accurate estimates of genetic model parameters are critical for genetic counseling and for genetic linkage analyses.

A twin study completed in the Child Study Center and Department of Human Genetics at Yale University also demonstrated the effect of relying on family history data for diagnostic purposes. [Price et al. \(1985\)](#) reported the concordance rate for TS to be 0.53 for MZ twin pairs and 0.08 for DZ twin pairs. The data for this study were obtained by questionnaires sent to the mothers of twins and from follow-up telephone interviews with those mothers.

The results from the twin study are comparable with those reported in some of the studies discussed earlier. Concordance rates for MZ twins can be interpreted as an estimate of penetrance if the underlying genetic mechanism is a single locus. Thus, the concordance rate of 0.77, when co-twins with either TS or CT are considered to be affected, can be thought of as a penetrance of 0.77. The estimate compares favorably with the estimates of penetrance reported by [Baron et al. \(1981\)](#), [Comings et al. \(1984\)](#), and [Price et al. \(1987\)](#). However, just as a number of possible reporting biases could affect the results of genetic analyses based on family history data, reporting biases also could affect the results in a twin study.

As a follow-up to the study by [Price et al. \(1987\)](#), investigators at the Yale Child Study Center contacted all twin pairs and conducted personal interviews with each twin. The resulting estimates of concordance indicate that even for twins, the rates of illness can be underestimated if the investigator relies on historical data provided by an informant rather than on data collected by direct personal interview of the subject. The concordance rates estimated from personal interview data increased to 1.0 for MZ twins when co-twins with either TS or CT were included as affected ([Walkup et al., 1987](#)).

Another major focus of the TS family studies has been the delineation of the behavioral phenotype associated with the underlying genetic diathesis. Although a number of psychiatric and behavioral disorders have been hypothesized ([Comings and Comings, 1987](#)), the strongest data concern obsessive-compulsive disorder (OCD). Evidence in support of this association comes from uncontrolled clinical studies ([Cummings and Frankel, 1985](#); [Fernando, 1967](#); [Jagger et al., 1982](#); [Kelman, 1965](#); [Montgomery et al., 1982](#); [Morphew and Sim, 1969](#); [Nee et al., 1980, 1982](#); [Steffl, 1984](#); [Yaryura-Tobias et al., 1981](#)). In addition, family study data indicate that OCD alone (no current or past history of tics) could represent a variant expression of the disorder ([Pauls et al., 1986](#)). Results from several more recent studies have supported these earlier findings ([Curtis et al., 1992](#); [Frankel et al., 1986](#); [Green and Pitman, 1986](#); [Robertson et al., 1988](#); [Walkup et al., 1987](#)), and it is generally accepted that in families of individuals with TS, the two disorders are etiologically related. In addition, [Pauls and Leckman \(1986\)](#) reported that in relatives of TS probands, girls were at greater risk for development of OCD without TS or CT than were boys. These data suggest that rather than a sex-specific frequency of the illness (limited to only TS or CT), there could be a sex-specific expression of the illness, with OCD representing the part of the TS spectrum more frequently expressed in girls.

To determine whether the occurrence of OCD in these families was consistent with genetic transmission of TS, CT, or OCD together, [Pauls and Leckman \(1986\)](#) performed segregation analyses to test specific genetic hypotheses. They concluded that the syndrome is inherited as an autosomal dominant condition. What is noteworthy is that regardless of who was included as affected, whether (a) only relatives with TS, (b) relatives with TS or CT, or (c) relatives with TS, CT, or OCD, the results all were consistent with an autosomal dominant hypothesis. The fact that the inclusion of OCD resulted in a significantly better fit to the observed data within families suggests that OCD is part of a genetically mediated TS spectrum. Penetrances estimated when relatives with OCD are included suggest that there may not be a large difference in the probability of expression of some form of the illness but that the expression may be more specific to a particular sex.

These findings have been replicated in two independent samples ([Eapen et al., 1993](#); [van de Wetering, 1993](#)). Eapen and coworkers studied the families of 40 consecutive TS probands seen in a London clinic and van de Wetering and colleagues studied the families of approximately 45 patients with TS seen in Rotterdam. Both studies found strong statistical evidence that the pattern of transmission of TS, CT with OCD, and OCD without tics was consistent with autosomal dominant inheritance. The penetrances obtained for these two samples were remarkably similar to those reported earlier in this section, ranging from 0.5 to 0.9 for male patients and 0.2 to 0.8 for female patients, depending on the diagnostic scheme used in the analyses. These consistent findings provide a strong rationale for the ongoing linkage studies.

An additional segregation analysis painted a more complex picture of TS inheritance. [Hasstedt et al. \(1999\)](#) reanalyzed 182 family members in a single large TS pedigree for which prior analyses had rejected mendelian inheritance. Those investigators did not use typical diagnostic criteria; rather, they assigned affected status based on a point system that incorporated the TS symptom types, the number of tics reported or observed, and any obsessive-compulsive symptoms. Also, the analyses incorporated an assortative mating correlation in the genetic model because the rate of TS in spouses of the pedigree descendants was greater than that seen in the general population. The new results showed an "intermediate" mode of inheritance, with a penetrance of 0.28 in heterozygotes and 0.98 in homozygotes.

The reanalysis by Hasstedt et al. is especially interesting in light of a significant finding of "bilineal transmission" of TS by [Kurlan et al. \(1994\)](#). The frequency of transmission of TS from both maternal and paternal sides of probands' families was determined by examining 39 high-density families (defined as five or more affected relatives within three generations of the proband) and the families of 39 consecutively evaluated TS clinic probands. Relatives within three generations of the proband were assessed; the presence of tics in relatives was confirmed by direct clinical examination of at least one member on both the maternal and paternal sides. Their results indicated that 33% of the high-density families and 15% of the consecutive-evaluation families showed bilineal transmission of TS. When obsessive-compulsive behaviors were included in the affected status, the proportions were 41% bilineal transmission in high-density families and 26% bilineal transmission in the consecutive-evaluation families. No consanguinity was evident in any of the families. In addition, this study demonstrated that the frequency of bilineal transmission is related to the severity of TS in the proband. An increased severity of symptoms among the affected offspring of two TS-affected parents also was reported by [McMahon et al. \(1996\)](#). Further support for significant bilineal transmission of TS also was provided by [Hanna et al. \(1999\)](#). In a sample of 51 families ascertained through a TS-affected proband, 57% exhibited unilineal transmission and almost 26% showed bilineal transmission.

Taken as a whole, these findings indicate a dosage-effect model of TS, wherein a TS proband who is homozygous for a TS susceptibility allele is likely to be more severely affected than if the same person were heterozygous. Because linkage studies are critically dependent on proper specification of the genetic model, it may be fruitful in future analyses of TS linkage data to include model parameters that reflect an additive gene-dosage effect.

Not all analyses, however, have indicated that the transmission of TS can best be modeled by Mendelian inheritance. In a report of the results of complex segregation

analysis of TS using regression-based methods, [Seuchter et al. \(2000\)](#) found no evidence to support Mendelian inheritance. Their analyses of 108 families, ascertained through single TS-affected probands, incorporated age-of-onset effects, as well as TS-spectrum disorders and major gene effects.

Most reports of TS genetic analyses, however, do support the concept of TS-spectrum behaviors as an inherited disorder and so genetic linkage and association studies are warranted to complete our understanding of the inheritance of this syndrome. Several early linkage studies of TS ( [Barr et al., 1999](#); [Heutink et al., 1990](#); [Pauls et al., 1990](#)) reported no significant evidence for linkage. [Pakstis and colleagues \(1991\)](#) pointed out that an important assumption of those analyses was that the major locus for TS was the same in different pedigrees under study; genetic heterogeneity could obscure a positive finding.

Some association studies in the early half of the 1990s gave evidence for an association between the dopamine D2 and D3 receptor loci and TS ( [Comings et al., 1991, 1993](#)), as did a small twin study published by Wolf et al. (1996), but these results have been refuted in studies using well defined, large samples of patients with TS. [Brett et al. \(1993\)](#) and [Nothen et al. \(1994\)](#) used robust analytic methods (haplotype relative risk) to control for undetected ethnic differences and any resultant skewing of allele frequencies observed in the sample. In fact, most of the genes in the dopamine system have been excluded, including the dopamine receptors D1, D2, D3, D4, and D5, dopamine b-hydroxylase, tyrosinase, and tyrosine hydroxylase ( [Brett et al., 1995](#)).

Additional studies giving evidence of exclusion of linkage of specific genes to TS include [Gelernter et al. \(1993\)](#), in which the dopamine receptor D1 was excluded by genotyping 124 individuals in a single pedigree segregating TS, and [Brett et al. \(1995\)](#), in which the serotonin receptor subtype 5HT-1A and the tryptophan oxygenase genes were excluded by linkage analysis of genotypes from 116 individuals in a single pedigree segregating TS.

Some positive, but not statistically definitive, evidence for TS linkage was reported by [Barr et al. \(1999\)](#). A panel of 386 markers were used to scan the genome at an average resolution of 10 centimorgans. No significant findings were observed using parametric, model-based linkage analyses that specified autosomal dominant inheritance with reduced penetrance. However, using the nonparametric, model-free affected pedigree member analytic method (APM), the authors reported eight markers that were statistically significant. That disparity in results, even though the same families were used, is not surprising because the model-based method has high false-negative rates when the model is misspecified, whereas the model-free method has comparatively high false-positive rates.

An important step in mapping genes for TS was the genome-wide scan using the affected sib-pair (ASP) method, performed by an international consortium of TS investigators ([Tourette Syndrome Association International Consortium for Genetics, 1999](#)). This study reported several chromosomal "hot spots" that may be important in the etiology of TS. Seventy-six families with two or more TS-affected siblings were genotyped on a panel of approximately 400 markers that spanned the entire human genome. None of the "hot spots" reached the level of clear-cut statistical significance, but several regions reached significance levels that justified intensive follow-up with more powerful analytic techniques and additional family samples. Although the ASP approach has been available for some time, only recently has it become evident that its application is increasingly important in the genetic study of disorders where there may be genetic heterogeneity and where the mode of inheritance is complex.

The singular advantage of the ASP method is that no prior assumptions regarding specific genetic mechanisms of a disease are required: It is essentially a model-free procedure but does not have the false-positive rate of the model-free APM method. The analytic approach compares the sharing of alleles at a given locus shared by two affected siblings. If that sharing is significantly higher than expected by chance, it suggests that a gene of etiologic importance for the trait in question is close to the marker being examined. There is a loss of statistical power when performing ASP analyses compared with family pedigree analyses; however, the ASP approach can provide important preliminary evidence for linkage, forming the basis for further investigations using more powerful techniques, as was seen in the TS ASP study.

Close on the heels of the sib-pair genome scan, a positive linkage finding for TS was reported ( [Mérlette et al., 2000](#)) in one large French Canadian family. In that kindred, 40 of the 127 family members examined were affected with TS-spectrum disorders. In a multipoint parametric linkage analysis based on the specification of specific genetic models, a LOD score of 3.24 was reported on chromosome 11 (11q23). Importantly, those investigators corrected for a false-positive signal due to multiple testing (multiple phenotypes and inheritance models).

Turning from linkage studies to cytogenetic evidence, [Comings and colleagues \(1986\)](#) reported a 46,t(7:18)(q22;q22.1) balanced reciprocal translocation in six relatives with TS. This report suggested that a gene for TS could be near the 18q22.1 breakpoint. [Subsequently, Donnai \(1987\)](#) reported a female patient with a mildly hypoplastic midface, ticlike movements, mild OCD, panic attacks, and visual hallucinations who carried a deletion of the long arm of chromosome 18 at 18q22.1. Given the relationship between OCD and tics, this report provided additional support for the hypothesis that a gene for TS might be located in this region. These two reports led to the still-tentative assignment of the TS gene to chromosome 18q22.1 by the chromosome 18 committee at the Human Gene Mapping Conference IX. A paper by [Boghossian-Sell et al. \(1996\)](#) reports the mapping of the breakpoint on chromosome 18; two markers (D18S61 and D18S488) are the closest proximal and distal (respectively) markers to the breakpoint. Two yeast artificial chromosome clones that span the translocation were isolated and should prove useful for the discovery and characterization of genes at the breakpoint and their potential involvement in TS.

Another cytogenetic abnormality [a *de novo* deletion, del(9)(qter@p2304:)] was reported in a Latin American male patient with TS by [Taylor and colleagues \(1991\)](#). This patient was mildly dysmorphic with microcephaly, prominent supraorbital ridges, and slight midfacial hypoplasia. In addition, he exhibited a number of characteristics of the 9p deletion syndrome in the oral cavity and the fingers. A study by [Gericke et al. \(1995\)](#) found that 12 male subjects with TS exhibited a chromosomal fragility at 22q12-13 that was not observed in 10 normal control male subjects. Unfortunately, linkage analyses using probes specific for these chromosomal regions have not confirmed linkage of a gene for TS to any of those regions ( [Heutink et al., 1990](#)).

Most recently, a family was reported with a balanced chromosomal translocation [t(1;8)(q21.1;q22.1)] in family members with TS and in relatives relating affected members. In a follow-up of that study ([Matsumoto et al., 2000](#)), the translocation breakpoints were cloned and sequenced. The CBFA2T1 gene was identified in close proximity to, but not spanning, the breakpoint. Sequencing of the CBFA2T1 exons in 37 unrelated patients with TS did not identify any mutations. Although changes in gene coding regions that result in altered amino acid sequences are the most obvious type of mutation, it is very possible that this translocation instead alters regulatory sequences controlling either the CBFA2T1 gene or other nearby genes.

In summary, our understanding of the genetics of TS has advanced steadily since the early 1980s. By combining analyses of the TS phenotypic spectrum with genotypic data, the field now stands at the threshold of identifying genes that have a major impact on the etiology of TS, and through those genes, gaining an understanding of the causative biology.

## Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) has a lifetime prevalence of approximately 2% in the United States ( [Robins et al., 1984](#)). Previously thought to be a rare disorder, it is now estimated that OCD affects nearly 5 million U.S. citizens. OCD is characterized by the presence of distressful, time-consuming obsessions or compulsions ([American Psychiatric Association, Committee on Nomenclature and Statistics, 1994](#)). Evidence for a genetic basis of OCD is found in family-genetic studies of OCD and TS, and in twin studies of OCD.

The notion that OCD has a familial form is well supported by the current literature. Family-genetic studies ( [Bellodi et al., 1992](#); [Black et al., 1992](#); [Lenane et al., 1990](#); [Leonard et al., 1992](#)) report an increased prevalence of OCD and related obsessional traits among first-degree relatives of OCD-affected probands. [Lenane et al. \(1990\)](#) show 30% of probands with at least one first-degree relative affected with OCD; including a diagnosis of subclinical OCD as affected, they find an overall rate of 22% among all first-degree relatives, 10-fold greater than either the control group or the general population prevalence (subclinical OCD was defined as meeting all DMS-III-R criteria except one of the following: symptoms occur less than 1 hour per day, lack of ego dystonicity/insight, or lack of interference/distress). In a similar study, [Black et al. \(1992\)](#) found that the risk of broadly defined OCD was increased in parents of probands but not in control subjects (16% vs. 3%). A study by [Leonard et al. \(1992\)](#) showed the age-corrected risk of OCD in all first-degree relatives of 54 childhood-onset OCD probands to be 17%, compared with the population prevalence of 2%; similarly, [Bellodi et al. \(1992\)](#) found an OCD rate of 9% among first-degree relatives of 21 childhood-onset probands. Few of the OCD family studies reported in the literature have failed to find an increased risk of OCD among first-degree relatives of probands; in those cases, methodologic questions concerning data collection techniques (e.g., reliance on family history information obtained from only one informant in each family) and diagnostic categories (e.g., subclinical OCD classified as an anxiety disorder rather than a form of OCD) may have contributed to an underestimation of the rate of OCD in relatives.

An OCD family study that addressed those shortcomings by combining a large sample size with a control group, use of sensitive family history methods, and blind best-estimate diagnoses was reported by [Pauls et al. \(1995\)](#). Results from that study showed the rate of OCD is significantly higher in the relatives of OCD probands compared with control subjects (10.3% vs. 1.9%). This also is true for subclinical OCD; 7.9% of the first-degree relatives of OCD probands are affected, compared with only 2.0% of the control subjects. The overall rate of OCD and subclinical OCD among relatives of OCD probands was 18.2%, compared with 4.0% among

control subjects. The rate of tics (TS and CT) among relatives of OCD probands was 4.6%, significantly higher than among control subjects (1%). The sex effect seen in previous studies of families of TS probands (with female relatives being more likely to have OCD without tics) was marginally supported in these data. There is a trend for a higher rate of tics among relatives of female probands compared with relatives of male probands. Interestingly, these data also suggest that not all OCD is related to TS because it is more likely that a relative will have tics if the proband also has tics: If all OCD was related to TS, the rate of TS and CT should be the same among relatives of OCD probands with and without tics. An important effect of the proband's age at OCD onset on the rates of illness among the first-degree relatives also was seen. If a child has onset of disease between the ages of 5 to 9 years, the risk to relatives increases until it is twice that of relatives of probands with onset between 9 and 18 years of age.

The most recent family study of OCD was that of [Nestadt et al. \(2000\)](#). In that study, 80 probands and 326 first-degree relatives were examined. Using a generalized regression model that incorporated age, sex, and type of interview, and also accounted for the potential effects of intrafamily correlations (resulting from assessment of multiple relatives for a disorder transmitted within a family), Nestadt and colleagues found a lifetime prevalence rate of OCD among first-degree relatives that was 11.7% versus 2.7% in the control relatives. Thus, the concept of OCD as a familial disorder continued to be supported, with a nearly fivefold increased risk of OCD among first-degree relatives of affected individuals. In an interesting examination of the obsessive-compulsive phenotype, the Nestadt et al. study showed that relatives of OCD probands are at a greater risk for obsessions than for compulsions. This indicated that the familial nature of OCD may be centered more on obsessive rather than compulsive symptoms, or that there may be a greater symptomatic heterogeneity underlying the category of compulsions. Finally, this study also replicated the previous finding that the familiarity of OCD is associated with early ages of onset (younger than 18 years of age). An interesting result seen in both the Pauls et al. and Nestadt et al. studies was that adults with OCD have fewer children than control subjects.

Family-genetic studies of TS (see the earlier section on TS) provide another line of evidence for a genetic basis of some form of OCD. Interestingly, in the study by Leonard et al. of OCD probands, TS was an exclusionary criterion for participation in the study; at follow up 2 to 7 years later, 12% of probands had onset with TS.

Twin studies of OCD also reveal a strong hereditary component. [Inouye \(1965\)](#) reported 80% concordance between MZ twins and 25% between DZ twins for obsessional neuroses, and 15 years later [Carey and Gottesman \(1981\)](#) reported 87% concordance between MZ twins and 47% between DZ twins. Both studies indicate a large heritability for OCD, although they are constrained by small sample sizes and diagnostic categories that no longer are used.

There are a handful of published segregation analyses using OCD probands. [Nicolini and colleagues \(1991\)](#) performed segregation analyses on data collected from 24 OCD families to examine whether transmission patterns were consistent with simple mendelian models of inheritance. The probands were ascertained through the UCLA Child Psychiatry Clinic; the mean age of onset was 9.1 years. Eleven of the 24 probands had a positive family history of OCD; no further characterization of the sample is given. All available first-degree relatives were directly interviewed, with family history information used for unavailable relatives. Segregation analyses were performed including as affected all individuals with a diagnosis of OCD, CT, or TS. These investigators were unable statistically to reject either an autosomal dominant or autosomal recessive model.

Later segregation analyses were consistent with the Nicolini study results ([Cavallini et al., 1995](#)). Using more comprehensive analytic methods, Cavallini and colleagues found evidence for a major gene effect in a sample of 92 families ascertained through an OCD proband. Although the most parsimonious result was an autosomal dominant model, other major gene solutions (i.e., additive) also could adequately explain the observed familial patterns with no significant difference among them.

[Alsobrook et al. \(1999\)](#) reported the results of complex segregation analyses of 100 families ascertained through adults with OCD. Using the entire dataset and a classification of OCD as affected for the relatives, the best-fitting model was the "mixed model" of a major genetic locus operating against a significant polygenic background. The lack of definitive results may have been because approximately half of the families did not have any relatives with OCD. This pattern of partial familiarity in family samples also has been observed in at least two other studies. [Nicolini et al. \(1991\)](#) also reported that approximately half of the 24 probands in their study did not have a family history of OCD. In addition, in an effort to incorporate phenotypic subtypes in the analyses, Alsobrook et al. used a four-factor symptom dimension [four symptom groups indicated as statistically significant from a factor analysis in the probands ([Leckman et al., 1997](#))]. Analyses limited to families of probands with high scores on symmetry and ordering symptoms indicated the involvement of a major genetic locus; however, these authors also were unable to discern the specific mendelian model.

[Cavallini et al. \(1999\)](#) also reported results from a complex segregation analysis of OCD families. Their approach included information from first- and second-degree relatives, although only a limited portion of the second-degree relatives was directly assessed. In a sample of 107 families ascertained through a proband with OCD, the transmission of OCD was best modeled by a major genetic locus. However, the analyses could not significantly differentiate among dominant, additive, or recessive models. When the affected phenotype was expanded to include TS and tic disorders, only the general unrestricted model of a major genetic locus and a multifactorial background fit the data. These results still support the concept of OCD as an inherited disorder, although the precise nature of the genetic transmission remains elusive. In addition, the analyses by Cavallini et al. strengthen the idea that OCD is genetically heterogeneous. Interestingly, approximately half of their sample of families (54 of 107) also consisted of sporadic cases.

Turning to molecular studies, there currently are no reports of a concerted effort to perform a genome-wide scan for OCD as was done in autism, RD, and TS. There are many reports analyzing individual candidate genes or suites of genes, but no clear evidence has emerged to implicate a specific gene strongly and reproducibly ([Billet et al., 1998](#); [Karayiorgou et al., 1999](#); [McDougle et al., 1998](#)). In many cases, the reports of positive gene associations are based on suboptimal experimental designs, whereas many reports are conflicting or unreplicated.

Our understanding of the genetics of OCD has grown significantly, particularly since the early 1990s. Because of the phenotypic heterogeneity, progress toward mapping genes involved in OCD will likely follow the same course as seen for RD, with efforts to delineate significant phenotypic subtypes occurring in parallel with further genetic and molecular genetic studies.

## SUMMARY

Although the notion that genetic factors are important in the manifestation of childhood psychiatric disorders is not new, most of the work done to examine genetic hypotheses is relatively recent. The evidence reviewed in this chapter supports the concept that genetic factors are important in the expression of some of the more serious neuropsychiatric disorders of childhood. Given the rapid pace of development of new methods for studying the inheritance of human disorders, coupled with progress in the nosology of child psychiatric conditions, we can anticipate major advances in our understanding of the genetic and biological mechanisms underlying childhood psychiatric disorders. This will ultimately lead to improved and individualized therapies, both pharmaceutical and behavioral. All of these efforts will be well served by the accomplishments of the Human Genome Project.

[Final Summary](#)  
[Chapter References](#)

Traumatic and infectious brain injuries affect large numbers of children worldwide. In industrialized countries, traumatic brain injury (TBI), primarily from motor vehicles, is an everyday risk of childhood. In the United States alone, an estimated 88,000 children per year sustain a TBI ( [Kraus, 1995](#)). In nonindustrialized countries, infectious brain injury (IBI) in the form of *Haemophilus influenzae* type b meningitis affects over 200,000 children annually ( [Salisbury, 1998](#)). Worldwide, more than 1 million children are known to be infected with the human immunodeficiency virus (HIV) ( [UNAIDS, 1998](#)), and of these children, almost one-fourth will develop an encephalopathy as part of the acquired immunodeficiency syndrome (AIDS) ( [Lobato et al., 1995](#)).

Acquired brain injury from trauma or infection concerns child psychiatrists for several reasons. First, children who survive severe TBI or IBI are at increased risk for overt neurologic impairments (e.g., cerebral palsy, mental retardation, epilepsy) ( [Menkes and Ellenbogen, 2000](#); [Weil et al., 2000](#)), which are associated with a markedly increased risk for psychopathology of all types ( [Rutter et al., 1970](#)). Second, accumulating evidence suggests that even those children who survive TBI or IBI without major neurologic impairment may be at increased risk for psychopathology ( [Brown et al., 1981](#); [Chadwick et al., 1981a](#); [Max et al., 1997c](#)). Third, because of individual differences in psychiatric outcomes after TBI or IBI, it is important for the clinician to be knowledgeable about the sources of this variability to interpret clinical information and plan interventions for individual children ( [Fletcher et al., 1995a](#)).

Potential sources of variability in psychiatric outcome after TBI or IBI include *brain injury characteristics*, such as the type severity, location, and age of the injury; *child characteristics*, such as age at the time of injury, age at the time of the follow-up, sex, and premorbid cognitive and behavioral characteristics; *family characteristics*, such as socioeconomic circumstances, premorbid family functioning, and family history of psychopathology; and *other possible outcomes* of brain injury, such as motor and sensory deficits, general and specific cognitive impairments, academic failure, impairment of adaptive functioning, and postmorbid family dysfunction ( [Fletcher et al., 1995a](#); [Shaffer, 1995](#)).

This chapter has three sections. The first provides a brief historical overview of important methodologic issues in research on the relation of TBI and IBI to childhood psychopathology. The second and third sections pertain to TBI and IBI, respectively. For each type of acquired brain injury, relevant background information is reviewed first, followed by a review of broadly consistent findings across studies with respect to factors that influence psychiatric outcomes.

### HISTORICAL OVERVIEW

Based on available methods for measuring brain injury and psychopathology in children, 20th century research on the contribution of TBI and IBI to childhood psychopathology can be divided into three overlapping but quite distinct periods.

During the first period, which dates from approximately 1900 to 1970, study of the psychiatric sequelae of acquired brain injury was limited to clinical observation. Especially influential were a series of case reports ( [Bond and Partidge, 1926](#); [Ebaugh, 1923](#); [Hohman, 1922](#)) describing postencephalitic children who exhibited hyperactivity, antisocial behavior, and emotional instability. A similar pattern of behavior was described in children after TBI ( [Blau, 1936](#); [Strecker and Ebaugh, 1924](#)). However, absent a comparison group similar to the affected children in all respects but the brain injury and absent information on the premorbid behavior of the affected children, no firm conclusion could be drawn that this pattern of behavior was due to the injury.

The second period, which dates from approximately 1970 to 1985, marks the beginning of controlled studies of psychiatric outcomes as measured with standardized instruments after TBI ( [Brown et al., 1981](#); [Shaffer et al., 1975b](#)) and IBI ( [Taylor et al., 1984](#)). During much of this period, reliable and sensitive methods of brain imaging were not available, and investigators for the most part relied on clinical signs of acute neurologic impairment [e.g., loss of consciousness (LOC), posttraumatic amnesia (PTA), or sensory or motor deficits] to determine the presence and severity of the brain injury. Psychopathology was measured with standardized instruments that had been developed in the general population of children. Children with TBI or IBI typically were compared with children with orthopedic injuries or with siblings, respectively. In the best studies, information about premorbid behavior was obtained prospectively, that is, as close to the injury or illness as possible to determine the temporal sequence needed to establish causality.

The third period dates from approximately 1985 through the present, and has witnessed an explosion of research effort that exploits advances in measurement of brain injury and psychopathology. Brain imaging methods such as computed tomography (CT), both structural and functional magnetic resonance imaging (MRI), and single-photon emission CT have permitted new ways of identifying brain injury and measuring its severity (e.g., [Kesler et al., 2000](#); [Marshall et al., 1991](#)). The assessment of psychopathology has been augmented by the development of new instruments that are sensitive to the types of behavior that are thought to occur characteristically, if not uniquely, after acquired brain injury ( [Barry et al., 1996](#); [Max et al., 2000](#)). Many of these behaviors are descriptively similar to those noted in case reports from the first period and include measures of Personality Change Due to a Medical Condition (PC) ( [American Psychiatric Association, 1994](#); [Max et al., 1997a, 1997c](#)) and the somatic, cognitive, and behavioral complaints termed the *postconcussional syndrome* ( [Roberts et al., 1996](#)). At the same time, other possible outcomes of brain injury, such as attentional ( [Dennis et al., 1995](#); [Ewing-Cobbs et al., 1998b](#); [Konrad et al., 2000](#)), memory ( [Anderson et al., 2000](#); [Proctor et al., 2000](#)), and language deficits ( [Chapman, 1995](#); [Dennis and Barnes, 1990](#); [Docking et al., 2000](#)), have been studied, as well as other indicators of outcome such as academic performance ( [Ewing-Cobbs et al., 1998a](#)), adaptive functioning ( [Cattalani et al., 1998](#)), social functioning ( [Andrews et al., 1998](#)), and family function ( [Andrews et al., 1998](#); [Max et al., 1998b](#); [Taylor et al., 1995](#)). Findings from these studies are being interpreted within more sophisticated models that view psychopathology as both an outcome and as a mediator or moderator of other outcomes, so that intervention can be applied at the most effective point ( [Taylor et al., 1995](#)).

From a methodologic standpoint, an ideal study of psychiatric outcomes after acquired brain injury (a) uses a representative sample of affected children (to avoid referral bias); (b) uses an appropriate control group; (c) enrolls subjects prospectively rather than retrospectively (to avoid recall bias and to determine the temporal sequence needed to establish causality); (d) uses widely accepted definitions of brain injury severity and other characteristics (to enable comparison with other studies); (e) uses both traditional psychiatric diagnostic instruments, as well as psychiatric outcome measures that are sensitive specifically to the effects of brain injury; (f) assesses other variables that may confound, mediate, or moderate the effects of brain injury on behavior, such as preinjury behavior and family

characteristics; and (g) assesses other indicators of outcome, such as school performance and family functioning.

Few studies meet all of these criteria, in part because our appreciation of these requirements has evolved over time. As a result, across studies, some of the variability in outcome after acquired brain injury is related to differences in methodology; this is noted where relevant. However, this chapter strives to emphasize broadly consistent findings across methodologically sound studies with respect to predictors of psychiatric outcomes, with particular attention to studies from the last decade. Because predictors of psychiatric outcome have been studied more systematically with respect to TBI, this topic is covered first.

## TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) is defined as physical damage or impairment in function of the brain secondary to the exchange of acute mechanical energy. This definition typically excludes other head injuries such as nondepressed and linear skull fractures, as well as other brain injuries resulting from birth trauma, poisoning and asphyxia, cerebrovascular events, or tumors ([Fife, 1986](#)).

### Classification, Pathophysiology, and Epidemiology of Traumatic Brain Injury

#### CLASSIFICATION BY CAUSE

At a first level, TBI is categorized as caused by either open or closed head injury. Open head injury occurs when the skull is penetrated, as by a bullet or by a depressed skull fracture. Closed head injury occurs when a mechanical load, either dynamic or static, is applied to the intact skull ([Rao and Lyketsos, 2000](#)). Dynamic loading, exemplified by high falls and motor vehicle accidents in which the child is a passenger, occurs when there is a sudden rapid movement of the head for less than 50 milliseconds, resulting in rapid acceleration and deceleration of the brain in the skull ([Duhaime et al., 1995](#); [Gennarelli, 1993](#)). Static loading, exemplified by crush injuries from heavy objects such as television sets, occurs when static forces are applied for longer than 200 milliseconds over a relatively large area, slowly deforming the cranium ([Gennarelli and Meaney, 1996](#); [Presad et al., 1999](#)). In children, more than 90% of cases of TBI are due to closed head injury ([Menkes and Ellenbogen, 2000](#)), and most involve a dynamic load ([Presad et al., 1999](#)). In the past, open and closed head injury were thought to result in “focal” and “diffuse” brain injury, respectively. However, recent neuropathologic and brain imaging studies, discussed later in the section on Pathophysiology, suggest that open and closed head injury are rarely pure in terms of focal and diffuse effects on the brain ([Fletcher et al., 1995b](#)).

#### CLASSIFICATION BY SEVERITY

Traditionally, severity has been assessed on the basis of initial level of consciousness, duration of coma, or extent of PTA ([Adams et al., 1991](#)).

Level of consciousness can range from the fully conscious state to a confusional state to stupor and coma ([Plum and Posner, 1980](#)). Coma is a state in which the patient lies with eyes closed and evidences no awareness or responsiveness to external and internal stimuli. The comatose patient fails to react to noxious stimuli with defensive localized movements, and does not speak ([Salzman, 1990](#)). The Glasgow Coma Scale (GCS) ([Teasdale and Jennett, 1974](#)) has become the standard index to assess initial level of consciousness in adults and measure duration of LOC. It assesses function in three domains: eye opening, verbal response, and motor response, yielding a range of scores from 3 to 15. The Glasgow Children's Coma Scale has been adapted for infants and toddlers; it emphasizes brain stem functions and does not assess higher integrative cortical functions ([Raimondi and Hirschauer, 1984](#)).

PTA, another index of severity, refers to the period after recovery from coma in which continuous memories are not stored ([Russell and Smith, 1961](#)). The period of PTA is on average four times longer than the coma stage ([Guthkelch, 1979](#)). For adults, the point at which they can correctly report what has happened to them and the circumstances of their hospitalization and accurately state the month, year, day of month, and day of week has been taken as the resolution of PTA ([Cronwall, 1989](#)). The Children's Orientation and Amnesia Test ([Ewing-Cobbs et al., 1990](#)) evaluates PTA in children 3 to 15 years of age and is considered valid ([McDonald et al., 1994](#)).

The most recent and widely accepted classification system for severity depends on the degree of the initial impairment, combining the initial GCS, the duration of LOC, and the duration of PTA ([Kraus, 1999](#)). *Mild* injury is defined as a GCS of 13 to 15, LOC of less than 30 minutes, or PTA of less than 1 hour; *moderate* injury is defined as a GCS of 9 to 12, LOC of 1 to 24 hours, or PTA of more 30 minutes to 24 hours; and *severe* injury is defined as a GCS of 8 or less, LOC of more than 24 hours, or PTA of more than 1 day. In the past, some studies have used only the GCS to classify the severity, whereas others have used LOC or PTA.

#### PATHOPHYSIOLOGY

Conventionally, a distinction is made between primary brain injury and two types of secondary brain injury. One type of secondary brain injury arises from the brain's normal response to the primary injury and the other from noncerebral insults such as hypoxemia or hypotension ([Adelson and Kochanek, 1998](#)).

Primary brain injury begins within the first few milliseconds of an injury to the brain, although it may take hours to days to evolve. Primary brain injury includes vascular injuries (e.g., subdural hematoma and subarachnoid hemorrhage), as well as three types of injuries to the brain substance: (a) cerebral laceration, (b) diffuse axonal injury, and (c) cerebral contusion ([Kraus and Sorenson, 1994](#)).

Cerebral laceration is relatively rare and usually is seen in open head injury as a result of a penetrating missile or depressed skull fractures. However, in infants, lacerations of white matter can occur without fracture owing to the soft consistency of the incompletely myelinated cerebrum and the pliancy of the infant's skull. Lacerations frequently involve the frontal and temporal poles and are associated with tears in the dura and major vessels and secondary thromboses, hemorrhages, and cerebral ischemia ([Menkes and Ellenbogen, 2000](#)).

Diffuse axonal injury, the most common lesion identified on MRI after a closed head injury, is caused by severe angular acceleration–deceleration forces that occur with dynamic loading ([Adams et al., 1991](#)). The most characteristic sign for diffuse axonal injury is LOC. The duration of unconsciousness is related to the degree of axonal injury, with widespread severe damage leading to deep or persistent coma ([Teasdale and Mendelow, 1984](#)).

Diffuse axonal injury is thought to be a major mechanism of damage in severe closed head injury. Children are more susceptible to diffuse axonal injury than adults because of their head-to-body ratio, weak neck musculature, and incomplete myelination ([Adelson and Kochanek, 1998](#)). Shearing forces sustained during injury are thought to stretch the axons, opening membrane channels at the moment of injury, with an influx of calcium that increases the activity of proteolytic enzymes that disrupt axonal architecture and result in axonal swelling ([Maxwell et al., 1997](#)). When axonal swelling exceeds a certain level, effective transection of the axon has occurred, without evident tearing or damage to adjacent blood vessels. The neuropathologic picture of diffuse axonal injury correlates well with findings on MRI, where it appears as small, oval, focal abnormalities in white matter tracts, usually adjacent to cortical gray matter, but sometimes in the splenium of the corpus callosum ([Gentry et al., 1988](#)). In very severe TBI, the white matter between the cortex and subcortical centers is transected, leading to death ([Weil et al., 2000](#)).

In mild TBI, lesser degrees of diffuse axonal injury and loss of cerebral autoregulation are thought to be responsible for concussion, defined as a transient but instant widespread loss of neuronal function ([Menkes and Ellenbogen, 2000](#)). The concept of concussion as a fully reversible injury with no structural alteration of the brain has been challenged on the basis of several studies using both CT scanning and MRI ([Levin et al., 1987a, 1987c](#)). These studies have demonstrated other occult intracranial lesions such as cerebral contusions (see later), intracranial hematomas, and subarachnoid hemorrhage in a significant number of patients designated as having mild head injury.

Cortical contusion is the second most common type of brain injury visualized by MRI after closed head injury ([Menkes and Ellenbogen, 2000](#)). Contusions consist mainly of petechial hemorrhages in the superficial cortical layers, occurring at the site of penetration or the impact (coup) area, or at the contrecoup area. After closed head injury, contusions are most likely to occur on the crests of gyri on the orbital aspects of the frontal lobes and the inferolateral aspect of the temporal lobes ([Courville, 1964](#); [Gentry et al., 1988](#)) because of bony protuberances on the anterior fossa and sphenoid region ([Miller and Becker, 1982](#)). The severity of brain damage caused by contusion depends on the extent of the vascular injury, but the injury tends to be focal rather than diffuse. Brain imaging studies have shown that the frontal lobes are particularly vulnerable to contusion in closed head injury, leading to a new appreciation of focal effects in closed head injury ([Ewing-Cobbs et al., 1995](#); [Fletcher et al., 1995a](#)).

The brain's normal reaction to primary brain injury is a cascade of physiologic and biochemical events within the brain. In children, where most cases are closed head

injury, diffuse injury to the brain may lead to cerebral swelling, which in turn leads to intracranial hypertension, ischemia, and vasospasm ( [Fishman, 1992](#)). Endogenous biochemical cascades of excitatory amino acids (glutamate, aspartate); cytokines; and complement may aggravate diffuse brain swelling. Children can be more prone than adults to sustain a hypoxic or hypotensive episode posttrauma, and these noncerebral events also contribute to diffuse brain swelling ( [Cruz et al., 1992](#)). The acute treatment of primary TBI in children is the province of neurology and neurosurgery and is primarily directed toward interrupting the brain's normal secondary response to injury, as well as avoiding and treating other noncerebral conditions, such as hypotension, that may contribute to brain swelling ( [Adelson and Kochanek, 1998](#)).

Seizures are a complication of TBI, occurring in 6% of mild and 35% of severe TBIs ( [Bruce, 1993](#)). Seizures associated with mild TBI are unique to childhood. Early seizures are more common in children younger than age 5 years, usually occur within 24 hours, and do not predict outcome ( [Hauser, 1983](#)). Early seizures should be distinguished from later-onset epilepsy, which develops in 5% of patients with TBI. Epilepsy occurs more commonly after open head injury and is more likely to occur as the level of severity increases. Partial seizures are more common than generalized seizures after head injury ( [Bruce, 1993](#); [Jennett and Teasdale, 1981](#)).

## EPIDEMIOLOGY

Approximately 15,000 children annually in the United States sustain a severe TBI ( [Di Scala et al., 1991](#)). According to the U.S. National Pediatric Trauma Registry, 73% or 210 of 286 children who were discharged from a major trauma unit with multiple functional impairments also had significant behavior problems ( [Di Scala et al., 1991](#)).

The rate, severity, and mechanism of TBI vary by age. The rate increases steadily up to 14 years of age, with a dramatic peak occurring at age 15 years. Ninety-three percent of all TBI in children ( [Kraus et al., 1986](#)), compared with 80% in adults ( [Kraus and Sorenson, 1994](#)), has been classified as mild. Mild TBI is most common in 10- to 14-year-olds, whereas the peak incidence of severe and moderate injury occur at age 15 years, but a relatively high proportion of moderate to severe injuries also occurs in infants younger than 1 year of age ( [Kraus et al., 1986](#)). In infancy, the male-to-female ratio is 1:1, but beginning at 5 years of age, boys begin significantly to outnumber girls ( [Courville, 1964](#)).

The predominant mechanism of injury also differs by age. In infancy, child abuse accounts for most cases of TBI. Among preschoolers, falls are the predominant mechanism, whereas among early elementary school-age children, pedestrian accidents are the most common source of TBI. In 10- to 14-year-olds, there is a dramatic increase in injuries from sport and bicycle accidents. Beginning at age 15 years, motor vehicle accidents in which the victim is a passenger becomes the most common cause of TBI ( [Kraus et al., 1986](#); [Rivera and Mueller, 1986](#)).

Demographic risk factors for TBI include poverty; single-parent households; and parental history of psychiatric disorder, drug and alcohol abuse, or physical illness. Child characteristics, such as risk-taking behavior, also are important ( [Bijur and Haslum, 1995](#)), although others ( [Donders, 1992](#); [Pelco et al., 1992](#)) have not found this relationship.

## Measurement of Psychopathology After Traumatic Brain Injury

Measures used to study psychopathology after TBI include traditional measures developed to assess psychopathology in the general population, including psychiatric interviews such as the Kiddie-Schedule for Affective Disorders and Schizophrenia ( [Chambers et al., 1985](#)) and others ( [Rutter et al., 1970](#)), as well as behavior problem checklists such as the Achenbach Child Behavior Checklist (CBCL) ( [Achenbach and Edelbrock, 1983](#)). Recently, more targeted measures have been developed to assess symptoms thought to be characteristic of TBI.

[Max et al. \(1998a\)](#) developed the Neuropsychiatric Rating Schedule, an interview designed to elicit the symptoms of Organic Personality Syndrome as per the third edition, revised, of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) ( [American Psychiatric Association, 1987](#)) and PC as per DSM-IV ( [American Psychiatric Association, 1994](#)). It consists of 22 items that cover affective instability, aggression and rage, markedly impaired social judgment (e.g., disinhibition), apathy, and paranoia.

The postconcussional syndrome, which is not a DSM-IV diagnosis, refers to a constellation of somatic and psychological symptoms, including headache, dizziness, fatigue, diminished concentration, memory deficit, irritability, anxiety, insomnia, hypochondriacally concern, hypersensitivity to noise, photophobia ( [Levin et al., 1982](#)), and seizure-like symptoms ( [Roberts et al., 1996](#)), frequently reported in patients with brief periods of coma or otherwise disturbed consciousness after TBI. Measures developed to assess postconcussional symptoms include the Iowa Interview of Partial Seizure-Like Symptoms ( [Roberts et al., 1996](#); Varney et al.) as adapted for children ( [Roberts et al., 1996](#)), the Pediatric Inventory of Neurobehavioral Symptoms ( [Roberts, 1990](#)), the Neurobehavioral Rating Scale ( [Levin et al., 1987b](#); [Vanier et al., 2000](#)), and the Post-Injury Symptom Checklist ( [Barry et al., 1996](#)).

## Predictors of Psychopathology After Traumatic Brain Injury

### BRAIN INJURY CHARACTERISTICS

#### Severity of Brain Injury

Severity as measured by initial neurologic impairment has been the most studied predictor of psychiatric outcome after TBI. Despite varying criteria for severe versus mild TBI, a fairly consistent finding across studies is that, after accounting for premorbid psychopathology, severe but not mild TBI increases the risk for psychopathology. However, as reviewed later, controversy continues over the psychiatric significance of mild TBI.

**Severe Brain Injury.** The first prospective study of closed head injury to use standardized psychiatric diagnostic assessments remains a benchmark in the field. Rutter and colleagues ( [Brown et al., 1981](#); [Rutter et al., 1980](#)) obtained an account of premorbid behavior as soon as possible after the injury and examined behavior change over time with a longitudinal design. The possibility of a threshold effect for severity of injury was examined by including a severe injury group, defined as having PTA of at least 7 days, and a mild injury group having PTA or more than 1 hour but less than 1 week. The comparison group consisted of 28 children who had received hospital care for orthopedic injuries.

The rate of newly appearing psychiatric disorders was much increased in the severe head injury group (60%), whereas new psychiatric disturbance in the mild head injury group (24%) was no different from that seen in the orthopedic control subjects (24%). This was true at 4 months, 1 year, and 2 years and 3 months after the accident. There appeared to be a threshold effect and a modified dose-response effect of severity: Among the mild injury group, children with less than 7 days of PTA had rates similar to those with less than 24 hours of PTA. In the severe injury group, those who had PTA for longer than 21 days had a higher rate of new disorder than those who had PTA of 7 to 21 days.

[Brown et al. \(1981\)](#) considered whether the psychiatric disorders that appeared for the first time after head injury were distinctive in pattern. At 1 year, among children in the severe brain injury group who had new-onset disorders, 14% had emotional disorders, 10% mixed emotional and conduct disorders, 5% conduct disorder, and 5% psychosis. Another 24% exhibited a disinhibited state. Typical behaviors included being unduly outspoken, making frequent personal remarks, or asking embarrassing questions and getting undressed in inappropriate social situations. Other behaviors included forgetfulness, loquaciousness, carelessness in personal hygiene, and impulsivity ( [Brown et al., 1981](#); [Shaffer, 1995](#)). The disinhibited children all had a PTA exceeding 3 weeks, and three showed persistent intellectual impairment, suggesting that brain damage was directly implicated in the etiology. The clinical picture in two of the children evolved to a picture of attention deficit/hyperactivity disorder (ADHD) by the second year ( [Shaffer, 1995](#)).

The findings of [Brown et al. \(1981\)](#) with respect to the excess risk for psychiatric disorder among children with severe, but not mild injury, are supported by other retrospective ( [Lemkuhl and Thoma, 1990](#); [Shaffer et al., 1975b](#)) and prospective studies ( [Max et al., 1997a, 1997b, 1997c](#)) of TBI. Moreover, ongoing work by Max et al. ( [Childers et al., 1998](#); [Max et al., 2000](#)) has extended the findings of [Brown et al. \(1981\)](#) with respect to the "disinhibited state" as a distinctive novel pattern of behavior after severe brain injury. In a both retrospective and prospective study, [Max et al. \(2000\)](#) studied the prevalence and correlates of the DSM-IV equivalent of the "disinhibited state," namely, the diagnosis PC Due to a Medical Condition (Head Injury). They found approximately 40% of consecutively hospitalized children with severe TBI had ongoing persistent PC an average of 2 years postinjury. Another 20% had a history of remitted and more transient PC. PC occurred in 5% of mild to moderate TBI but was always transient. The PC most often was a combination of the PC subtypes included in DSM-IV, with the labile, aggressive, or disinhibited subtypes being the most common, the apathetic subtype being transient, and the paranoid subtype rare. In subjects with severe TBI, persistent PC was significantly associated with severity of injury, particularly impaired consciousness over 100 hours, adaptive and intellectual functioning decrements, and concurrent diagnosis of

secondary ADHD. However, persistent PC was not related to psychosocial adversity.

As reviewed by [Max et al. \(2000\)](#), PC is the most recent name given to a syndrome or syndromes of behavioral change attributed directly to brain injury from various causes. The behavioral changes are distinct from disorders resembling affective, anxious, psychotic, and disruptive behavior disorders that may or may not be the direct result of acquired brain injury. In the past, terms given to this group of behaviors include *organic personality syndrome* ([American Psychiatric Association, 1987](#)); *frontal lobe syndrome* ([Lishman, 1978](#)); *compartmental learning disabilities* ([Price et al., 1990](#)); *posttraumatic chronic behavior disorder* ([Blau, 1936](#)); and the *regional prefrontal syndromes*, including the dysexecutive type (dorsal convexity system) disinhibited type (orbitofrontal system), and apathetic type (mesofrontal system) ([Duffy and Campbell, 1994](#)).

**Mild Brain Injury.** As reviewed previously, prospective studies using psychiatric diagnoses as outcomes do not find that mild TBI increases the risk for psychopathology. Moreover, two well designed prospective studies that focused on mild TBI and used behavior problem checklists developed in the general population also failed to find effects of mild TBI on psychopathology.

The first of these studies is the UCLA Study of Mild Closed Head Injury in Children and Adolescents ([Asarnow et al., 1995](#)). This study was a prospective cohort follow-up of a representative sample of children diagnosed with mild closed head injury in area emergency departments. Comparison groups consisted of children with other nonhead/brain injuries admitted to the same emergency departments as the cases and noninjured children in area schools who were demographically similar to the cases. Mild TBI was defined as an uncomplicated closed brain injury, which operationally meant that each child had a minimum of two concussive symptoms documented in the emergency department records and GCS score greater than 12. Within 1 month of the injury, parents were asked to complete the CBCL for the 6 months before injury and were asked to complete it again at 12 months postinjury. The mild TBI group did not show an increased rate of behavior problems at 12 months postinjury compared with the 6 months before injury. The investigators stressed that the mild TBI group would have had elevated rates of behavior problems had they not measured preinjury level of functioning. The children in the mild TBI group actually had higher levels of behavior problems before the injury, and the rates of behavior problems actually declined in the 12 months after the injury, consistent with the view that mild TBI did not directly cause an increased rate of behavior problems, at least as measured by the CBCL.

In the second study, [Bijur and Haslum \(1995\)](#) studied 12,000 children enrolled in the British Cohort Study and assessed at ages 5 and 10 years. Mild injury was defined as parental report of a head injury that resulted in concussion or LOC and treatment as an outpatient or admission overnight to the hospital. Using behavior problem checklists, the head-injured children were compared with a random sample of children who had no injuries and with children who had limb fractures, children with lacerations, and children with burns. Behavior problems did not differ significantly across groups. Although parental ratings of hyperactivity were highest in the brain-injured group, even after control for preinjury hyperactivity, hyperactivity scores in the groups with other injuries also were higher than in control subjects. This suggested that differences between the brain-injured group and control subjects were due to factors that elevate the risk for any injury. Moreover, children with multiple mild head injuries did not show adverse behavioral sequelae. Other controlled studies of mild TBI in children have been consistent with these findings (e.g., [Fay et al., 1993](#)). Although it is clear that most children with mild TBI do not experience psychiatric morbidity, a "miserable minority" ([Ruff et al., 1994](#)) do experience problems, often described as the postconcussional syndrome. [Roberts et al. \(1990\)](#) have argued that behavior problem checklists developed in the general population, such as the CBCL ([Achenbach and Edelbrock, 1983](#)), are not sensitive to postconcussional symptoms, which include episodic or spell-like symptoms ([Roberts et al., 1990, 1995, 1996](#)). Using an adaptation of an interview to assess partial seizure-like symptoms, they found that children with mild and severe injury were equally likely to endorse symptoms of staring spells; there was no dose-response curve relating frequency or severity of episodic symptoms to injury severity. Other investigators ([Barry et al., 1996](#)), however, have found the frequency of postconcussional symptoms as assessed with the Post Injury Neurobehavioral Checklist was related to severity of injury in children with moderate to severe injury, suggesting that similar symptoms may be useful in identifying sequelae associated with mild TBI. In adults with mild TBI, postconcussional symptoms have been linked to abnormalities in neuropsychological assessment and in functional neuroimaging ([Barry et al., 1996](#)).

#### *Site of Brain Injury*

The only study to date of open head injury ([Shaffer et al., 1975a](#)) found no significant effects for site of injury after controlling for psychosocial correlates. Although closed head injury in general has been considered to be diffuse, brain imaging studies suggest that contusional injuries of the frontal lobe may be more common than previously thought ([Filley et al., 1987](#); [Fletcher et al., 1995b](#); [Levin et al., 1993](#)). In a small sample of 53 children with closed head injury, [Filley et al. \(1987\)](#) found that children who had persistent behavior problems at long-term follow-up (average, approximately 3 years) displayed either a profile of overarousal, with inattentiveness, irritability and hyperactivity, often accompanied by impulsivity, inappropriate behavior, and aggressiveness, or a profile of underarousal with apathy, poor motivation, and social withdrawal. All of these patients had either discrete frontal lesions on CT or prolonged coma with slow recovery of attention, thought to be due to diffuse axonal injury and consistent with the disinhibition noted in clinical observations and more recent research. Although [Max et al. \(2000\)](#) found no relation between site of lesion (frontal, temporal, parietal, occipital) as recorded from the initial CT scan and labile, aggressive, or disinhibited subtypes of PC, they noted that CT is relatively insensitive in detection of diffuse injuries, subcortical lesions, and small lesions.

#### *CHILD CHARACTERISTICS*

##### *Child Age at Injury*

Two studies ([Max et al., 1997b](#); [Shaffer et al., 1975b](#)), both of severe TBI, examined the child's age at injury in relation to psychiatric outcomes, and neither found an effect. This contrasts with cognitive outcomes, where younger children usually sustain greater impairment.

##### *Premorbid Cognitive Functioning*

[Brown et al. \(1981\)](#) found that new disorders after TBI were more common among children with initial intellectual impairment.

##### *Premorbid Behavioral Functioning*

Preinjury behavior was a powerful predictor of later problems in all brain injury groups.

#### *FAMILY CHARACTERISTICS*

##### *Family Functioning*

Premorbid family adversity has consistently been found to increase risks for psychopathology after injury ([Brown et al., 1981](#); [Max et al., 1997b](#); [Shaffer et al., 1975b](#)). In a prospective study of closed head injury, the rate of appearance of new disorders was significantly greater in children who experienced the combination of a severe head injury and psychosocial adversity but was not greater than that expected from the two alone, suggesting an additive rather than a synergistic effect ([Brown et al., 1981](#)).

Both retrospective ([Perrott et al., 1991](#)) and prospective studies ([Rivara et al., 1992, 1993](#)) have found adverse effects of severe TBI on family functioning. A more recent study by [Taylor et al. \(1995\)](#) confirmed that child behavior outcomes after injury are related to postinjury family function, parental psychological distress, and the perceived impact or burden of the injury on the family. Six months after an initial postinjury assessment, parents of children with TBI report more family disagreements than do parents of children with orthopedic injuries, and parents of children with TBI tend to report more psychological distress. To the extent that these family characteristics are attributable to the injury itself (i.e., were not present before injury), the results also support the hypothesis that child outcomes depend in part on how the injury has affected the family ([Taylor et al., 1995](#)).

##### *Family Psychiatric History*

In a 2-year prospective, longitudinal study of children with TBI, [Max et al. \(1997b\)](#) found that a rating of family history of psychiatric disorder was not by itself significantly related to new-onset psychiatric disorder at 2-year follow-up.

## Other Outcomes

### NEUROLOGIC DEFICITS

In a study of closed head injury ([Brown et al., 1981](#)), psychiatric disorder was most frequent among the children showing persistent neurologic abnormalities at the 2½-year follow-up.

### ATTENTION DEFICIT/HYPERACTIVITY DISORDER

[Max et al. \(2000\)](#) found that persistent PC after severe TBI was associated with a diagnosis of secondary ADHD. [Gerring et al. \(1998\)](#) found that children in whom new-onset of ADHD developed after closed head injury had significantly greater premorbid social disadvantage and exhibited more emotional lability and aggression, other psychiatric disorders, and overall disability than children in whom new-onset ADHD did not develop. They noted that the diagnoses of ADHD and PC due to closed head injury both have deficit of inhibition as a primary feature.

In a recent study, Konrad et al. ([Eide and Tysnes, 1992](#)) compared 27 children with TBI to 31 children with developmental ADHD and 26 matched control subjects aged 8 to 12 years. Children with TBI and ADHD showed a pervasive deficit in their inhibitory control processes with respect to inhibition of both prepotent and ongoing responses. In addition, children with TBI were found to have a general slowing of their information processing that was not correlated with the inhibition deficits.

### NEUROPSYCHOLOGICAL DEFICITS

The relation between psychiatric sequelae and cognitive sequelae of TBI in children remains a theoretical and clinical conundrum. A considerable body of evidence has established that severe TBI, but not mild TBI, is associated with decrements in general intellectual functions ([Chadwick et al., 1981b, 1981c](#); [Max et al., 1999](#)), memory functions ([Anderson et al., 2000](#); [Levin et al., 1995](#)), and attention ([Chapman, 1995](#); [Dennis et al., 1995](#); [Max et al., 1999](#)).

[Max et al. \(1999\)](#) have shown that a neuropsychiatric factor that combines severity of injury measures and novel postinjury psychiatric disorders was significantly associated with cognitive and memory outcome after childhood TBI. New postinjury psychiatric disorder significantly added to indices of TBI severity in explaining some cognitive outcomes. Furthermore, cognitive outcomes were independently related to psychosocial disadvantage. Improved understanding of how neuropsychiatric and psychosocial disadvantage affect outcome is important for treatment. Treatment of novel psychiatric disorders and family therapy may be hypothesized to improve cognitive outcome. If, on the other hand, postinjury psychiatric disorders are a consequence of neurocognitive deficits rather than their cause, then cognitive rehabilitation and educational remediation after TBI may help prevent postinjury psychopathology.

## Treatment for Psychopathology After Traumatic Brain Injury

In the absence of controlled studies demonstrating clear-cut efficacy for specific treatment interventions, a broad-based, multidisciplinary approach seems most reasonable, based on accumulated clinical experience to date ([Silver and Yudofsky, 1994](#)). Insofar as many of the psychiatric disorders encountered in the wake of TBI are representative of the spectrum of child psychopathology in general, those treatment strategies that would ordinarily apply would still pertain to specific psychopathology encountered in the wake of brain injury. However, a few additional considerations particularly pertinent to the brain-injured child are addressed here.

In the psychopharmacologic domain, the greater sensitivity of brain-injured patients to the sedative and anticholinergic effects of various psychotropic medications leads to the advisory of starting with lower doses and raising them in small increments over time. Similarly, because of the greater incidence of disinhibited, impulsive, and aggressive behavior documented in children with brain injury, it is important to avoid indiscriminate use of neuroleptic drugs in such patients, in the absence of documented psychosis ([Silver et al., 1992](#)). This is true not only because of potential sedative and anticholinergic side effects and the dangers of tardive dyskinesia, but because neuroleptics may lower the threshold for seizures, to which brain-injured patients are particularly vulnerable (see the section on epilepsy in [Chapter 61](#)).

A double-blind, placebo-controlled study of methylphenidate in 15 adult patients with TBI found improvement in mood and cognition in all but one patient ([Gualtieri and Evans, 1988](#)). However, this study has not been replicated in younger patients. Promising work in adults with dopaminergic agents such as amantadine, levodopa ([Kraus and Maki, 1997](#)), and bromocriptine ([Goldberg et al., 1982](#); [Taverni et al., 1998](#)) has not been replicated in children.

The use of anticonvulsants may be indicated in children with episodic or spell-like symptoms after head injury. [Roberts et al. \(1996\)](#) found that divalproex sodium (Depakote; Abbott Laboratories, Abbott Park, IL) improved functioning in a high proportion of pediatric patients with episodic symptoms after head injury. There is some anecdotal support for the use of carbamazepine in children with disinhibited aggression, affective lability, and other psychopathologic states in the wake of brain injury ([Lewin and Sumners, 1992](#)). This would be particularly justified if the patient's electroencephalogram (EEG) demonstrated epileptiform abnormalities despite the absence of clinical seizures. Clinical experience, however, has expanded our awareness of potentially untoward effects of carbamazepine, including the possible worsening of irritability and aggressive behavior, as well as precipitation of mania ([Pleak et al., 1998](#)). There have been a number of reports regarding the potential merits of using b-adrenergic blocking medications for the treatment of uncontrolled aggressive outbursts in patients with organic brain impairment ([Connor, 1993](#); [Williamson et al., 1982](#)). This can be done in conjunction with or independent of any concomitant anticonvulsant medication. Clinical experience to date, which requires controlled replication, suggests that some patients demonstrate improved behavioral control of aggressivity and irritability after appropriate dose titration. Knowledge of appropriate monitoring and titration procedures is important and easily mastered.

Probably of equal importance to any psychopharmacologic intervention are behavioral and psychosocial measures that are widely used and of apparent benefit to a significant proportion of brain-injured youngsters, although again the results have received limited systematic evaluation. These measures include parental counseling, individual and family education and supportive psychotherapy, speech therapy, associated rehabilitative therapies, and academic tutoring. [Warschausky et al. \(1999\)](#) have reviewed the empirical support for psychological and behavioral therapies for the behavioral and psychosocial sequelae of TBI. While noting the success of operant conditioning in decreasing aggression during acute recovery and later, they noted the lack of outcome studies for treatment of internalizing disorders in particular.

Also, it has been suggested that it is possible to improve the performance of head-injured subjects by slowing down the pace at which information is presented, reducing background distractions or noise, or allowing additional time to complete tasks ([Ponsford and Kinsella, 1992](#)). Although systematic studies undoubtedly are desirable in this area, the many clinical variations in the broad spectrum of brain-injured youngsters will continue to require individual tailoring of treatment plans to meet the unique needs of individual patients.

Further complicating the assessment of minor head injury and the postconcussional syndrome are individual patient variables, including preexisting neuropsychiatric disorder, nonspecific effects of hospitalization after trauma, and secondary emotional factors, including the possible effects of potential litigation. Each of these factors may contribute disproportionately to the apparent sequelae of a head injury, quite apart from actual neurologic and neuropsychiatric sequelae.

It seems reasonable to suggest that, when a patient presents after minor head injury with persistent symptoms associated with the postconcussional syndrome, a full reassessment addressing the aforementioned differential diagnostic possibilities should be pursued. In addition to neurologic reassessment and a repeat EEG, neuroradiologic reassessment often is advisable. Thus, [Levin et al. \(1987a, 1987c\)](#) reported that, of 16 consecutive admissions with minor or moderate closed head injury, 14 had abnormalities on MRI, although their prior CT scans were normal or showed fewer abnormalities. Similarly, an apparent decline in academic performance, emotional responsiveness, or behavioral appropriateness should prompt formal neuropsychological and psychiatric consultation, with the previously outlined considerations in mind. If a patient shows no objective evidence of neurologic or cognitive impairment on the various diagnostic parameters enumerated, a supportive psychotherapeutic strategy geared to reassuring both the patient and family regarding a generally favorable prognosis and avoiding the secondary gains of invalidism is most judicious. Advising prompt settlement of any outstanding legal claims is helpful in this regard.

## Prevention of Traumatic Brain Injury

Children younger than 4 years of age who are not restrained in safety seats are 11 times more likely to be killed in motor vehicle accidents ([Silver et al., 1992](#)). Conversely, child safety seats have been found to be 80% to 90% effective in the prevention of serious injuries to children. All 50 states in the United States and the District of Columbia have mandatory laws for child safety seats. Public education to encourage compliance with these laws would contribute to primary prevention of a

large proportion of pediatric TBIs.

The potential success of prevention programs was demonstrated recently by a hospital-initiated program that targeted traffic injuries among school-age children in one section of New York City. The program included traffic safety education, expanded areas for safe play, bicycle safety education and helmet distribution, and supervised recreational activities. During the intervention, the average incidence of traffic injuries among this age group declined significantly by 36% relative to the preintervention period ([Durkin et al., 1999](#)). More effective public health measures to curb child abuse, alcoholism (especially drunk driving), and preventable accidental injuries also would be desirable.

### Conclusions Regarding Psychiatric Sequelae of Traumatic Brain Injury

First, severe but not mild brain injury markedly increases the risk for all types of psychiatric disorders as measured by traditional instruments, even after controlling for other child characteristics, such as intelligence or premorbid behavior, and family characteristics. Second, among the severely injured, those with chronic neurologic deficits have the highest risk for psychopathology; however, some severely injured children without chronic neurologic deficits also develop new psychopathology after the injury. Third, the most common type of new psychiatric disorder after severe TBI in children is PC due to TBI, and the most common symptoms are consistent with the labile, aggressive, and disinhibited subtypes ([Max et al., 2000](#)). Fourth, mild brain injury does not increase the risk for psychiatric disorders in general or for PC in particular, but may increase the risk for a constellation of cognitive, somatic, and behavioral symptoms known as the *postconcussional syndrome* ([Roberts et al., 1996](#)); further research in this area is needed. Fifth, family functioning is an extremely important predictor of outcome in both severe and mild TBI, and TBI itself may be a cause of family dysfunction. Finally, burgeoning research on the brain imaging abnormalities and neuropsychological deficits associated with postinjury psychopathology in children promises new advances in our understanding of children's outcomes after TBI.

## INFECTIOUS BRAIN INJURY

Although modern thinking about the contribution of acquired brain injury actually began with observations after IBI, psychiatric outcomes after IBI have been studied far less systematically or extensively than TBI. A detailed review of the medical diagnosis and treatment of the various forms of IBI is beyond the scope of this chapter, and the reader is referred to other texts ([American Academy of Pediatrics, 2000](#)).

### Terminology

Central nervous system (CNS) infection usually is classified by pathogen (i.e., bacterial, spirochetal, fungal, viral, protozoan). The brain responds to infection in a limited number of ways, regardless of the nature of the pathogen. CNS infections have in common a number of clinical and pathologic features, with the clinical presentation being determined by the virulence of the pathogen, the site and the extension of the infection, and the immunologic response of the individual ([Weil et al., 2000](#)). Although bacterial infections have a different presentation from viral infections, it can be difficult to distinguish bacterial from fungal infections and viral infections from chronic granulomatous, viral, spirochetal, or protozoan infections solely from the history and physical examination of the patient. The diagnosis requires laboratory studies, including the isolation and, if possible, propagation of the suspected organisms.

For the purpose of this section, we use the following definitions: *Meningitis* denotes inflammation of the meninges and is identified by an abnormal number of white blood cells (WBCs) in the cerebrospinal fluid (CSF). *Septic or purulent meningitis* denotes meningitis with evidence of a pathogen in the CSF. *Aseptic meningitis* denotes meningitis with no evidence of a bacterial pathogen detectable in the CSF by usual laboratory techniques. Most cases of aseptic meningitis have a viral etiology but also can be caused by rickettsiae, spirochetes, and other nonbacterial infections, as well as by noninfectious diseases such as systemic lupus erythematosus, multiple sclerosis, malignancies, and others. *Encephalitis* denotes inflammation of the brain. *Meningoencephalitis* denotes inflammation of the brain accompanied by meningitis.

### Bacterial Meningitis

#### EPIDEMIOLOGY

Bacterial meningitis is a serious childhood illness. Although *H. influenzae* type b (Hib) disease has been dramatically reduced in North America, northern Europe, and other countries like New Zealand ([Robbins et al., 1996](#)), it is still a leading cause of bacterial meningitis ([Salisbury, 1998](#)) in developing countries, with over 200,000 cases and more than 40,000 deaths occurring annually ([Mulholland et al., 1997](#); [Salisbury, 1998](#)). Moreover, *Neisseria meningitidis* and *Streptococcus pneumoniae* continue to be important pathogens ([Schuchat et al., 1997](#)). Recurring epidemics of meningococcal disease ([Booy and Kroll, 1998](#)), increased antibiotic resistance among pneumococci ([Goldstein et al., 1996](#)), and failure to introduce conjugate Hib vaccines in developing nations make bacterial meningitis a serious worldwide health problem.

In the United States, the most common cause of meningitis for all age groups older than 1 month is now *S. pneumoniae*, followed by *N. meningitidis*, b-hemolytic *Streptococcus*, and *Listeria monocytogenes* ([Schuchat et al., 1997](#)).

#### PATHOGENESIS

Regardless of the age of the child, most cases progress through four stages: (a) infection of the upper respiratory tract, (b) bacteremia from the respiratory focus, (c) seeding of the meninges by blood-borne bacteria, and (d) inflammation of the meninges ([Evans, 1987](#); [Weil et al., 2000](#)).

Inflammatory exudate then enters the subarachnoid space, leading to arteritis, arterial or venous thrombosis, and perineuritis, and in some cases communicating or noncommunicating hydrocephalus ([Evans, 1987](#); [Klein et al., 1986](#); [Weil et al., 2000](#)). The increased intracranial pressure or the acute hydrocephalus may reduce the perfusion of blood to the brain. The resulting changes in neuronal metabolism may cause edema or predispose to seizures. If the edema advances rapidly, it can lead to cerebral herniation and death. If the edema advances more slowly, for several days, glial proliferation occurs. The changes in nerve cells may be slight, or there may be widespread destruction of cortical cells and myelinated fibers. Dysfunction of cortical neurons, with altered mental status or seizures, occurs as much as several days before microscopic changes; this is the result not of bacteria in the substance of brain but of a metabolic or toxic encephalopathy ([Klein et al., 1986](#); [Weil et al., 2000](#)).

#### CLINICAL DIAGNOSIS

As a rule, findings in neonates and young infants are minimal and often subtle, making early diagnosis difficult to establish clinically ([Klein et al., 1986](#)). Infants may present with fever (50%), lethargy, respiratory distress, jaundice, lack of interest in feeding, vomiting, diarrhea, irritability (30%), poor muscle tone, alterations in consciousness, convulsions (40%), and a bulging fontanel (30%) ([Klein et al., 1986](#)).

In children, fever, headache, photophobia, nausea, vomiting, mental confusion, lethargy, and irritability are the usual initial complaints. These manifestations are nonspecific and are like those of nonmeningeal viral infections or other febrile illnesses. Stiff neck and other meningeal signs, seizures, and coma occur less commonly and usually later in the illness. However, when encountered, these are sufficiently characteristic of meningitis to prompt physicians to perform an immediate diagnostic lumbar puncture ([Klein et al., 1986](#); [Weil et al., 2000](#)).

The definitive diagnostic test of meningitis is the examination of the CSF by spinal tap. The routine CSF analyses are bacterial cultures, protein and glucose determinations, cell count, and differential Gram stain. If available, detection of capsular antigens using counterimmune electrophoresis or other techniques also can be helpful ([Klein et al., 1986](#); [Weil et al., 2000](#)).

#### NEUROLOGIC SEQUELAE

As much as 50% of the survivors of meningitis have some sequelae of their disease ([Evans, 1987](#); [Klein et al., 1986](#); [Weil et al., 2000](#)). Specific sequelae or complications of bacterial meningitis that have been observed include cranial nerve involvement, which often improves with time. However, 10% remain with hearing loss, hemiparesis or quadriparesis, muscular hypertonia, ataxia, mental retardation, permanent seizure disorders, or hydrocephalus. The syndrome of inappropriate antidiuretic hormone secretion develops in 30%, but this rarely is persistent or clinically significant. Subdural effusions develop in approximately 40% and occur so

frequently in young children that they can be considered as part of the general disease process rather than as a complication ( [Evans, 1987](#); [Klein et al., 1986](#); [Weil et al., 2000](#)).

### PSYCHIATRIC SEQUELAE

In general, studies that have used siblings as control subjects ( [Sell et al., 1972](#); [Taylor et al., 1984](#); [Tejani et al., 1982](#)) have found that children who survived Hib meningitis without major neurologic sequelae do not differ from the siblings on behavioral measures, although they had somewhat lower IQ scores.

[Taylor et al. \(1992\)](#) compared two groups of children with normal IQ who had recovered from complicated and noncomplicated Hib meningitis. The two groups had similar normal hearing and similar verbal IQs. The complicated group, however, had lower mean performance IQ and performed less well on perceptual neurologic tests. Parent and teacher ratings of behavior and frequencies of grade repetitions and special education placement, however, failed to distinguish the two groups.

More recently, a prospective, 7-year follow-up in New Zealand ( [Grimwood et al., 1995](#)) of children surviving bacterial meningitis and their classroom peers found that by school age, survivors had mildly decreased IQ scores and performed less well on a broad range of neuropsychological tests, with greatest impairment in verbal skills and organizational capacity ( [Anderson et al., 1997](#); [Davies, 1989](#); [Grimwood et al., 1995](#); [Taylor et al., 1990](#)). Compared with 11% of control subjects having minor disabilities, 27% of children surviving meningitis had either neurologic and behavior problems or cognitive impairments ( [Anderson et al., 1997](#); [Grimwood et al., 1996](#)). Risks for adverse outcomes were greatest in those with meningitis in infancy and in those who experienced delays in diagnosis or acute neurologic complications. Another follow-up of the same cohort and control subjects at 12 years of age found that differences in general intellectual, neuropsychological, and academic functions were maintained ( [Grimwood et al., 2000](#)). Lower-order skills improved, whereas behavioral scores as measured by the Achenbach CBCL deteriorated significantly in the meningitis group ( [Grimwood et al., 2000](#)).

Bacterial meningitis may constitute a risk factor for psychopathology in a significant minority of children; however, it should not by itself be presumed to affect negatively the behavioral outcome of any individual child. It seems that behavioral sequelae after bacterial meningitis are seen mainly in those cases with neurologic complications during the acute phase of the illness and may emerge later than cognitive sequelae ( [Grimwood et al., 2000](#); [Taylor, 1992](#)).

### Spirochetal Central Nervous System Infections

The major spirochetal infections of concern to child psychiatrists are syphilis and Lyme disease.

#### SYPHILIS

Syphilis is caused by the spirochete *Treponema pallidum*. The incidence of neurosyphilis, like that of CNS tuberculosis, declined dramatically with the introduction of antibiotics. In the United States, between 1943 and 1960, the rate of first admissions to psychiatric hospitals because of neurosyphilis fell from 4.3 per 100,000 to 0.4 per 100,000 ( [Adams and Victor, 1993](#)). Syphilis in the United States now is close to eradication. However, syphilis is worthy of review here, not only because it remains a problem in other countries, but because the clinical picture of general paresis has been considered exemplary of a chronic frontotemporal encephalitis superimposed on a chronic meningitis ( [Adams and Victor, 1977](#)).

Children may acquire syphilis through sexual contact or abuse, but most often are infected by transplacental inoculation from the mother at any time from the fourth to seventh month of gestation. Of the children of untreated syphilitic mothers, 25% to 80% contract syphilis; 2% to 16% of these children will acquire congenital neurosyphilis. Of those children in whom neurosyphilis develops, 50% to 80% will have one or more of the physical stigmata of congenital syphilis; these include interstitial keratitis; chorioretinitis; defective teeth (centrally notched mulberry molars; widely spaced, peg-shaped upper central incisors); abnormal facies (frontal bossing, saddle nose, poorly developed maxilla), bilateral knee effusions (Clutton's joints); and rhagades (linear scars at the angles of the mouth, nose, or anus) ( [Weil et al., 2000](#)).

The neuropathologic and clinical syndromes of pediatric neurosyphilis, whether congenital or acquired through sexual contact or abuse, are very similar to those seen in adults; all stem from a chronic spirochetal meningitis. The treponeme typically invades the CNS within 3 to 18 months after infecting the patient. The initial event in the neurosyphilitic infection is an asymptomatic meningitis that can be revealed only by lumbar puncture. This meningitis may remain asymptomatic until ultimately, after a period of years, it causes parenchymal damage, or it may spontaneously remit. However, as stressed by [Adams and Victor \(1977\)](#), all forms of neurosyphilis begin as a meningitis, and a more or less active meningitis invariably accompanies all the forms of neurosyphilis.

The early-appearing forms of neurosyphilis are congenital symptomatic meningitis and meningovascular syphilis. Syphilitic meningitis declares itself typically between 3 and 12 months of age with convulsions, listlessness, and other nonspecific symptoms; chronic meningitis may lead to hydrocephalus and, in some cases, retarded mental and motor development. Meningovascular syphilis declares itself somewhat later in the first months or years of life by a stroke with involvement of cerebrum, brain stem, and spinal cord, as well as diverse vascular syndromes due to arteritis and thrombosis of cerebral vessels ( [Weil et al., 2000](#)).

The later clinical forms of neurosyphilis begin 5 to 25 years after infection and include tabes dorsales, ameningoradiculitis, general paresis, and ameningoencephalitis. Tabes dorsales is rare in congenital syphilis. General paresis is the most common form of late congenital neurosyphilis. Histopathologically, it is characterized by filling of the perivascular spaces of the brain parenchyma with lymphocytes, plasma cells, and mononuclear cells and loss and degeneration of nerve cells with an increase in microglia and astroglia, deposition of iron, and presence of spirochetes in the cortex. The changes are most pronounced in the frontal and temporal lobes.

In congenital neurosyphilis, general paresis usually begins between 6 and 21 years of age, the average age of occurrence being 13 years ( [Friedland et al., 1995](#)). Girls and boys are equally affected. Approximately half the children affected by general paresis have been severely retarded since very early childhood, and in these cases, the onset of juvenile paresis is very difficult to date. In children who are mildly to moderately retarded or of normal intelligence, onset of general paresis is marked by loss of previous accomplishments. As noted by [Adams and Victor \(1977\)](#): "Silliness, forgetfulness, irascibility and inattentiveness are noteworthy behavioral abnormalities. There may be outburst of agitation and depression but rarely delusions of grandeur such as are observed in adult cases." In the late stage, the neurologic syndromes are very diverse: Approximately 25% of cases have conspicuous cerebellar deficits, 50% have limb spasticity, and up to 40% have seizures. Peculiar choreiform movements, twitches, and action tremors, pyramidal signs, and Argyll Robertson pupils are present ( [Weil et al., 2000](#)). Without treatment, the disease steadily progresses to death in 2 to 5 years ( [Friedland et al., 1995](#)).

Fortunately, neurosyphilis is highly treatable. Penicillin G is the drug of choice for treatment of all stages of neurosyphilis. Details of treatment are beyond the scope of this text. The reader is referred to the *Red Book* of the American Academy of Pediatrics ( [American Academy of Pediatrics, 2000](#)).

#### LYME BORRELIOSES

Lyme disease is caused by the spirochete, *Borrelia burgdorferi*. At least four genospecies are recognized worldwide, each with its own degree of neurovirulence ( [American Academy of Pediatrics, 2000](#)). The occurrence of cases in the United States correlates with the distribution and frequency of infected tick vectors, *Ixodes scapularis* in the East and Midwest and *Ixodes pacificus* in the West. The incubation period from tick bite to the first stage of the disease, erythema migrans, ranges from 3 to 31 days and typically is from 7 to 24 days. Late manifestations may occur months to years later. In the United States, Lyme disease has a bimodal age of distribution, with the highest incidence rates in children between ages 5 and 9 and adults older than 30 years ( [Pfister et al., 1994](#)). Lyme neuroborreliosis occurs once in every 620 infected children ( [Christen et al., 1993](#)).

The clinical manifestations of Lyme disease are divided into three stages: early localized, early disseminated, and late disease. In early localized disease, the site of recent tick bite gives rise to a unique skin lesion, erythema chronica migrans. Erythema migrans begins as a red macula or papule and enlarges over days to weeks to become a large, annular, erythematous lesion that is 5 cm or more in diameter, sometimes with a partial central clearing. The skin lesion can be accompanied by systemic systems such as fatigue (54%), myalgia (44%), arthralgia (44%), and fever, chills, or both (39%). However, the rash may not occur in approximately 10% to 20% of patients. Early disseminated disease typically manifests as multiple erythema migrans, reflecting spirochetemia with dermal dissemination. Neurologic complications of early disseminated illness occur in approximately 15% to 20% of patients, with or without the skin lesions, and include cranial nerve palsies, meningitis, and a broad range of other neuropsychiatric symptoms. In Europe, more than 80% of childhood neuroborreliosis manifests as facial palsy or an aseptic meningitis ( [Christen et al., 1993](#); [Hansen, 1994](#)), whereas in the United States, headache, stiff neck, and subtle encephalitic signs with less radiculopathy are more common ( [Reik et al., 1986](#)). A broad range of psychiatric manifestations may occur during early disseminated disease, including psychosis ( [Csaszar and Patafalvi,](#)

1994; [Stein et al., 1996](#)) and schizophreniform disorders ([Hess et al., 1999](#); [Pfister et al., 1993](#); [Roelcke et al., 1992](#); [van den Bergen et al., 1993](#)). [Fallon et al. \(1998\)](#) stress that Lyme disease may go undiagnosed in patients who present with atypical neuropsychiatric symptoms.

Late (third) stage disease is seen in untreated patients 1 to 3 years after the initial infection. It is marked by chronic arthritis that usually affects the large joints. Late disease occurs in 6% of children ([Christen et al., 1993](#)) and also is chronic. A wide spectrum of abnormalities also is seen. Although a destructive chronic meningoencephalitis can progress over many years in untreated individuals ([Bensch et al., 1987](#)), the most common neurologic complication is subacute encephalopathy characterized by cognitive deficits and disturbances of mood and sleep ([Ackermann et al., 1988](#); [Spach et al., 1993](#)). EEG changes, usually in the form of moderate generalized slowing, occur in one-third of children with late Lyme neuroborreliosis. Late disease is uncommon in children who are treated with antimicrobials in the early stage of the disease.

### Pathology

*Borrelia burgdorferi* appears in the CNS within days of the tick bite. Once in the CNS, a local inflammatory reaction may occur, resulting in meningitis or encephalitis, or the organism may remain dormant, causing illness months to years later ([Tager et al., 1999](#)).

The pathologic process of neuroborreliosis is characterized by an inflammatory thrombotic vasculopathy that can cause axonal degeneration of the peripheral nerves through involvement of the vasa vasorum, and causes ischemic lesions of the CNS ([Weil et al., 2000](#)). In fatal cases, large areas of demyelination in periventricular white matter as lymphocyte vasculitis have been found ([Oksi et al., 1996](#)). Cellular and humoral autoimmune mechanisms also are important, and the serum of infected patients contains immunoglobulin M (IgM) antibodies that cross-react with an axonal component ([Sigal and Tatum, 1988](#)).

### Neuropsychological Sequelae

Treatment within the first year of infection results in a more favorable clinical response than later therapy and probably reduces the incidence of neurologic and psychiatric complications ([Adams et al., 1994, 1999](#)). If not treated until well after the initial infection, children may be at risk for cognitive problems. [Tager et al. \(1999\)](#) found increased mood, attention, and learning problems in a subgroup of children with Lyme disease referred because of persistent cognitive complaints that developed concurrently with Lyme disease. Case studies have linked Lyme disease in children and adolescents with anorexia nervosa ([Pachner et al., 1989](#)); with obsessive-compulsive and panic disorder ([Fallon and Nields, 1994](#)); with psychotic features ([Neumarker et al., 1989](#)); and with Tourette syndrome ([Riedel et al., 1998](#)).

In adults, Lyme disease has been associated with impairments in memory, attention, mental activation, language, and motor functions ([Garcia-Monco and Benach, 1997](#); [Pollina et al., 1999](#); [Svetina et al., 1999](#)), and memory impairments may persist even after treatment ([Kaplan et al., 1999](#)). In a study of children with late Lyme disease, [Bloom et al. \(1998\)](#) found that the most prevalent neurocognitive symptoms were behavioral changes, forgetfulness, declining school performance, headache, and fatigue. General intellectual functioning was normal, but particular deficits related to auditory or visual sequencing were found.

### Diagnosis

The diagnosis of Lyme disease is based on clinical presentation supported by findings from serologic and CSF tests. For epidemiologic monitoring purposes, the [Centers for Disease Control and Prevention \(CDC\) \(1995\)](#) defined Lyme disease as the presence of erythema migrans rash 5 cm or larger in diameter, or laboratory confirmation of infection with *B. burgdorferi* and at least one objective sign of musculoskeletal, neurologic, or cardiovascular disease and a history of exposure to an endemic area. However, as stressed by Tager and Fallon (2001), these criteria were not intended nor are they adequate for clinical diagnostic purposes, for several reasons: Approximately one-third of patients do not remember a rash; encephalopathy, one of the most common signs of late neurologic Lyme disease, is not on the CDC list of objective neurologic signs; and a sizable proportion of patients do not have an adequate immune response to *B. burgdorferi* and therefore have negative results on routine serologic antibody tests. Therefore, the clinical history is particularly important and should address the main signs and symptoms as well as exposure. The differential diagnosis includes viral infections, rheumatoid arthritis, primary psychiatric disorders, connective tissue disorders, thyroid disorders, sleep disorders, other central or peripheral neurologic disorders, fibromyalgia, and chronic fatigue syndrome ([Tager and Fallon, 2001](#)).

The diagnosis is made most reliably by demonstrating the presence of IgM antibodies to *B. burgdorferi* or by polymerase chain reaction. Positive results from Western blot and enzyme-linked immunosorbent assay strongly support the diagnosis of Lyme disease ([Weil et al., 2000](#)). However, the child psychiatrist must work with local experts on Lyme disease regarding diagnosis and treatment.

### Treatment

For treatment of early localized disease, oral antibiotics such as doxycycline are recommended for children older than 8 years of age and ampicillin for children younger than 8 years of age. Early Lyme disease usually is treated for 14 to 21 days, but the optimal duration of treatment is not known. Oral treatments also are recommended for some forms of early disseminated and late disease, but CNS disease is treated with parenterally administered antibiotics such as ceftriaxone or penicillin. The reader is referred to the *Red Book* for more detailed discussion and guidelines ([American Academy of Pediatrics, 2000](#)).

If the cause of a neuropsychiatric disorder is active infection, then antibiotic therapy is necessary in addition to pharmacologic therapy for symptoms ([Logigian et al., 1999](#)). As reviewed by [Nields and Fallon \(1998\)](#), psychopharmacologic strategies include the use of selective serotonin reuptake inhibitors for irritability, carbamazepine and gabapentin for neuropathic pain, and methylphenidate, modafinil, and bupropion for fatigue and attention problems.

### Viral Central Nervous System Infections

The incidence of viral meningitis ranges, in different years, from 1.5 to 4 cases per 100,000 population. The incidence in children actually is much higher because aseptic meningitis also is a disease of the young (CDC, 1977). The incidence of viral meningoencephalitis is greater than that of bacterial meningitis in children, although the morbidity usually is less than that of bacterial meningitis. The major exception is infection due to herpes virus, the morbidity and mortality of which is very high ([Evans, 1987](#); [Weil et al., 2000](#)). The most common mode of viral CNS infection is hematogenous. The virus enters the CNS through the choroid plexus and then enters the CSF by replication in the capillary endothelium of the brain. The other route of CNS inoculation is contiguous spread through the peripheral nervous system, as in the case of herpes virus infection or rabies. Injury occurs by the process of viral replication and by vascular injury, which causes destruction of neurons and glial cells. The pathologic process of viral encephalitis is manifested by vascular mononuclear cells and neuronal destruction. In approximately 60% of cases, a specific virus can be identified by either culture or serology ([Evans, 1987](#); [Weil et al., 2000](#)).

The clinical spectrum of viral CNS infections ranges from aseptic meningitis to encephalitis to chronic infections and postinfectious neural illnesses. The clinical picture of aseptic meningitis is similar to that of bacterial meningitis. Chronic infections are discussed later, and postinfectious diseases (e.g., Guillain-Barré syndrome) are described in [Chapter 61](#).

### NEUROLOGIC AND PSYCHIATRIC SEQUELAE

Enteroviral meningitis accounts for at least 50% of cases of viral meningitis in the United States. Most of the patients are infants younger than 1 year of age, and most of the infections are mild ([Evans, 1987](#); [Weil et al., 2000](#)). Enteroviral meningitis had been reported to produce a low frequency of adverse neurologic, cognitive, or language sequelae ([Bergman et al., 1987](#); [Sells et al., 1975](#)). [Bergman et al. \(1987\)](#) followed 33 8-year-old survivors of enteroviral meningitis that occurred when the children were between the ages of 4 months and 1 year and compared them with 31 siblings. None of the survivors had a major neurologic sequela, and they performed as well as the control subjects on the cognitive and behavior tests administered.

Similarly, [Farmer et al. \(1975\)](#) followed for 6 years 15 infants with meningoencephalitis due to coxsackievirus B5 and compared them with 15 control subjects matched by age, sex, socioeconomic status, birth weight, and gestational age. There was no difference in the IQ and visual perception tests between both groups.

Some studies followed children for various periods of time after California arbovirus encephalitis ([Chun et al., 1960](#); [Gunderman and Stamler, 1973](#); [Matthews et al., 1968](#); [Rie et al., 1973](#); [Sabatino and Cramblet, 1968](#)) and found an incidence rate of between 0% and 40% for such neurologic complications as soft signs, seizures, or hemiparesis, some nonspecific behavior difficulties, and nonsignificant depressed IQs. By contrast, other studies ([Earnets et al., 1971](#); [Finley et al., 1953](#)) have reported high rates of neurologic morbidity (up to 69%) and mortality in children who had Western equine encephalitis, especially in those children younger than 1

year of age. In general, studies of morbidity after viral infections are flawed by methodologic problems that limit the generalization of their findings.

## Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Human immunodeficiency virus (HIV) type 1 is a retrovirus that causes AIDS, a severe condition characterized by infections with opportunistic microorganisms. The immunologic deficit is associated with viral infection of certain cell populations of the immune system, essentially T4 lymphocytes and macrophages. AIDS in children was first reported in 1983, when it manifested as an acute, lethal disease that involved the brain in up to half of cases (Epstein et al., 1986). Treatment advances have transformed HIV infection into a subacute chronic disease. As a result, psychiatric concern with respect to HIV infection must encompass not only the neuropsychiatric complications of brain involvement but coping with chronic illness and loss, often under conditions of severe psychosocial stress and behavioral aspects of prevention (Brown et al., 2000). For further discussion of some aspects of HIV, see [Chapter 98](#).

### EPIDEMIOLOGY AND ROUTES OF TRANSMISSION

Worldwide, more than 1 million children are known to be infected with HIV ([UNAIDS, 1998](#)). Best estimates suggest that three times that number are in fact infected. In the United States, there are more than 2,000 children younger than the age of 13 years with AIDS, and AIDS is now the sixth leading cause of death among 15- to 24-year-olds. Approximately 80% of pediatric AIDS cases are due to vertical (mother-to-child) transmission, 20% to transfusion of blood or blood products, and approximately 1% to sexual contact in adolescents ([Aicardi, 1992](#)).

In vertical transmission, perinatal infection probably is the most common route of infection ([Oxtoby, 1990](#)). Approximately one-fourth of infants born to an untreated HIV-infected mother also are infected ([European Collaborative Study, 1994](#)). Prenatal and perinatal administration of zidovudine has been shown to reduce transmission of HIV by over half ([Wade et al., 1998](#)). However, the pros and cons of mandatory HIV testing continue to be hotly debated ([Nakchbandi et al., 1998](#)). HIV also can be transmitted in breast milk, but many factors influence transmission risk, including the age of the child, the severity of the maternal HIV infection ([Dunn et al., 1998](#)), vitamin A deficiency ([Greenberg et al., 1997](#)), and specific blood types ([Tess et al., 1998](#)).

Among adolescents, sexual intercourse accounts for most new AIDS cases, with same-sex contact accounting for the preponderance of risk among male adolescents and heterosexual contact among female adolescents (CDC, 1997). A small percentage of cases is attributable to sexual abuse ([Stolar and Fernandez, 1997](#)).

In the United States and internationally, rates of infection are increasing most rapidly among adolescents and among heterosexual women. Despite increasing infection, advances in therapies have led to 70% of children with HIV living to the age of 6 years and 50% to the age of 9 years (Tovo et al. 1992). In children with perinatally acquired infections, the risk of encephalopathy is higher in those with AIDS (up to 23%) than in those with asymptomatic infection (approximately 10%) ([Lobato et al., 1995](#)); the estimated median survival after diagnosis of encephalopathy is 22 months.

### PATHOPHYSIOLOGY OF BRAIN INFECTION

Productive HIV-1 infection of the brain probably is limited to macrophages, microglia, and astrocytes; HIV rarely has been documented to infect neurons. The most commonly cited mechanisms of brain tissue damage have been related to mediators of the inflammatory response to HIV-1, an indirect pathophysiologic effect ([Goodkin et al., 2001](#)). HIV is carried into the brain by infected monocytes that differentiate into macrophages in brain tissue. The macrophages in effect become a storehouse of virus because, unlike in the CD4 lymphocyte, HIV-1 does not have a cytotoxic effect on these cells. Over time, in these cells, evolution toward strains associated with greater neurovirulence or cytotoxic T-lymphocyte escape may occur. These macrophages become nonspecifically activated and secrete substances, such as cytokines and chemokines, that are part of the normal inflammatory process at greater-than-normal concentrations. Among the proinflammatory cytokines are tumor necrosis factor- $\alpha$  associated with demyelination; interleukin-1 associated with neuron cell loss; and interferon- $\gamma$  associated with quinolinic acid, which is excitatory at NMDA receptors ([Goodkin et al., 2001](#)). Other indirect mechanisms include the effects of viral products on neurons and other cells of the brain ([Johnson, 1998](#)).

In children, as in adults, the encephalopathy associated with HIV-1 appears to be largely subcortical. Autopsy findings are characterized by inflammatory cell infiltrates, multinucleated cells, microglial nodules, white matter pallor, and calcification mainly in the vessels of the basal ganglia and deep cerebral white matter ([Dickson et al., 1989](#); [Falloon et al., 1989](#)). Studies of viral load and strain in the brains of adults support the concept that subcortical regions specifically are affected by HIV-1 infection ([Goodkin et al., 2001](#)).

### NEUROCOGNITIVE SEQUELAE

Among HIV-infected children, three patterns of abnormal neurocognitive development have been described ([Belman, 1992](#)). The first is a rapidly progressive encephalopathy characterized by impaired brain growth (secondary microcephaly), motor weakness with pyramidal tract signs that progresses to spastic quadriplegia, pseudobulbar signs, and loss or plateauing of developmental milestones ([Mintz et al., 1996](#)). Among HIV-infected children, progressive encephalopathy has an estimated prevalence of 13% to 23% ([Lobato et al., 1995](#)). The second is a subacute progression of encephalopathy with relatively stable periods, and the third is a static encephalopathy with a failure to achieve new milestones (Gay et al., 1995). Regular neurologic and psychometric assessments are recommended to differentiate these patterns further. Tardieu et al. (1995) found that among 133 survivors, only 67% had normal school achievement at a mean age of 9.5 years, 54% had impaired performance on visual-spatial function and time orientation tests, and 44% had speech or language delay or articulation disorders.

In a sample of 87 previously untreated children with HIV infection, Brouwers et al. ([Woods, 1998](#)) found the overall CT brain scan severity rating was highly predictive of the level of cognitive functioning. There was a higher rate of CT abnormalities (cortical atrophy, ventricular enlargement, white matter changes) in vertically infected children compared with transfusion-infected children, and intracerebral calcifications were seen only in the vertically infected group. In a study of 40 children with symptomatic HIV infection, high levels of the neurotoxin quinolinic acid in the CSF were correlated with encephalopathy, decreased performance on IQ test, and increased mortality and inflammatory neurologic disorders ([Brouwers et al., 1993](#)). In a sample of 36 HIV-infected children younger than 10 years of age, CT scan abnormalities were significantly correlated with poorer receptive and expressive language functioning, and expressive language was more severely impaired than receptive language among those with encephalopathy ([Wolters et al., 1995](#)).

Antiretroviral drugs inhibit or halt the progression of HIV and thus improve most indices of general health in pediatric AIDS. In addition, these drugs improve cognitive deficits in children with AIDS, at least for a limited period ([Pizzo et al., 1988](#); [Wolters et al., 1994](#)). [Brady et al. \(1996\)](#), in the largest study to date with children 3 months to 12 years of age, found an improvement in cognitive abilities over a 3-year period; improvement was greatest for patients 6 years of age or older. A number of smaller studies have demonstrated improved adaptive functioning with antiretroviral treatment ([Brivio et al., 1991](#); [Brouwers et al., 1994](#); [Moss et al., 1994](#)). Motor skills, however, do not appear to improve with antiretroviral therapy ([Wolters et al., 1994](#)).

### PSYCHOPATHOLOGY ASSOCIATED WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

In the only study of psychiatric diagnoses of HIV-positive adolescents, 44% presented with current major depression, 85% had at least one Axis I DSM-IV diagnosis as determined by structured interview, and 53% had a history of psychiatric diagnosis before diagnosis of HIV infection ([Pao et al., 2001](#)). Diagnosis of a mood disorder also can be complicated by physiologic factors. For example, a child with AIDS who is withdrawing because of physical pain may be incorrectly diagnosed as depressed ([Stuber, 1992](#)). Almost 60% of children with HIV experience pain, which may negatively affect their quality of life and sleep patterns ([Yaster and Schecter, 1996](#)).

Several controlled studies suggest that HIV-infected pediatric patients experience more distress than noninfected peers. [Havens et al. \(1994\)](#) found that a group of 26 HIV-infected children with prenatal drug exposure scored significantly higher on the internalizing, somatic problems and depression/anxiety scales of the Achenbach CBCL than did uninfected children with prenatal drug exposure; this relation withstood control for age, race, and IQ. In addition to symptoms of anxiety and depression, some parents report more hyperactivity and conduct problems in their HIV-infected children ([Moss et al., 1994](#)). Another study that compared HIV-positive children with hemophilia to HIV-negative children with hemophilia and children with asthma found that anxiety disorders were more frequent in the HIV group than in the other two groups, whereas both groups of children with hemophilia were found to have lower levels of intrafamilial stress than the group with asthma ([Bussing and Burket, 1993](#)). [Brown et al. \(2000\)](#) speculate that low levels of intrafamilial stress in the hemophilia group result from the extensive support network of the National Hemophilia Program ([Cohen, 1994](#)).

## TREATMENT OF PSYCHOPATHOLOGY IN CHILDREN WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

There are three main categories of antiretroviral medications: nucleoside analog reverse transcriptase inhibitors (NRTIs), nonnucleoside analog reverse transcriptase inhibitors (NNRTIs), and protease inhibitors (PIs). Each group has numerous side effects and special instructions on administration (CDC, 1997). The behavioral and cognitive side effects are poorly understood, and the pharmacokinetics and impact on the developing nervous system of these drugs are not known. NNRTIs and PIs are inhibitors of the cytochrome P-450 enzyme system; because this enzyme system is responsible for the metabolism of many commonly prescribed drugs, the potential for drug–drug interactions must be considered (Deeks et al., 1997). In general, these drugs are not recommended for concurrent use with antihistamines and sedative-hypnotics or amphetamines. The PI agents inhibit enzymes responsible for the metabolism of antidepressants and anticonvulsants. Drug interactions are particularly difficult to determine in complex protocols known as highly active antiretroviral therapy (HAART), in which multiple drug therapies are used in combination with a PI. The complex relationship of HAART to psychotropic medications due to shared degradative metabolic pathways is just beginning to be understood, and the clinical efficacy of multiple regimens is virtually unknown in children and adolescents (Gonzalez and Everall, 1998).

### COPING

In a metaanalysis of 38 studies investigating children's psychological and behavioral adjustment to various physical disorders, Lavigne and Faier-Routman (1993) found that parent and family risk factors were more strongly related to child adjustment than to specific disease and disability factors. The available literature on children and adolescents living with HIV infection and AIDS is consistent with this finding (Brown et al., 2000), which points to the importance of family-focused treatment. One study (Mellins and Ehrhardt, 1994) found that family-focused mental health services for children with HIV infection reduced isolation, improved family functioning, and encouraged the use of other services such as respite care.

Disclosure is an important issue confronted by all families with an HIV-infected child. The literature on chronic illnesses suggests that disclosure of the developmentally appropriate facts about illness improves psychological adaptation (Brown et al., 2000). Brown and DeMaio (Brown et al., 1992) describe two HIV-infected adolescents with hemophilia to illustrate how, if not properly managed, secrets concerning infection may interfere with optimal health care and the patient's subsequent emotional adjustment.

Many common HIV-related symptoms and physical limitations reported by young patients are emotionally based, but most of these patients are underserved (Ammann, 1994). Examples of programs that offer multidisciplinary services for HIV-positive children and adolescent are the 10 service projects of the Special Projects of National Significance Program (Woods, 1998).

### PREVENTION

The few studies on sexual risk behaviors in adolescents living with HIV suggest that both psychotherapeutic and psychoeducational approaches are appropriate (Henry, 1996; Lewis et al., 1994). A psychoeducational program was shown to improve the safety of sexual behaviors in adolescents with hemophilia (Brown et al., 1998). Although most programs targeting uninfected individuals strive to increase awareness of susceptibility to HIV and strengthen the desire for safety, more appropriate goals for infected adolescents are to increase empathy and the desire for responsible behavior (Brown et al., 2000).

### Slow Virus Infections

Slow virus infections of the CNS may be classified into those caused by unconventional agents (e.g., kuru, Jakob-Creutzfeldt disease) and those caused by conventional agents [e.g., subacute sclerosing panencephalitis (SSPE) due to measles virus, progressive rubella encephalitis, progressive multifocal leukoencephalitis (herpes simplex)]. Characteristically, slow viruses multiply in the host for prolonged periods without producing clinical symptoms. These viruses are not recognized as "foreign" by the host, and the immune response is either very late or absent. Therefore, the disease produced by a slow virus may be the result of either gradual destruction or an autoimmune response caused by termination of tolerance (Weil et al., 2000). All of these infections are characterized by progressive dementia and neurologic symptoms such as ataxia, involuntary movements, and seizures.

Subacute sclerosing panencephalitis is more likely to occur in children who had measles early in childhood. Its incidence ranges from 0.475 per million in urban populations to 1.4 to 1.8 per million in rural or suburban areas. It affects more boys than girls, in a ratio of 5:1.

Initial symptoms appear after a latency period of 4 to 15 years and are manifested by personality changes and deterioration in school performance, followed by myoclonic seizures, involuntary movements, dementia, and ataxia. The alterations in the brain consist of subacute encephalitis accompanied by demyelination lesions that usually involve the cerebral cortex, hippocampus, thalamus, brain stem, and cerebellar cortex. Characteristic EEG abnormalities may be seen as early as 4 years before the clinical appearance of myoclonus and are manifested by generalized paroxysmal bursts of high activity, with spike discharges followed by a short period of flattened activity–suppression burst pattern (Evans, 1987; Weil et al., 2000).

Rubella panencephalitis has been described in children with congenital rubella. It has an earlier onset than SSPE but has similar clinical features. Children with immunologic disorders may develop chronic enteroviral encephalitis or progressive multifocal leukoencephalitis, also manifested by dementia and movement disorders.

Kuru is a progressive degenerative disease of the CNS with predominantly cerebellar features; it is limited to a population in New Guinea that, until recently, practiced cannibalism (Evans, 1987; Weil et al., 2000).

### Congenital Infections of the Central Nervous System

Infections of the fetal CNS may cause significant damage and multiple defects. The extent and type of induction of congenital anomalies in the infected embryo depends on the time of action of the teratogen. After the second trimester, congenital malformations pursuant to congenital infections become increasingly uncommon. The main pathway of transmission of infection to the fetus is the transplacental route. Most of these congenital infections remain subclinical during the neonatal period (Menkes, 1990; Starr et al., 1970).

### RUBELLA

The frequency of congenital rubella after maternal infection with rash is more than 80% during the first 12 weeks of pregnancy, 54% at 13 to 14 weeks, and 25% at the end of the second trimester. When the CNS is involved during prenatal life, congenital malformations, including microcephaly, hydrocephalus, and spina bifida, may develop but may not be recognized until delayed motor development or speech retardation becomes obvious. Retarded language development may be due to peripheral hearing loss, focal CNS damage, or mental retardation. Most long-term survivors are deaf and have cataracts and chorioretinopathy. Severe mental retardation may occur in 24%, and spasticity is frequent, but most patients who have sustained severe neurologic damage die during the early years of life. Among the survivors, some children manifest limitations of language, cognition, and social relatedness similar to those found in autistic children (Chess, 1977; Desmond et al., 1969; Evans, 1987).

### CYTOMEGALOVIRUS

Cytomegalovirus (CMV) infection of the fetus is typically manifested at birth by persistent jaundice, hepatosplenomegaly, thrombocytopenia, anemia, and neurologic abnormalities. CMV frequently reaches the developing fetus when the mother is infected and may have important CNS sequelae. It has become clear that most newborns with CMV infections are asymptomatic at birth and remain so throughout infancy. However, Hanshaw et al. (1976) found that 10% of infected neonates had delayed psychomotor development and observed that impaired hearing may increase the number of these infants at subsequent neuropsychiatric risk. Reynolds et al. (1974) followed 18 asymptomatic CMV-infected children for 38 months and compared them blindly through IQ tests with normal control subjects. The mean IQ was 92 for the CMV carriers (seven had IQs < 90 and one > 32) and 100 for the control subjects. Hanshaw et al. (1976) followed 44 asymptomatic children with positive CMV titers in blood and compared them with a similar group of control subjects and a random sample of normal siblings. The children had psychometrics, school evaluations, and physical examinations at the ages of 3.5 to 7 years. The CMV group mean IQ was significantly lower, and they experienced failure at school 2.7 times more frequently than the matched control subjects and 8 times more frequently than the randomly selected siblings. Bilateral hearing loss was present in 1% of the CMV group. All children with IQs below 80 were positive for CMV and belonged to a low socioeconomic class. There was no school failure among the

CMV-positive children of higher socioeconomic status. The authors concluded that a child born with serologic evidence of congenital CMV infection is at higher risk for school failure if he or she is born into a family of a lower socioeconomic group.

## TOXOPLASMOSIS

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii*, which is infectious to a wide range of birds and mammals. Pregnant women may acquire the infection by ingestion of oocysts in uncooked meat or from cat feces. As is the case for other congenital infections, chorioretinitis and neurologic symptoms may not be present at birth but may appear late in infancy or childhood. Rarely, toxoplasmosis may be responsible for seizures or psychomotor retardation. However, a 4-year follow-up of *Toxoplasma*-infected children with apparent neurologic disease in infancy disclosed mental retardation in 89% and seizures in 83% (Weil et al., 2000). Saxon et al. (1973) followed eight children 2 to 4 years of age who were identified at birth as having subclinical congenital toxoplasmosis and compared them blindly with eight normal children. There was no difference in assessments of behavior or motor development. The mean IQ for the untreated cases was 93, whereas for the control subjects and three children who were treated for toxoplasmosis, the mean IQ was 110.

## Conclusions Regarding Psychiatric Sequelae of Infectious Brain Injury

Children may experience permanent neuropsychiatric sequelae as a result of diverse congenital and acquired CNS infections. Children who were infected at an early age, did not receive prompt or appropriate treatment, were infected by certain virulent pathogens, or had focal seizures or residual neurologic deficits are at risk of remaining with greater degrees of mental retardation, school failure, and nonspecific behavior problems. This is especially so if they are from lower socioeconomic backgrounds, have independently inherited a predisposition for low-level intellectual functioning, or have a previous history of psychiatric disorder.

The neuropsychiatric problems emerging after CNS infections have not yet been adequately studied. Emerging emotional problems may be secondary to the CNS injury itself but may also involve mental retardation, deafness, language disorders, environmental or hereditary factors, or a combination of these. PC due to IBI has not been studied in the children. A multidisciplinary professional approach is recommended for the follow-up, remediation, and prevention of CNS infections and their neuropsychiatric complications.

## FINAL SUMMARY

It is now clear that severe forms of IBI and TBI increase the risk for psychopathology in children. In the near future, our understanding of the psychiatric sequelae of TBI and IBI is likely to be advanced rapidly by newer brain imaging techniques that may specify the circuits and neurotransmitters that have been affected. These methods will likely clarify whether specific patterns of behavior are related to site or extent of injury. As in the past, TBI and IBI are likely to contribute to our understanding of the brain substrates of psychopathology even in the absence of brain injury. In the meantime, the task for the child psychiatrist remains one of interpreting prognostic data for individual brain-injured patients and their families and planning interventions with the greatest likelihood of success. Children with prior histories of psychopathology, cognitive impairment, and family dysfunction warrant intensive support and continued monitoring, as do their families.

### [Chapter References](#)

The study of behavioral teratology has a long-standing tradition beginning as early as Hippocrates' warning about "uterine suffocation" with maternal opiate use ([Hans, 1992](#); [Zagon and McLaughlin, 1984](#)) and the Old Testament advice to a pregnant woman to "drink not wine nor any strong drink" (Judg. 13:7, cited in Heath, 1991). These traditional and deep-seated cautions woven into the fabric of each culture's protection and valuing of a pregnancy have also fueled a long-standing scientific tradition—the investigation of the potential physical, acute, and long-term physiologic and immediate and long-term neurodevelopmental effects of prenatal exposure to drugs and other environmental substances. More than 20 agents have been shown to have teratogenic and postnatal toxic effects ([Levy and Koren, 1992](#)), whereas for many others, concern persists, but data are inconclusive. In many instances, science takes its initial cue from the prevailing public belief and fear about how a given drug or substance negatively affects its adult user and, thus, how detrimental it may be to the fetus. Because of this, commonly the first reports about the effects of prenatal exposure to a given drug or substance describe far more deleterious and severe outcomes than are true once larger and more heterogeneous samples are examined. That the first probands of any epidemic or new illness are often the most severe, most obvious, and least representative of the natural history of a condition is an observation not limited to behavioral teratology ([Day and Richardson, 1993](#)). Nonetheless, it is particularly relevant to considerations of drugs such as alcohol, opiates, or cocaine in which negative attitudes regarding adult substance abusers may also color both science and common belief regarding the developmental sequelae of maternal addiction during pregnancy ([Woods et al., 1998](#)).

The thalidomide tragedy notwithstanding, in most instances, demonstrating links in humans between prenatal drug exposure and immediate physical, neurologic, or later developmental and psychological outcomes is fraught with problems. These include determining frequency, dose, and duration of exposure and taking into account the conditions usually associated with substance abuse (e.g., poor nutrition, polydrug use, parental stress, and psychiatric illness) that also affect development. These associated conditions may either moderate the apparent direct effects of the drug on fetal neurologic development or serve as mediators for the relation between any neurologic sequelae and prenatal exposure ([Baron and Kenny, 1986](#)). Animal models provide some basis for comparison, particularly about physical effects, but they are less useful for studies of complex developmental capacities found only in higher-order primates and humans (e.g., language, complex problem-solving tasks, and neuropsychological functions such as certain domains of memory). (See, for example, [Stanton and Spear, 1990](#), for a comparison of findings in studies of animal models and prenatal cocaine exposure with findings in infants.) Moreover, although there is increasing literature for each drug about physical and behavioral teratologic effects in the infant and child related to maternal substance abuse during pregnancy (see later) ([Day, 1992](#); [Hans, 1992](#); [Mayes, 1992](#); [Streissguth, 1992](#); [Zuckerman and Frank, 1992](#)), far less systematic information is available about the effects of any one drug on parental or family functioning or the interaction between the effects of prenatal drug exposure on development and the effects of drug abuse on parenting. In the next section, we review what is known about the effects of alcohol, heroin, marijuana, and cocaine on fetal development and later behavior and developmental outcome. After that overview, we also discuss how substance abuse influences the caregiving environment.

## NEUROTOXICOLOGY OF PRENATAL SUBSTANCE ABUSE

Several crucial issues cut across all studies of prenatal drug exposure regardless of the specific drug being studied. Some of these issues are inherent to a longitudinal study design that examines the relationship between later and early events. All are particularly problematic in studies of prenatal exposure to drugs. (For more detailed methodologic reviews, see [Brooks-Gunn et al., 1994](#); [Griffith and Freier, 1992](#); [Lester et al., 1995](#); [Neuspiel, 1995](#).) These methodologic issues fall into the following broad areas: (a) definition and ascertainment of the independent exposure variable; (b) identification of crucial covariates often associated with substance abuse and exploring interactive as well as main-effects models; (c) definition of hypothesis-driven outcome variables; and (d) distinguishing between short-term and long-term effects, later effects not apparent early on, and transient effects that nonetheless may influence other developmental functions later.

### Definition of the Exposure Variable

Human models of prenatal drug exposure usually present complicated dilemmas regarding definitions of the exposure variable. This issue alone may be the single most problematic one in neurobehavioral teratologic studies. Substance abusers typically do not report consistently or reliably the frequency or amount of their drug use ([Babor, 1990](#); [Chasnoff et al., 1990](#); [Grissom, 1997](#); [Weiss et al., 1998](#)). Various strategies have been devised to improve the reliability of self-reports of substance use including use of time lines, careful training of interviewers, and narrow windows for retrospective recall ([Callahan et al., 1992](#); [Carey, 1997](#); [Rogers and Kelly, 1997](#); [Richardson and Day, 1994](#)). Even with these more sophisticated interviewing strategies, self-report of single or polydrug use typically, although not uniformly ([Richardson et al., 1993](#)), underestimates the amount of exposure particularly of illicit drugs.

Frequency of exposure obtained through self-report histories is usually expressed as a number of days per unit time (e.g., per month, use in last 30 days, use per week). Self-reports are typically, although not universally, augmented with toxicologic sampling of urine for drugs such as cocaine, marijuana, or opiates. Repeated toxicology screening throughout pregnancy may provide some confirmation or identification of users, and, not uncommonly, toxicologic screens are obtained from both infant and mother at the time of delivery. Urine toxicology testing provides a relatively narrow window on use. For example, for cocaine users, a urine toxicology test is typically positive no longer than 36 hours after use, and that window varies for other drugs. For cocaine, infants' meconium and hair (infant's or mother's) have gained some support as particularly good samples to ascertain or confirm infant exposure because they provide a longer window for ascertaining exposure. Some data suggest that meconium or hair from the newborn may be a reliable measure of exposure as far back as the middle of the first trimester of pregnancy ([Callahan et al., 1992](#); [Graham et al., 1989](#); [Kline et al., 1997](#); [Ostrea, 1995](#)). However, despite early enthusiasm for these types of longer window measures and despite their obvious utility, they do not provide a reliable quantitative estimate of exposure.

With these various problems in obtaining accurate estimates of frequency and amount of exposure, most studies of prenatal exposure to date have defined the independent exposure variable as dichotomous—exposed or not exposed. Grouping all exposed infants and children together obscures potential dose-related effects, and including those only minimally exposed in the exposed group may reduce the likelihood of detecting exposure effects. Thus, growing numbers of studies are attempting to create some metric of heavy, moderate, and light drug use to examine dose-related effects that follow either linear or nonlinear models ([Frank et al., 1998](#); [King et al., 1995](#); [Tronick et al., 1994](#)).

Route of use presents a third problem in defining the severity or amount of exposure. Although the total amount is always an important metric in defining severity of exposure, amount of time above a certain peak blood level may also be important in some models of teratogenicity. Stated another way, the teratogenic effect is carried not by total amount of exposure time but only by those times when the level of exposure is above a certain threshold. Certain aspects of fetal alcohol effects may follow this threshold rather than linear dose-related model. Blood levels peak at different levels following use depending on the preferred route of use. Intravenous use, as with heroin, and smoking crack, with rapid absorption through the pulmonary vascular bed, provide rapid and large peak blood levels to both mother and fetus. Few to no studies, particularly of cocaine, in which the routes of use may be quite varied, have examined differences in outcome depending on preferred method of use.

A fourth problem in the definition of exposure variables is polydrug use. Rarely do addicts use one drug only. Although they may consider one drug of abuse their

primary drug, polydrug use and exposure are the rule rather than the exception. For example, for cocaine users, a very typical combination is alcohol and tobacco in combination with cocaine. The same issues of defining frequency and amount of use for each drug pertain, but also there are questions of interactive effects among drugs such as alcohol with cocaine and the resulting metabolite cocethylene.

A fifth problem specific to studies of prenatal exposure is obtaining reliable estimates of frequency and amount of exposure by trimester of pregnancy. Different drugs have different effects during the three trimesters of pregnancy. For example, in the first trimester, prenatal cocaine exposure may have a direct effect on neuronal migration and brain structure formation, whereas in the third trimester, the central nervous system (CNS) effect may be on synaptogenesis in specific brain regions (Dow-Edwards et al., 1988; Frank et al., 1998; Mayes and Bornstein, 1995). Related to breaking down exposure by trimester is continued exposure postnatally. Particularly among agents that may be inhaled passively (e.g., crack, tobacco, marijuana), postnatal exposure is relatively common (for example, Bender et al., 1995; Kjarasch et al., 1991; Lustbader et al., 1998).

### Identification of Covariates and Development of Interactive Models

Substance abuse of one or multiple drugs rarely occurs isolated from other developmentally salient variables. Drug abuse is often associated with other factors that contribute to poor fetal health and infant outcome apart from or interactive with the specific teratologic effects of any one agent. Women who are chronic alcohol, heroin, marijuana, or cocaine abusers often fail to seek prenatal care and are themselves in sufficiently poor health to compromise the growth and well-being of the fetus. Thus, among pregnant women who are substance abusers, associated complications include preterm deliveries and infants who are intrauterine growth retarded or small for gestational age. The difficulties of caring for preterm infants or those who are small for gestational age are well documented because these infants often have labile states, and interaction with them is difficult (Watt, 1990; Watt and Strongman, 1985), problems that will likely be compounded if the substance-abusing environment is chaotic and inconsistent. Additionally, substance abuse often defines a postnatal environment associated with serious risks to infants' and children's development. These factors include severe poverty, virtual homelessness, early histories of abuse and neglect, chronic and acute violence, and multigenerational substance abuse with resulting parental isolation, and lack of family support systems (see also later).

It is conceptually and statistically naive to discuss all these events simply as covariates of prenatal substance exposure. Although they usually occur in association with substance use, they may or may not be related to the outcome of interest. Conversely, many of these variables probably serve as either mediators or moderators of the relation between prenatal exposure and later neurocognitive outcome (Baron and Kenny, 1986; Frank et al., 1993). For example, infants exposed prenatally to cocaine (see also later) appear more likely to have disorders of arousal or emotional regulation (e.g., Mayes et al., 1998). The strength of the relationship between prenatal cocaine exposure and the expression of this particular vulnerability may be mediated by the quality of postnatal care the infant and young child receives.

Considering mediating and moderating variables also brings up the issue of interactive as well as main-effect models. Traditionally, behavioral teratology studies have relied on main-effect conceptualizations: How much of the variance of a given neurodevelopmental outcome is explained by the prenatal exposure status? Although this is important and a first step, most developmental questions relating to prenatal exposure are probably better addressed as interactions. For example, as already cited, interactions between caregiving and prenatal exposure may more explain more of the variance in neurodevelopmental outcome than main effects alone. Interactions among a given genetic predisposition (e.g., for attentional disorders), exposure to drugs *in utero*, and postnatal neglect define another cluster of effects that are both more generalizable than single-effect exposure models and more biologically plausible.

### Definition of Outcome and Windows of Effect

Outcome variables and timing of outcome measurement vary widely in traditional behavioral teratology studies. Traditional models of teratology address both categories of outcome and window of effect (e.g., Abel, 1989; Vorhees, 1989). Typically, teratologic outcomes are expressed as CNS effects (including neurochemical, neuroanatomical, cognitive, behavioral, social-emotional); physical growth deficits (including brain growth); and malformations, and these outcomes are typically more manifest as the dose of exposure increases. At lower doses, CNS effects may still be apparent even in the absence of morphologic changes. Some effects on the CNS may only be manifest at later stages of development. These are often referred to as *latent effects* or *sleeper effects*, and examples of these are found both in studies of prenatal alcohol and marijuana exposure (e.g., Day et al., 1994). Certain developmental periods mark periods of neurologic reorganization (e.g., puberty, early school age, later half of the first year) and often prove to be important times to look for either latent or exacerbated effects of prenatal exposure. Within latent effects are those functional impairments that are apparent only under stressful, challenging, or novel conditions. In the work on cocaine in animal models, a considerable body of evidence has accumulated that this pattern may be particularly relevant to the neurotoxicity of cocaine (Spear et al., 1998).

Just as profiles of first cohorts may present a picture of more severe impairment, so are the initial outcome variables of study often more globally defined and less linked to hypotheses about pharmacologic action of the drug. Besides physical or morphologic impairment, neurobehavioral studies of prenatal drug exposure have most often focused on global measures of intelligence and general developmental functions such as memory, school performance, and incidence of maladaptive behavior. More recently, studies of *in utero* drug exposure have begun to use more functional measures such as reaction time and to focus on individual components of more general functions (e.g., visual versus auditory attention). Outcome measures such as these may be more reflective of hypotheses that are directly linked to understanding the site of action of the drug in the CNS.

Finally, it is important to make explicit that potential teratogens may exert their effects through different mechanisms. Most often assumed is a direct effects model in which the teratogen directly impairs a specific area of function in the CNS or otherwise. (Even claiming a "direct" effect on CNS is far too global a statement that does not allow for the remarkable complexity of any effect on developing neural tissue. The levels of effect in the CNS span direct toxicity to developing cells, impaired synapse or connectivity, to facilitated or impaired induction of genes that, in turn, regulate neural development.)

A second, less often explicitly discussed model is one in which the potential teratogen contributes to a domain of vulnerability that is expressed or not, depending on environmental conditions. A third model particularly relevant to conditions in which the potential teratogen is also a drug of abuse is that the drug itself may not be teratogenic for the developing child. Rather, in this third model, it may be that the context of drug abuse so alters the child's caregiving environment that any presumed teratogenicity is actually expressed through the effects of environmental chaos and deprivation.

## PRENATAL ALCOHOL EXPOSURE

Studies of the teratologic effects of prenatal alcohol exposure have been ongoing for many years since the initial reports of fetal alcohol syndrome (FAS) (Jones and Smith, 1973; Jones et al., 1973). Alcohol acts as a direct neuroteratogen affecting not only fetal facial morphology and growth but also brain growth, structure, and function through mechanisms not yet elucidated (Goodlett and West, 1992; Schenker et al., 1990). In addition to the direct effects of ethanol, prenatal alcohol exposure may also affect the fetus indirectly through maternal undernutrition and placental dysfunction and the teratogenicity of acetaldehyde, the product of ethanol oxidation (Shibley et al., 1999).

In infancy, FAS is characterized by the following: (a) intrauterine growth retardation with persistent postnatal poor growth in weight or height; (b) a pattern of specific minor physical anomalies that include a characteristic facial appearance; and (c) CNS deficits including microcephaly, delayed development, hyperactivity, attention deficits, intellectual delays, learning disabilities, and in some cases, seizures (Claren and Smith, 1978; Smith, 1982). The characteristic facial features include microphthalmia, short palpebral fissures, a thin upper lip, midface hypoplasia, and a smooth or long philtrum. Children with a history of *in utero* alcohol exposure who have either the characteristic physical appearance or CNS dysfunction are given the diagnostic label of having fetal alcohol effects (Claren and Smith, 1978). In the general population, the syndrome occurs in approximately one or two live births per 1,000, and the incidence of FAS among women with alcoholism is between 2.5% and 10% (Sokol et al., 1980). Even in the absence of FAS, infants born to mothers with *alcoholism* show an increased incidence of intellectual impairment, congenital anomalies, and decreased birth weight (Aronson et al., 1985; Day, 1992; Sokol et al., 1980). Partial expression of FAS and the issue of fetal alcohol effects have led to certain studies relating amount of exposure to the presence or absence of diagnostic criteria and to the severity of the CNS manifestations.

Nonetheless, hundreds of reports of children with FAS are now available detailing the delayed development in the first 2 to 3 years of life of children exposed to alcohol prenatally (e.g., Coles et al., 1987; Gusella and Fried, 1984; O'Connor et al., 1986). However, significantly fewer studies describe follow-up findings through school age and adolescence (Streissguth, 1992). Coles and colleagues (1991), studying children at age 70 months who were exposed to alcohol throughout gestation, reported deficits in sequential processing and on some measures of academic skills including reading and mathematics. Streissguth (1976) reported on a 7-year follow-up of 23 children of alcoholic mothers compared with 46 children of nonalcoholic mothers matched for socioeconomic status, age, education, race parity, and marital status. At 7 years of age, children of the alcoholic mothers had significantly lower intelligence quotient (IQ) scores and poorer performance on tests of reading, spelling, and arithmetic, and 44% of the children of alcoholic mothers, compared with 9% in the control group, had IQ scores in the borderline to retarded range. Significant differences in height, weight, and head circumference were also apparent. In a study of 21 children of alcoholic mothers, again compared with a

matched control sample, [Aronson and colleagues \(1985\)](#) described significantly greater problems with distractibility, hyperactivity, and short attention spans in the alcohol-exposed group. Similar behavior problems have been described for other cohorts (e.g., [Steinhausen et al., 1982](#)), and deficits in balance ([Roebuck et al., 1998](#)), as well as impairments in concentration and attention, social withdrawal, and conduct problems, continue to be described for adolescents and young adults ([Streissguth et al., 1991](#)).

Alcohol use also has an impact on the effects of other pregnancy risks such as prematurity and polydrug use. Preterm infants of women who used a high, not moderate, level of alcohol during pregnancy suffered an increased risk of developing brain hemorrhage and white-matter damage ([Holzman et al., 1995](#)). In addition to the effects of alcohol alone, more and more studies are exploring the effects of polydrug use. Numerous studies have reported that most women who use cocaine also use alcohol ([Brown et al., 1998](#)). One study compared cocaine-polydrug users who used and who did not use alcohol and found that alcohol did not account for a significant amount of the variance on birth weight, birth length, ponderal index, or irritability ([Brown et al., 1998](#)). In addition, [Brown and associates \(1998\)](#) reported that length of gestation moderated the effects of cocaine-polydrug use and alcohol-only use on fetal growth variables and irritability of infants, such that growth deficits were more pronounced in later-born infants, whereas increases in irritability were more evident in earlier-born infants.

In addition to the direct effects of prenatal ethanol exposure, the consumption of alcohol after a woman knows that she is pregnant serves as a marker for other possibly harmful behaviors. One study found that adolescent girls who continued to drink in the second and third trimesters of their pregnancies had a higher incidence of other high-risk behaviors such as smoking cigarettes and marijuana use, and they also had more prior pregnancies and less adequate prenatal care ([Cornelius et al., 1999](#)). Conversely, adolescents who stopped drinking after discovering their pregnancy had more prenatal care visits, fewer depressive symptoms, and parents with more education. These young women did not suffer the same ill effects as those mothers who continued to drink. This finding suggests that a low level of alcohol consumption for a brief period during pregnancy may carry less risk for the mother if she has access to a more advantaged environment and more psychological resources ([Cornelius et al., 1999](#)).

## PRENATAL OPIATE EXPOSURE

In contrast to those exposed to alcohol, newborns who have been exposed prenatally to opiates (heroin or methadone) are born passively addicted to the drug and exhibit withdrawal symptoms in the first days to weeks after delivery ([Desmond and Wilson, 1975](#)). Numerous studies have now also replicated the finding that prenatal opioid exposure reduces birth weight and head circumference ([Finnegan, 1976](#); [Hans, 1992](#); [Jeremy and Hans, 1985](#); [Kaltenbach et al., 1987](#); [Wilson et al., 1981](#)). Similar findings in animal models that control for exposure to other drugs such as alcohol or tobacco and for poor maternal health support the finding of an opiate effect on fetal growth ([Zagon and McLaughlin, 1984](#)). Prenatal exposure to opiates also contributes significantly to an increased incidence of sudden infant death syndrome. In some studies, the incidence of sudden infant death syndrome is eight times that reported for non-opiate-exposed infants ([Finnegan, 1979](#); [Hans, 1992](#); [Rosen and Johnson, 1988](#); [Wilson et al., 1981](#)).

On neurobehavioral assessments in the newborn period, opiate-exposed infants are more easily aroused and are more irritable ([Jeremy and Hans, 1985](#); [Marcus and Hans, 1982](#); [Strauss et al., 1976](#)). They exhibit proportionately less quiet compared with active sleep and show increased muscle tone and poor motor control (e.g., tremulousness and jerky movements). Opiate-exposed infants are less often in alert states and are more difficult to bring to an alert state. The dramatic neurobehavioral abnormalities seen in the newborn period generally diminish over the first month of life ([Jeremy and Hans, 1985](#)) for most infants and are, thus, assumed to reflect the transitory symptoms of narcotic withdrawal rather than evidence of permanent neurologic dysfunction ([Hans, 1992](#)).

Past the neonatal period, some studies have documented small, and not usually statistically significant, delays in the acquisition of developmental skills as measured by Bayley's Scale of Infant Development ([1969](#); [Hans, 1989](#); [Hans and Jeremy, 1984](#); [Rosen and Johnson, 1982](#); [Wilson et al., 1981](#)). However, much more consistent and significant across studies have been the findings of persistent problems in poor motor coordination, high activity level, and poor attention among opiate-exposed infants in the first year of life ([Hans and Marcus, 1983](#); [Hans et al., 1984](#)). These state and motor regulatory difficulties make it hard for even a well-functioning adult in a relatively nonstressed environment to care for the infant and present significant problems for an opiate-addicted adult experiencing his or her own state and attentional regulatory problems ([Hans, 1992](#)).

Follow-up studies through early childhood of opiate-exposed compared with non-opiate-exposed children have continued to report few to no differences in cognitive performance ([Kaltenbach et al., 1987](#); [Strauss et al., 1976](#); [Wilson et al., 1979](#)). However, opiate-exposed school-aged children show higher activity levels, are often impulsive with poor self-control, show poor motor coordination, and have more difficulty with tasks requiring focused attention ([Olofsson et al., 1983](#)). There is also an increased incidence of attention deficit disorder among opiate-exposed school-aged children ([Hans, 1992](#)). Two studies have described altered sex-dimorphic behavior in opiate-exposed boys ([Sandberg et al., 1990](#); [Ward et al., 1989](#)). Opiate-exposed boys showed more stereotypically feminine behavior than non-opiate-exposed boys, but there were no differences between opiate-exposed and non-opiate-exposed girls. These findings are consistent with similar observations of male rats exposed to opioid drugs *in utero* ([Ward et al., 1983](#)).

Past the years of early childhood, there are few studies of the long-term effects of prenatal opiate exposure, and those available usually lack a non-opiate-exposed control group or are not based on a longitudinal design ([Hans, 1992](#)). The data from these studies suggest that, by adolescence, opiate-exposed children exhibit an increased incidence of behavior and conduct problems including impulsivity, involvement in criminal activities or in early substance abuse, more antisocial behavior, and increased school dropout rates ([Bauman and Levine, 1986](#); [Sowder and Burt, 1980](#); [Wilson, 1989](#)). It is not altogether clear how much these problems in conduct and impulse regulation are attributable to persistent effects of prenatal opiate exposure and how much they are the consequence of cumulative exposure to the discord and dysfunction often characterizing substance-abusing households.

## PRENATAL MARIJUANA EXPOSURE

After alcohol, marijuana is the most commonly abused drug in the United States, and, like alcohol, marijuana abuse cuts across different socioeconomic groups and strata. *Marijuana*, also known as cannabis, is obtained from the flowering tops of the hemp plant from which more than 300 natural compounds including at least 61 different cannabinoids are extracted. Of these, tetrahydrocannabinol (THC), or marijuana, is the most potently psychoactive ([Levy and Koren, 1992](#)). THC readily crosses the placenta and, among heavy users, is also concentrated in breast milk ([Blackard and Tennes, 1984](#); [Perez-Reyes and Wall, 1982](#)). THC has a strong affinity for lipids and is stored in fatty tissue throughout the body ([Kruetz and Axelrod, 1973](#)). Thus, a single dose of THC in humans has a half-life of 7 days, but it may take up to 30 days to be excreted completely and accumulates throughout the body with chronic use ([Nahas, 1976](#)).

The rate of women reporting marijuana use during pregnancy varies from 5 to 34% ([Zuckerman, 1988](#)). During pregnancy, THC has documented effects in animals and humans on pituitary ovarian function, prolactin secretion, and uterine contractility ([Harclerode, 1980](#)). However, no relation has been documented between marijuana use and length of gestation or birth weight ([Fried et al., 1983](#)). Birth weight reductions associated with marijuana use have been described by others studying higher-risk, lower-income families ([Hingson et al., 1989](#)), and the results are conflicting ([Zuckerman et al., 1989](#)). Marijuana has an indirect effect on fetal oxygenation through the high levels of carbon monoxide found in marijuana smoke, levels higher than in cigarette smoke ([Wu et al., 1988](#)), which, in turn, result in fetal hypoxia. This type of effect may influence fetal growth, particularly in instances of heavy marijuana use ([Zuckerman and Frank, 1992](#)).

Few physical anomalies have been reported with marijuana exposure ([O'Connel and Fried, 1984](#); [Rose et al., 1982](#)), although several studies have suggested a link between prenatal marijuana exposure and features similar to those of FAS ([Hingson et al., 1989](#); [Qazi et al., 1982](#)). In one study, the incidence of FAS-like features was estimated to be five times higher in users of THC. It is quite likely, however, that heavy marijuana users are also abusing alcohol, and thus, the similarity to fetal alcohol effects is more likely to reflect the accompanying alcohol use ([Fried et al., 1984](#)). Several neurobehavioral findings in the newborn period point to decreased responsiveness on the Brazelton Neonatal Behavioral Assessment Scales (NBAS), particularly in visual, but not auditory, responsiveness to both animate and inanimate stimulation ([Fried, 1980](#); [Fried, 1982](#)) and a higher-pitched cry ([Fried and Makin, 1987](#)). Another characteristic of newborns exposed to heavy maternal THC use are tremors and increased startle in the first 7 to 14 days of life ([Levy and Koren, 1992](#)). Changes in sleep patterns have also been reported, including a decrease in the amount of trace alternans quiet sleep ([Scher et al., 1988](#)) and lower sleep efficiency and maintenance as measured by sleep electroencephalography by as late as 3 years of age ([Day and Richardson, 1991](#)).

Postnatally, marijuana has been identified in the urine of breast-fed infants whose mothers continue to use the drug after delivery ([Perez-Reyes and Walls, 1982](#)). However, no acute toxic effects have been identified with this level of passive exposure, although a few studies suggest possible developmental effects related to heavy postpartum exposure through breast milk ([Zuckerman and Frank, 1992](#)). In one study, marijuana exposure through breast milk in the first postpartum month was related to decreased motor development at 1 year, and there appeared to be a dose-related pattern to the level of association between exposure and motor delay ([Astley and Little, 1990](#)). Longer-term studies of the outcome of prenatal marijuana exposure are few. In one study, no association was found between prenatal marijuana use and developmental scores at 12 and 24 months ([Fried and Watkinson, 1988](#)). When these children were 4 years of age, heavy prenatal use (more than

six joints per week) was associated with lower scores on memory and verbal subscales of standard preschool intelligence tests. These findings pertained in comparison with the scores of children whose mothers had not used marijuana and after controlling for factors such as the home environment ([Fried and Watkinson, 1990](#)), although by age 5 and 6 years, these differences in IQ score had diminished ([Fried et al., 1992a](#)). In contrast, a second study ([Streissguth et al., 1989](#)) found no correlation with IQ scores at age 4 years. Behaviorally, children exposed to marijuana prenatally may show increased impulsivity and difficulties with sustained attention ([Fried et al., 1992b](#)). By early adolescence, there is a suggestion that those children exposed prenatally to marijuana may have more difficulty with complex visual processing problems ([Fried and Watkinson, 2000](#)), although further follow-up through adolescence is warranted.

## PRENATAL COCAINE EXPOSURE

Since the mid-1980s, many investigations have focused on the potential physical, neurodevelopmental, and neuropsychological effects of prenatal cocaine exposure on infants and young children. These studies have used a variety of designs including longitudinal, cross-sectional, case-control, and retrospective cohorts, have defined in multiple ways the independent variables, that is, the amount and duration of cocaine as well as other drug exposure, and have emphasized a host of different outcomes. (For a review of central methodologic issues in studies of prenatal cocaine exposure, see [Brooks-Gunn et al., 1994](#); [Frank et al., 1998](#); [Lester et al., 1995](#); [Mayes and Fahy, 2001](#); [Neuspiel, 1995](#)). Although still inconsistent or inconclusive on many crucial issues and marked by methodologic problems, published studies to date nonetheless reveal the beginnings of a profile of possible cocaine-related effects on neuropsychological functions subserving arousal and attention regulation and reactivity to stressful conditions. (For reviews, see [Frank et al., 1993](#); [Mayes and Bornstein 1995](#); [Mayes et al., 1998](#); [Richardson et al., 1993](#); [Singer et al., 1992](#).) That profile is further elaborated by findings from several animal models in which important factors such as duration and type of exposure as well as environmental conditions may be more adequately controlled ([Dow-Edwards, 1991, 1993](#); [Spear, 1995](#); [Spear, 1996](#); [Spear et al., 1998](#)). In particular, studies of prenatal and preweaning exposure in the rat point to direct effects of cocaine on the dopaminergic-mediated circuitry that is particularly important in arousal regulation and attentional reactivity ([Dow-Edwards et al., 1997](#); [Friedman and Wang 1998](#); [Friedman et al., 1996](#); [Howard et al., 1997](#); [Minabe et al., 1992](#); [Wang et al., 1995](#); [Weese-Mayer et al., 1993](#)).

Most often, infants exposed prenatally to cocaine are also exposed to other risk factors that may contribute to impaired development ([Mayes, 1992](#)). These include exposure to other substances of abuse including alcohol and tobacco, as well as opiates, marijuana, and amphetamines. Mothers who abuse cocaine often have associated health problems including a higher incidence of human immunodeficiency virus–positive titers with or without acquired immunodeficiency syndrome–related illnesses, and they have pregnancies more often complicated by preterm delivery and intrauterine growth retardation. Postnatally, infants exposed to cocaine continue to be exposed to ongoing parental substance abuse, they are more often neglected and abused, and they have parents with more frequent depression and higher overall levels of stress and anxiety ([Mayes, 1995](#)). Any one of these factors may also influence the development of early attentional and arousal regulatory functions, later language, and potentially overall developmental competence.

There are several candidate mechanisms proposed for the effect of prenatal cocaine exposure on the ontogeny of neural systems and, by extension, for cocaine-related neurobehavioral profiles ([Mayes et al., 1998](#); [Olsen, 1995](#)). These are effects on monoaminergic system development, changes in neural growth factors, alteration of ion channel and monoamine transport development, effects on other neurotransmitter systems such as neuropeptides including substance P, dynorphin, g-aminobutyric acid and glutamate sites, and alteration of immediate early gene expression ([Kosofsky et al., 1995](#); [Nestler et al., 1997](#); [Olsen, 1995](#)). Cocaine also has potent vasoconstrictive effects that may have a more generalized and less system-specific hypoxia-related deleterious effect on neural growth. The nonspecific but frequent mixture of acute and chronic stress characterizing the postnatal caregiving environments for many prenatally exposed children may also have enduring effects on attention and arousal system ontogeny perhaps through some of the same monoamine-related mechanisms.

At pharmacologically active doses in mature animals, cocaine inhibits the reuptake of monoamines (norepinephrine, dopamine, and serotonin) at the presynaptic junction. This leads to increased concentration of these neurotransmitters in the synaptic cleft and higher levels of activation in the central catecholaminergic systems ([Gawin and Ellinwood, 1988](#); [Wise, 1984](#)). Presynaptic depletion and a compensatory increase in synthesis parallel the increase in postsynaptic transmitter levels. Concomitant up-regulation of postsynaptic receptors may also result in supersensitivity to catecholamines ([Nunes and Rosecan, 1987](#)). Monoamine cell groups in the brain stem and striatum and presynaptic transporter proteins to which cocaine binds appear early in fetal development ([Choi and Ronnekleiv, 1996](#); [Lauder and Bloom 1974](#); [Pickel et al., 1980](#); [Verney et al., 1991](#)). Monoamines play critical trophic roles through all phases of CNS ontogeny—cell proliferation, neural migration, growth, and maturation, and synaptogenesis ([Lauder, 1983](#); [Lauder, 1988](#); [Mattson, 1988](#)). Additional suggestive evidence for the role of monoamines and their receptors in fetal brain development is that some receptors for serotonin and dopamine appear to be overexpressed in the immature brain and expressed in regions where they are absent in the adult ([Miller and Friedhoff, 1986](#); [Seeman et al., 1987](#); [Whitaker-Azmitia, 1991](#)). (Indeed, as a general principle, this observation of early overexpression is true of many components of the developing nervous system.) Thus, it seems reasonable to hypothesize that cocaine's effects on the developing nervous system may be mediated in part through effects on monoamine system ontogeny and monoamine function at the level of neurotransmitter and receptor synthesis, receptor sensitivity and binding, and monoamine system projections to other regions. These effects at a cellular, structural, and functional level may also be expressed behaviorally in disrupted patterns of arousal and attention regulation, given that these domains are connected intimately to monoaminergic systems.

In fetal brain development, dopamine, serotonin, and norepinephrine play critical roles in defining brain structure and neuronal formation by influencing cell proliferation, neural outgrowth, and synaptogenesis ([Lauder, 1988](#); [Mattson, 1988](#)). Cocaine readily crosses the placenta, as well as the blood–brain barrier, and brain concentrations of cocaine have been reported as high as four times those of peak plasma levels ([Farrar and Kearns, 1989](#)). Thus, cocaine may affect the formation and remodeling of brain structures through this effect on the release and metabolism of monoamines. Additionally, cocaine may influence the actual ontogeny of the neurotransmitter systems and, thus, again may modify certain critical processes in brain development. In prenatally cocaine-exposed animal models, several structures associated with mesocortical dopamine activity, including the cingulate cortex and the ventral tegmental area, as well as the ventral thalamic nucleus, show significant changes in dopaminergic activity compared with that in controls ([Dow-Edwards, 1989](#); [Dow-Edwards et al., 1988](#)). Effects on developing monoaminergic neurotransmitter systems have wide-reaching implications because they may lead to mistimed neurogenesis between the affected and unaffected areas of the brain with resultant changes in synaptic connections ([Lauder, 1991](#)). By altering monoaminergic neurotransmitter control of morphogenesis, chronic exposure to cocaine *in utero* may adversely affect autonomic function, state regulation, and regulation of attention in the developing nervous system.

The effect of cocaine on fetal development may also be expressed through the norepinephrine-related effects of cocaine on vascular tone. These consist of decreased uteroplacental blood flow, severe uteroplacental insufficiency (acute and chronic), maternal hypertension, and fetal vasoconstriction ([Moore et al., 1986](#); [Woods et al., 1987](#)), in turn, resulting in a relative state of fetal hypoxia. Moreover, in humans, cocaine use has been associated with spontaneous abortion, premature labor, and abruptions ([Bingol et al., 1987](#); [Cherukuri et al., 1988](#); [Lindenberg et al., 1991](#)). The effect of cocaine use on placental blood flow probably contributes to the relation between cocaine and fetal growth (low birth weight and microcephaly) reported by several investigators ([Fulroth et al., 1989](#); [Hadeed and Siegel, 1989](#); [MacGregor et al., 1987](#); [Mayes et al., 1993](#); [Oro and Dixon, 1987](#); [Ryan et al., 1987](#)). One report showed that crack-exposed infants were 3.6 times more likely to have intrauterine growth retardation than were infants born to non–drug-using women matched for age, socioeconomic status, and alcohol use ([Cherukuri et al., 1988](#)). Cocaine-exposed neonates may also show a greater effect on head growth, that is, the head circumference is disproportionately smaller than would be predicted by birth weight and gestational age ([Bateman and Chiriboga, 2000](#)). Additionally, because of the effect of cocaine on overall adult nutrition, compliance with prenatal care, and the usual association between cocaine use and use of other drugs such as alcohol, tobacco, and opiates ([Amaro et al., 1989](#); [Frank et al., 1988](#)), women using cocaine while they are pregnant are in an overall poorer state of health, which, in turn, increases the risk of impaired fetal outcome and fetal growth retardation. Intrauterine growth-retarded infants who are small for gestational age show persistent problems with irritability and distractibility well into the first year of life ([Watt, 1990](#); [Watt and Strongman, 1985](#)). A higher rate of congenital malformations in infants exposed to cocaine has also been reported ([Chasnoff et al., 1988](#); [Isenberg et al., 1987](#); [Teske and Trese, 1987](#)), but when various confounding factors are taken into account, only the relation between genitourinary malformations or spontaneous abortions and gestational cocaine exposure remains significant ([Lutiger et al., 1991](#)).

Behavioral and cognitive outcome measures beyond the neonatal period in studies of children exposed to cocaine prenatally have, for the most part, used general measures of developmental competence ([Mayes and Fahy, 2001](#)). On general measures of developmental competence such as the [Bayley Scales of Infant Development \(1969\)](#) that index information processing and indirectly attention, few differences are apparent between cocaine-exposed and non–cocaine-exposed infants ([Chasnoff et al., 1992](#)). The developmental profiles of a group of 106 cocaine- or alcohol-exposed 24-month-old children who were followed-up from birth were compared with the performance of 45 toddlers exposed to marijuana or alcohol but not cocaine and 77 non–drug-exposed children ([Chasnoff et al., 1992](#)). Mothers of infants in the two comparison groups were similar to the cocaine-using mothers in socioeconomic status, age, marital status, and tobacco use during pregnancy. On repeated developmental assessments using the [Bayley Scales \(1969\)](#) at 3, 6, 12, 18, and 24 months, albeit with a high rate of attrition from the original cohort, there were no mean differences in either the mental or motor domains. However, the investigators cautioned that a higher percentage of cocaine-exposed infants scored two standard deviations below the mean ([Chasnoff et al., 1992](#)). At least five other investigative groups have reported similar failures to find differences among cocaine-exposed groups on general measures of developmental competence in the first, second, and third years of life ([Anisfeld et al., 1991](#); [Arendt et al., 1993](#); [Billman et al., 1991](#); [Hurt et al., 1997](#)) and extending to no differences in IQ scores by early school age ([Wasserman et al., 1998](#)). Despite these apparent lack of differences in general measures of developmental competence, persistent motor delays at least through 2 years of age have been reported ([Arendt et al., 1999](#)).

Findings such as these have required a reevaluation of earlier concerns about global developmental delay in cocaine-exposed children. Conversely, as more children who were prenatally exposed have been evaluated in a variety of research and clinical contexts, more evidence is beginning to accumulate about impairments in specific functions such as neonatal habituation, attentional or arousal regulation, reactivity to novelty, and conditioned learning ( [Alessandri et al., 1993](#); [Coles et al., 1999](#); [Eisen et al., 1990](#); [Mayes et al., 1993](#); [Mayes et al., 1994](#); [Potter et al., 2000](#); [Struthers and Hansen, 1992](#)). Impairments in these domains would potentially make the normal parenting activities of contingent responsiveness and structuring attention more important for those prenatally cocaine-exposed infants who are more reactive and are easily overaroused ( [Mayes et al., 1994](#)).

In studies of newborns and 3- to 6-month-old cocaine-exposed infants, impairments have been reported in startle responsivity, auditory information processing, habituation, recognition memory, and reactivity to novelty. Persistent electroencephalographic abnormalities including lower spectral power have been reported through 1 year of age in cocaine-exposed infants ( [Scher et al., 2000](#)). [Anday and colleagues \(1989\)](#) reported that cocaine-exposed newborns are more reactive to reflex-eliciting stimuli as well as to specific auditory stimuli. Similarly, using measures of auditory information processing, deficits in habituation to auditory information were described for cocaine-exposed neonates; these same infants showed similar deficits in auditory habituation *in utero* ( [Potter et al., 2000](#)). In the neonatal period, findings of neurobehavioral impairments as measured by the Brazelton NBAS have been inconsistent. [Chasnoff and colleagues \(1989\)](#), among others ( [Datta-Bhutata et al., 1998](#)), reported impairments of orientation, motor, and state regulatory behaviors on the NBAS. In contrast, [Coles et al. \(1992\)](#) reported that NBAS scores for all infants fell within a clinically normal range regardless of cocaine or alcohol exposure, but they did not examine the habituation cluster for all infants. [Eisen and colleagues \(1990\)](#), studying neonates who were urine screen-positive only for cocaine at birth and whose mothers denied opiate use, and [Mayes et al. \(1993\)](#) found significant deficits in cocaine-exposed infants in habituation performance as assessed by the NBAS. No other aspects of neonatal performance were affected.

Links between the dopaminergic system and attentional mechanisms that are likely to involve information processing ( [Coles and Robbins, 1989](#)) make it plausible to hypothesize that prenatal cocaine exposure could affect the infant's early information processing performance as indexed by recognition memory or habituation procedures. [Struthers and Hansen \(1992\)](#) reported impaired recognition memory among cocaine or amphetamine-exposed infants compared with a non-drug-exposed group between 7 and 8 months of age. Similarly, [Alessandri and colleagues \(1993\)](#) reported delays in novelty responsiveness and conditioned learning well into the second half of the first year of life; cocaine-exposed infants also showed less positive affect during play with their mothers and a persistent negative response after the stressful still face procedure ( [Bendersky and Lewis, 1998](#)).

Recognition memory tasks rely in part on habituation processes, and although they measure infant responsiveness to novel versus familiar stimuli rather than decrement of attention over time, they nevertheless require an integrated capacity to attend selectively to novel information. [Mayes and colleagues \(1993\)](#) found that, compared with a non-drug-exposed group, infants exposed prenatally to cocaine were significantly more likely to fail to begin a habituation procedure and significantly more likely to react with irritability early in the procedure. However, most infants reached the habituation criterion, and among those who did not, significant differences emerged between cocaine-exposed and non-cocaine-exposed infants in habituation or in recovery to a novel stimulus. Thus, for at least a subgroup of cocaine-exposed infants, initial reactivity and selectivity toward novel stimuli appear impaired. As a similar finding, in older children, it has been reported that, despite no apparent differences on either motor or mental indices on the [Bayley Scales \(1969\)](#), cocaine-exposed 24-month-old children appear to have more difficulty attending to several objects at the same time and in structuring an approach to a nonfamiliar task on their own in the context of the developmental assessment ( [Hawley and Disney, 1992](#)). Using physiologic measures of arousal regulation (e.g., heart rate in response to novel or stressful stimuli), findings consistent with earlier behavioral observations describe dysregulated arousal and stress response systems (e.g., accelerated heart rate indicating stress instead of deceleration indicating attention) in cocaine-exposed infants ( [Coles et al., 1999](#); [Bard et al., 2000](#)).

Longer-term follow-up of cocaine-exposed children into school age is necessary to explore the implications of impairments in reactivity and attention and state regulation for later learning. A few studies are now available suggesting persisting arousal regulatory difficulties. For example, using the auditory startle response as a measure of stress response, [Mayes and colleagues \(2000\)](#) demonstrated an attenuated startle response in cocaine-exposed 4.5- and 5.5-year-old children. By early school age, cocaine-exposed children also appear to exhibit more disruptive behavior problems ( [Delaney-Black et al., 1998](#)).

However, as a caveat, establishing cause-and-effect relations between prenatal cocaine exposure and emotional regulation or attentional deficits is problematic, given the number of additional variables that may affect vulnerability for such neurodevelopmental outcomes. In addition to a direct effect on developing monoaminergic neurotransmitter systems in fetal brain, prenatal cocaine exposure may potentially affect attentional and state regulation indirectly because of effects on fetal growth, and, in humans, cocaine use is usually accompanied by at least alcohol use. Moreover, continued maternal postnatal use of cocaine affects the child's caregiving environment at two levels, and this may contribute to attention regulation. Adults who are under the influence of cocaine are less able to respond adequately to their children at any given time ( [Bauman and Dougherty, 1983](#); [Mayes, 1995](#)). The effects of cocaine on memory and attention impair the adult's ability to care for a child. More generally, because of the lifestyle adjustments necessary with cocaine use, including, for example, prostitution, crime, exposure to violence, and the overwhelming power of the addiction, the overall environment for these children is often chaotic, violent, and neglectful ( [Black and Mayer, 1980](#); [Regan et al., 1982](#)). Specific outcomes in children such as attentional regulation are also influenced by maternal interactive style ( [Bornstein, 1985](#); [Bornstein and Tamis-LeMonda, 1990](#); [Tamis-LeMonda and Bornstein, 1989](#)). Similarly, the psychological and personality factors that lead an adult to substance abuse may have genetic as well as experiential implications for the fetus. For example, attention deficits or chronic affective disorders in the adult, both of which may be partially medicated by cocaine ( [Khantzian, 1983](#); [Khantzian and Khantzian, 1984](#); [Rounsaville et al., 1982](#)), are associated with genetic risks for similar disorders in the child, and these disorders, particularly depression, also impinge on the adult's capacity to care adequately for the child ( [Fendrick et al., 1990](#); [Field, 1995](#)).

Thus, prenatal exposure to alcohol, heroin, marijuana, or cocaine may contribute to specific short-term and long-term impairments or vulnerabilities in arousal modulation, activity level, or attentional regulation, which may make it more difficult for an adult to parent the child. Moreover, when that adult is involved in substance abuse, his or her addiction and the associated environmental, psychiatric, and neuropsychological effects may further impair the interactions between the child and parent, as assessed through both indirect measures of the incidence of abuse and neglect and direct observational measures of parenting attitudes and behaviors.

## POSTNATAL SUBSTANCE-ABUSING ENVIRONMENT

Each of these presumed effects relating prenatal drug exposure to neurobehavioral and developmental dysfunctions must be viewed in the context of the postnatal substance-abusing environment in which many prenatally drug-exposed children remain. As already mentioned, the postnatal drug-using world carries certain risks to children's development. These include exposure to extreme, often chronic violence, virtual homelessness, poverty, parental neglect and abuse, and parental depression and associated psychopathology. Each of these factors, in turn, influences the parenting behaviors of adults who are also substance abusers.

Addiction to any substance (or condition) points to personality characteristics, disabilities, or impairments, each of which may have significant implications for an adult's ability to parent a child. Moreover, all substances of abuse alter, in varying degree, one's state of consciousness, memory, affect regulation, and impulse control and may become so addictive that the adult's primary goal is to be able to supply his or her addiction to the exclusion of all else and all others in his or her life. These alterations likely influence markedly at any given moment the adult's capacity to sustain contingent, responsive interactions with an infant and young child. For example, neuropsychological impairments in concentration and memory associated with chronic cocaine abuse ( [O'Malley et al., 1992](#)) may be expected to influence certain parenting behaviors such as the capacity to sustain an interaction.

There are differences in the behavioral and personality characteristics of substance-abusing adults according to the specific substance of abuse. Systematic studies of psychopathology among substance abusers find, for example, that abuse of cocaine versus opiates is associated with a different spectrum of psychological disorders ( [Khantzian, 1985](#)). Heroin addicts are generally considered a more psychiatrically deviant group than cocaine abusers ( [Rounsaville et al., 1991](#)), but there are higher incidences of drug abuse and alcoholism among the relatives of cocaine abusers than among the relatives of heroin addicts ( [Rounsaville and Luthar, 1992](#)). These factors influence treatment issues according to the specified drug of abuse and probably also affect the adult's parenting capacities. Moreover, abused drugs differ markedly in their psychological and physiologic effects on the user, and these effects, in turn, differentially influence the adult's capacity to respond to a child. Agents such as alcohol, marijuana, heroin, or antianxiety drugs such as diazepam (Valium) tend to depress mood, whereas stimulants such as cocaine or amphetamines increase activity and contribute to a sense of euphoria and elation. In either case, the adult's moment-to-moment responsiveness to children's needs is impaired, but in one case, the impairment is toward depression and withdrawal and in the other toward unpredictable activity and impulsivity. Although the distinctions are not absolute, because, for example, chronic cocaine abusers often experience depression and persons with alcoholism may be quite agitated, the child's experience will differ depending on whether the parent is predominantly withdrawn or unpredictably agitated. Moreover, as cited earlier, for some substance-abusing adults, the drug of choice may also in part indirectly reflect different preexisting conditions that the drug use may be intended to self-medicate ( [Khantzian, 1985](#); [Khantzian and Khantzian, 1984](#)). These conditions, such as depression or anxiety disorders, not only carry potential genetic risks for the child but also surely influence parenting in the domains of affective availability, capacity to foster the child's independence, and the parent's tolerance for the child's aggression.

The social context of the particular abused substance varies markedly, and these factors also indirectly influence parenting. Alcohol, when abused, poses major

health and psychological problems, but it is legally available, and its use is more socially acceptable for women and men than cocaine, heroin, or even marijuana abuse, all of which are illegal. Abuse of cocaine far more often involves the user directly or indirectly in criminal activities such as prostitution, theft, or drug dealing (Boyd and Mieczkowski, 1990), and it exposes the user, as well as his or her children, to personal and property violence. Because of these activities, cocaine-abusing adults are more likely to be arrested and incarcerated repeatedly, thereby exposing their children to multiple episodes of parental separation and placements usually with different foster families or with other (often substance-abusing) neighbors or relatives (Lawson and Wilson, 1980). Additionally, substance-abusing parents often report feeling more isolated and lonely, with few friends or relatives in their neighborhoods or immediate communities whom they identify as supportive and helpful (Tucker, 1979). Feelings of isolation and self-denigration may reflect both premorbid and postmorbid states related to the adult's substance abuse, but in any case, parents who experience isolation and separateness may be at greater risk of having problems in caring for their children, especially when their isolation is compounded by the psychological effects of their addiction. Multiple studies from substance abuse treatment programs also document the high incidence of unemployment and less than a high school education among participating substance-abusing women (Hawley and Disney, 1992). Among this population, the rate of unemployment has been shown as high as 96% (Suffet and Brotman, 1976). The level of violence in substance-abusing families, particularly between women and their spouses or male friends, is markedly high and exposes children to a considerable amount of witnessed violence (Regan et al., 1982). Studies have repeatedly documented the markedly increased occurrence of severe, often multigenerational, impairments in parenting among substance-abusing families as measured by the incidences of physical and sexual abuse, neglect, abandonment, and foster placement (Black and Mayer, 1980; Lawson and Wilson, 1980; Wasserman and Leventhal, 1993). Neglect and out-of-home placement are extremely common among the children of opiate-using adults. In a sample of heroin-exposed children followed through school age (Wilson, 1989), only 12% were living with their biological mother, 60% lived with extended family or friends, and 25% had been adopted. By their first birthday, nearly half (48%) of these children as infants were living away from their biological mothers.

There are surprisingly few direct observational studies of parent-child interactions among substance-abusing mothers and their children, and most of these have involved adults addicted to alcohol or opiates (Mayes, 1995). In 1985, Lief presented a series of clinical descriptions of interactions between mothers in treatment and their infants and toddlers. Described as points for intervention were the impoverished use of language between substance-abusing mothers and their infants, restriction of exploration that was seen as the infant's "getting into things" (Lief, 1985), and a diminished responsiveness to the infant's bids for social interaction. Few studies have systematically investigated the interactive behaviors between substance-abusing mothers and their infants. The measures employed have been quite variable both in the amount of interactive detail studied and in the aspects of interaction considered potentially impaired by substance abuse.

Most studies have reported impairments in certain interactive domains, although these differences have not always been attributed to substance abuse only. Householder (1980, cited in Hans, 1992), reporting on the interactions between opioid-using mothers and their 3-month-old infants, describes more physical activity, less emotional involvement with the infant, and less direct gaze toward the infant than non-opioid-using mothers. Opiate-addicted mothers tended either to withdraw completely from the interaction or to be persistently physically intrusive. In a study of 15 mothers in a methadone maintenance clinic compared with 15 non-opioid-addicted women interacting with 2- to 6-year-old children (Bauman and Dougherty, 1983), addicted women were more likely to use a threatening, commanding, or provoking approach to discipline and "to reinforce a disruptive method of attention seeking" (Bauman and Dougherty, 1983) in comparison with nonaddicted mothers, who relied more on positive reinforcement. The 2- to 6-year-old children of the substance-abusing mothers in that study also were significantly more provocative and complaining with their mothers.

Studies of attachment profiles among prenatally and postnatally substance-exposed children are, to date, few. Goodman (1990, cited in Hans, 1992) studied attachment patterns in 35 methadone-exposed and 46 nonexposed 1-year-old infants. Methadone-exposed infants more often showed disorganized (group D; Main and Solomon, 1986) or mixed insecure attachment patterns. Similarly, Rodning and colleagues (1989, 1991), studying 18 13-month-old children who were prenatally exposed to cocaine, phencyclidine, heroin, or methadone compared with 41 socioeconomic status-matched preterm children, showed that drug-exposed toddlers were more likely to be insecurely attached to their mothers, whereas most of the non-drug-exposed premature infants were securely attached. In addition, the drug-exposed children showed higher rates of disorganized attachment behaviors. In a similar study of maternal alcohol use (O'Connor et al., 1990, reported in Griffith and Freier, 1992), maternal interactions and maternal prenatal alcohol use significantly predicted infant attachment behaviors at 1 year of age.

Several studies have emphasized that, although the substance-abusing mothers had apparently more impaired interactions than comparison groups, some associated (e.g., comorbid) factors in addition to, or instead of, their substance abuse seemed to predict poor parenting. Jeremy and Bernstein (1984), reporting on the dyadic interactions of a cohort of 17 methadone-maintained women and their 4-month-old infants compared with 23 non-opioid-using mothers (Bernstein et al., 1984, 1986), found that drug use status alone did not significantly predict maternal interactive behavior. Instead, maternal psychological and psychosocial resources, as measured by assessments of maternal IQ and semistructured, diagnostic psychiatric interviews, were more predictive of the quality of the maternal-infant interaction than was drug use status. Indeed, maternal drug use, when analyzed together with other maternal variables, was not a significant predictor of mothers' interactive performance. However, coexisting maternal psychopathology contributes to greater impairments in parenting interactions among substance-abusing adults compared with non-substance abusers and with those substance abusers with no coexisting psychiatric disturbance. Hans and colleagues (Hans et al., 1990, reported in Griffith and Freier, 1992) reported that mothers using methadone who were also diagnosed as having antisocial personality disorders were significantly more dysfunctional in their interactions with their 24-month-old children than were methadone-maintained mothers who had either no significant psychopathology or affective disorders alone. Moreover, the latter group did not differ in their interactions from drug-free mothers. Findings such as these, albeit from small cohorts, point to the importance of not considering drug use alone as the single determining variable for observed differences in maternal interactive behaviors, but rather as a marker for several predictor variables that are more often associated with substance abuse (Mayes, 1995).

## CONCLUSIONS

The field of behavioral and developmental teratology focuses on identifiable effects of prenatal exposure to substances such as alcohol, heroin, marijuana, and cocaine. Children developing amid the violence, substance abuse, poverty, and discord increasingly common in inner city neighborhoods are at risk of dysfunctional development on several accounts. Although specific syndromes such as that associated with maternal alcoholism during pregnancy have been clearly identified, controversy and conflicting findings still pertain regarding long-term effects of any one of these agents on cognitive and intellectual development. Suggestive findings, particularly with prenatal cocaine exposure, point to impairments in more basic neurodevelopmental domains of arousal and attentional regulation, functions that underlie learning and information processing. However, the postnatal substance-abusing environment, both in its more general factors of poverty, homelessness, and violence and in the specific dysfunctions of parenting that accompany substance abuse, almost certainly exacerbates the effects of prenatal substance exposure.

The impact of separations from loved ones and of associated or unique deprivation experiences on children's development has been an issue for child psychiatrists and other children's specialists for many years. John Bowlby's groundbreaking investigations into the potentially psychopathologic effects of separation and his ultimate construction of attachment theory in the 1950s and 1960s directed attention to the developmental significance of separation experiences in the lives of young children. Although many of his colleagues at the time believed that childhood experiences could have lasting consequences on personality development, it was not believed that separation from or loss of the primary caregiver could be of particular long-standing importance, if other adults stepped in to care for the child ( [Colin, 1996](#)). Bowlby's work changed conventional views and stimulated an enduring interest in understanding and ameliorating adverse consequences of separation and of depriving experiences on infants and young children.

The clinical questions most basic to understanding separation experiences for children often address how these experiences are handled by adults responsible for the child, including both family and professionals. For example, how can separation experiences in the life of the young child be managed by adults, so that distress is lessened, and adaptive and defensive mechanisms that protect and facilitate development are evoked? How can parents and day care providers best help an infant or young child cope with the stresses inherent in being separated from parents for long hours day after day? How can the impact of separation on disabled or sick infants be lessened, or, similarly, how can hospitalization of a child be made less stressful for the child and family? When the separation includes placement of the child outside the family, what can be done to improve outcomes for children in the foster care system? How can knowledge of child mental health and development be more effectively communicated to influence decision making in child placement and custody cases? Is it possible to design residential group care programs for infants and young children that foster development and address individual needs, including therapeutic needs?

To be sure, issues of separation and deprivation are not the only considerations in the foregoing questions, but they are of central importance and exert a strong influence on recommendations for the care of children and on choice of intervention for a variety of service settings. The role of child psychiatrists and other child mental health professionals includes a wide range of possibilities, from public policy advisor to the more traditional roles of consultant, diagnostician, counselor, and therapist for the individual child and family. Crucial for each of these roles is an understanding of the meaning of separation both for an individual child and for the broader study of children's development.

Separation experiences are myriad in the lives of children and are a part of expected development. Allowing a parent to leave for work or saying good-bye at the door to school, sleeping overnight at a friend's house, and accepting care from another, less familiar, family member are examples of the many expected, indeed, under optimal circumstances, developmentally promoting, separations for the preschool and school-aged child. More potentially disruptive experiences include the loss of a parent through parental divorce or a severe debilitating illness or death. Similarly, separations that occur in the context of child abuse or neglect and subsequent foster placements impose multiple burdens on development in addition to the loss of a parent who may or may not have been the abuser.

Even this altogether too cursory typology illustrates that separation is not a single-dimension experience. The field has moved past the time when separation was regarded as an event that had a predictable effect whenever it occurred in the earliest years. Similarly, deprivation cannot be discussed as though insufficient nutrients, the condition of "not enough," had sufficient explanatory value. Such oversimplification disregards the complexity of brain and psychological development and the influence of developmental change on syndrome expression. It is known that a particular clinical disorder can be the result of multiple factors and that similar insults (e.g., deprivation and traumatic separation) may result in different outcomes. Any one separation experience is mediated by the developmental age and competence of the child, by the previous history of loss and separation for the child and family, and by how the family or responsible adults respond to the particular experience in terms of themselves and the child.

For example, separations occurring in the early preschool years have a potentially greater developmental impact than those that occur later. For children with biologically based vulnerabilities such as a sensitivity to novelty and transitions, even expected separations may impose a greater degree of stress than for another, less sensitive child. Similarly, for children with specific or general developmental delays, age-expectable separations (e.g., entry into preschool) may be experienced with a degree of anxiety and developmental stress more like that of a younger child. From the environmental side, how parents or caring adults help the child cope with the separation experience plays a crucial role in the child's short-term and long-term responses. In many circumstances, the adult most responsible for the child is unable, because of psychological and functional limitations of, for example, substance abuse, to mediate the experience for the child. Or if the adult caring for the child is also acutely affected, as by the death or illness of a spouse, the child may experience a double loss as his or her remaining parent is less available and is more acutely depressed. Situations of extreme family disruption, such as occur when families are displaced from their homes, impose not only the potential loss of cared-for persons but also the loss of familiar surroundings and routines. There is also the mediating factor of how well cared for the child has been up to the separation. Children from chronically depriving or abusing environments are at much greater risk of having severe developmental sequelae of a separation experience. Thus, separation involves more than a single type of experience, either for an individual child or family or for any group of children at a given developmental age or life circumstances. On this and related notes of caution, selected currently recognized constructs about effects of separation and deprivation follow.

### CHANGING DEFINITIONS AND CONCEPTS

In respect to separation, current concepts include consideration of separateness, that is, becoming a separate person, and separation events, which occur across the life cycle ([Bloom-Feshbach and Bloom-Feshbach, 1987](#)). Coping with experiences of separation is a lifelong challenge, not only inevitable but necessary for healthy

development ([Provence, 1987](#)). In childhood, some separation experiences facilitate psychological growth and personality organization by mobilizing new opportunities for learning and adaptation. Others, especially those involving loss of important persons, precipitate states of confusion, anger, anxiety, and grief and are painful and traumatic. Between these two extremes are many separation experiences involving varying degrees of psychological and psychobiological stress; adaptive and defensive mechanisms are called into play with varying degrees of effectiveness, and feelings of mastery or helplessness are aspects of these responses.

Traumatic separation and deprivation often, but not always, go hand in hand. The condition of deprivation, for many years called "maternal deprivation," has most often been seen as the lack of adequate physical care and of social and emotional stimulation and interchange. As investigators and clinicians looked more closely at specific components found in the environments of infants who were developing well and, by contrast, what was missing in the experience of those who were not doing well, and as we have become more aware of the impact of sensory deficits such as deafness and blindness, *deprivation* has been recognized as encompassing other conditions as well. *Experiential deprivation* is a more useful and accurate term than maternal deprivation to express the variety of "not enough" situations that characterize the lives of many children. In addition, multiple risk factors often operate and are cumulative in their impact. [Yarrow \(1961\)](#), in a landmark article, outlines more rigorous and productive methodologic approaches to the study of maternal deprivation and to a conceptual reevaluation of clinical and research studies on the subject. The literature on maternal deprivation has included the following: children residing in institutions for prolonged periods; those only temporarily separated because of illness of child or parent; those cared for by several different persons and, thus, enduring multiple separations; and children grossly neglected or mistreated by their families who experience not only the lack of adequate nurturance in the positive sense but also the trauma of insensitive, intrusive, or hostile treatment by parental figures.

Complex mixtures of experiential deprivation may be encountered. Brain insults and congenital or acquired disabilities, prematurity, and neonatal illness increase the probability that an impoverished environment will have an adverse effect on development ([Shonkoff and Marshall, 1990](#)). Sensory deficits such as deafness and blindness create a situation of needs requiring special environmental response in aspects of child care and education ([Fraiberg, 1977](#); [Freedman, 1981](#)). When sensory deficits are multiple or combined with motor disabilities, vulnerability to the influence of deprivation is heightened. When parents are markedly dysfunctional, however, even the most biologically resilient infant will be at risk for later problems.

## THEORIES OF PROCESS AND MECHANISMS

How does one understand what happens to the young child who experiences traumatic separation or deprivation? There is no unitary theory of psychological development that can be called on to guide diagnostic, therapeutic, and preventive efforts. Nonetheless, empirical data derived from research, practice, and theory from developmental psychologies are organized into sets of constructs. Such systematic efforts permit the type of interaction of clinical experience, data of observation, and theoretical propositions that leads to the refinement of each.

In the following discussion, aspects of attachment theory, psychoanalytic theory, and cognitive psychology are presented because of their contributions to the most current thinking about separation and deprivation. The distress of the young child at separation and the adverse effects of deprivation are understood in part by each. Clearly, one cannot here do full justice to any one of them, but a guide to the salient outlines of each theory is provided.

### Contributions from Attachment Theory

Bowlby's *attachment theory* employs an evolutionary perspective that draws on ethologic principles and animal behavior and combines these with aspects of psychoanalytic theory to understand the formation of human social bonds. The infant's survival mechanisms and the adult's nurturing tendencies "bias" them to behave reciprocally and to form an attachment. *Attachment*, as defined by [Bowlby \(1969\)](#) and as used by Ainsworth and colleagues ([Ainsworth, 1964](#); [Ainsworth et al., 1978](#)), is an affectional tie that forms with another specific person, a tie that endures over time and ultimately becomes a part of an individual's psychic structure.

The biological function of the attachment relationship is protection. Early in life, an infant's biologically rooted attachment behaviors become organized into a goal-directed system with proximity to the attachment figure as the goal ([Colin, 1996](#)). Activators of the system often are external conditions (e.g., frightening events, strangeness, and particularly distance or separation from the attachment figure), but they also may include internal conditions (e.g., fatigue, illness, or pain). Attachment behaviors include a repertoire of actions (e.g., distress, reaching, following) that serve ultimately to bring the infant or child into proximity and contact with the attachment figure. The resulting contact and proximity are system terminators. Although the fundamental nature of this system remains the same throughout childhood, its external character is quite variable. The particular conditions that activate the attachment system, the intensity of activation, the types of attachment behavior used by the infant or child, and the degree of proximity or contact necessary to terminate activation differ with the developmental level of the child and also with the quality of the attachment relationship ([Colin, 1996](#)).

An important result of the attachment interactions between caregiver and child is the internalized social-cognitive model that the child ultimately constructs of close relationships. This "internal working model" ([Bowlby, 1969](#)) is defined as the child's psychological representation of self and of key caregivers, and their relations. It is an important form of mental structure or representation that guides and regulates human functioning and permits, for example, the mental representations of attachment figures to be accessible and emotionally available in time of need and of the self as worthy and lovable.

Distress at separation from an attachment figure is intensified when the young child is placed on a long-term basis in a strange environment and is cared for by a succession of strange persons. A typical sequence of protest, despair, and detachment ensues. Robertson and [Bowlby \(1952\)](#) first defined these three major phases. *Protest* is a phase of angry, loud, tearful behavior during which the child looks for the mother and expects her return. The second phase, *despair*, is one of acute pain and diminishing hope, when there is usually a subdued manner and little interest in the surroundings. In the third or *detachment* phase, the child shows renewed interest in the environment and may be quite friendly and outgoing to others, but specific reactions to the mother, when she reappears, such as ignoring and walking away, suggest that detachment serves a defensive function. The three types of responses are seen as phases of a single process. Acute anxiety recurs when there is fear or anticipation of losing the mother again. The onset of psychiatric conditions, in Bowlby's view, is linked to premature detachment that masks "strong residual yearning for and anger at the lost object . . . ready for expression at an unconscious level" (1961). This leads [Bowlby \(1980\)](#) to argue that, because there are cumulative effects, strong preventive efforts are called for, and "the safest dose [of separation] is a zero dose." Such a prescription, although certainly applicable to acute and unanticipated loss or abandonment, does not as easily apply to the vicissitudes and developmentally promoting aspects of expectable, anticipated, and usual separations in early childhood.

[Bowlby \(1973\)](#) agrees with Freud's view that anxiety is a response to the danger of loss of a love object; pain or mourning is the response to actual loss, and defenses are mobilized to cope with pain. [Bowlby \(1960\)](#) uses the terms *mourning* to characterize the psychological process set in motion by loss and *grief* to denote the sequences of subjective states that follow loss and accompany mourning and suggests that mourning in the infant differs in no material way from mourning at later ages. Anna Freud (1960), in responding to Bowlby's hypotheses, agrees with the descriptions of behavior and the painfulness of the experience but takes issue with his view of mourning. She proposes that the term *bereavement* be used and that the term *mourning* be reserved for later reactions when development in object relations and ego maturity make it possible for the mourning process, as defined in psychoanalysis, to occur.

Since Bowlby, extensive empirical research (see [Bretherton and Waters, 1985](#); [Goldberg, 1991](#); [Waters et al., 1995](#), for reviews) using the *Strange Situation* has documented at least four patterns of 12- to 18-month-old children's response to brief separation: secure, avoidant, ambivalent or resistant, and disorganized. The crux of the separation situation designed to elicit these behavior patterns is a standard sequence of separations and reunions during which the infant experiences increasing distress and a greater need for proximity ([Ainsworth and Wittig, 1969](#); [Ainsworth et al., 1978](#)). The strategies children use to cope with their increasing needs for proximity with the adult are considered indicators of the quality of the attachment. The individual behavioral components that go into an attachment category include seeking and maintaining contact with the adult, avoidance, and resistance to physical contact. Behaviors on reunion appear to be the most salient in distinguishing among these different attachment categories. In the secure category, infants seek their caregiver only when their security is threatened, as when they are left in a novel or frightening place. When the adult returns, these children are able to explore comfortably and securely. Avoidant or dismissing children appear not to notice or be distressed by the caregiver's absence or return, whereas ambivalent children are often overly distressed even when they are not in danger. Children with ambivalent attachment patterns are often unable to resume their usual play even on the adult's return. In [Ainsworth and Wittig's original study \(1969\)](#), 65% of toddlers exhibited secure patterns of attachment, 21% an avoidant pattern, and the remaining 14% an ambivalent pattern. These patterns and their distribution are consistent for infants and toddlers from several different cultures ([van IJzendoorn and Kroonenberg, 1988](#)). Moreover, under stable environmental conditions, individual attachment patterns are stable over short periods and into childhood ([Howes and Hamilton, 1992](#); [Howes et al., 1998](#); [Main et al., 1985](#); [Waters, 1978](#)). Some studies have shown that securely attached infants are more competent than insecure infants in several later cognitive and social domains ([Kerns, 1994](#); [Matas et al., 1978](#); [Sroufe et al., 1983](#); [Waters et al., 1979](#)). A longitudinal study of children followed from the first year through puberty reports the positive relation between

early attachment behaviors and later social competence ([Sroufe et al., 1990](#)).

Studies of attachment under at-risk conditions such as prematurity, maternal depression, and maltreatment have shown mixed patterns of attachment emerging from these early stressful situations and have led to the creation of a fourth attachment category, the disorganized pattern ([Main and Solomon, 1990](#)). Infants classified as disorganized during the Strange Situation exhibit confused, often fearful reactions to the adult's return and have few to no strategies for coping with the stress of separation. Identification of the disorganized pattern has led to a surge of interest in uncovering its determinants and effects ([Solomon and George, 1999](#); [Vondra and Barnett, 1999](#)). Research suggests that disorganized attachment patterns occur more frequently among groups of abused or neglected children ([Barnett et al., 1999](#); [Carlson et al., 1989](#)), and these patterns may result from frightened (e.g., helpless, fearful) or frightening (e.g., hostile, punitive) maternal behaviors ([Main and Hesse, 1990](#); [Lyons-Ruth et al., 1999](#)). In terms of developmental consequences, "attachment disorganization in infancy forecasts controlling behavior with caregivers, aggressive and fearful peer relationships, and internalizing and externalizing problems in preschool, kindergarten, and elementary school, as well as dissociative symptoms and elevated psychopathology during adolescence" ([Lyons-Ruth and Jacobvitz, 1999](#)).

Studies of attachment behaviors beyond the second year of life have also been extended to preschool-aged children, to 5- to 7-year-olds, and to adults. For children, the most common procedures again rely on separations and observations of reunions; however, another method involves asking children to complete stories related to attachment issues ([Bretherton et al., 1990](#); [Goldberg, 1991](#)). For adults, the most validated and widely used instrument for assessing attachment is the Adult Attachment Interview, a semistructured interview about the person's experiences and current thoughts regarding his or her early relationships ([George et al., 1985](#)). Categories similar to those described in toddlers apply to older children and to adults. The secure-autonomous pattern describes a child who acknowledges the adult's return, but who usually continues to play and finds a way to invite the adult to join the activity. For adults, secure attachments are indexed by both a valuing of close relationships and a realistic acceptance of the strengths and weaknesses of those persons. Avoidant preschoolers and older children appear to be more interested in other activities than the adult's return, and although they may greet the adult, they show minimal response to overtures for engagement and little effort to include the adult in their play. Avoidant or dismissing adults idealize their childhood experiences and downplay the importance of close, intimate relationships in their lives. Dependent-ambivalent children, like their infant counterparts, are preoccupied with the adult's whereabouts at the expense of all else including their own play and other activities. Similarly, the adult analog describes a person caught in old struggles, lacking a sense of personal identity of his or her own role within relationships. The fourth category, disorganized, describes a child who is not so much behaviorally disorganized but rather is controlling the interaction. The child works hard to keep the parent happy and engaged or is controllingly hostile and demanding. For the adult, this attachment pattern may be inferred from unresolved mourning over losses of important others in which there is continuing cognitive disorganization around discussions of the lost figure.

These techniques for studying attachment patterns in older children and adults have permitted closer study of both the stability of attachment across the life span and the transmission of attachment patterns across generations. There appears to be a high degree of concordance between adult attachment patterns and their relations to their infants ([Main and Hesse, 1990](#)). Parents who are secure or autonomous in their view of their own parenting tend to have securely attached infants, whereas those who are dismissing tend to have avoidant infants, and those who are preoccupied have ambivalent infants. Studies of adult attachment do not purport to provide a "historically accurate" picture of an adult's childhood—adults with extremely traumatic early childhood experiences may nevertheless be securely attached. Rather, the studies of adult attachment tap into how the adult views important relationships in his or her life (the internal object world in the language of psychoanalysis), and these views, in turn, influence how the adult responds to his or her children.

### Contributions from Psychoanalysis

[Lieberman's \(1987\)](#) discussion of separation in infancy and early childhood presents suggestions for a synthesis of aspects of attachment theory and psychoanalysis. The effort to select relevant propositions from psychoanalysis regarding separation and deprivation is immediately challenged by the complexity of the theory, which emphasizes the uniqueness of the inner life of each child in determining the influence of a reality event, such as separation. The nature of the child's relationships with loved ones is seen as centrally important in determining how he or she will experience, cope with, and defend against separation from them. Antecedent experiences and phases of psychosexual, cognitive, and psychosocial development, with their expectable sources of conflict, anxiety, and satisfaction, as well as the effectiveness of adaptive and defensive mechanisms, play a part in how events acquire psychological meaning. Given this complexity, one can only illustrate this point by defining a few developmental lines and psychological processes, selected because of their demonstrated usefulness in dealing with separation issues in the very young.

In psychoanalytic developmental theory, the concept of separation involves two related but distinct perspectives: separation as a *process*, through which the child develops an awareness of the physical and mental self as distinct from all others, and separation as an *event*, in which someone experiences being parted from those to whom he or she is most strongly attached. Separation events occur throughout the life cycle, as [Bloom-Feshbach and colleagues \(1987\)](#) summarize, and the influence of these events is determined by multiple, interacting factors. The landmark studies of Margaret Mahler and her colleagues ([Mahler, 1963](#); [Mahler et al., 1975](#)) address the separation-individuation process and trace "the psychological birth" of the human infant. Mahler's theory of separation-individuation emphasizes that, although the process is never finished and reverberates through the life cycle, the principal psychological achievements are placed within the period from the fourth or fifth month of life to the 30th to 36th months. "The normal separation-individuation process . . . involves the child's achievement of separate functioning in the presence of, and with the emotional availability of, the mother. . . . This normal separation-individuation process takes place in the setting of developmental readiness for, and pleasure in, independent functioning" ([Mahler, 1963](#)).

The development of a sense of awareness of the body and mental self as distinct from all others and the gradual formation of a personal identity are aspects of the individual's view of his or her totality as a person. The self as a cohesive psychological organization is, as [Loewald \(1980\)](#) emphasizes, contingent on the differentiation between self and other. In the life of the infant, these distinctions develop in myriad day-to-day experiences and transactions with persons, sensations, and actions, in concert and interwoven with other lines of development. The awareness or *sense* of a personal identity is influenced by factors affecting perception of the external world; that is, there are important cognitive elements. Comparisons and contrasts become clearer through intellectual growth. Identity is maintained by continual redefinition ([Greenacre, 1971](#)). In this process, the nature of the child's relationships with others is a vital factor. "There is wide agreement . . . that it is those to whom the child is most strongly attached with whom the most important patterns of separation and individuation are played out as part of the process through which awareness of the separate self identity and self-esteem come into being" ([Provence, 1987](#)).

In psychoanalytic theory, *anxiety* is a response to the danger, real or imagined, of loss of a love object, but it is viewed in much more complex terms than it is in attachment theory. Inherent in the fear of object loss is the mixture of feelings that characterize love relationships: Loving, tender feelings are mingled with hostile feelings. Libidinal and aggressive cathexes of the mental representations of loved persons coexist. Longing for that person and sadness at separation or anticipation of loss, as well as shame or guilt about one's hostile wishes and feelings, stimulate eagerness for reunion.

The studies of Benjamin ([1961, 1963](#)) and Spitz ([1957, 1965](#)) contribute much to psychoanalytic approaches to understanding developmental aspects of anxiety. Freud's ([1926/1959](#)) introduction of the concept of anxiety, psychological pain, and mourning as responses to object loss forms the background of these and other studies. Two overlapping but different anxiety responses occur during the first year, defined operationally as *infantile stranger anxiety* and *infantile separation anxiety*. Fear of loss of the loved person in reality, fear of loss of that person's love and approval, fear of loss of the loved self, and fear of one's own disapproval in sequence overlap and span the years of infancy and early childhood. Each of these phase-associated anxieties influences the way in which separation or the withdrawal of parental interest is experienced by the child.

The developmental progression in the child's psychological life in regard to separation anxiety begins with reaction to loss of what Benjamin calls a *preobject*, a person or persons who can reduce tension and provide security and pleasure, and it progresses to fear of loss of a *differentiated* object, a particular person one knows and loves. [Benjamin's \(1963\)](#) hypothesis that fear of loss of the person one loves and depends on is the immediate dynamic determinant of separation anxiety appears valid. With its later derivative, fear of loss of love, it is universal or nearly universal in our culture in psychologically healthy children, although varying in intensity.

Psychoanalytic developmental theory also brings to bear on separation propositions regarding the stability and permanence of psychic representations. In this connection, the construct of *object constancy* has relevance. It is believed that the child's ability to cope with the stress of separation events leans heavily on the capacity to evoke reassuring mental images of those to whom the child attributes his or her sense of security and well-being. Solnit's definition is useful: "Object constancy is that state of object relations in which the child has the capability to retain the memory of the emotional ties to parents, . . . and to feel their nurturing, guiding presence even if they are a source of frustration or disappointment or when they are absent" ([Solnit, 1982](#)).

[Fraiberg \(1969\)](#) does much to clarify issues regarding the development of object constancy, a term that has been used differently by various psychoanalytic theorists and investigators. She supports a view put forward by [Nagera \(1966\)](#) that one may distinguish between the very beginnings of object constancy in the first year and its attainment at the end of the second year. Similarly, [Mahler \(1966\)](#) indicates that the achievement of object constancy is a characteristic of the fourth subphase of

separation-individuation, when, as [Hartmann \(1962/1965\)](#) suggests, mental representations of the mother become intrapsychically available. Fraiberg reviews the concept of object constancy in its libidinal and cognitive aspects and distinguishes between the formation of the libidinal tie during the first year and the attainment of object constancy, which requires the development of crucial cognitive structures. Evocative memory, demonstrable in the middle of the second year, is probably a necessary, although not sufficient, condition for the child's awareness that the loved figure from whom he or she is separated has not been lost. Object permanence and mental representation in Piaget's sense, occurring at around 18 months, appear to be cognitive predecessors for the development of object constancy in the psychoanalytic sense. Anxiety at separation, however, is not necessarily traumatic. The concept of anxiety as a signal affect through which adaptive and defensive mechanisms are prepared and mobilized is relevant. If not overwhelming at a given point, anxiety sharpens perception of the self and others and of the ways in which challenges can be met and, thus, contributes to personality organization and health.

### Contributions from Other Developmental Psychologies

Other psychological theorists and investigators have contributed constructs that have heuristic value in views of separation and deprivation. [Escalona \(1963\)](#), in bringing together aspects of ego psychology and Lewin and Piaget's studies of the development of intelligence, says

My data suggest the possibility that what Piaget proposes for cognition is true of all adaptive aspects of mental functioning: namely, that the emergence of such functions as communication, modulation of affect, control over excitation, delay and aspects of object relations, and hence identification; all are the result of a developmental sequence in sensory motor terms before they merge as ego functions in the narrower sense.

Deprivation experiences, in particular, would begin to exert a noxious effect on these adaptive functions from early in life. [De Carie \(1965\)](#) demonstrates a significant correlation between stages of affectivity and Piaget's theory of cognitive constructions of the inanimate object. [Bell \(1970\)](#) finds that infants develop a concept of a person's independent existence (person permanence) even more quickly than a homologous concept of inanimate objects, findings that reflect Piaget's realization of the emotional importance of the mother. Piaget sees affectivity as the energy source on which the full functioning of intelligence depends. Neither can exist functionally without the other. Emotional processes can accelerate, delay, or disturb mental acquisitions ([De Carie, 1978](#)). Concepts of recognitory versus evocative memory, means-end relationships, time and space, progression from prerepresentational sensorimotor schemes to representational and symbolic thinking, verbal communication, fantasy, and perception of reality are among other cognitive constructs found useful in examining issues of the effect of separation and deprivation experiences.

### PARENTING REQUIREMENTS FOR SECURE ATTACHMENT AND RELATED DEVELOPMENTAL CAPACITIES

[Winnicott \(1961\)](#) emphasizes that the young baby is essentially part of a relationship; that is, if you set about to describe a young infant, you find you are always describing a baby *and someone else*. Synchronous communication begins in the newborn period as the nurturing adult responds and learns the baby's rhythms, attentional behaviors, comfort-discomfort "messages," and affective states ([Condon and Sander, 1975](#); [Sander, 1980](#)). The very terms *dialog* ([Brazelton and Cramer, 1990](#)) and *the dance* ([Thoman and Browder, 1987](#)) are efforts to capture the reciprocity, mutuality, and transactional nature of the relationship from the beginning. However, it is an uneven partnership because the baby's dependence needs are great, and so we define a facilitating environment as one that parent figures have the responsibility, gratification, and fulfillment to provide. That parenthood demands adaptation and growth and that the tasks and responsibilities are, at times, strenuous and worrisome are reality.

A conviction about the central importance of the child's human relationships for his or her growth and development physically, cognitively, and emotionally is shared by several developmental theories. Whether one prefers psychoanalytic formulations regarding object relations, ethologic attachment theory, social learning theory, self-psychology, or other perspectives, there is strong consensus about the essential role of relationships with parents and others close to the child for his or her psychological well-being and the damage, short-term or long-term, that may occur when relationships are seriously deficient or jeopardized. When infants are deprived of the experiences that comprise good nurturance from their caregivers, and when there is significant discontinuity of care through separation events, there can be interferences and distortion in many aspects of development.

Among the important features of the type of parental care that facilitates development are the following: continuity of care and affection from primary persons who are predictable and trustworthy; the development of a close relationship between adult and child, initiated by the parents' desire to love and nurture and the infant's responsiveness; specific types of stimulation addressed to physical, social, emotional, language, and intellectual growth; models for the development of controls, self-regulation, and socialization through education and guidance in an atmosphere of loving attention; and transmission of societal and cultural values through influencing the manner in which the child solves the tasks imposed by each phase of his or her epigenetic psychosocial development.

Continuity of affectionate care by one or a small number of caregivers who can give of themselves emotionally, as well as in other ways, originates the development of the child's love relationships. The formation of social bonds and of social and emotional communication, the development of a sense of confidence or trust in others, the perception of the parent as the source of security and protection, and feelings of self-esteem depend on such care and its reliability. Affectionate and stable patterns of experience facilitate the baby's ability to organize physiologic and psychological processes ([Escalona, 1968](#); [Greenspan, 1981](#); [Sander, 1980](#)) from early on and influence perceptions of the outer world and of the child's inner sensations, feelings, and thoughts. For example, being loved and esteemed by others is believed to be at the heart of the ability to love oneself, and self-love is a part of the capacity to love another in turn. For another example, having repeated experiences of being comforted when distressed is a part of developing one's own capacity for self-comfort and self-regulation, and later, the capacity to provide the same for others.

Specific types of experiences likely facilitate the formation of secure attachments and, moreover, enhance particular aspects of a child's development. For example, the infant's being talked to by his or her caregivers is very important in speech development. Progress in the ability to communicate verbally occurs when intrinsic maturational events interact with environmental influences that organize and give meaning to the child's utterances. The presence of a speaking, interested social partner is vital. Similarly, motor skills, as opposed to mere motor discharge, are stimulated by an array of tactile-kinesthetic experiences that occur in the process of good care and later by opportunities to practice emerging skills in a safe environment. The growth of intelligence in the early years is enhanced by variety, contrast, and novel stimuli when these occur in the context of essentially stable and developmentally appropriate patterns of experience with the environment. The provision of toys and other inanimate objects to manipulate and explore is important for negotiating the stages of sensorimotor intelligence ([Piaget, 1952](#); [Piaget and Inhelder, 1969](#)), which takes place in concert with structuring of the affective life. The parent also is important as educator and guide, helping the child to identify aspects of reality, that is, both as a source of information and as a reinforcer or modifier of the child's cognitive expectations.

The parental role in the child's coming to interact effectively with the environment is significant in both its learning and its motivational aspects. [Hartmann \(1958\)](#) emphasizes the importance of the child's social relationships in the learning that is essential for many of the child's adaptation processes. Robert [White \(1959\)](#) and Lois [Murphy \(1974\)](#) emphasize the beneficial influences of experiences of mastery in adaptation. Coping involves original, imaginative, and innovative behavior and helps the child to manage both his or her inner experience and the demands of the outer environment. Studies of the origins of competence in the child, motivation for mastery, and relationships between motivation and cognition ([Harter and Zigler, 1974](#); [White, 1975](#); [Yarrow, 1981](#); [Yarrow and Pederson, 1976](#)) further support the view of the importance of an environment in which adults sensitively respond to the child's needs and provide responsive materials.

Parents, as models for the child in the establishment of controls over impulse and behavior, make a significant contribution to the development of a healthy personality. Whether one regards the process as establishing ego control over the drives or as the socialization process, the influence of good parenting is acknowledged. Through the relationship and with the necessary guidance in an atmosphere of loving attention, the child comes to wish to please those persons he or she loves and is motivated to behave in ways of which they approve. The child imitates, identifies with, and gradually incorporates aspects of their behavior, attitudes, and values, making them his or her own. This condensed statement greatly oversimplifies the process through which the child moves toward ego maturity, control over sexual and aggressive impulses, affect regulation, and superego formation. Here, perhaps, it can only be repeated that parents as models and guides play a central role, and, in their absence or severe dysfunction, this aspect of personality development suffers.

### SEPARATION AND DEPRIVATION AS THREATS TO SECURE ATTACHMENT AND RELATED DEVELOPMENTAL CAPACITIES

Traumatic separation and deprivation endanger the development of healthy attachment relationships with others and the formation of social bonds. If one accepts the idea that the child's sense of security, basic trust, and knowledge of others and of self are anchored in and flow from the care of one or a small number of affectionate, available caregivers, then frequent and long disruptions in the interactions with the person one has come to trust and love or deprivation of essential nutrients in caregiver-child interactions can be identified as threats. Infancy research and clinical experience confirm that a growth-inhibiting environment for an infant in the first year exists when caregivers are unavailable, are understimulating or overstimulating, are emotionally distant, are ambivalent, or fail to respond contingently to the

infant's communication across multiple sensory and affective systems ([Greenspan, 1981](#)). In contrast, a growth-promoting environment is characterized by invested, comforting, guiding caregivers who “woo” the infant, encourage the “dialog,” respond appropriately to the infant's communications, and, in the process, transmit feelings as well as bits of “information” about the human and inanimate world that become vital factors in general learning, as well as in relationships with others. Progression from sensorimotor modes to the organization of internal representations of self and other persons and other symbolic elaborations of mental imagery is also sensitive to severe deprivation in the environment and to multiple changes in the continuity of adequate child care. Thus, there is reason for concern about interferences and distortions, especially in the young child's coming to love himself or herself and others, and in his or her relationships with caregivers, peers, and others in his or her social environment.

Language, both speech and nonverbal communication, is particularly sensitive to deprivation and separation. Even though speech and the elaboration of social signals have an inner, biological, and maturational basis, their blossoming as agents of communication is closely related to the releasing and stimulating influence of the environment. Infants and toddlers, for example, who are not talked to by their caregivers in families and elsewhere are delayed in speech development ([Provence and Lipton, 1962](#); [Spitz, 1945](#); [Spitz and Wolf, 1946](#)). Many years ago, Lewis wrote: “When does a child begin to speak? . . . If not at the moment of birth, then certainly during the first day. For as soon as a child cries and someone pays attention to his cry, the first steps are taken; the essentials of language are there” ([Lewis, 1959](#)). The presence and attention of the primary parent, usually the mother, influence the development of speech in several ways, through reinforcing the baby's vocalization, the development of mutually imitative vocalizations that encourage the use of an expanding repertory of sounds, and the “labeling” of people, toys, actions, feelings, and the like ([Bornstein, 1989](#)). The mother's speech is also a carrier of emotions and an organizing influence on the infant's psychological life. The sounds that form the building blocks for speech are believed to gain specific meaning because of the parents' response to them. For example, the “Mama” and “Dada” sounds that emerge as a result of maturation at somewhere around 9 months become names for the parents because of their strong affective response and reinforcement. Speech development is a very complex function, and there is considerable variability in its development within what we consider normal. That being acknowledged, the sensitivity of speech development to disruptions in relationships with the partners in communication and to a verbally impoverished environment is a signal to the clinician to look closely at the child's experiences with his or her caregivers.

The adverse and often long-lasting consequences of traumatic separation or deprivation are rooted in changes to the developing brain. Because of a high degree of neural plasticity, it is generally believed that the infant's and young child's brain is particularly sensitive to experiences that promote or hinder development in not only sensory and linguistic but also emotional domains. The underlying mechanisms, although not completely understood, involve synaptic formation and pruning. “Neuronal groups of cells that are frequently and/or intensely stimulated through environmental stimulation are thought to be selectively amplified, forming cortical maps with defined functions. Conversely, cells that do not form functional synapses are retracted” ([Nelson and Bosquet, 2000](#)). For example, evidence suggests that infants between 6 and 18 months who are repeatedly exposed to negative or flat affect and to little positive affect and synchronization during social interactions with their clinically depressed mothers develop atypical electroencephalographic patterns reflecting a hyperarousal of the right frontal lobe (which mediates negative affect and withdrawal behavior) and a hypoarousal of the left frontal lobe (which underlies positive affect and approach behavior) ([Nelson and Bosquet, 2000](#)). Once established, these and other patterns of brain organization and activity become somewhat resistant to change.

## CONTRIBUTING AND MEDIATING FACTORS

### Poorness of Fit

*Goodness of fit* and *poorness of fit* are terms used to describe the way in which infants and their parents enter into and achieve good adjustment to one another or have great difficulty doing so. Difficult temperamental characteristics ([Thomas and Chess, 1977](#)), unusual sensitivities ([Bergman and Escalona, 1949](#)), and congenital characteristics of activity and reactivity ([Korner, 1974](#)) can make some infants difficult to care for by even the most expert of parents. Some infants' characteristics, even if not difficult, may not fit well with their caregivers' preferences ([Colin, 1996](#)). Other infants may be disappointing to their parents because of their unconscious meaning. These problems in mutual adjustment interfere with a beneficial parent–child relationship and become a pathogenic influence. Various forms of deprivation and traumatic separation events may result from such situations ([Kris, 1962](#); [Provence, 1965](#); [Provence, 1983](#)). Among the more significant opportunities for preventive intervention is the early recognition of parent–child interaction that reflects problems in reciprocity and mutual adjustment.

### Maternal Factors

Many conditions in the mothering person contribute to or complicate deprivation. Maternal depression, for example, often results in a mother's being psychologically unavailable to the child at times, appropriately and lovingly attentive at times, and intrusive and hostile at others. Her failure to respond contingently results in deprivation experiences for the baby, even when she is physically present ([Cohn, 1993](#)). Maternal ambivalence in behavior and attitude toward the child is both confusing and painful, interfering, among other things, with a secure attachment and the orderly progression of separation-individuation, self-esteem formation, and affect regulation. Children who are uncertain of the parent's love, guidance, and protection are especially vulnerable to separation. Mothers with severe psychiatric disorders become dysfunctional in a variety of ways. A mother whose own reality awareness is impaired is unable to represent reality for her infant. If she is unpredictable in her behavior toward her infant, those developmental steps that flow from a sense of trust and security will be impeded; if she is severely disorganized, the baby is likely to suffer from pervasive problems of regulation, both of physiologic and psychological functions. If the baby is a part of her delusional system, the baby may be in gross danger ([Anthony, 1974](#)).

A mother impaired by drugs or alcohol is unable to provide the type of care that promotes the child's development, both because of her unavailability in the positive sense and because poor control of aggressive behavior may result in abuse ([Mayes, 1995](#)). If she has been a substance abuser during pregnancy, the infant is potentially at both biological risk and environmental risk ([Chasnoff et al., 1984](#); [Howard et al., 1989](#); [Jones and Lopez, 1988](#)). Parental substance abuse presents a continuum of vulnerability and risks for the children involved. Chronic substance abuse (e.g., alcohol, heroin, or cocaine) may impair an adult's psychological functioning in domains basic to parenting (e.g., persistence, concentration, memory). Moreover, for the most part, substance abuse involves the adult in related environmental conditions including poverty and homelessness, frequent violence and family discord, poor physical health, and unstable, erratic relationships with others. Mothers who are chronic substance abusers most often cite their social isolation and deep loneliness as the states of being that most interfere with their ability to reduce or stop their addiction ([Mayes, 1995](#); [Tucker, 1979](#)).

Physical abuse and sexual abuse are actions by parental figures against children that stem from the psychological and social pathology of adults. They may be concomitants of deprivation; traumatic separation experiences may be part of the picture. Abusive acts may also occur in child-rearing environments that contain positive features as well. For such children, careful clinical assessment is the basis for recommendations about whether the dangers to physical and emotional survival outweigh the advantages of remaining with the parent. The presence or absence of family members who can adequately protect the young child will be an important determinant of decision making. Separation from abusing parents and placement in a nurturing environment may permit emotional healing and may restore the young child's chances for adequate development ([Goldstein et al., 1979](#)).

### Child Factors

Factors in the child that heighten his or her vulnerability to deprivation and traumatic separation are referred to throughout this chapter. However, young children vary in their vulnerability to noxious biological influences, as well as to environmental situations associated with poor developmental outcome in others.

Genetic disorders associated with mental subnormality (chromosomal or biochemical), malformations of the central nervous system of obscure origin, toxic insults, infections, malnutrition, and perinatal insults such as hemorrhage and hypoxic injury make the young child more vulnerable to the adverse effects of separation and deprivation. Sensory deficits such as deafness and blindness and musculoskeletal disabilities, whatever their cause, delay or disrupt the developmental process. Children deemed vulnerable or in need of particularly skilled parenting, such as those called temperamentally slow to warm up or difficult, those with sensory processing problems, and those with unusual sensitivities, often come to attention because of difficult behavior or delays in aspects of development. Such children often have difficulty with many phase-specific aspects of early development including the usual day-to-day separations between parent and child.

Child characteristics, congenital or acquired, may underlie clinical disorders for two reasons: Intrinsic factors may complicate the nurturing process, and maladaptive child-rearing styles and attitudes may be evoked in the parent by these specific characteristics. Thus, there is often an interaction between basic biology and patterns of parenting that further exacerbates developmental vulnerabilities and responses to situations such as separations.

The child's developmental level and personality organization at the time of separation or deprivation are of great import in determining their influence. A 10-month-old infant, for example, will have both the perception of loss of the differentiated object and distress and despair if a separation is prolonged and there is no satisfactory surrogate. The infant will have very limited resources for self-comfort and will be largely dependent on others to alleviate his or her distress. The 4-year-old child who

has been well cared for and who is developing adequately, in contrast, can identify and verbalize feelings and ask questions. He has enough sense of time (before and after, today and tomorrow) and place to use explanations and reassurance. He has play skills that enable him or her to express as well as to work at mastery of the anger and discomfort through action and fantasy. He will also have available mental representations of those whom he loves and who are sources of security that can be evoked in time of need, and he will have developed coping strategies and defense mechanisms that can be mobilized to deal with the stress of separation.

### Mother-Child Relationship Qualities

The effects of separation or deprivation are mediated not only by the developmental level of the child and by the presence of child and maternal risk factors, but also by the nature of the caregiver-child relationship. "The risk for psychopathology is highest when multiple factors coincide to increase the child's anxiety about his or her parent's availability" (Kobak, 1999). Insecurely attached children are more likely to interpret even temporary disruptions as threats to parental availability. Moreover, for older children, the effects of disruptions such as divorce, parental dysfunction or illness, or even parent-child conflict are likely biased by the nature of current communication in the relationship and not only by the child's internal working model (Kobak, 1999). Although open communication and secure working models often go hand in hand, for insecurely attached children, dysfunctional communication patterns may exacerbate a child's insecurity and symptomatic expressions. Research is only beginning to attend to the role of problematic communication in influencing the perception of separations as threats to availability and, thus, to attachment security.

### Alternative Attachment Relationships

Attachment research generally has focused on the mother-child relationship. However, in the United States, children now are regularly cared for by multiple caregivers (e.g., fathers, grandparents, child care providers), and the role of alternative attachment figures is becoming the subject of increasing empirical research (Howes, 1999; van IJzendoorn et al., 1992). The organization of multiple attachment relationships and internal working models remains unclear (i.e., hierarchical versus integrative or independent), as is their influence on children's long-term development (Main, 1999). Yet there is emerging support for a nonhierarchical model of organization (Howes, 1999; Howes et al., 1998; Suess et al., 1992), and thus developmental consequences may be best predicted by considering the quality of all attachment relationships or even may be linked to particular attachment figures. Further research is needed to clarify how or whether alternative attachment relationships buffer the child who experiences disruption or deprivation in his or her relationship with a mother figure.

### Situational Events

As indicated, whether deprivation and separation are short term or long term and occur in a well-functioning or dysfunctional family will also make a difference in impact on the capacity of the family to respond to a crisis or a planned separation in a way that is protective of the young child. The latter includes, for example, the adequacy of the child-rearing arrangements during the parents' absence. Other factors that precipitate separation, such as illness of child or parent, divorce, natural catastrophe, and social upheaval, are diverse examples of the contexts of separation, each bearing its own set of conditions that affect the child and those closest to him or her.

## CLINICAL OUTCOMES

Clinical experience is replete with examples of consequences of deprivation and traumatic separation, described as delays, syndromes, or disorders.

### Problems in and Disorders of Attachment

Insecure and disorganized attachments, as classified by the Ainsworth Strange Situation, have been increasingly reported as characterizing infants whose mothers, for a variety of reasons, have been unable to respond to them sensitively and contingently (Ainsworth et al., 1978; Bretherton, 1985; Easterbrooks et al., 1993). Although less than ideal in quality, insecure and disorganized attachments reflect typical variation in attachment security observed among infants and children in the Strange Situation. The disorganized pattern is the most problematic of the nonsecure classifications because it is associated with many adverse sequelae (Lyons-Ruth and Jacobvitz, 1999). The Strange Situation is a superb research tool and can be useful to clinicians as a marker suggesting the need for further exploration of the child-rearing environment in that it captures aspects of the mother-infant relationship. However, the results of the Strange Situation are not established as valid for clinical work in individual cases, and the data derived must be integrated with other knowledge about the infant from other sources, to be useful as a clinical instrument (Ainsworth, 1980; Gaensbauer and Harmon, 1982; Greenspan and Lieberman, 1988; Weitzman and Cook, 1986).

Conversely, clinicians, using information from a broad context, are accustomed to diagnosing reactive disorders of attachment in infants and young children that are often the result of multiple separations and depriving environments (Tibbitts-Kleber and Howell, 1985). A current conceptualization of attachment disorders and diagnostic criteria have been proposed by Zeanah and his colleagues (Lieberman and Zeanah, 1995; Zeanah and Boris, 2000). This approach delineates three broad types of attachment disorders: (a) disorders of nonattachment, (b) secure-base distortions, and (c) disrupted attachment disorder. It is recommended that criteria be viewed as dimensional such that if behavioral signs are usually or often present, then an *attachment disorder* is defined, whereas if behavioral signs are only somewhat or sometimes evident, then an *attachment disturbance* is present (Zeanah and Boris, 2000).

First, *disorders of nonattachment* are characterized by the absence of a preferred attachment figure. There are two types: (a) *nonattachment with emotional withdrawal*, in which the child is also emotionally blunted, markedly restricted in comfort seeking and affection, and avoids or fails to respond to social overtures; and (b) *nonattachment with indiscriminate sociability*, in which the child not only fails to use a preferred caregiver for support, protection, and nurturance but seeks proximity, interaction, and comfort indiscriminately, even from strangers, without age-appropriate anxiety toward unfamiliar people (Zeanah and Boris, 2000).

The second general type of attachment disorder is known as a *secure-base distortion* in which a child's relationship with an attachment figure is marked by serious behavioral disturbances *specific to that relationship*. Four different types of secure-base distortions have been described: (a) *attachment disorder with self-endangerment*, in which the child fails to return to his or her secure base and engages in dangerous and provocative behaviors such as running out into traffic, climbing up on ledges, and self- or caregiver-directed aggression; (b) *attachment disorder with clinging or inhibited exploration*, in which the child is unwilling to venture away and explore; (c) *attachment disorder with vigilance or hypercompliance*, in which the child neither clings to the caregiver nor explores, and instead engages in emotionally constricted watchfulness and obedience; and, finally, (d) *attachment disorder with role reversal*, in which the child appears oversolicitous and preoccupied with the caregiver's emotional well-being. The final type of general disorder of attachment is referred to as *disrupted attachment disorder* and applies to a child who is suddenly separated from an attachment figure from days to weeks and reacts to the loss of that attachment relationship with the typical sequence of protest, despair, and detachment (Zeanah and Boris, 2000).

### Object Constancy Delay and Instability

Disturbances in the development of a sense of self and the separation-individuation process occur when the benevolence and reliability of caregivers are grossly inadequate. As already indicated, children who do not feel valued cannot value themselves. Those whose sense of self is not nurtured and reinforced by the affection, protection, and guidance of parent figures have little opportunity to develop the pleasure and confidence in independent functioning that is an integral part of healthy personality development. The attainment of emotional object constancy and a stable sense of self is a main task of the subphase of separation-individuation, occurring, roughly, in the third year of life (Mahler et al., 1975). Disturbances in the separation-individuation process are inferred from the behavior of young children in the third year and beyond, when separation becomes a severe problem, and maladaptive "solutions" to the feelings associated with separation are manifest. Many empirical studies of children entering nursery school support several clinical impressions. Bloom-Feshbach (1987), in studies of 3-year-old children, found clear distinctions between emotionally healthy children and those with problems. After an initial period of adjustment, including protest at separation, emotionally healthy children were better able to seek and use teachers for help and comfort when needed, they investigated the environment more actively and with greater satisfaction, they interacted more confidently with peers, and they regulated their feelings more adaptively. Their behaviors suggest favorable progress in personality organization, healthy coping with stressful events, and the ability to make use of and enjoy a larger world of experience. In contrast, children with problematic separations were marked by the emergence of symptomatic behavior ranging from severe and prolonged distress, to defiance, to apathy. Symptomatic behavior may reflect internal difficulties in differentiation, self-esteem, and identity formation. According to Mahler, Pine, and Bergman (Settlage, 1974), danger signals during the separation-individuation process during the second and third years include the following: the absence of the normal mood of elation related to a sense of power, expected in early toddlerhood; a proclivity toward a depressive mood; and, in some instances, a marked increase in aggressive behavior. Among the behavioral signs of a tendency toward marked ambivalence toward the parent is a greater than average separation anxiety. Clinging, demanding behavior, and protest, as well as superficial indifference and detachment, may occur.

## Affect Regulation Dysfunction

Disturbances in modulation and regulation of affect are frequently found in infants and young children who encounter deprivation and traumatic separations. Range, differentiation, intensity, and expression of feelings as reflected in behavior are interfered with in these children. Regulatory mechanisms that favor the infant's capacity (a) to recognize pleasure and joy, and their opposites, in himself or herself and in others; (b) to tolerate these perceptions; and (c) to develop self-regulation strategies to modulate feelings depend, at least in part, on the infant's interactions with the environment. Insufficient "supplies" and severe disruptions tend to starve or overwhelm the system. Responses and "solutions" ensue, which may have short-term utility but prove to be maladaptive in the long run. At the mercy of poorly regulated affects, young children manifest various problems, including difficulties in peer relationships, severe anxiety, constriction or wide swings in expressive behavior and mood, and conflicts with parent figures. Outbursts of anger, "giddy" excitement, impulsive actions, and panicky behavior may coexist with excessive compliance, blunted affect, depression, or apathy.

## Developmental Delays

Developmental delays in motor, language, intellectual, and social or emotional behavior occur singly or, more often, in combination in instances of repeated separations with deprivation. The classic example of multiple developmental delays found in infants living in foundling homes and other residential institutions has produced a very extensive literature, of which only a small sample is cited here ( [Ainsworth, 1972](#); [Bowlby, 1951](#); [Bowlby, 1958](#); [Provence and Lipton, 1962](#); [Yarrow, 1961](#)). Disturbances in the quality of social relationships and emotional expressiveness occur simultaneously with difficulties in versatility in coping with challenge or stress and in flexibility in thought and problem-solving. Major improvements in the environment, especially the quality of nurturing, are accompanied by encouraging gains, and yet concerns about long-term effects on capacities for mature interpersonal relationships and adequate functioning in the society remain. Less pervasive developmental delays are found in situations that may not immediately be identified as depriving. Infants of mothers with masked depression, for example, may present with delays in discrete areas, such as speech or range and variety of emotional expression, in which developmental findings in the infant are clues to maternal dysfunction ( [Coleman and Provence, 1953](#); [Fendrick et al., 1990](#); [Field, 1995](#); [Provence, 1983](#)).

## Failure to Thrive and Eating Disorders

Environmentally based failure to thrive, as a syndrome defined as a severe deficit in rate of weight gain in the absence of physical disease, was first described, according to [Drotar \(1985\)](#), in association with compromised nurturing in institutional environments ( [Chapin, 1908](#); [Chapin, 1915](#); [Spitz, 1945](#)) and family settings ( [Patton and Gardner, 1963](#); [Talbot et al., 1947](#)). Reduced human potential, as well as the need for a spectrum of services from pediatric hospital care, to foster homes, to psychiatric treatment of severe emotional disturbance, are associated with this condition. Studies have underscored significant individual differences in origin, age of onset, severity of growth deficits, developmental and behavioral problems, and family stress ( [Chatoor and Eagan, 1983](#); [Drotar, 1985](#); [Ferholt and Provence, 1976](#); [Mayes and Volkmar, 1993](#); [Woolston, 1983](#)).

Eating disorders are not uncommon in infants and young children experiencing depriving environments and traumatic separations. They range from anorexia to insatiable appetite, from food refusal to overeating, and from malnutrition to obesity. Deprivation in regard to feeding has several meanings: fewer calories than are required for normal growth; being fed, not according to one's own appetite and rhythms but by the schedules or whims of the caregivers; and missing the physical and social stimulation and connectedness that occur when one is fed by an attentive, attuned feeder. The "stomach love" of the young infant for the mother is a metaphor for a mosaic of sensations, perceptions, emotions, and mutual adjustments. Multiple factors determine the extent to which unsatisfactory feeding experiences will result in clinical disorders, including, as is true in other respects, antecedent experiences, the phase of development during which they occur, and the child's unique endowment and state of physical health. However, when the positive conditions of a satisfactory feeding experience are in short supply, when the relationship with the feeder is disrupted, when mealtime is a time of turbulence or battle, when the child's cognitive and affective expectations are repeatedly violated, eating problems of one type or another may ensue. The finding that these disorders are usually not the sole clinical findings or necessarily the most significant ones for emotional health requires the coordinated efforts of pediatric and mental health experts. A developmental approach to feeding disturbances that looks at numerous factors in the child and the environment is likely to lead to improved understanding, treatment, and preventive intervention ( [Chatoor et al., 1985](#); [Mayes and Volkmar, 1993](#)).

## Psychiatric Disorders

Psychiatric diagnosis in the early years of life is fraught with difficulty. Aside from agreement about certain syndromes associated with troubled parent-child relationships, including those in which deprivation and separation play a part, clinicians encounter the problem that currently available systems of classification are far from adequate. Examples of efforts to clarify the diagnostic nosology for younger children include the *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood (Zero to Three, 1994)* and Zeanah's typology of disturbances in attachment cited earlier ( [Lieberman and Zeanah, 1995](#); [Zeanah and Boris, 2000](#)). Limited data on the outcome of early-onset disorders, how developmental change affects syndrome expression, and the degree of dysfunction that should be labeled as clinical disorder complicate classification. That infants and young children become depressed and develop psychophysiologic and psychosomatic symptoms and behavior problems is well known, but there is need for a more systematic developmental approach to the classification of early childhood disorders. Disorders of affect, in the early years, for example, can be defined as those that pose serious risk for distortion of expectable development. For a diagnosis of *anxiety disorder*, the child should exhibit the following: (a) excessive levels of anxiety and fear, as manifested by multiple or specific fears; (b) excessive separation or stranger anxiety; (c) panic without clear precipitants; or (d) inappropriate absence of expectable anxiety or fear. *Mood disorders* include the following: (a) prolonged bereavement or grief reactions that interfere with development; that is, normal grief reactions qualify for designation as a disorder if they are excessive; (b) depression of infancy and early childhood, reserved for those who exhibit a pattern of depressed mood with diminished interest or pleasure in developmentally appropriate activities; or (c) a diminished repertory of social interactions and initiative. The term *deprivation syndrome* may be reserved for those in whom gross parental neglect of basic physical or psychological needs or the absence of a stable primary caregiver is evident ( [Volkmar and Provence, 1990](#)).

## INTERVENTION

The rapidly growing literature on early intervention programs addresses effectiveness of treatment for the impact of separation and deprivation. These programs vary widely in sponsorship, specific types of problems addressed, and theoretical orientation of those who conduct them.

### Psychotherapy

In general, *clinically oriented programs* can be classified as (a) those directed primarily at strengthening or supporting families in their child-rearing functions (i.e., caregiver-focused services); (b) those that provide direct services to the child with little or much parent involvement; (c) those whose focus is on simultaneous work with parent and child, aimed at facilitating the relationship between them; and (d) those that take place in extrafamilial settings. One model of caregiver-focused intervention is the parent as recipient of developmental guidance, a generally educative model, but also conceived as a process in which facts and information are provided in the context of a working relationship and in accordance with what parents are ready to hear and able to use. The assumption is that such guidance will enhance the parents' ability to function more competently and comfortably as parents for the child in question ( [Seitz and Provence, 1990](#)). Three models of work with parent and infant simultaneously or conjointly illustrate the use of the child's presence as a catalyst for change primarily in the parent. The child's development, actions, and reactions during the sessions facilitate and shape the direction of the work. For example, the method of parent-infant psychotherapy created by Fraiberg and her colleagues ( [Fraiberg et al., 1980](#); [Fraiberg et al., 1981](#); [Pawl and Pekarsky, 1983](#)) is directed at alleviation of severe conflict between parent and infant or toddler, in which the infant's development has been adversely affected. Experience with this method shows that it can be used in a broad range of cases. Emotional support, interpretation, nondidactic guidance, and counseling are integral to the process.

The Tripartite Therapeutic Design developed by [Mahler \(1968\)](#), in which parent and therapist join in the treatment of the psychotic child, engages the parent in an emotional-intellectual learning experience that permits her or him to sustain the corrective experiences for the child. This method has more recently been effectively used in other types of cases, for example, in cases of young children with severe hearing impairments in which there are problems of social and emotional communication between child and parent ( [Fields et al., 1993](#)). Still another is the Parent-Infant Interaction Model ( [Bromwich, 1981](#)), which focuses on the process of attachment. It is the role of the intervention to assess the nature of the interaction and to enable infant and parent to behave more reciprocally and with mutual enjoyment. The consequences of a positive outcome in the short term can have long-range benefits, primarily because of an increase in the sensitivity and self-confidence of the parent ( [Provence and Naylor, 1983](#)).

Preschool children and their parents are also treated in the conventional child psychiatric modes, in which simultaneous work with child and parent is carried out with careful attention to its coordination. Treating toddlers and young children singly or in small groups and treating mother-toddler groups are other useful and effective

methods of treatment. For the very young, psychotherapy has a considerable educational component directed at enhancing autonomous ego functions but with careful attention to its appropriateness in the child's emotional life ( [Dahl, 1983](#); [Pruett, 1983](#)).

### Home Care for Troubled Families in Crisis

Since the mid-1970s, efforts have intensified to prevent the breakup of families and placement of children in foster care and to promote family reunification through around-the-clock response to troubled families. The Tacoma Homebuilders Model ( [Kinney, 1978](#); [Kinney et al., 1977](#)), using teams of professionals, was a successful effort that has been replicated or adapted for use elsewhere, often under public auspices ( [Schorr and Schorr, 1988](#)). The advantages of improving family functioning to avoid the many separations experienced by infants and young children in the foster care system is obvious. Paraprofessional home visitors backed up by professionals have also demonstrated success ( [Adnopo, 1993](#)). Services for the children that specifically address their psychosocial needs, as well as their educational and health needs, are essential to the success of such efforts, to minimize the impact of the deprivation and traumatic experiences that are common in troubled families. This approach requires sustained efforts to coordinate community services.

### Foster Home Care

Foster care, as part of the child welfare system, is so overburdened that many professionals perceive it as a sentence to certain emotional damage and disability for many children. That families willing to care for a child not their own would be sought as a next-best choice to the child's own family makes eminently good sense, and there are children who have been well served by marvelous foster parents. What has caused great alarm, however, is the frequency of multiple placements, long periods in limbo awaiting decisions about custody or for rehabilitation of dysfunctional parents, the inability of some foster parents to encourage a close relationship with the foster child, and, in some instances, neglect and abuse of foster children. Separation and deprivation are dangers found in situations leading to foster home placement in children of all ages. One of the most urgent needs is for timely and targeted assistance to families in trouble, to prevent their disintegration as child-rearing environments through a spectrum of family support services. Another is to recognize that the passage of time while an infant or young child is in a "temporary" situation can become a great enemy. Clinics, child welfare, mental health services (unless they define themselves as crisis oriented), and, surely, the judicial system have their own rhythms and calendars, not geared to prompt and constructive response to the compelling needs of the very young, in spite of laudable intentions. Whatever can be done to persuade the various systems involved that the dangers of physical and sexual abuse are not the only situations deserving prompt mobilization of services for children or a particular child will make for improvement in the current scene ( [Goldstein et al., 1979](#)).

### Group Residential Care

There is reason to believe that, in the spectrum of services required to care for vulnerable infants and young children, the group residential setting has a place. As a temporary place for healthy infants without families, a residential setting of good quality can be used to avoid "bouncing" from one foster home to another while a permanent placement or restoration to the infant's own family is arranged. In addition, as a therapeutic environment for infants impaired by drugs, repeated traumatic experiences, and other conditions that render them extremely difficult to be effectively cared for in families, a group residential setting may be the treatment of choice.

Such care must be organized as an active therapeutic program that includes carefully designed, individualized treatment, as well as general developmentally appropriate care. The duration of residential care for each child should be determined by the time at which he is judged to be healthy enough and well-organized enough (at whatever level) that home care by parents or foster parents has a good chance of success ( [Provence, 1989](#)).

That such a position is advocated by one whose studies of infants in institutions speak strongly against such care ( [Provence and Lipton, 1962](#)) is a measure of the growing need for alternative solutions for caring for children who cannot be maintained in their own families. It is also a realization that group residential care, in and of itself, does not have to be damaging. It appears to be a much-needed service at this time, and the knowledge of how to create a facilitating environment for infants and young children is advanced enough to make a strong argument for residential care in the spectrum of clinically sound services.

## TREATMENT OUTCOMES

Treatment outcomes in the short term are relatively easy to evaluate in infants and young children in terms of improvement across certain developmental and behavioral domains. However, judgment about the extent to which the type of treatment chosen and its specific elements have brought about change is not a simple matter. Long-term outcomes of treatment are even more difficult to evaluate. Nevertheless, the aggregation of individual carefully studied cases, as well as epidemiologic studies and evaluation of the later status of participants in early intervention programs will continue to inform the mental health field. The effectiveness of early childhood programs for socioeconomically disadvantaged infants and young children is now well established, including their long-term benefits. However, long-term outcomes, important in understanding the natural history of syndromes, should not determine the development of treatment programs. It is enough that we can recognize the need of a young child and family for psychotherapeutic and supportive services and have at hand clinically sound rationales and methods of implementing them.

## CONCLUSION

Studies of children's response to separation or deprivation inherently involve notions of risk and vulnerability and are fundamentally about the interaction between children's endowment and their parenting environment. [Werner's \(1990\)](#) report on protective factors and individual resilience—the positive counterparts of vulnerability and risk—summarizes major studies in this area. In the longitudinal study of the children of Kauai, protective factors, as well as risk factors, were identified. "The majority of resilient boys and girls were characterized by their caregivers as very active, affectionate, cuddly, good-natured, and easy to deal with, when they were infants" ( [Werner, 1990](#)). All elicited a great deal of warmth from their caregivers. Similar reports regarding resilient children ( [Murphy, 1987](#)) in middle-class families describe notable responsiveness to people and objects. Secure attachments to another family member were found in alert, responsive infants of abusive mothers ( [Farber and Egeland, 1987](#)). Resilient infants appear successfully to elicit positive attention, tend to be active, alert, and sociable, and have experienced nurturance from nonparental sources and have learned to trust its availability ( [Werner, 1990](#)).

In the contexts of secure, stable, loving relations, infants and children are more able to respond to separations, brief and long, in developmentally adaptive and facilitating ways that lead to adaptive coping, structure formation, and healthy defenses. In these contexts, separations prime the child's psychological immune system, allowing him or her to accommodate to the experiential viruses of the real world. Persistent distress, as in repeated moves from one foster home to another, predispose a child to failure in developing the ability to feel safe and secure with others or when alone, to enjoy reciprocity, or to be able to tolerate normal frustrations. Such distress is heightened in the presence of biological impairments, chronic illness, parental discord, psychiatric impairment, and inconsistent care. What constitutes a normal, immunizing dose and what overwhelms the mental adaptive immune system remain crucial questions for understanding the growth-promoting and growth-inhibiting factors involved in separation and loss.

Although separation and deprivation are not the principal topics of most contemporary empirical studies, continuing developmental research, in laboratory and clinical settings, in almost any special field one can imagine, will contribute to further understanding of early development and the impact of separation and deprivation. A trend of particular importance is in the acknowledgment of complexity in developmental processes and the trend away from isolation of variables and pursuit of linear concepts of causality toward the study of concurrent and interactive effects of multiple variables and the formulation of nonlinear concepts of causality ( [Sander, 1980](#)). A recognition of such complexity is reflected in the range of factors investigated by research since the 1980s as potential influences on infant and child attachment patterns (e.g., maternal clinical disorders, maltreatment, drug use, social support and marital quality, employment, and infant temperament, premature birth and illness) and by a concomitant increase in the number of studies that examine interactions between multiple variables. Nonetheless, a fuller understanding of the relative influence and complex relationships among identified and unidentified risk and resilience factors remains a task for future research.

[Bereavement as a Risk Factor for Psychopathology](#)  
[Differential Diagnosis](#)  
[Treatment](#)  
[Research Directions](#)  
[Chapter References](#)

The death of a loved one is one of the most painful experiences that one can suffer. Unfortunately, bereavement is not uncommon in children. For example, 4% of children will lose a parent by the age of 15 years ( [National Center for Health Statistics, 1997](#); [Ventura et al., 1998](#)). The death of a parent is a traumatic loss that can jeopardize the child's sense of security and may have long-term adverse effects. Although there has been increased recognition of the impact of parental loss on children, relatively few methodologically sound prospective studies have examined the effects of parental loss, grief, its short-term and long-term sequelae, and the value of intervention. The significance of other losses, such as death of a sibling, is even less well understood.

In a discussion of grief, several terms need to be clarified. *Bereavement* is defined as a separation or detachment that leaves one despondent. It is the physical separation from the deceased. *Grief* is the emotional pain or anguish a person feels after the loss of a loved one. *Anticipatory grief* is a similar emotional pain that may occur before an impending death. It may be experienced before the expected loss of a loved one from a terminal illness such as cancer. *Mourning* is somewhat different from grief. According to Bowlby ( [1961a](#), [1961b](#), [1980](#)), it is defined as the psychological processes that are set in motion by the loss of a loved object that lead to the relinquishment of the object.

According to the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) ( [American Psychiatric Association, 1994](#)), normal bereavement is not considered a psychiatric diagnosis. Instead, it is classified as a V code condition. V codes are conditions that may be a focus of clinical attention, but they are not attributable to any of the mental disorders. The DSM-IV suggests that, sometimes, with additional information, the presence of a mental disorder may become apparent. In some instances, however, a thorough evaluation fails to uncover any mental disorder. In other cases, the scope of the diagnostic evaluation has not been sufficient to establish the presence of a mental disorder. However, it may be useful to note the reason for contact with the mental health care system in these cases.

In adults, a depressive syndrome is frequently a normal reaction to the death of a close friend or relative. The most common symptoms are insomnia, poor appetite, and weight loss. Morbid preoccupation with worthlessness, marked psychomotor retardation, and prolonged impairment are uncommon symptoms that, if present, may suggest that bereavement is complicated by the development of major depression. The reaction to the loss rarely occurs after 2 or 3 months. The duration of "normal" bereavement varies among different cultures. In a classic bereavement study by [Clayton and Darvish \(1979\)](#), 42% of widows were depressed immediately after the death of a spouse. By the end of 1 year, however, only 16% were clinically depressed.

A prime concern regarding bereaved children is whether parental loss in childhood leads to psychopathology in adulthood. There is a lack of consensus on whether the death of a parent during a person's childhood increases the risk of problems in adulthood. Several studies address this issue from different perspectives. However, there is no clear answer. In studies of psychiatrically disturbed adult patients, there are two schools of thought. The first believes that loss of a parent in childhood has a detrimental effect that lasts into adulthood. Psychopathologic conditions such as depression, schizophrenia, drug abuse, and alcoholism have been attributed to childhood bereavement. Other investigators believe that parental loss in childhood does not contribute to adult psychopathology if the care of the child is assumed by parental substitutes ( [Osterweis et al., 1984](#)). Breier et al. (1988) conclude that child care after the loss of a parent is a crucial factor in relation to adult psychopathology.

[Kissane et al. \(1996\)](#) examined the psychosocial morbidity and coping patterns among 115 family members using a family functioning typology. These investigators found that sullen families displayed the most intense grief and the most severe psychosocial morbidity. Supportive and conflict-resolving families were considered well functioning. They resolved their grief and had a more adaptive adjustment than their less functional counterparts. The authors suggest that families at risk of increased morbidity may be identifiable and can be treated preventively to reduce psychosocial morbidity among surviving parents and children.

[Dilworth and Hildreth \(1998\)](#) believe that prior research efforts to study the long-term impact of childhood bereavement often produced ambiguous results because much of this research was conducted in psychiatric populations. When these investigators studied a normative population, the symptoms of unresolved grief of adult survivors of early parental death were identified by using an extended model of Bowlby's variants of grieving in children ( [Bowlby, 1980](#)). These variants included persistent anxiety, desire to die, persistent blame and guilt, compulsive self-reliance, and aggressive outbursts. The authors maintain that practitioners will be better able to identify and treat unresolved grief if these variants can be identified in affected adults. However, [Rainieri and Lester \(1997\)](#) did not find an association between bereavement and increased depression or suicidality in a sample of undergraduate students who lost parents during their first 18 years of life.

Additional research is needed to describe more clearly the prevalence and nature of psychiatric morbidity among adults who were parentally bereaved as children. It seems prudent, however, that practitioners attempt to recognize and address the signs and symptoms of complicated bereavement in children in an effort to minimize the possibility of morbidity and dysfunction in later life.

### EPIDEMIOLOGY

As stated earlier, 4% of children lose a parent by the age of 15 years. Yet childhood bereavement has not been studied, as well as some conditions that are far less common. The reason may be, in part, that death is a topic that many wish to avoid altogether. It is difficult for many people to be objective about this subject.

Although the death of a parent is known to be a traumatic loss for a child, there is little known about how a child may be affected by the death of a sibling. Some investigators theorize that the loss of a child in a family may have a greater impact on parents than the loss of a spouse, and this could, in turn, contribute to a more troubled environment for surviving children ( [Worden et al., 1996](#)). Some have hypothesized that if adults could come to terms with death themselves, they could better handle the emotional reactions of their children to death.

A child's reaction to death depends on his or her emotional and cognitive maturity because this affects one's understanding of death. After studying 378 children, [Nagy \(1948\)](#) believed that a child's concept of death falls into one of three categories, based primarily on age. Three- to 5-year-old children look at death as sleep or a long journey. Children from 5 to 9 years old are able to accept the fact that someone can die; however, they do not believe it happens to everyone and especially not to themselves. By 9 to 10 years of age, children are able to think of death as inevitable and know it may happen to them ( [Chapter 94](#) and [Chapter 104](#)).

There is little consensus among researchers on the percentage of surviving children who are at risk of disturbed behavior. Studies to date have methodologic limitations that include the following: (a) a lack of demographically matched nonbereaved controls; (b) the use of different measures to assess psychological problems, a feature that makes comparisons across studies difficult; (c) the use of parents and teachers as informants to the exclusion of the children; (d) the use of small and unrepresentative samples of bereaved children; and (e) the use of different age cohorts. Most studies use a cross-sectional design rather than a longitudinal design, which is preferred, given developmental changes in children with time ( [Worden, 1996](#)).

The most widely cited research on the impact of parental death on children consists of retrospective studies of psychiatrically ill adults who lost a parent in childhood and prospective studies of psychiatrically ill children who were in psychiatric treatment before their parent's death ( [Furman, 1974](#); [Wolfenstein, 1966](#)). Often such studies have few subjects, so it is difficult to generalize their findings.

Another group of studies comes from three different research groups that studied the same sample of bereaved adolescents at different points in time ( [Bendickson](#)

and Fulton, 1976; Gregory, 1965; Markusen and Fulton, 1971). The bereaved adolescents were compared with normal control subjects who were recruited at the same time and were also followed-up at the same time intervals. When first studied in the tenth grade, the bereaved group had a higher rate of delinquency. In their early twenties, the bereaved group had more legal offenses. Finally, when studied in their thirties, the bereaved subjects reported more serious medical illnesses and less satisfying lives.

Kaffman and Elizur (1983) conducted a prospective study of children 2 to 10 years of age who lived in a kibbutz and who had lost a parent in a national war. These children often had sleep disturbances, social withdrawal, and restlessness. When these children were compared with age-matched children who had lost a parent but who did not live in a kibbutz, living in a kibbutz did not appear to be a protective factor for the development of psychiatric symptoms.

The Child Bereavement Study (Worden, 1996) investigated a community-based sample of 125 parentally bereaved children from 70 families and compared them with matched controls. This study sought to identify behaviors that were overrepresented in bereaved children when compared with matched controls. The surviving parent and the child were assessed using semistructured interviews. In addition, the Childhood Behavior Checklist (CBCL) and measures of self-concept and self-efficacy were obtained. Subjects were interviewed 4 months after the parent's death and again at the first and second anniversaries of the loss. Worden et al. found bereaved children as a group showed the same number of disturbed behaviors as did controls on the total problem scales up to 1 year after the death of a parent. Interviews of these same children at 2 years after the loss showed significant differences from their controls. When age and gender were considered, preteen bereaved girls showed more disturbances than matched controls at 2 years after the parent's death; however, these differences were not apparent at 1 year. After 2 years, preadolescent girls were experiencing more anxiety, depression, and aggressive behaviors than controls. Adolescent boys were more withdrawn and had more social problems than their matched controls. Adolescent girls and preadolescent boys showed no differences from their matched controls at 1 or 2 years. At 2 years, bereaved children exhibited higher levels of anxiety, depression, and social withdrawal. There were no significant group differences in delinquent behavior, aggressive behaviors, somatic complaints, or attention-seeking behaviors at either 1 or 2 years. The bereaved children had significantly lower scores on measures of self-worth and locus of control than did their age-matched controls. Most bereaved children in this study did not exhibit signs of serious emotional or behavioral disturbances. However, a sizable proportion of bereaved children at 1 year (19%) and at 2 years (21%) manifested serious problems that could require intervention.

Some studies suggest that the cause of parental death may influence the adjustment of bereaved children (Ness and Pfeffer, 1990; Shepard and Barraclough, 1976). For example, each year, 7,000 to 12,000 children lose a parent to suicide (Small and Small, 1984). Children who are bereaved as the result of a parent's suicide have been assumed to be at significant risk for psychopathology. However, only a few controlled studies have studied this situation. Pfeffer and colleagues (1997) examined 22 children aged 5 to 14 years from 16 families in which a parent or child had committed suicide. These children showed internalizing symptoms and problems with school adjustment 1 to 36 months after the death. Approximately 40% of these children experienced symptoms of posttraumatic stress disorder; 25% of families had children with elevated Children's Depression Inventory scores. Unfortunately, use of a clinically referred sample, absence of a control group, and wide variations in the time interval between death and assessment limit the generalizability of this study.

Gutierrez (1999) examined the effects of exposure to suicidal behavior in a parent on suicidal behavior in the child. Subjects were 25 parentally bereaved adolescents aged 13.4 to 19.6 years who were not clinically referred. They were assessed with semistructured interviews. Although these adolescents had experienced the death of a parent, they were not clinically depressed, did not express serious levels of suicidal ideation, and had relatively little suicidal behavior. Limitations of this study included small sample size, absence of a comparison group, and lack of minority participation.

Cerel et al. (1999) compared 26 parentally suicide-bereaved (SB) children with 332 parentally non-suicide bereaved (NSB) children in a 2-year longitudinal study. The purpose of the study was to determine the impact of parental suicide on children's grief reactions, psychiatric symptoms, and psychosocial functioning after the parent's death. SB children were more likely to experience anxiety immediately after the death, followed by anger at 6 months and shame at 1 year after death, relative to NSB children. They were less likely than NSB children to report relief immediately after the death or acceptance 1 and 2 years after the death. SB and NSB children did not differ regarding symptoms of posttraumatic stress disorder, suicidality, depressive symptoms, or severity of depression or psychosocial impairment. SB children had fewer missed days of school because of illness and had fewer physician visits for health-related problems. Limitations of this study included small sample size and underrepresentation of minority populations.

In an extension of the foregoing study, Cerel et al. (2000) examined psychopathology in the deceased and surviving parent, family stability before entry into the study, family functioning before and after the parent's death, and changes in social support and religious practices in the same 26 SB children and in 332 NSB children. Parents who had committed suicide demonstrated more psychopathology than parents who died by other means. Surviving SB parents were not more severely impaired than surviving NSB parents. SB families were less stable than NSB families. The SB children appeared to have a poorer relationship with the deceased parent than the NSB children. However, SB and NSB children had a similar relationship with their surviving parent. SB and NSB families had few differences in social supports or changes in religious beliefs after the parent's death. In general, SB children came from families with a history of psychopathology and a high degree of family disruption. Surviving SB parents, however, did not exhibit higher rates of psychopathology than NSB parents, and most had positive relationships with their children.

## SIBLING LOSS

A child's response to the death of a sibling has been studied less than a child's response to the death of a parent. Studies to date suggest that the loss of a sibling is potentially traumatic (McCown and Davies, 1995; Stahlman, 1996). When a child dies, a parent's grief is more likely to be severe, to be "complicated," and to last longer than grief associated with other losses (Rando, 1986). Thus, a sibling-bereaved child must deal both with his or her own grief and with the family environment, which is likely to be altered as a result of the parents' profound grief. For example, the surviving parents' ability to fulfill parental roles may be compromised

McCown and Davies (1995) examined 90 sibling-bereaved children over a 2-year period. Subjects were aged 4 to 16 years. Parents were interviewed about their children's behavior using the CBCL. Most children demonstrated externalizing behaviors that fell onto the aggression subscale of the CBCL. Behaviors such as "demands a lot of attention," "is disobedient at home," "is stubborn, sullen and irritable" were observed in a majority. Boys showed almost exclusively aggressive behaviors. Girls scored high on the internalizing depression subscale "self-conscious" or "easily embarrassed." The highest occurrence of behavior problems was in preschool and school-aged children. Most of the foregoing behaviors declined with increasing age. The lowest occurrence of behavior problems was in adolescents. Behaviors observed in more than 50% of adolescent girls included secretiveness and a preference for being alone. The three behaviors most frequently observed across age groups were "argues a lot," "is stubborn or irritable," and "is self-conscious easily embarrassed." This study was limited by the exclusion of children as informants.

Mahon and Page (1995) assessed sibling bereavement during childhood in 35 subjects from 11 families using qualitative measures. Surviving siblings ranged in age from 4 to 23 years at the time of assessment. Children's perception of their own bereavement and parents' perception of their children's bereavement were studied. Children reported the following as helpful: mother's support, support from friends who had lost someone through death, activities that were supportive before the sibling's death, and open communication with parents and surviving siblings. Children reported the following as not helpful: large number of funeral attendees who gathered at their homes, friends who avoided them after the sibling's death, and withholding of factual information about the death. In a few cases, the father was identified as unhelpful. All the children were functioning well. This study also suggests that children benefit from being informed of imminent death and that children should have an opportunity to decide whether to be at the deathbed or attend a funeral to say their good-byes.

Although the death of a parent and the death of a sibling are both traumatic events, there is limited information on whether a child's bereavement response varies depending on which type of loss occurs. Worden et al. (1999) combined two samples of bereaved children: (a) parent-bereaved children from the Massachusetts General Hospital study by Worden and Silverman and (b) sibling-bereaved children from the study by McCown and Davies (both studies are cited earlier in this chapter). The CBCL was administered to subjects in both studies at 4 months, 12 months, and 24 months after the death of the child's parent or sibling. This study, looking at data from the assessment conducted at 4 months, found no significant difference in the total number of CBCL-identified problems. Nor were there significant group differences between syndrome subscale scores until gender was considered. Overall, most children were doing well and did not need clinical intervention during the first year of bereavement. However, boys who lost a parent had significantly higher scores on withdrawn behavior than boys who had lost a sibling. The difference was greater for preteen boys than for teenage boys. Girls who lost siblings were more anxious, were more depressed, and had more cognitive difficulties than girls who had lost a parent. Girls who had lost a sibling tended to have more attention problems, somatic problems, and delinquent behaviors than did girls who had lost a parent. The boys who had lost a parent were more likely to have scores falling into the clinically significant range on the inward-directed problems scale, specifically withdrawn behavior, than sibling-bereaved children. More of the sibling-bereaved girls fell into the clinically significant range on the inward-directed problems scale, specifically the anxious, depressed, attentional, and thought problem scales. Of the boys who lost a parent, most had lost fathers. This was identified as an important risk factor during the first year of bereavement. For the girls in the sibling study, most had lost a sister.

The few studies of sibling loss suggest that children who lose a sibling are at no greater risk of emotional or behavioral problems than those children who lose a

parent. Most children who lose a sibling go on to do well and do not need clinical intervention. However, some of these children need help after these losses. These studies suggest that younger children (preschool and school-aged children) and girls may have more difficulties adjusting to the loss of a sibling and may manifest these difficulties with internalizing symptoms such as anxiety, depression, withdrawn behaviors, or externalizing behaviors such as attention problems or aggression. Although these studies are preliminary, they highlight the need for further study of this group of children, to help those who care for grieving children understand their behavior and to give them the support they need.

## CLINICAL DESCRIPTION

A child psychiatrist may be asked to evaluate a bereaved child to determine whether the child manifests normal grief or whether symptoms represent more serious psychiatric disturbance. Unfortunately, at present, only limited information is available from research studies to help to delineate normal grief from psychopathologic conditions in children. To provide systematic data to address this issue, Weller and Weller are conducting a research project sponsored by the National Institute of Mental Health to describe grief in parent-bereaved psychologically normal children. Although this study is not yet completed, preliminary data will be presented in the hope of providing some useful information.

In the bereaved prepubertal children studied to date, the most common presentation includes sadness and yearning for the dead parent. Prepubertal children often state that they wish to die, so they can see and visit the deceased parent. They clearly say that they do not seek death in the same way that a child with major depression does. Suicide attempts are very rare in bereaved children and should be immediately evaluated if they occur. Problems with sleep, appetite changes, difficulty with concentration, and not "having fun" with normally pleasurable activities are common. Frequently, surviving parents are not aware of these difficulties in their children. Schools tend to be sympathetic toward bereaved children and will not send them for treatment unless there is a major problem with academic or social functioning. Sometimes, bereaved children with headaches and stomachaches are taken to pediatricians for evaluation. In adolescents, problems are similar but tend to be less frequent than those observed in bereaved prepubertal children. However, it is not clear whether adolescents actually have fewer symptoms or merely report fewer symptoms. It is possible that adolescents may be either more hesitant to disclose their discomfort or unwilling to report symptoms that make them appear different from peers ([Hogan and Greenfield, 1991](#)).

A child's reaction and adjustment to a parent's death often appear to be related to the adjustment of the surviving parent. An earlier study by [Weller et al. \(1991\)](#) compared symptoms of 38 bereaved children and 38 depressed children. DSM-IV suggests that thoughts of death such as "the survivor feeling that he or she would be better off dead" or "should have died with the deceased person" are normal after bereavement. In this study, 61% of the bereaved children had suicidal ideation either by parent or child report. None, however, actually attempted suicide. Eighty-nine percent of the referred clinically depressed children reported suicidal ideation, and 42% of them had attempted suicide. Depression and other psychiatric problems in bereaved children were predicted by preexisting psychiatric disorders in the child or a family history of a psychiatric disorder (most often depression) in the surviving parent. Most children had their psychiatric symptoms "peak" at 1 month after the parent's death. However, one-third had peak symptoms 6 months after the parent's death, and one-sixth had peak symptoms 1 year after the death.

It is important to be supportive of a family that has had a major loss. This is especially true in the case of a bereaved family that includes dependent children. In this situation, the surviving parent often becomes depressed, especially if he or she has a predisposing factor (e.g., past history of depression or family history of depression). Bereaved families experience hardships, both financial and emotional. The socioeconomic status of a bereaved family usually declines. This may result in a move to a home in a neighborhood with a lower socioeconomic level and a change in schools. Moreover, the surviving parent may choose to move closer to his or her family of origin to receive more support from them. This change causes the child to be uprooted from familiar surroundings and to lose friends in addition to losing a parent.

As a practical matter, a grieving child often loses more than the deceased parent or loved one. Surviving parents are often engulfed in their own grief and are unable to provide normal parenting. In the case of the death of a parent, the surviving parent is most often the mother because 70% of parents who die with dependent children are men ([Gutierrez, 1999](#)). As a result of the death, a mother who had not been previously employed outside the home may now have to join the workforce to support the family. Children tend to resent this change, especially when they are asked to do additional chores in the home or to stay at home alone before or after school while waiting for the working parent to return. Children may also resent the surviving parent if he or she shows interest in dating or having adult companionship. Children may feel this as a betrayal of the dead parent. As children grow and mature, the manner in which they manifest grief may change. For example, a child whose grief appears to be resolving may show a resurgence of symptoms when an upcoming birthday or graduation ceremony approaches. Adolescents especially tend to grieve over the role the dead parent would have had in their lives (e.g., the bereaved parent will not be present for special events such as their marriage or birth of a child).

As discussed earlier, there is limited literature comparing parental and sibling loss. Although the death of a sibling represents a loss, it does not usually have the same implications for interfering with development that death of a parent does ([Nagera, 1970](#)). However, the loss of a sibling does present unique issues. The surviving sibling may have particular difficulty dealing with guilt, denial, a heightened sense of vulnerability, and fear about his or her own well-being ([Stephenson, 1986](#)).

As a result of his work with parent- and sibling-bereaved children, [Worden \(1996\)](#) developed the following list of the differences between parent loss and sibling loss.

1. Loss of a child may have a greater impact on parents than loss of a spouse and, thus, may contribute to a more troubled environment for surviving children.
2. Sibling loss leaves two parents to support the child, whereas parent loss leaves one.
3. Marital tensions that occur in child loss are not present in parent loss.
4. Sibling loss increases the child's personal awareness of death more than parent loss.
5. The sibling-bereaved child may experience the parents' need to replace the deceased child.
6. Parents who lose a child may overprotect the surviving children more than the single surviving parent who remains when a spouse dies.
7. After the death of a child, there may be a need to blame or scapegoat. This can also happen in parent loss but is less frequent.
8. In sibling loss, the surviving child(ren) may have been jealous of the sick sibling. Thus, there may be ambivalence to work through after the death.
9. Survival guilt after sibling loss may be exacerbated by sibling rivalries.
10. In sibling loss, children may be angry with parents for not protecting the dead sibling.
11. In some families, one of the parents may feel that the "wrong" child died.
12. Outsiders may provide more support for the child who loses a parent than for the child who loses a sibling.

---

### CASE ILLUSTRATION

J.W. was a 9-year-old boy who had two siblings with a rare genetic disorder that manifested cardiac symptoms. Four months after the death of his 7-year-old brother, J.W. was referred to an outpatient psychiatrist for evaluation of "feeling like he wanted to die by choking himself." J.W. believed that he should be with his brother but was not sure whether he would choke himself. His mother, a single parent, reported that J.W. had been sadder, more withdrawn, and less interested in "everything" since his brother's death. He had previously been a good student with many friends but was now performing poorly at school and had lost interest in his friends. He now worried that his mother and his remaining siblings would die, especially his younger sister, who had a similar cardiac condition. He had difficulty sleeping at night and had some appetite loss. He reported feeling guilty because he should have been taking care of his little brother and had sometimes fought with him. He was quite expressive about missing his brother and was worried that his sister and his mother would die. His mother reported that he used to talk to her about things but stopped after his brother's death and would never discuss his sadness about his deceased brother. The family was referred for counseling.

Seven months after his brother's death, J.W. was doing better. He was able to talk to his mother about his worries and concerns. He shared his worries about his sister's dying during surgery and was better able to talk with his mother about his deceased brother. He began to show improvement in his academic performance and to socialize more with his friends. His mood and affect improved, but he acknowledged his sadness about his brother. He denied any further death wishes or thoughts of joining his brother.

---

### CASE ILLUSTRATION

M.S. was 14 years old when her father died of lung cancer. She had been anticipating his death for a year. She was the youngest of seven children and was a good student in advanced English and science classes. She was closer to her father than to her mother. When she knew her father was dying, she refused to leave the hospital for 1 week and stayed by his bedside until he died. One month after the death, she had dysphoria, loss of interest, insomnia, loss of energy, recurring nightmares, and trouble concentrating. She was also having repeated stomachaches because of "worrying." Her menstrual cramps had become worse since her father's death, and her grades dropped in school. She was not sure whether her friends understood her feelings and was trying "to be strong for my mother." She was not pleased with her mother's decision to move out of their home "to get away from the memories." Six months after the death, she was not able to talk about her father without crying. She reported her father's death as "a shock," and she was visiting his grave twice a week. Her mother had begun dating, and this was upsetting to M.S. She had no energy and was becoming a loner. She had thoughts of suicide but reported, "I couldn't do it because it would be painful to my mom." She was staying in bed and not going to school because she was unable to fall asleep and was frequently waking up in the middle of the night. She was referred for counseling and evaluation for adjunctive pharmacotherapy.

---

## BEREAVEMENT AS A RISK FACTOR FOR PSYCHOPATHOLOGY

As mentioned earlier, bereavement in childhood has been considered a potential risk factor for subsequent psychopathology (Brier, 1989). The most common

psychiatric syndrome experienced both by children and adolescents in the immediate period after parental death is depression ( [Weller and Weller, 1990](#) ). The data for children and adolescents with sibling loss are less clear. However, depression, anxiety, and externalizing aggressive behaviors have all been described ( [McCown and Davies, 1995](#); [Davies, 1998](#); [Worden and Silverman, 1996](#); [Worden et al., 1999](#) ). Interestingly, a preliminary study found that bereaved children with a positive dexamethasone suppression test have more DSM-IV depressive symptoms than do bereaved children with a negative dexamethasone suppression test ( [Weller et al., 1990](#) ).

In regard to anxiety symptoms, earlier studies by the authors found few anxiety symptoms in the short-term period (1 to 3 months) after parental death in children and adolescents ( [Weller et al., 1991](#) ). Children reported anxiety symptoms more often than adolescents. Worrying about their surviving parent and worrying about “little things” were significantly more common in children than in adolescents. [Worden \(1996\)](#) found no difference in the presence of anxiety symptoms in children after the death of a parent until 2 years after the loss. At 2 years, the bereaved children showed higher levels of anxiety, social withdrawal, and social problems, as well as lowered self-esteem and self-efficacy. Although most bereaved children showed no serious emotional or behavioral disturbances, significant numbers of children at 1 year (19%) and 2 years (21%) had severe emotional and behavioral problems.

Somatic symptoms have been hypothesized to be increased in bereaved children because they may use such symptoms to express their emotions. [Sood et al. \(1992\)](#) found that bereaved children reported significantly more somatic symptoms than did bereaved adolescents, but overall, there did not appear to be a marked increase in somatization. The most common complaints were headaches, stomachaches, and nausea. The absence of higher rates of somatization among bereaved children has been reported in studies of parent- and sibling-bereaved children ( [Cerel et al., 1999](#); [McCown and Davies, 1995](#); [Worden and Silverman, 1996](#) ).

One group of parent-bereaved children who appear to be at particular risk of psychopathology comprises those who lost a parent to suicide. In the sample of SB children studied by [Cerel et al. \(1999\)](#), these children had more overall symptoms of psychopathology than NSB children at every time period in the study except the month preceding the death and 2 years after the death. These children were also reported to be more globally behaviorally dysregulated than the NSB children. They also showed higher overall levels of anxiety and significantly more depressive episodes and symptoms in their lifetimes. However, suicidality was not increased. Furthermore, because parental suicide is thought to be associated with a family history of mental illness, specifically mood disorders or substance abuse, these children may be at increased genetic risk of developing these disorders.

### Differential Diagnosis

The DSM-IV clearly differentiates *bereavement* (a V Code) from *adjustment disorder with depressed mood* ( [American Psychiatric Association, 1994](#) ). The DSM-IV categorizes an *acute adjustment disorder* as having symptoms that last less than 6 months after a disturbance. *Chronic adjustment disorder* occurs when symptoms last for longer than 6 months after a major stressor that has enduring consequences. Adjustment disorder with depressed mood does not fulfill the criteria for major depression, but significant depressive symptoms are present over a period of less than 6 months. The disorder is considered chronic if symptoms are present for more than 6 months.

As mentioned earlier, all the signs and symptoms of depression may occur after bereavement. A preliminary study found that 37% of bereaved prepubertal children met criteria for depression 1 month after parental death ( [Weller et al., 1991](#) ). In major depression, suicidal thoughts and attempts are common. In grief, suicidal thoughts may be present. Such thoughts, however, usually focus on wanting to reunite with the dead parent and do not involve self-deprecatory thoughts of wanting no longer to exist. Suicide attempts are uncommon in uncomplicated grief. Thus, if they occur, these children should be brought to immediate psychiatric attention. Anxiety symptoms may occur, but diagnosable anxiety disorders are uncommon immediately after death ( [Sanchez et al., 1994](#); [Worden and Silverman, 1996](#) ). Thus, the presence of an anxiety disorder should not be automatically attributed to the grieving process and should be evaluated. Somatic symptoms should be handled in a fashion similar to that for anxiety disorders because somatization in bereaved children and adolescents is uncommon ( [McCown and Davies, 1995](#) ). When somatic symptoms occur, headaches and stomachaches are the most frequent complaints, especially in prepubertal children ( [Sood et al., 1992](#) ).

The possibility that conduct disorder may occur was suggested by [Markusen and Fulton \(1971\)](#). However, more recent studies ( [Worden and Silverman, 1996](#) ) found no differences in delinquent behavior between bereaved children and age-matched controls.

### TREATMENT

If grief is a normal and necessary reaction to the death of a loved one ( [Bowlby, 1961a](#) and [1961b](#), [Bowlby, 1980](#); [Bowlby, 1982](#); [Freud, 1966](#) ), then intervention may not be necessary. Most people go through the grief process with a painful sense of growth and responsibility. Being a compassionate listener and lending support to grieving families may be all that is necessary for most bereaved families. One of the first decisions a grieving parent has to make is how to inform the children of the death. Questions such as who should tell the children, how should the death be explained, and should the children be allowed to attend the funeral need to be addressed. Earlier studies on the advisability of children's attending their parents' funerals are somewhat contradictory. To address this issue, [Weller et al. \(1988\)](#) studied psychologically normal prepubertal children shortly after the death of a parent. Results found that the surviving parent most often told their children about the death. Most children wanted to go to the funeral and participated in making arrangements for the funeral. Most also reported that participating in these activities made it easier for them to accept the loss and that they were glad they attended the funeral. However, children should be prepared for the funeral process. The parents should identify a familiar person to accompany the child who will be able to comfort the child or to remove the child from the situation if the child becomes unduly distressed. This is especially important if the parent will be unable to comfort the child ( [DeMaso et al., 1997](#); [Schaefer and Lyons, 1993](#) ).

In explaining death to children (especially very young children), it is important not to compare death to sleep because this may increase a child's anxiety about whether he or she too could die when going to sleep. A good explanation is to describe death as cessation of bodily activities. Often grieving parents and children find comfort in reading about the subject. Some, but not all, may benefit from self-help groups. Sometimes these groups combine bereaved and divorced families. This combination, however, should usually be avoided. The issues for the two groups can be quite different, and resentment can occur in such combined groups. For example, grieving children tend to be less angry than children from a family experiencing divorce. Grieving children yearn for the dead parent and want to remember good times. Bereaved children often know that the dead parent did not choose to part from the child. However, children from a divorced family often blame the parents for wanting to part from them. Children from a divorced family often have friends who are from divorced families, whereas fewer children have friends who have lost a parent through death. Thus, it is more difficult for grieving children than for children from a divorcing family to find peers with whom to identify. A parent should not be pushed to join an adult support group unless the parent wants to participate.

For parents dealing with loss of a child, it is important to explain the death to the surviving siblings in an age-appropriate and developmentally appropriate way ( [Nolen-Hoeksema and Larson, 1999](#) ). This requires parents to use concrete language, to be open and honest about the child's illness and death, and to share their feelings of sadness and grief with their children ( [Koocher, 1974](#) ). Consistent family routines and discipline should be maintained. It is also important to secure the support of family and friends who are familiar to the child, to help provide continuity in the bereaved child's daily family life ( [DeMaso et al., 1997](#) ).

Baker et al. (1992) believe that treatment after the loss of a child's loved one should be psychoeducational. Parents of the child may need education on the needs of a grieving child. This information can help them to explain death and mourning to the child and also help with any questions a child may have. Children's literature, such as the E.B. White classic *Charlotte's Web* (1952), *Daddy's Promise* by Cindy Klein-Cohen (1997), and *Sad Isn't Bad* by Michaelene Mundy (1998), may provide some additional help for parents in these discussions ( [Johnson and Johnson, 1982](#); [Sims, 1988](#) ). These and other selections provide life-affirming advice for coping with loss as a child. They can help children to process their grief and help parents to understand the behaviors they may see in their grieving children.

If a child needs to have a new caregiver selected, as a result of the deaths of both parents or the inability of the surviving parent to care for the child, first-degree biological relatives should be given primary consideration in accordance with the permanency planning guidelines of the [Adoption and Safe Families Act \(1997\)](#). Additionally, the developmental and emotional needs of the child should be taken into account when a new primary caregiver is selected. The more permanent a child's placement, the more likely he or she will be to adapt to the new environment and progress through the bereavement process.

Individual therapy can be helpful for those with complicated grief, that is, grief that has become pathologic. Individual therapy may help the bereaved work through their grief and achieve a healthy outcome. Family therapy can be helpful for a dysfunctional family in which some family members are having difficulty adjusting to the loss.

In adults, sleep disturbances and appetite disturbances are symptoms frequently treated by family physicians. However, these are also symptoms of depression. One should ensure that major depression is not overlooked. Sleeping pills are not the best medications for depression. An antidepressant may be helpful to a grieving parent who develops clinical depression and “can't shake it,” especially if there is a history of depression that preceded the bereavement and that responded to

pharmacologic intervention.

In children and adolescents, few data are available on how to differentiate normal grief from pathologic grief. Guidelines on when to intervene are lacking. In cases of pathologic grief, depression should always be considered. Further, in such situations, extreme caution should be taken to ensure that the child is not suicidal or involved in acts that could put his or her life in danger (e.g., drug or alcohol abuse or reckless driving). Major depression that interferes with a child's ability to function (scholastic, family, peer group) should be carefully evaluated and treated with individual therapy and medications as indicated ( [Weller, Weller, and Fristad, 1984](#) ). Children with a history of depression before the bereavement may be more likely to require antidepressant treatment than those who have no such history. In considering the use of an antidepressant medication in children and adolescents, the clinician should always take into account the lethality of such medications in a potentially suicidal patient. In children and adolescents, having a responsible adult (i.e., a parent) in charge of dispensing medication can minimize the risk of medication overdose.

In the parent-bereaved family with a clinically depressed child, the surviving parent may also be depressed. Thus, extra care should be taken in selecting the adult to be responsible for the child's medication. When using medication, a physical examination, thyroid, and liver function tests should always be done. Available evidence suggests that the selective serotonin reuptake inhibitors are well tolerated by children and adolescents and may be a good choice for treating depression in these groups ( [Ambrosini, 2000](#); [Emslie et al., 1997, 1999](#) ). [Emslie et al. \(1997\)](#) completed a randomized, double-blind, placebo-controlled trial of fluoxetine in children and adolescents with severe, persistent major depressive disorder. These investigators report fluoxetine to be superior to placebo and well tolerated. Current recommendations are that fluoxetine be initiated at a dose of 5 mg per day and increased every 7 days until a dose of 20 mg per day is obtained. The recommended maximum daily dose of fluoxetine is 80 mg. Most children respond to 20 mg per day.

Paroxetine has also been found effective and well tolerated in the treatment of major depression in children ( [Rey-Sanchez and Gutierrez-Casares, 1997](#) ). Paroxetine should be initiated at a dose of 10 mg per day and increased every 7 days up to a maximum dose of 60 mg per day.

Generally, bereaved children do not show serious emotional or behavioral disturbances after the death of a parent. However, some children do exhibit serious emotional and behavioral problems after such a loss ( [Cerel et al., 1999](#); [Pfeffer et al., 1997](#); [Worden, 1996](#) ). Many of the children who exhibit persistent psychiatric symptoms are not identified until 1 to 2 years after the death of a parent ( [Weller et al., 1991](#); [Worden, 1996](#) ), even though they did not express these symptoms early in the process of grieving. Children who may be identified at higher risk of developing psychopathologic conditions after parental loss are SB children ( [Cerel et al., 1999](#) ), children with preexisting psychopathology, and children whose families resolve conflicts poorly or exhibit high rates of psychopathology ( [Cerel et al., 2000](#); [Kissane et al., 1996](#) ). These children and their families may benefit from early supportive interventions, education about the potential for difficulties long after the death, and longer follow-up periods after the death of a parent.

## RESEARCH DIRECTIONS

Previous studies of grief in children have suggested a possible link between bereavement and subsequent illness. However, many early studies suffer from small sample size and methodologic weaknesses that limit their generalizability. Several studies have suggested that a depressive syndrome is common sequela of bereavement in adults. Studies of bereaved children and adolescents suggest that depressive symptoms are also common soon after the death of a parent or sibling ( [Cerel et al., 2000](#); [Weller et al., 1991](#); [Worden and Silverman, 1996](#); [Worden et al., 1999](#) ). However, long-term prospective studies of larger groups of subjects using standardized assessment techniques are needed to describe the natural course of grief and possible pathologic outcomes more completely. Some studies have suggested that several of the emotional and behavioral problems related to grief do not manifest themselves until 2 years after the loss ( [Geis et al., 1998](#); [Worden, 1996](#) ). Longitudinal studies that will follow these children prospectively into adulthood are needed. This will be especially important because most hospice programs for families and most bereavement groups currently follow children for only 1 year.

There continues to be a paucity of literature describing the grief process in preschoolers. One of the difficulties in studying this age group has been the lack of standardized instruments to assess 3- to 6-year-old children effectively ( [Kranzler et al., 1990](#) ). There are also few methodologically sound studies on sibling loss. Many of the studies on sibling loss are based on interviews with parents or other adult caretakers and not on interviews with surviving children.

In addition, studies of children's responses to the death of a loved one in relation to the circumstances of death would be important. For example, SB children are at risk of increased psychopathology ( [Cerel et al., 1999](#) ) compared to NSB children. Israeli adolescents who lost a parent in a national war had fewer psychiatric symptoms than those who lost a parent in an accident ( [Bachar et al., 1997](#) ). Younger siblings of murder victims were reported to exhibit more psychiatric symptoms after the death of the sibling than those who lost a sibling from other causes ( [Freeman et al., 1996](#) ). Further research in sibling loss, as well as on the response of children to the loss of close friends and grandparents, is needed. In all these studies, the risk factors for psychopathology need to be identified to allow for early intervention and possible prevention.

Evolutionary theory suggests that living things should be concerned with the production and rearing of offspring to ensure genetic representation in the next generation ([Barash, 1977](#)). In fact, human adults all over the world see children as helpless, needing protection and training, but also as a valuable asset to society ([Mead and Wolfenstein, 1955](#)). This explains the common aim of parents everywhere to raise their children to be independent, responsible adults capable of full participation in society ([LeVine, 1977](#)), and it may also be reflected in the great similarity that has been found in early child-rearing practices all over the world ([Ainsworth, 1957](#)).

Conversely, because children and their parents have different genetic makeups and different needs, parental behaviors will not always be optimal for each infant at all times. The degree to which these variations can affect the development of children is examined in this chapter.

## THEORETICAL ISSUES PERTAINING TO DISORDERED PARENTING

Textbooks of child and adolescent psychiatry have not traditionally defined what constitutes adequate, optimal, or disordered parenting. This is undoubtedly the result of the enormous complexity of the caretaking function. In addition to the instrumental tasks involved in keeping a child healthy and providing him or her with sufficient clothing and shelter are the many psychological factors that make up the parenting role. Parenting also has an important developmental component. For example, mothering an infant and a teenager requires some common skills, such as patience, but it also draws on very different ones. Whereas a newborn needs a mother who “understands” his or her body language and helps the infant to organize his or her psychological states into predictable rhythms, a teenager will more directly benefit from a parent who can step back and allow him or her to explore the range of socially acceptable experiences.

Describing its instrumental and developmental variations is only one way to characterize good and inadequate parenting. Another way of understanding parenting practices is to see them in terms of theoretical models of development. For example, there is a rich literature, based on psychoanalytic theory, that deals with such issues as maternal overprotectiveness ([Levy, 1943](#)) or the formation of abnormal defense reactions in children with particular family constellations ([Freud, 1937](#)).

Conversely, we have a large literature that describes how specific psychiatric or medical conditions may influence parenting styles. For example, we talk about the effects of maternal depression ([Cox et al., 1987](#); [Puckering, 1989](#); [Weintraub et al., 1986](#)) or abuse by adults ([Cicchetti and Toth, 1995](#)) on children and how children who live with “disordered” parents fare in their overall development. The advantage of this literature is the empirical nature of the presented data. However, many of these studies tend to ignore that the association between parental behavior and child disorders is not unidirectional, and it is necessary to evaluate possible contributions of genetic or other factors within the child in each case.

Other investigators have focused on the ecologic perspective of parenting. For example, parenting is usually embedded in the context of a family or a community, with all its stresses and potential support structures ([Bronfenbrenner, 1979](#)). Degrees of risk emanating from these contexts have been called “distal” factors ([Luthar, 1993](#)).

Despite the interest of developmentalists and clinicians in the effects of the environment on behavior, few studies have examined continuities of contextual risk, because such studies are complex. Nevertheless, there is strong evidence that the best predictors of competence during early childhood are (a) the number of years a family has spent in poverty ([Duncan et al., 1994](#)) and (b) the number of distinct adversities children and families have experienced ([Sameroff et al., 1998](#)).

As can be seen from this brief review, the literature on parenting has been driven by a wide range of theories and empirical data. This situation has often led to seemingly contradictory popular advice. Yet two things seem to be clear. Theories based on classical psychoanalytic or learning principles have failed to stand up to modern empirical findings because they do not sufficiently explain important aspects of children's development. Conversely, increasing evidence considers parenting to be based on genetic principles and the laws of developmental psychopathology ([Rutter et al., 1997](#); [Sroufe and Rutter, 1984](#)), thereby highlighting the importance of genetic and functional factors (e.g., parental emotional support, the role of an intimate confiding relationship) and structural factors (e.g., low socioeconomic status or mental illness in the family) for the quality of parenting. Thus, the emphasis has shifted from the classical psychoanalytic position in which undue importance was placed on the very early years of a child's life to determine later mental health to conceptualizing life as an ongoing developmental process.

This chapter first briefly reviews the history of work that has linked parenting styles with later problems in children. We then attempt to summarize some major characteristics present-day investigators associate with competent caretaking and comment on how specific parental disorders influence these characteristics. Because troubled parents communicate their difficulties through their child-rearing activities, we then examine some of the clinical manifestations of disordered parenting skills and how they develop. At that point, we also evaluate how children influence the parenting they receive and illustrate this with examples of children with developmental disorders. The chapter ends with some thoughts on the efficacy of parent education and draws attention to some unresolved issues requiring further study.

## VIEWS OF PARENTING, THEN AND NOW

The importance of linking specific caretaking experiences in early life with later psychopathology has long been recognized. John Locke (1632 to 1704) wrote an essay in 1693 entitled “Some Thoughts Concerning Education,” wherein he described the consequences of specific parenting styles. He admonished parents to observe their children carefully to understand their “native propensities” and emphasized their role in “weeding out” their faults and “planting good habits” early in life (Locke, 1947). Locke's influence was such that he has been called the Dr. Spock of the 18th century ([Brant and Cullman, 1980](#)).

One hundred years later, Jean-Jacques Rousseau wrote extensively about the consequences of specific parenting practices such as coddling and neglect on the

future development of young children. In his book *Emile* ([Rousseau, 1762/1979](#)), he spoke at length about the need for and style of punishment that should be used to help children in their socialization.

Later, clinicians concentrated on specific child-rearing practices and evaluated them by their effects on a child's alleged later development. For example, Luther Emmett Holt (1855 to 1924) wrote a book entitled *The Care and Feeding of Children*, which went through 75 printings between 1894 and 1943 ([Holt, 1902](#)). Among other things, he warned of the dangers of early swaddling and of playing with children younger than 6 months old because such practices would lead to various mental and physical problems.

In the beginning of the 20th century, clinicians from the psychoanalytic school began to label specific parental activities as pathologic for the development of children. Examples are Freud's early concerns about the prohibition of masturbation in young children and the impact of specific psychosexual stages on children's relationships with their parents ([Freud, 1909, 1958](#)). Anna Freud and others later extended this work by discussing how children develop defense mechanisms that compromise development in response to overindulgent or rejecting parental attitudes ([Freud, 1937](#); [Levy, 1943](#)).

Others write about more practical aspects of caretaking. For example, [Buxbaum \(1959\)](#) discussed the need of children to breast-feed to obtain sufficient oral pleasure, and [Sears et al. \(1957\)](#) emphasized the need for children to be allowed adequate genital play. These authors also believed that certain activities, such as the type and length of toilet training or breast-feeding a child experiences, carry distinct predictions for the infant's future mental health.

However, in a careful review of the then-available data on child rearing, [Caldwell \(1964\)](#) concluded that neither the timing of various aspects of child care nor the method of toilet training have particular psychological consequences. This finding suggests that parenting cannot be explained by studying single dimensions, but it has to be understood as a multifactorial phenomenon, including child factors such as genetic predispositions and developmental status, as well as parental behaviors.

During the last 25 years, developmental theories have changed dramatically as some learning and many psychodynamic principles have been translated into the language of information processing, that is, a cognitive-behavioral mode. This approach presumes that past experiences create predictable biases and distortions in mental representations that can then function as risk or protective factors for later psychological disturbances. Problematic or secure experiences of the child with early attachment figures are frequently used to demonstrate this principle ([Lyons-Ruth and Jacobovitz, 1999](#)), thus indicating the continuing notion that the unfolding of psychopathology occurs in the context of the family and the child's primary socialization environment (Petit et al., 1997).

In the 1990s, quantitative behavior genetics seriously challenged classical socialization theories with their associated emphasis on parenting. For example, [Rowe \(1994\)](#) writes: "parents in most working to professional class families may have little influence on what traits their children may eventually develop as adults." He also states that an undesirable trait displayed by a child cannot be significantly modified by anything a parent does. This strong statement is partly based on the general recognition that the overall connection between early parenting and later socialization turns out to be quite weak, and many of the demonstrated correlations can be interpreted as driven by the child's genetically predetermined predispositions ([O'Connor et al., 1998](#)). This suggests that many influences, previously considered environmental, are or could be actually genetically mediated ([Kendler et al., 1996](#)) and that only up to 20% of behaviors, based on nonshared environmental effects, are related to child-rearing practices ([Plomin, 1994](#)).

## WHAT IS THE CONTRIBUTION OF GENETICS TO DEVELOPMENTALLY APPROPRIATE PARENTING?

We stated earlier in this chapter that children's behavioral adjustment and parent-child interaction operate through bidirectional family processes, some of which have genetic roots ([Kuczynski et al., 1997](#)). Nevertheless, some investigators, using a developmental model of genotype-environment, do not just look at the effect of genes or the environment on specific behaviors because this would ignore the contribution parenting makes in all these conditions. Genetic factors, in their opinion, are therefore seen more as risk or protective factors, and specific behaviors of children are conceptualized as evocative, that is, as challenging and demanding a response from parents ([Deater-Deckard, 2000](#)). Evocative behaviors are thought to have a genetic basis because of the observation that parents behave more similarly toward siblings who are genetically more similar ([Lollis and Kuczynski, 1997](#)). It also seems that evocative behaviors are more closely associated with externalizing symptoms, as described by [Patterson et al. \(1992\)](#) and [Ge et al. \(1994\)](#), and not with internalizing conditions. In fact, in one study, [O'Connor and colleagues \(1998\)](#) assessed 88 adopted boys and their adoptive families when the boys were 7, 9, 10, 11, and 12 years old. They report that both positive (e.g., warmth) and negative (e.g., negative control or lax responses) parenting factors were highly consistent over time, but much more so toward children with externalizing than with internalizing behaviors. This finding suggests that aggressive or other externalizing behaviors are highly evocative, whereas internalizing symptoms are not. [Loeber and colleagues \(2000\)](#), reporting on the stability of family interaction in 1,517 antisocial boys of the Pittsburgh Youth Study, also show a very high "absolute stability" in family interaction measures from ages 6 to 18 years. Across-age correlations generally are between 0.58 and 0.69 on such measures as bad relationship, poor supervision, low positive parenting, physical punishment, and poor communication. The authors suggest that reciprocal behaviors between children and their parents are influenced by genetic factors.

In contrast, gene-environment correlations, which describe underlying common genetic links between parent and child, also called *passive* correlations, do not seem to contribute to child antisocial behaviors substantially ([Hershberger, 1994](#)). Poor parenting in this situation would much more likely lead to depression in children with a genetic "risk" for this condition. An example of this is provided in a study by [Deater-Deckard \(2000\)](#), in which 125 same-sex identical and fraternal twin pairs aged 42 to 45 months were visited at home and were videotaped during interactions with their mothers on two occasions. Parental control, affect, and discipline, as well as the difficult behavior of the children, were assessed based on parent, interviewer, and observer ratings. Results indicate that children who were observed to have more difficult behaviors and who were rated by their parents to have a conduct problem lived in homes with more negative control and less positive affect, showing a genetic component of 40% to 50%. However, correlations between ratings by parents and observers on parenting affect were low. Thus, parents reported themselves more directly to respond to individual children's behaviors than did the observers, a finding suggesting that parents sometimes rate identical twins more similarly, presumably because they think that they should be similar.

The focus of these gene-environment correlation investigations has been the effect of specific child-rearing practices or "proximal" factors on the child. Discipline, personal warmth, the amount and type of interaction, and parental regulation of affect are other examples of dimensions that have been studied ([Emde, 1989](#); [Maccoby and Martin, 1983](#); [Minde et al., 1988](#); [Patterson, 1982](#)).

## WHAT OTHER FACTORS CONTRIBUTE TO DEVELOPMENTALLY APPROPRIATE PARENTING?

On the most general level, raising children requires an environment that provides them with sufficient material and emotional care to further their physical, cognitive, and social development. At least six ingredients have been identified that determine developmentally sensitive parenting: sensitive responsiveness, the parent-child dyad, parental mental health, parenting experience, the extended family, and direct caretaker-child interactions ([Emde, 1989](#)).

### Sensitive Responsiveness

How parents respond to their children's behaviors, demands, and distress ([Mrazek et al., 1982](#)) and how they resolve interpersonal conflicts ([Shure and Spivak, 1978](#)) is a key aspect of parenting. Adequate parents are generally observed to be sensitive to their children's cues in relation to their developmental needs ([Rutter, 1989](#)).

[Emde \(1989\)](#) suggests that it is the parents' sense of protectiveness with regard to their small children that provides the basis for their sensitivity; that is, it is survival-oriented. Parents show this sensitivity when they engage in both the physiologic regulation of their infants' needs (e.g., by keeping them warm and well fed) and the regulation of affect. The latter is demonstrated in the caregiver's empathic responsiveness to the child's overall adaptive needs. This means that parents tend to protect their child from experiencing extremes of excitement, anger, or distress. It is of interest that these clinically observed characteristics have also been found to be essential for the normal development of the brain. For example, it is now established that during the first 2 years of life, sequential growth, proliferation, and, in fact, overproduction of axons, dendrites, and synapses occur in different regions of the brain. This process is genetically determined. However, by the age of 2 years, many synaptic connections are "pruned," that is, have died off from lack of use ([Singer, 1995](#)). This means that the brain in the early stages can be physically changed by environmental input, such as parenting behavior, resulting in change of the "hard wiring" of the brain. In other words, parenting practices can modify the expression of genetically determined behaviors. Another important aspect is the distinction between what [Greenough and Black \(1992\)](#) call the "experience-expectant" and "experience-dependent" aspects of early brain maturation. Other authors state that for an orderly process of synaptic connections to occur in the presence of multiple environmental influences, the maturing brain is genetically programmed to expect stimuli to be presented in a way that is "safe, nurturing, predictable, repetitive, gradual and attuned to a child's developmental stage" ([Perry and Pollard, 1998](#)). To ensure this is the central task of the child's caretakers and fits well with the concept of parental sensitivity, which, in turn, furthers a secure attachment of the child to his or her parents.

In contrast to the genetically driven experience-expectant brain maturation, the experience-dependent process generates new synapses only in response to environmentally determined experiences. This has, for obvious reasons, been most clearly documented in animals. For example, rats whose mothers licked and groomed them a great deal during their first 10 days of life showed lower adrenocorticotrophic hormone and adrenal corticosterone in response to stress when they were adults. They also exhibited behavioral aspects associated with superior “programming” of the hypothalamic-pituitary-adrenal response to stress ( [Caldji et al., 1998](#); [Liu et al., 1997](#)). A more recent study extended this work by fostering rat pups of low-frequency licking and grooming to high-frequency licking and grooming mothers and vice versa. In both cases, the pups behaved like their foster mothers in mothering their own children later ( [Francis et al., 1999](#)). This finding suggests that intergenerationally transmitted parenting patterns can be modified by interventions, and the new patterns, in turn, are transmitted to the next generation. Very similar results have been shown in genetically impulsive rhesus monkeys that were foster reared from birth by unrelated multiparous females and became calm and nurturing mothers to their own infants ( [Suomi and Levine, 1998](#)).

### Parent-Child Dyad

Parenting is always determined by the individual parent–child relationship ( [Minde, 1986](#)). It therefore has very special qualities that are specific to each particular dyad, although it also forms part of a broader system of relationships involving other family members, neighbors, and friends. [Emde \(1989\)](#), in his previously described treatise, suggests that the initial and enduring tie between parent and child is an important determinant of this relationship. Bowlby and others have convincingly shown that the quality of this tie or attachment plays an important role in the overall social and emotional functioning of a child ( [Ainsworth et al., 1978](#); [Bowlby, 1969, 1980](#); [Bretherton, 1985](#)).

Given the complexity of human motivation and behavior, it is not surprising that the early mother–child relationship has a strong intergenerational component. Main and her group showed that a mother’s understanding of her own early experiences with her caretakers is an important predictor of the internal representations she has of her child and that these representations, in turn, determine the quality of the infant’s attachment to the mother ( [Fonagy et al., 1991](#); [Main and Goldwyn, 1984](#); [Main and Hesse, 1990](#)). This means that both the interpretation we as parents make of the behaviors of our children and the way we respond to them are significantly determined by how we have learned to interpret the world through past experiences with our own caretakers.

More recent work has further substantiated these connections. Most important is the repeated observation that interactive processes can both trigger and prevent a genetic vulnerability. For example, [Mrazek et al. \(1999\)](#) reported that high ratings of specific parenting difficulties made 3 weeks after the birth of a child by trained lay personnel, together with frequent infections and an elevated level of immunoglobulin E, predicted the onset of asthma at age 3 years with a 70% probability in a cohort of 100 children born to asthmatic parents. Equally important, in a subsequent study of 140 newborns with the same asthmatic risk factors, a specified family intervention program instituted when these infants were 3 weeks old was associated with a significant decrease in the incidence of asthma in these children at age 3 years versus an untreated control group ( [Mrazek, 2000](#)).

### Extended Family and the Social System

Parenting, even though primarily practiced within the individual parent-child relationship, is also a reflection of a broader social nexus. Because parenting is not a natural behavior but must be learned, society will obviously have a powerful impact on this process, and in this respect, parenting competence must be seen as a reflection of the balance between external stresses and supports ( [Belsky and Vondra, 1989](#)). It is in this area that dramatic changes have occurred in recent years. Most striking has been the change in the percentage of working mothers of young children, a number that has surpassed 50%, whereas fathers’ contribution to domestic and parenting work has not grown correspondingly ( [McBride and Mills, 1993](#)). This leaves more children in day care than ever before. Yet costs for such care have gone up, and parents spend between 9% and 11% of their incomes on child care ( [Marshall and Marx, 1991](#)). The overall cost of raising a child has also gone up and is now estimated to be more than \$150,000 up to age 18 years ( [Arendell, 1997](#)).

At the same time, single parenting has become more common. We have seen divorce rates triple between 1960 and 1982 and now come close to 50% in North America; there are also between 2 and 5 million lesbian mothers who have between 6 and 14 million children, and 25% of children are born to unmarried women ( [Patterson, 1992](#)). In fact, 72% of all teen births in 1993 were by single teens, up from 18% in 1963 ( [Children’s Defense Fund, 1996](#)). In the case of teen mothers, we know that they are less effective in interactions; for example, they have less eye contact with their infants and show less verbal and less positive expressiveness ( [Culp et al., 1991](#)). Most of these single-parent families also struggle financially. The U.S. census in 1990 showed 51.1% of African Americans to be poor, and here again mostly single-parent families. The demands and stresses associated with poverty obviously make it difficult for a parent to be consistently attuned to a child’s needs. Indeed, financial problems are associated with harsh, inconsistent parenting ( [Ge et al., 1994](#)), the use of frequent derogatory comments, and little interaction characterized by praise ( [Conger et al., 1984](#)).

To provide the necessary social supports from the community requires persons who have a commitment and the ability to give emotionally and to share with others. Garbarino calls these communities “free from drain,” in contrast to the many communities that operate on a “scarcity” economy, that is, have citizens who fear exploitation and reciprocity because they distrust the caregiving practices of their neighbors ( [Garbarino and Kostelny, 1993](#)).

Another issue that needs to be considered here is the role and involvement of fathers in parenting. As mothers increasingly have moved into the workforce, fathers have taken on more responsibility in the care of their children. Thus, in 1993, more than 46 million preschoolers were cared for by their fathers while their mothers were at work ( [Casper and O’Connell, 1998](#)). This is 23% of all preschoolers with working mothers. The number of single fathers with children at home has also increased by 25% in the preceding 3 years to 2.1 million in 1998 ( [Bureau of the Census, 1998](#)).

Three components of father involvement have been proposed ( [Lamb, 1997](#)): engagement (father has direct contact), accessibility (father is available to child regardless of type of interaction), and responsibility (father understands and meets economic or planning need of child). It is not yet clear which of these components affect which outcome in children.

### Direct Caretaker-Child Interaction

The actual behaviors parents and children show toward each other can vary from mutually supportive and helpful to oppositional or hostile. Interactions are affected by characteristics of both child and parent ( [Maccoby and Martin, 1983](#)).

The best studied aspect of the caretaker-infant interaction is the impact of specific attachment patterns on caretaking quality. Thus, in keeping with Ainsworth’s original theorizing, ratings of maternal sensitivity in the first year of life are linked to later social and interactional competence in children of all cultures and social strata ( [van IJzendoorn and Kroonenberg, 1988](#)). Likewise, sensitive mothers also provide their children with moderate, appropriate stimulation as well as with warmth, involvement, and responsiveness. These characteristics, in turn, lay the foundations for children to develop an interpretative capacity ( [Fonagy and Target, 1998](#)), which can function as a significant protective factor against externalizing disorders ( [Greenberg, 1999](#)), even when they grow up in families whose members are at risk for such disorders, and to become sensitive and responsive caretakers as adults.

Other systems and factors are also important determinants of parenting competence, among them parenting experience and parental mental health. Experience counts, because both in monkeys and in people we find mothers to be more patient, sensitive, and competent with later-born than with first-born children ( [Rutter, 1981](#); [Suomi, 1987](#)). Experienced mothers also provide more appropriate stimulation ( [Jones et al., 1980](#); [Ragozin et al., 1982](#)). The parents’ psychosocial functioning is another essential component in the quality of the parenting they can provide. As we see in the next section, parenting functions can be severely compromised by mental disorders and the associated distorted internal representations of the world they can cause.

## PARENTAL PSYCHIATRIC DISORDERS

Empirical studies that examine the effects of specific parental disorders on the development of children go back to the early part of the 20th century. [Janet \(1925\)](#) concluded that mental disorders of parents had a negative effect on their children because of their impact on the social life in the family. He based this conclusion on his observations of three of 18 families in which the precipitating mental illness occurred in stepparents and, hence, affected children who were not genetically related to them. He also described cases in which children of psychiatrically ill parents had fared well because they had been brought up away from their biological families. Canavan and Clark ( [1923a, 1923b](#)) undertook the first controlled study by examining, from 1912 to 1921, the 463 children of 136 married patients diagnosed as having dementia praecox, or schizophrenia. The authors compared these youngsters with 581 children of 145 families attending a medical outpatient clinic. These

investigators found the incidence of conduct disorders among the children in the study group to be significantly higher than in the control children (9.5% versus 1.6%).

Other early investigators ([Gardner, 1949](#); [Preston and Antin, 1933](#); Ramage, 1925) confirmed these findings. They suggested that, overall, the children of psychotic patients showed comparatively few mental peculiarities and virtually no occurrence of the parental illness ([Canavan and Clark, 1936](#)). Although this early work suggested a nongenetic intergenerational transmission of psychiatric illness, it was Rutter's monograph, *Children of Sick Parents* ([Rutter, 1966](#)), that set a new standard for examining the effect of a parent's emotional or physical handicap on his or her children. From 922 children who had attended the Maudsley Hospital Children's Department (London, UK) in 1955 and 1959, Rutter selected specific subsamples, children who had at least one parent with a mental illness (n = 137), children who were bereaved (n = 85), and a third group in which the parents had either a chronic or a recurrent physical disease (n = 190). The following are some of the relevant findings of this study:

1. There was a strong association between parental illness and psychiatric disorder in children.
2. This was true for both psychiatric illness and physical illness in the parent.
3. Because parental illness usually preceded the development of the child's disorder, it is reasonable to suggest a parent-to-child effect.
4. Parental disorder was most likely to be followed by behavioral disturbances in children when the parent exhibited a "long-standing abnormality of personality."

Later studies involving general population samples ([Richman et al., 1982](#); [Rutter et al., 1975](#)) and case-controlled comparisons of the children of parents with a mental disorder ([Beardslee, 1986](#); [Cytryn et al., 1984](#)) further extend our knowledge and permit us to ask some specific questions about the linkage between parental and child psychiatric disorder.

### **How Close Is the Demonstrated Link Between Psychiatric Disorder in Parents and Children?**

The answer is "significant but not very close." This is illustrated by data from [Rutter and Quinton \(1984\)](#), who evaluated 137 newly referred psychiatric patients with 292 children who were less than 15 years of age in London and followed them prospectively for 4 years (1966 to 1967 and 1970 to 1971). All were initially interviewed at home to obtain their diagnosis and family characteristics. At that time, about one-third of the boys and one-fourth of the girls were judged to have handicapping problems. Four years later, only 21% of the boys versus 11% of the girls were still seen as abnormal by their teachers.

### **Do Some Parental Psychiatric Disorders Have a More Detrimental Effect on the Development of Children Than Others?**

The evidence seems to support this notion. As early as 1925, Janet observed that children of psychiatrically ill parents were most affected if there were family conflict and other disturbances, in addition to the mental illness. In the previously mentioned study by [Rutter and Quinton \(1984\)](#), similar findings emerged; the presence of a conduct disorder in one or both parents was the most significant factor in the incidence of childhood psychopathology. In those cases, 45% of the children were identified as disturbed on the teacher questionnaire, and 48% were similarly identified in the psychiatric interview. This finding was in contrast to 21% of children whose parents had "just" a psychosis or an affective disorder.

Children with one psychotic or depressed and one healthy parent did not show any increased risk of a psychiatric disorder. However, many of the disturbed parents also had a disturbed partner, and in these families, children showed a high rate of disorders (20% versus 54%, as determined by the psychiatric interview).

These findings support those from Wynne's project in the Rochester Longitudinal Study ([Harder et al., 1980](#); [Kokes et al., 1980](#)), in which boys aged 7 and 10 years who had nonpsychotically ill parents showed far less overall psychological competence than those with schizophrenic or affectively ill parents. A more recent analysis of the 18-year outcome of the Rochester Longitudinal Study sample examined whether cognitive competence and mental health were related to 10 specific environmental risk factors, such as a history of maternal mental illness, high maternal anxiety, and large family size ([Sameroff et al., 1993](#)). Although there were statistically significant effects for each single risk factor at the population level, most children with only one risk factor were doing well, whereas 14% of those with three or four risk factors and 27% of those with five or more risk factors showed clinical problems. This finding indicates that poor parenting is just one of many other risk factors for later mental health.

The Minnesota Study by Garmezy and his group can also be considered here ([Garmezy, 1984](#); [Garmezy and Devine, 1984](#)). In that investigation, children, aged 9 to 11 years, of schizophrenic and internalizing (primarily depressed) mothers were studied using peer and teacher ratings and school records. Initial findings suggested that the children of internalizing (i.e., depressed) mothers were most like the control group. Seven years later, however, only 48% of the children of depressed mothers received an overall good outcome score, whereas 82% of the controls did ([Garmezy and Devine, 1984](#)). [Rutter and Quinton \(1984\)](#), in their previously cited study, also reported that continuing psychiatric abnormalities in their sample of children were not related to a particular parental diagnosis but to the associated presence of quite specific types of family interactions. Most important here was the child's exposure to hostile parental behavior. Thus, 17% of boys with nonhostile fathers and mothers versus 40% of those with hostile mothers and 71% with hostile fathers showed persistent disturbance.

### **Are There Age Differences in the Susceptibility of Children to the Adversities of Having a Mentally Ill Parent?**

This question has never been examined directly. However, some related findings suggest that one can expect to see developmental differences. For example, it is well known that repeated hospitalization is especially difficult for children between the ages of 6 months and 5 years ([Quinton and Rutter, 1976](#)) because young children cannot "understand" that the separation from the family they experience is not permanent and has nothing to do with anything "bad" they have done. One would therefore expect that certain characteristics of a mentally ill mother or father, such as their need to be hospitalized at unpredictable intervals, would be associated with difficulties in younger children, whereas the presence of concrete or overinclusive thinking in some schizophrenic patients may be more traumatic to older children.

These data suggest that some interactive factors, such as hostility, may be pathogenic for a wide age range of children, whereas others, such as parental sadness, may be especially problematic for younger children. Thus, infants of depressed mothers remain disturbed even after their mothers have been treated for their depression and are functioning well ([Field et al., 1997](#)), whereas this is not true for older children.

### **Are There Sex Differences in the Susceptibility of Children to Parental Mental Illness?**

The data here are not very clear. In general, it has been documented that boys are more susceptible to psychosocial stressors than are girls ([Maccoby and Martin, 1983](#)). However, the reason may partly be that, as we have seen, an ongoing parental personality disorder, especially one associated with hostile interpersonal child-rearing practices, shows the strongest association with persistent emotional or behavioral disturbance in the child. Personality disorders are more common in men, and because parental disturbances seem to affect the children of the same sex more, one would expect boys to be more affected by their fathers' problems.

Rutter and Quinton's findings confirm that children of the same sex as the mentally ill parent are more profoundly affected. In their study, 40% of the boys versus 23% of the girls were judged disturbed by teachers when the father was mentally ill, whereas 11% of daughters of mentally ill mothers versus 0% of daughters of mentally ill fathers were seen as abnormal ([Rutter and Quinton, 1984](#)).

### **To What Extent Are Psychiatric Disorders in Children of Mentally Ill Parents Simply a Reflection of the Common Gene Pool Between the Generations?**
