The dyadic therapeutic relationship provides an introspective opportunity for the child and also serves to foster identification with an appropriate adult model. Indeed, the child may "borrow" strength, clarity, and organization from the psychotherapist as the child struggles to deal with an acute development crisis. Further, the loving relationship in itself and the feeling of being understood have important therapeutic effects, perhaps regardless of any insight that may have been achieved ( [Rothstein, 1989](#)). Another significant therapeutic force is the change from despair to hope, leading to a therapeutic optimism. Concomitant work with other family members also leads to shifts in the dynamic equilibrium within the family; releases the child and parents from their locked-in, fixed positions; and allows development to proceed. Last, the extended moment of time, the opportunity to examine in detail, itself contributes to clearer, more direct communications for all concerned.

## EVALUATION OF OUTCOME OF PSYCHOTHERAPY

Evaluation of the effectiveness of psychotherapy is in general a complex undertaking ( [Heinecke and Ramsey-Klee, 1986](#); [Kazdin, 1988](#); [Strupp and Hadley, 1977](#)), and such research is plagued by methodological problems ( [Hine, 1982](#)). [Parloff \(1982\)](#) reviewed nearly 500 controlled studies providing research evidence on outcome and concluded that all forms of psychological treatment are comparably effective in producing therapeutic benefits and that such benefits are reliably superior to those found in controls. Subsequent outcome studies ( [Casey and Berman, 1985](#); [Weisz et al., 1987](#)) have not contradicted this global conclusion, although [Weiss and Weisz \(1990\)](#) reported that: (a) behavioral treatments are associated with significantly larger effect sizes than nonbehavioral treatments; (b) most studies of child psychotherapy in actual clinical practice show very small effects ( [Weisz et al., 1992](#)); and (c) psychodynamic treatments have an effect size that is even smaller than client-centered treatments (0.01 versus 0.56, respectively). [Shirk and Russell \(1995\)](#), however, have expressed concern about major methodological flaws in many of the studies used in the Weiss et al. metaanalytic approach and have suggested that all such flawed studies should be excluded from metaanalytic comparisons. Improved scientific methodology in studies of child psychotherapy remains an important goal for future studies.

Other factors that may influence outcome include the motivation for help in the child and his or her family, psychiatric disorders in the parents, and current social conditions ( [Graham, 2000](#)).

In one controlled study of psychoanalytic psychotherapy it was shown to improve compliance in so-called brittle diabetes ( [Moran et al., 1999](#)).

In another albeit limited but controlled study, longer and more intensive treatment was independently associated with a greater likelihood of reliable improvement, particularly among children with severe overanxious or generalized anxiety disorders, although the majority of older (>11 years), severely disordered children remained diagnosable at termination. Moreover, if severely disordered children were treated nonintensively (once- or twice-weekly psychotherapy), more than half (56.5%) got worse or showed no improvement. Less severely disordered children were as likely to benefit from nonintensive treatment as from intensive treatment ( [Target and Fonagy, 1994](#)). (For a critical review of the psychotherapies, see [Chapter 87](#)).

From a clinical viewpoint, outcome in psychotherapy is largely a value judgment, requiring that the therapist recognize the multiple values, criteria, and factors that go into such judgments. Meanwhile, research on psychotherapy with children remains sparse ( [Barrett et al., 1978](#); [Levitt, 1971](#); [Shaffer, 1984](#)). More focused scientific

research is needed. [Marans \(1989\)](#) has suggested specific questions concerning which aspects of the therapeutic process are especially useful for a particular child.

## 80 USE OF PLAY IN PSYCHODYNAMIC PSYCHOTHERAPY

Henry P. Coppolillo, M.D.

---

[Historical Notes on the Psychology of Play](#)  
[Preconditions Necessary for Therapeutic Play](#)  
[Conditions Regarding the Therapeutic Environment](#)  
[Play in the Service of Psychotherapy](#)  
[Conclusions](#)  
[Chapter References](#)

The essence of psychodynamically oriented psychotherapy is the communication and exploration of the patient's subjective states and convictions even when these are dimly perceived by the patient or are unconscious. This is an arduous task when it is undertaken with an adult, who usually comes to the psychotherapeutic situation with a well-developed repertoire of signals, signs, and symbols as communicative vehicles. With the child, the task becomes more difficult because his or her complement of culturally validated signals and symbols is as yet incomplete. The play of the child can often more than compensate for this immaturity. In this chapter the use of play as a vehicle for therapeutic effectiveness and the conditions that facilitate that use are explored. A word of caution: Many of the concepts regarding psychotherapy are deceptively easy to understand. It is their application in the living situation that is difficult. For this reason, in order to become competent beginning psychotherapists must avail themselves of competent supervision as a necessary companion piece to texts and to reading and hearing case presentations.

### HISTORICAL NOTES ON THE PSYCHOLOGY OF PLAY

It is beyond the purpose of this chapter to explore the ideas of all who have been interested in play. Suffice it to say that play has been scrutinized by members of disciplines as widely disparate as military theory (war games) and philosophy of religion ( [Berger, 1969](#)). Closer to our interest, one of the first psychodynamic considerations of play is found in [Freud's \(1955\)](#) development of the concept of the repetition compulsion. A small boy whose parents were away used the repeated tossing and retrieving of a spool of thread as an example of the wish to master a trauma. [Waelder \(1933\)](#) extended the understanding of the broad and varied psychological functions that play serves.

[Hug-Hellmuth \(1913, 1921\)](#) wrote the formal articles on the use of play in the therapeutic situation when she described the psychoanalysis of children. The modality had become broadly accepted and used by therapists by the time [Klein \(1932\)](#) and [Anna Freud \(1946\)](#) published their texts on the use of play in the treatment of children.

By 1940, child therapists had begun to utilize play in therapeutic efforts that conceived of specific, more restricted goals than did psychoanalysis. [Levy \(1939\)](#) aimed at achieving a therapeutic effect with a cathartic resolution of conflict or tension through the child's play. [Allen \(1942\)](#) described the use of the play situation to develop and sustain the relationship that he felt had central therapeutic significance in the child's life. Solomon suggested a variation in the technique of using play (1955) as he guided the child's play in an effort to help the child achieve psychological integration.

A relatively more subtle conceptual variation is to be found in Virginia [Axline's work \(1947\)](#). Basing her ideas on the Rogerian concepts of "client-centered therapy," she used play to reflect back to the child his states, wishes, or convictions without attempting interpretations of unconscious motives or conflicts. The articulation that the child conveyed was considered therapeutically effective.

A moving and profoundly significant explanation of the meaning of play is offered by [Peter Berger \(1969\)](#) in his book, *A Rumor of Angels*. Berger follows the historian Huizinga, novelist C.S. Lewis, and Freud in ascribing the wish to be joyful, playful, and pleasure-seeking to the very nature of human beings. He then proposes that it is this joy and exuberance that can emerge most easily in play, because portions of reality can be suspended in play. The portions of reality that he believes are most important to suspend are pain and death. At the same time he describes the preservation and extension of parts of reality through the principle of transcendence. By transcendence he means, "phenomena that are to be found within the domain of our 'natural' reality but that appear to point beyond that reality" (pp. 65–66). Berger then proposes that human beings tend to order or organize their realities and possess an "intrinsic impulse to give cosmic scope to this order" (p. 70). Human beings can suspend certain painful aspects of their reality in play, even as they preserve other components of that reality and live out the wish to maintain order and pleasurable predictability in their universe. He summarizes his views in a beautiful passage by describing the play of children (p. 74).

Some little girls are playing hopscotch in the park. They are completely intent on their game, closed to the world outside it, happy in the concentration. Time has stood still for them or more accurately, has been collapsed into the movements of the game. The outside world has for the duration of the game, ceased to exist. And, by implication (since the little girls may not be very conscious of this), pain and death, which are the law of the world, have also ceased to exist. Even the adult observer of this scene, who is perhaps all too conscious of pain and death, is momentarily drawn into beatific immunity.

Although Berger is not a clinician and his philosophical exploration may not have direct bearing on the technical uses of play in therapy, we see in the following how closely his thoughts parallel the thinking of a clinician who used play with great therapeutic effectiveness.

[D.W. Winnicott \(1953\)](#), in his timeless paper on transitional objects, articulated concepts that are useful for understanding the developmental and therapeutic functions of play. He proposed that, in addition to the capacity of a child to experience external reality and the internal world, an intermediate area of experience is available to the child to which internal and external experiences both contribute. He called this the intermediate area of experience, and he called the objects that were experienced in this way "transitional objects." Concrete objects as well as songs, rhymes, or even the babbling of an infant can be experienced in the intermediate area. According to Winnicott, having the intermediate area of experience available to him, the child can begin to relieve the strain of relating internally generated wishes with the rigidity of external reality; once acquired, this mode of attaining self-soothing continues throughout life. Winnicott further states that "This intermediate area is in direct continuity with the play area of the small child who is 'lost in play'" (p. 96). For example, a bored or sad child may pick up a teddy bear to play with. The child can easily appreciate the external reality of its button eyes, soft fur, and the inviting demeanor its manufacturer provided. But as he brings it into the intermediate area of experience, it becomes a transitional object and, as such, is also appreciated as a soothing companion, the reciprocator of a loving hug or even the worthy opponent in a wrestling match for the championship of the child's preschool class. The teddy bear has been transformed from a toy into a character in a drama that reveals the wishes and impulses, the convictions and visions of the little author who provided him his script. Bringing a physical entity into the intermediate area of experience allows the entity to be imbued with qualities currently significant to the child. Those elements of the subject's inner world that are brought into the intermediate area and are thus attached to an object can be played with and mastered with just the right intensity. If a child becomes disturbed by the intensity of his own aggression when playing with his teddy bear he can readily turn his attention to the real qualities of the toy and thus escape the threat of his own impulses until he is ready once more to face them in play. It is this capacity's persistence that allows adults to transform a combination of sound waves into the *Eroica* or the *Appassionata* and allow great visions or tender images to sweep away the tedium of daily living without losing the ability to address the reality of daily living when necessary.

[Rapaport \(1951, 1958\)](#) envisioned how the ego would be handicapped by the extremes of being totally engrossed by events of the external world or responsive only to the impulses and images of the inner world. In the former condition the person would be oppressed by stimulus slavery, whereas in the latter state we would have to say he was handicapped by madness. Transitional objects become excellent vehicles for maintaining a balance between the tides of stimuli from the external and internal worlds. When a child takes an object or a story or song into the intermediate area of experience, he takes with it a quantity of reality that is reliably there but is unobtrusive when he imbues the object with qualities that serve to play out a wish or impulse from his inner world. If his wishes or impulses become too threatening to him, he can attend to the realistic qualities of the object more fully. If the reality of the toy is insufficient to provide him relief from tedium, he can suspend some of that reality ([Coppolillo, 1976](#)). These are the conditions of this kind of play that render it invaluable as a vehicle for the modulated, manageable expressions of the inner states of the child. The thinking of Berger, Winnicott, and Rapaport had many points of overlap and concordance even though they developed their ideas quite independently and were addressing different aspects of life and theory. The work of [Peller \(1954\)](#) on the function of play in development seems also to coincide with their thinking as she states, "Small quantities of anxiety are mastered in play" and further asserts that unconscious impulses can be acted out in play without reaching awareness (p. 181). In this chapter the work of these authors is the theory that supports the suggestions for using play as a psychodynamically therapeutic tool. (For a

more extensive review of the literature on this topic, see [Gardner, 1979.](#))

Play in this chapter is considered as both an adjunct to communication and as a vehicle of communication between child and therapist that reveal to the therapist states of the child's inner world. These states may include (but are not limited to) misconceptions and misinformation about himself or herself or misconceptions about the child's world. These states may contain unrealistic wishes, anxiety-laden impulses, conflicts, and frightening expectations of retaliations. Of course this is not to say that even as the child is struggling with these conflicts other phenomena are not occurring simultaneously. For example, it would be surprising if the child were not enjoying the growing relationship with a caring and warm therapist even as they are struggling to understand the origins of an irrational fear. Or for some children the time playing in the presence of the therapist may be one of the few moments in their lives when they feel soothed. Deconditioning or relearning may be occurring, or perhaps the narcissistic gratification of being the only object of the therapist's attention may be helpful to the child. Conflict resolution often combines with these other bonuses of human relatedness to produce therapeutic benefits.

## PRECONDITIONS NECESSARY FOR THERAPEUTIC PLAY

The following sections apply to play as used in individual psychotherapy. See [Lewis and Blotcky \(1997\)](#) for a summary of the uses of play in group therapy.

There are times in the course of a treatment process that play loses its usefulness as a communicative or therapeutic tool. This may happen even when the therapist seems to be conducting the sessions in a technically correct manner and has his or her own internal world in order in terms of fatigue, personal gratification, and countertransference ([Coppolillo, 1987](#)). Often the causes for the derailment of the process may be found in the preparation of the child and therapist to conduct therapy. For this reason some attention must be paid to conditions that will make the play an activity that is considered therapeutic by both the clinician and child, rather than one in which something will hopefully happen that will somehow benefit the child. A brief review of these conditions may be helpful.

### Conditions Regarding the Therapeutic Environment

#### PHYSICAL ENVIRONMENT

The physical conditions that are necessary to conduct safe and dignified psychotherapy are more fully discussed elsewhere ([Coppolillo, 1987](#)). Here it is sufficient to say that the physical environment needs to be safe, sufficiently well contained to convey the notion of confidentiality to the child, and allow the adults waiting for the child to be comfortable, especially if they must sit with a younger child while the patient is in the consulting room.

There is some question as to whether or not a separate "play area" is desirable. There are advantages and disadvantages on both sides of the question. A separate play area sometimes invites the child to make an artificial distinction between "talking time" and "playing time" and to therefore resent or resist inferences made by the therapist from the play. On the other hand, a single office may have rugs, furniture, and paintings that the child may damage, to the therapist's horror. If the child senses this concern, it may inhibit his or her play or spontaneity. Giving some thought to the problem allows the therapist to compensate for one or the other disadvantage.

Another specific issue that arises is how to equip the play area. Some therapists' play areas look like toy stores, with the variety of games and equipment on display. Others prefer to have only a small number of toys and drawing materials immediately available. Anna Freud is quoted as saying, "The special role of the toy as a therapeutic agent has been greatly overvalued" ([Sandler et al., 1980](#), p. 39). By this she meant that the use the child makes of the toy is by far more revealing than the choice of the toy itself. Children can use checkers to build a wall between them and some imagined threat and may use blocks to play a competitive game with the therapist. In addition, an important issue is what toys the therapist feels allow him or her to most comfortably assume an attitude of inquiry. If the therapist is vulnerable to compulsive reactions of neatness when his or her child patient is ruining a model by smearing glue all over it, it would be a good idea not to have models to build on his or her shelf. If the therapist finds himself or herself sliding into unproductive competitive feelings with a youngster, board games may not be the toys he or she would choose to have on display. One suggestion might be to have a few basic items of play in the office, such as drawing and coloring material, a doll family and simple dollhouse, toy vehicles, and toy soldiers. If the child then appears to want or need other things to play with, he can be asked as the treatment progresses if or how other toys will help both therapist and child to understand his or her worries or problems. This keeps the ultimate purpose of the play in the child's mind. What the therapist should keep in mind is that, in the optimal situation, it is the benign interest and attentive inquiry of the therapist that is helpful to the child and engages him or her, and not the allure of the toys. If the child cannot use this interest and attention (and where else in life can a child get 45 minutes to 1 hour of undivided attention from an adult), this inability needs to be addressed and worked through and not bypassed with the seductive appeal of toys.

#### PRECONDITIONS IN THE THERAPIST

We must hope that the therapist will come into the therapeutic sessions well rested, with few worries of his or her own, sufficiently confident that his or her own skills and techniques are adequate to help most children (so that the child does not *have to* get well for the sake of the therapist), and with enough play in his own personal life to ensure that the child is playing for the child's own reasons and not the therapist's. These are conditions to strive for, of course, and not ones that must be attained every minute of every day. If they were constant essentials, few of us could ever treat anyone. However, if the therapist does detect a persistent disturbance in any of the conditions mentioned, it is essential that remediation through environmental or psychological change take place in the therapist for the therapist's own and the patient's sake.

In addition to the unending self-scrutiny that the therapist must undergo, of course, is the intellectual preparation required to make play meaningful in terms of what it can reveal about the child's developmental achievements and arrests, as well as about the current state of his or her psychological organization. This requires a vivid, living picture of stages and processes in development as well as mental images of how children function in health and illness. Training in the recognition of these states as well as education in theories of human development make it possible for the clinician to utilize the rich, profound revelations that play provides.

#### PRIOR TO PLAY

Before all else, a history of the child's development and the difficulties that bring him or her to the clinical situation must be gathered ([Coppolillo, 1987](#); [Simmons, 1981](#)). Usually this history is gathered from the parents. The therapist must recall that we are all vulnerable to retrospective falsification, and especially when the historian is as emotionally involved as most parents are with their children. Remember too that the clinician is not just interested in whether a phase of development was deemed "normal." More often than not, normal is judged by whether or not the child was troublesome to the adults around him or her. It is most useful to learn of the style in which the child faced the stress of a new developmental phase; the defenses used in adapting to it, and whether or not there was pride in leaving behind old modes of adaptation and enthusiasm in adopting new talents. In short, conjuring an image of the living child as he or she developed is far more productive than pasting a label of "normal" or "abnormal" across a developmental phase.

The same considerations may be applied to the history of the difficulties that brought the child to the clinical situation. In this segment of the preparation, however, the clinician must anticipate and deal with two conditions that may become obstacles to the treatment later. The first of these is that the people who referred the child or are paying the bill may expect that the therapist will act as their agent. The situation can become critical if a school or court has referred the child and awaits guidance from the therapist. If there is any question about whom the therapist is representing, every effort must be made to clarify expectations at this stage of the treatment process. If they are not clarified, later in the treatment the child may sense divided responsibility in the therapist and feel that the therapist has betrayed him or her.

A second related issue occurs when, without meaning to do so, people bring a child to the clinical situation to be made *good* and not necessarily *well*. If the therapist inadvertently participates in trying to make the patient good, he or she joins the multitude of people who must seem to the child to wish only that he or she behave in a certain manner and to care little about the anguish or the forces that the child feels so powerless to resist. If the child reaches this conclusion, acquiescence may be possible, but revelation of his inner world is unlikely.

---

#### CASE ILLUSTRATION

A 16-year-old girl was treated, with parental approval, after the juvenile court had adjudicated her "an unruly child." She had run away from home twice in 6 months and was returned both times by the police. It was only after she became convinced that her therapist was *her* agent and not insistent on her behaving in any predetermined manner that she could reveal that she was running away from an incestuous situation at home. She had turned to a number of adults in her environment for help and had encountered blank stares or deaf ears. Running away from home, the very action that was labeled "bad" and for which she had been sent to therapy, had been the most adaptive action she felt she could have taken under the circumstances. Had the therapist been intent on making her good by convincing her of the evils of running away she would have probably not revealed her secret.

---

---

After the history is gathered, the more formal aspects of treatment begin, and it is in this phase that we come to see what an important asset the initiative of the child can be to the treatment. Yet let us review for a moment the manner in which many children are brought to our offices. One day the mother or the father says, "You are having trouble with such and so, and we are going to see a doctor about this." Often without further explanation the child is taken to the family car, where he or she sits *passively*, until he or she is escorted to a strange waiting room, where once more the child *passively* waits until initiative is further taken from the child by his being led into the consulting room. Then the child is invited to become *active*. How strange this must seem to the child! One way to avoid this dilemma is to come to an agreement with the parents about the time that the child can be seen. If it is possible, make more than 1 hour available in order to allow the child a choice in case there is some activity that is especially important to *the child* that might compete with the agreed-on hour. Then ask the parents to have the child call to make the appointment. Some parents say that the child will not call, but few children actually refuse to do so. When they do call from the safe environment of their home, the therapist can demonstrate awareness and respect for the fact that the child has activities that are important to him or her, and also demonstrate that language or concepts that will leave the child hopelessly perplexed will not be used. An added advantage of this is that it demonstrates to the child that what he or she has to say or show will be heeded ([Coppolillo, 1987](#)).

The therapeutic alliance, as essential for any child therapy as it is for adult work, has already begun with the phone call. In the succeeding hours it must be continued, developed, and fortified. It must be stated as well as demonstrated to the child that no conclusions will be reached without the child's awareness and, whenever possible, participation. The child must come to realize that the clinician will not "spring something" on him or her through a gimmick or ploy, and that the work will be accomplished with cooperative respect. The child will produce the data that the clinician and child will examine together to reach conclusions. Phrases like, "We'll put our heads together to see if we can figure out what things mean" are helpful in forging and reforging the therapeutic alliance. As part of this alliance and the therapeutic contract, the therapist must convey to the child the message that play will be primarily for the purpose of helping them both to understand what causes some of the child's troublesome feelings and behavior to occur. To fail to mention this and then, when the child is lost in play, to interpret the play tends to make the child feel what we feel when in a social situation we make a painfully revealing slip of the tongue and that is then "interpreted" by a "parlor analyst" who feels impelled to interpret the slip for all to hear. The child is far less troubled when he knows that his play will be used for revelation and the interpretation begins with a phrase something like, "I wonder if your play means that . . ."

Although the suggestions in the preceding paragraphs apply to the whole phase of the beginning of treatment, it should be remembered that the foundations for the therapeutic alliance are laid during the first contacts with the family. To ignore this may mean that, if treatment is recommended after the diagnostic workup, the therapist may have to undo some distasteful or even frightening convictions that the parents or child may have drawn about the child's treatment during the early contacts with the therapist.

Another necessary element in treatment planning that influences the therapeutic alliance is setting the number of times per week and the hours that the patient is seen. Although it may not be possible to accommodate the child's wishes as to the time that he or she can be seen, thoughtful consideration to the child's schedule is a powerful support to the alliance.

Setting the frequency of the sessions requires consideration of a number of variables. The finances of the parents and the therapist's fees are one variable; however, the nature of the pathology and what its treatment will require should be the central consideration. There is another issue frequently not considered. The child's improvement in the therapeutic sessions counts for little if there is not concomitant improvement in his or her feelings and behavior in the everyday world. This requires working through the conflicts uncovered in treatment. Often this working through cannot be accomplished in the home environment, because the parents inadvertently keep the conflict alive in the adaptation that the family group has made to the child's behaviors. In addition to consultations with the parents, the child needs a milieu in which he or she is free to try out the different behaviors that result from the resolution of conflicts. If the child is scheduled so tightly that he or she has little or no time for spontaneous play with peers or the relaxation that supports spontaneity, scheduling more sessions may be counterproductive, especially if the scheduled treatment hours are at the expense of his "free time." Therefore, setting times should be done with an eye to how the therapeutic hours will influence and be influenced by the rest of the child's daily life.

---

#### CASE ILLUSTRATION

A 9-year-old girl was being seen for a delayed and inhibited grief reaction occasioned by the loss of her father when she was 4. She had been given hours before school largely because her after-school hours were filled with all manner of activities (which were also used as defenses against the recognition of her unremitting loneliness). A phase of her therapy that was shallow and unproductive had lasted for several months. During this phase she had taken to drawing a number of "wilderness scenes" in which the woods and mountains she drew contained various animals that were depicted and described as busily going about their customary activities without interacting in any way. When the therapist commented on the absence of interaction and that the animals must be lonely, she first associated to the idea that if they stayed busy they would not fight, and then to the more general notion that if they stayed busy they would not feel any disturbing affects. After the therapist likened this to her staying busy in general and in her treatment hours in specific, she could acknowledge that she was afraid that if she cried during her treatment hour she would go to school with red eyes and everyone would wonder why. It was only after a conference with her mother, a reduction of the after-school activities that she had scheduled, and the setting of her appointments after the school day that she could begin to see that the reluctance to experience and show sad affects was based on her fear that her grief would upset her mother (and in the transference, her therapist). It was only when the real concern that she would be embarrassed by her red eyes in school could be addressed that she could address *neurotic* conviction that her negative affects would disintegrate her mother. Few defenses are as effective as a bit of reality that is used as a defense.

---

Having attended to the notion that events prior to formal therapy may influence the therapy itself, we can turn to those technical considerations that render the process of play useful for therapy.

### PLAY IN THE SERVICE OF PSYCHOTHERAPY

A paradox to be reckoned with in the use of play is that play is so revealing that we sometimes fail to see what it conceals. If in watching a child play we come to a conclusion prematurely and misunderstand the significance of the play or understand only one part of the play, the misunderstanding or partial understanding can be used as a defense against revealing more important significances. The therapist must be ready to wait for the cues and learn to avoid taking assumptions made from his or her own past experiences for granted.

---

#### CASE ILLUSTRATION

Joey, a bright 6-year-old boy, was being treated for his tendency to isolate himself from his parents and his passive disobedience at home and school. He had been in treatment before, which his parents had deemed ineffective and had terminated. His former therapist stated that all Joey had wanted to do was to play board games. In one of the early sessions of his second treatment Joey picked up some checkers and went to the table where children usually played. The therapist, sure that the child again wanted to play a board game picked up the checker board on his way to the table, and as he picked it up he remembered the comments of Joey's former therapist. He replaced the board and sat down to see what Joey would do. Joey said nothing but began to use the checkers as blocks. He built a wall between himself and the therapist, commenting on how difficult it was to build a good wall with checkers. The therapist answered that if Joey really wanted to show him how important a wall was, he would get some blocks with which he could more easily build a wall. The blocks became unnecessary. The discussions about walls between people were necessary and revealing.

---

Even the therapist's very natural presupposition that Joey wanted to play a board game with him would have led to a compliant and counterproductive defense on Joey's part in this instance. Thus the adage: "Wait until the cues are clear to make an inference or an interpretation."

Generally there are four ways that children play during their treatment hours. They can become lost in play and play alone in the presence of their therapist. They can play alone but with a demand, either explicitly stated or conveyed implicitly through body language, that the therapist watch their play attentively. They may play with the therapist in unstructured play with no rules other than that the game evolves. They may express a wish to play a structured game such as a board game, guessing game, or a hiding game. The meaning of each of these modes will eventually become clear if the therapist keeps a number of principles in mind.

The first of these principles is that while minding the content of the play the therapist must also notice the process by which the play is chosen and how it progresses.

---

#### CASE ILLUSTRATION

Tommy was a 10-year-old boy with little self-esteem despite a remarkable talent for drawing and better than average intelligence. In the course of his treatment he would suddenly break off discourse or some form of play and would ask to draw. He would then engross himself so deeply in his drawing that he would not attend to questions about the content of his picture or the techniques he had used to produce it. When finished with what was usually a remarkably good drawing he would present it to the therapist and give bland, nonrevealing answers to anything that he was asked about the picture. One day he came to the office ahead of his mother and announced that he wanted to draw a picture. Before the therapist and Tommy could move to the inner office the mother arrived and announced that she had to tell the therapist that Tommy had gotten grades that were far below his competence in a number of his classes. The therapist waited until they were in the inner office then recalled that Tommy felt his compelling desire to

draw on a number of occasions when they had discussed or gotten close to discussing issues that Tommy felt would cast him in a bad light. When the therapist mentioned that he had just begun to notice when Tommy wanted to draw, Tommy himself said, "Yeah. When I get in trouble." By noticing the process rather than being stuck on the content of the drawings, the therapist and Tommy found a great amount of material to explore together.

---

---

Another issue to contemplate is that of body language that serves communication during play. Recall the pinched, tight control of the perfectionistic youngster who is attempting to draw the perfect picture to win approbation. Think of the increasingly less purposive movements of the impulsive child who gets "carried away" by aggressive impulses while playing with toy soldiers. And who can ignore the apathy and anhedonia conveyed by the lack of tone and movement of the depressed child?

---

---

CASE ILLUSTRATION

Annie, a 4-year-old girl who had lost her mother, displayed both the longing for close contact as well as the rejection of substitute relationships in her play. On a number of occasions she demanded that the therapist sit on the floor near a dollhouse as she played with the dolls. Several times she stumbled "accidentally" or had another accident that would land her in the therapist's lap. On other occasions she would clearly avoid any physical contact with the therapist. In one instance she asked the therapist to fix the clothes on the doll with which she was playing. She shrank away as the therapist reached for the doll she was handing him. The therapist, by asking her to notice her movement, made it possible to discuss her ambivalence about feeling close to anyone else while mourning her mother.

---

---

The third issue that requires attention as play progresses is the previously mentioned countertransference that can occur at any point. These are subtle and can be insidiously destructive to the therapeutic process. Countertransference may take any number of forms. They are facilitated by the regressive pull of the child's immaturity and his or her play and generated by a variety of states and conflicts in the therapist. Lewis offers a list of examples of countertransference in the preceding chapter on intensive, individual psychotherapy of children ( [Chapter 79](#)). The only comment to add here is that when countertransferences occur in a positive form, as in the wish to rescue or defend the child, or be protective of the child or when he or she is already being protected, they are much more difficult to detect. Negative feelings toward the child become a foreign body in the awareness of the therapist more readily than those that are compatible with our self-image of loving, caring adults. However, positive countertransferences can be as destructive to the process as negative ones ( [Coppolillo, 1969](#)). Rather than think of these as sins that must be abolished, it is useful to view them as additional cues to consider regarding the nature of the transaction. The therapist who understands that he or she is vulnerable to rejection, for example, may come to understand that a feeling of irritation or boredom is being occasioned by a withdrawn child's need or wish to become "lost" in solitary play in order to avoid the burden of relating. Again, the therapist who depends on the affection of the child may find that the child seeks play that he or she thinks will please the therapist in order to charm or seduce the therapist away from recognizing conflicted, negative feelings in more spontaneous play.

Finally, an eye must be kept on the content of the play. Here the help of the child is needed in order to ascertain in what way the play is significant *to the child*. Questions about what is happening in the play can be asked both when the child is playing alone and when the play is interactive. When the child has assigned the therapist a role in the play and demands that he or she act out the role, asides or stage whispers can be used as parentheses in which the questions may be posed.

---

---

CASE ILLUSTRATION

A 4-year-old child, whose mother had suffered a serious accident after the child had been sent to bed for her afternoon nap, was playing out her fear and chagrin about being coerced to go to sleep. She made the dolls with which she was playing be sent to bed by the therapist and then had them hop out of bed to ask for drinks, food, and other favors.

Child, holding the doll in the therapist's face: "I want some milk."

Therapist, in a stage whisper behind his hand: "What does he say?"

Child, in a stage whisper: "He says 'go to bed.' "

Therapist, gruffly: "Go to bed!"

Child puts the doll in the doll bed while she pretends to be crying.

Therapist, again in a stage whisper: "What do you wish he had said?"

Child: "Why can't you sleep, little girl?"

His inquiry allowed the therapist to then meet her plea for understanding instead of coercion.

---

---

In addition to inquiry about the content of the play, the therapist must continually look for the associations that may explain the shift from one play activity to another.

---

---

CASE ILLUSTRATION

An 8-year-old boy, the son of a physician, had played "going to doctor school" in the therapist's office by looking through an anatomy text. When it became clear to the therapist that the child was demonstrating more than a passing interest in the genitalia and breasts in the female illustrations, he asked him if the medical school play was to hide his embarrassment at his curiosity about women's bodies. The boy was able to acknowledge this. Later in treatment the therapist noticed that on several occasions the boy returned to the medical school play after having talked about his sister. With some gentle questioning the therapist discovered that the boy was chronically anxious and stimulated because of the fondling and exploration to which he had been subjected by an older sister.

---

---

On occasion, a seemingly disconnected or spontaneous comment during play offers a revealing association.

---

---

CASE ILLUSTRATION

A 4-year-old boy, brought to treatment for voluntary retention of feces and fear of using the potty, became obsessed with flat tires in play. The toy cars he played with always developed flat tires. He drew cars with flat tires and repeatedly requested that the therapist draw cars with flat tires for him. On one occasion when the therapist was drawing one of these cars for him, the boy commented that the therapist had a big belly. When the therapist asked him what he meant and how it was connected to the cars, the boy answered, "Your belly is round and not flat." Having made the connection of flatness between car tires and bellies, the boy could tell of when he was riding with his father in the car when they had a blowout that sent the car out of control and frightened him. He could then say that he was afraid of getting flat (out of control) if he went to the bathroom.

---

---

Finally, the therapist must allow some disciplined play to his own creativity and imagination in making abstractions about the content and process of the play he is observing. For example, if a child is playing with cars and labels one a fire truck, another a police car, and still another an ambulance, the abstraction that would occur to the therapist that would tie them together would be responses to an emergency. Then, depending on the age of the child, and with his history in mind, the therapist might be able to determine if the child was in the process of mastering a trauma that he had experienced, like a home fire, or was symbolically conveying anxiety about something unpredictable or uncontrollable occurring such as an impulse getting out of hand.

And so, by having the patience and interest to wait for the cues, the serenity to keep an eye on his or her own countertransference, the imagination and creativity to envision patterns of significance in the content and process of the child's play, the therapist can, with tact and kindness, return to the child, in a manageable form that which the child has anxiously revealed symbolically in his or her play.

## CONCLUSIONS

Theoretical considerations often provide frames of reference that permit the user of a technique of disciplined creativity in the use of that system. Instituting rules for the use of a technique often does just the opposite, by simply constricting rather than enabling. For this reason, a brief review of how the mentioned concepts of Winnicott and Rapaport are indicated, because they specifically apply to the therapeutic use of play.

[Winnicott \(1953\)](#) demonstrated how bringing an object into the “intermediate area of experience” alleviated the strain of relating external reality to the inner world of wishes and subjective convictions.

[Rapaport \(1951, 1958\)](#) described how attending to the inner world of drives and impulses, as well as to one's own values and self system, presents a stimulus barrier to the world of external reality and shelters one from slavery to external circumstances. He continued his exploration by noting that, conversely, human beings were not simply expressions of sublimated drive activities. Both the autonomous functions of the ego and attentions to external reality provide the human being with a measure of autonomy from the inner world.

Integrating the work of these two authors ([Coppolillo, 1976](#)) permits us to appreciate the powerful effects of play in the adaptation of the human being to his or her environment. In the therapeutic use of play, we may join Winnicott in considering the immersion into play as providing a “holding environment” ([Winnicott, 1965](#), pp. 50–51). The privacy, and nonthreatening and nonintrusive qualities of the ambiance then act as a shield against any coercive qualities the child may ascribe to the external world, and thus increase the child's sensitivity to his or her inner world. At the same time, “the reality” of the therapist's presence, his or her absence of fear or anxiety about the child's impulses, the regularity of the hours, and the therapist's commitment to understanding rather than judging, reassure the child that his or her own impulses will not be overwhelming. Into this setting a toy, game, or idea can be taken into the intermediate area by the child and there further regulate and titrate the amount of anxiety the child can tolerate as either fear of his or her impulses or dangers ascribed to the external world. For example, if the child is playing out destructive fantasies with the use of soldiers and an impulse to destroy becomes too transparent or intense, the child may turn his or her attention to the realistic quality of the soldiers and decide that they are too small, too few, or just toys. If aspects of reality become too coercive or boring, the child may allow himself or herself to be a bit more lost in the unrealistic quality of the play and imbue the toy with more aggression or creative ways to bring down the opposing general. With each new awareness achieved through these adventurous explorations, the child becomes more secure, expansive, and above all, more confident that the revelations his or her play brings will be useful and not threatening or destructive. In this way, more profound and subtle issues can be addressed in the process of play until one day, with that bit of sadness that accompanies all developmental steps, child and therapist recognize that the healing brought by play no longer needs the catalytic action of the therapist. Even without being aware of it, the child has developed another function for play, another way to find healing and soothing.

## HISTORY

The field of child and adolescent behavior therapy has become much more accepted into the mainstream practice of psychotherapy, but it nevertheless remains often misunderstood and thus misapplied. The general definition of behavior therapy is quite broad and frequently refers to a variety of approaches related only by their reliance on standardized methodologies and measurable outcome results. Although the more widespread use of behavior therapy is encouraging, the increase in untrained clinicians who bill themselves as behavior therapists is unfortunate. Too often, unsuccessful treatment attempts are attributed to inadequate behavior therapy techniques rather than inept clinical applications of appropriate interventions. This chapter attempts to define and clarify the basic assumptions of behavior therapy, introduce its applications, and discuss the current issues in the field.

Behavior therapy refers to a set of related assumptions, principles, and techniques that are rooted in learning theory and used to change human behavior. Although the intellectual foundations of behavior therapy date back to the 17th century empiricism of Locke and the 19th century utilitarianism of Bentham, behavior therapy's more recent past can be divided into two relatively distinct periods: an early history dating from approximately the turn of the 20th century to the early 1950s, and a more recent period dating from the 1950s to the present.

The early history of behavior therapy is characterized by seminal contributions from key figures that frequently were not recognized for their relevance to human problems until the mid-20th century. Examples of this are the work of [Ivan Pavlov \(1927\)](#) on the conditioned reflex, Edward [Thorndike \(1911\)](#) on connectionism and the law of effect, and John B. [Watson \(1913\)](#) on behaviorism. Watson and his colleagues, Rosalie Raynor ([Watson and Raynor, 1920](#)) and Mary Cover Jones ([Jones, 1924a, 1924b](#)), were particularly influential in drawing popular attention to the importance of behavioral principles of conditioning in shaping human behavior. In addition, they were the first to show that these principles could be used to ameliorate infant and childhood problems. Despite these and other efforts, behavioral approaches were overshadowed during this period by the prevailing *zeitgeist*, then dominated by psychoanalysis and the emerging child guidance movement. Even a 1938 appeal by Arnold Gesell, a leader in that movement, for professionals to pay greater attention to behavioral principles had little impact on the use of behavioral approaches ([Ross, 1981](#)). The subsequent influence in the 1940s of Carl Rogers and his client-centered therapy further delayed the acceptance of behavioral approaches ([Meyers and Craighead, 1983](#)).

It was not until the 1950s that mental health professionals began to adopt behavioral approaches more widely for the treatment of mental disorders. This period was marked by a critical evaluation of the limitations of traditional therapeutic approaches to human problems and an eagerness to consider more scientifically based approaches. Works by [Skinner \(1953\)](#), [Wolpe \(1958\)](#), [Eysenck \(1960\)](#), and [Bandura and Walters \(1963\)](#) were particularly influential in demonstrating how learning theory principles could be used to ameliorate human problems. Patients with psychoses, severe anxiety neuroses, and autism became candidates for the application of the behavioral strategies and techniques identified in these works because few of the traditional approaches offered much hope for symptom improvement ([Ferster and DeMyer, 1962](#); [Ross, 1981](#)). The success of these approaches in the 1950s and early 1960s with the most seriously disturbed adults and children enhanced the credibility of behavior therapy and increased its acceptance among professionals ([Kazdin, 1978](#)). This heralded the appearance of a host of behavioral journals during the 1960s, which began to provide a scientific basis for the field. Success with more disturbed patients also prompted professionals to begin to apply behavioral approaches to a wider range of problems, particularly to those presenting in outpatient settings. This prompted behavior therapists to reconceptualize the role of cognitions in changing behavior, such that they came to be viewed not only as a potential *target* of treatment but also as a possible *mechanism* for behavior change. The integration of cognitions into behavior therapy, coupled with developments in the emerging field of information processing, sparked the development of social learning theory and cognitive-behavioral approaches in the late 1960s and early 1970s ([Meyers and Craighead, 1983](#)). The latter approaches dramatically increased behavior therapy's scope, the settings in which it could be practiced, and its potential for human betterment. Today, behavior therapy includes such a diverse array of therapeutic principles, practices, targets, and settings that it may be more accurate to use the term behavioral *interventions* to describe the additional preventive, promotive, and consultative efforts in the field.

## BASIC ASSUMPTIONS

Behavior therapy rests on a common set of assumptions that distinguish it from other forms of therapy. The primary assumption is that most behavior develops and is maintained according to the principles of learning ([Herbert, 1988](#); [Johnson et al., 1986](#); [O'Leary and Wilson, 1987](#); [Rimm and Masters, 1979](#)). Learning may be defined as a process in which behavior is initiated or is changed in reaction to internal or external stimuli that are not the result of "native response tendencies, maturation, or temporary states of the organism" ([Hilgard and Bower, 1966](#), p. 2). Specific behavior therapy techniques are derived from each of the four types of learning: respondent conditioning, operant conditioning, cognitive behavior modification, and social learning.

The principles of respondent conditioning are perhaps the most widely known among these. Respondent conditioning is based on the observation that certain behaviors, known as *respondents* (e.g., salivation, increased heart rate), are elicited involuntarily in response to certain stimuli (e.g., having food in one's mouth or being startled by a loud noise). Such behaviors are known as *unconditioned reflexes* or *unconditioned responses* because they occur "automatically" in response to a particular stimulus. Stimuli that are able to elicit such responses are known as *unconditioned stimuli*. When unconditioned stimuli are paired repeatedly with a previously neutral stimulus, eventually the neutral stimulus is able to elicit a conditioned response that usually resembles the unconditioned reflex. This was first demonstrated by [Pavlov \(1927\)](#) in a now-classic experiment with dogs, in which he paired a previously neutral stimulus—a bell—with the presentation of food, such that eventually his dogs began to salivate merely at the sound of the bell. Respondent conditioning in humans was first demonstrated by [Watson and Raynor \(1920\)](#) in their experiment with Albert, an 11-month-old infant. After allowing Albert to play comfortably with a furry white rat, the experimenters began to startle Albert with a loud noise (an unconditioned stimulus) whenever he began to play with the rat. After only seven pairings, Albert's pronounced startle to the noise was capable of being elicited exclusively by the sight of the rat, thus revealing a conditioned fear response. Importantly, Albert's fear also was elicited to a lesser degree when he was

in the presence of other furry animals and objects, illustrating the related principle of *stimulus generalization*. [Seligman \(1971\)](#) has argued that humans are more “prepared” to be conditioned to certain objects, thus accounting for the observation that persons are more likely to be conditioned to some objects than to others.

Another form of learning is *operant conditioning*. Based on Thorndike's observation that behavior is strengthened or weakened by its consequences, operant conditioning was first identified by [Skinner \(1938, 1953\)](#) as involving behaviors that could be modified or maintained by their consequences. Skinner termed such behaviors *operants* because they operate on the surrounding environment to generate consequences. Thus, behavior that is followed by pleasant consequences is likely to increase in frequency, whereas behavior followed by unpleasant consequences is likely to decrease in frequency. Operants differ from respondents in two primary ways: (a) They involve voluntary behavior that is “emitted” (i.e., as thoughts or actions) rather than “elicited” (i.e., as involuntary reflex responses); and (b) in the stimulus–response science of behavior, they are linked to properties of the response (e.g., its strength, frequency, duration) rather than to those of the stimulus ([Hilgard and Bower, 1966](#)). Because [Skinner \(1953\)](#) argued that most human behavior is operant in character, he advocated that the principles of operant conditioning be used to solve many types of behavior problems, an approach known today as *applied behavioral analysis*.

A third type of learning is *cognitive behavior modification* ([Beck, 1976](#); [Ellis, 1962](#); [Mahoney, 1974](#); [Meichenbaum, 1977](#)). This has been described as an attempt to integrate internalism with behaviorism because of the primacy of cognitive and symbolic processes in mediating behavior ([Meichenbaum, 1977](#)). A basic assumption of cognitive–behavioral approaches is that cognitive processes (e.g., attributions, cognitions, expectations, beliefs) influence one's behavior and affect. Irrational and faulty cognitive processes foster the development of maladaptive behavior patterns that are best reversed directly through the modification of maladaptive cognitions. Techniques such as cognitive restructuring and problem solving are common tools used by cognitive–behavioral therapists to correct maladaptive cognitive processes that are believed to cause behavioral problems. Cognitive–behavioral approaches do not concern themselves with intrapsychic, biological, neurologic, or genetic factors in the development of child behavior problems ([Kendall, 1985](#)). Rather, a major focus of cognitive–behavioral approaches is determining how cognition and behavior influence the development of child behavior problems. Although cognitive–behavioral approaches place less emphasis on the influence of affective, familial, and social processes on human behavior, they seek to integrate understanding of these processes with cognitive and behavioral factors to produce change (Kendall, 1993).

*Social learning theory*, also known as *social cognitive theory*, describes the final category of learning ([Bandura, 1969, 1977, 1986](#); [Bandura and Walters, 1963](#)). Social learning theory is an attempt to integrate the two types of conditioning theories with our understanding of cognitive processes. According to [Bandura \(1977\)](#), learned behavior is governed by three types of regulatory processes: paired stimulus–response events (as in respondent conditioning), environmental consequences (as in operant conditioning), and symbolic cognitive processes (described partially in cognitive behavior modification). The most important among these are cognitive processes, and particularly those that involve observational learning, a process in which behavior change occurs by observing a model. For example, a child who views another child being rewarded for a particular behavior is more likely to perform similar behaviors. The centrality of observational learning in social learning theory is one of its distinguishing features. Another important feature is the view that behavior is characterized by “triadic reciprocity”; that is, behavior is determined by the reciprocal interplay among three forces: behavior, cognitive and other personal factors, and environmental influences ([Bandura, 1986](#)). A final distinguishing characteristic of social learning theory is that it emphasizes the person's capacity for self-directed change. The latter two characteristics are clear departures from the more deterministic view of human nature and causality offered by respondent and operant conditioning theories, and to a lesser extent by cognitive behavior modification ([Bandura, 1986](#)).

A second major assumption of behavior therapy is that observable behavior should be the primary focus of therapy ([Kazdin, 1985a](#); [Rimm and Masters, 1979](#)). Subjective experiences such as feelings and cognitions, as well as psychophysiological processes such as electrodermal activity, are viewed as integral and essential elements of the therapeutic enterprise as long as observable behavioral referents for their occurrence are identified. In general, behavior therapists eschew treatment formulations that hypothesize a distal underlying cause for an observed behavior, preferring instead to focus on environmental contingencies proximal to the behavior in question. In this connection, although behavior therapists acknowledge the importance of biological and genetic factors that may contribute to the emergence of a problem behavior, they seek to identify and modify environmental contingencies that are presumed to maintain it in the here and now.

A third major assumption of behavior therapy is that treatment techniques should be empirically based ([Johnson et al., 1986](#); [O'Leary and Wilson, 1987](#); [Rimm and Masters, 1979](#)). Many of the techniques behavior therapists use were derived from laboratory experiments and have their roots in experimental psychology. As a result, behavior therapists view their work as an “applied science” ([O'Leary and Wilson, 1987](#)) because it involves the application of these techniques to clinical problems. A related byproduct of this development is that behavior therapists emphasize the setting of clear and precise goals in treatment, which enables them to validate treatment goals and outcomes empirically.

A fourth major assumption of behavior therapy, related to the previous one, is that treatment should be action oriented and directive ([London, 1986](#); [Rimm and Masters, 1979](#)). This assumption is based on the belief that action, rather than insight, is the primary mechanism for change, and that symptom change is the appropriate focus of treatment rather than some ill-defined and unspecifiable “underlying cause.” The primacy of action means that behavior therapists take an active, directive role in treatment (“homework” is assigned for patients to complete between sessions, specific treatment goals and strategies are discussed directly with patients, behavioral contracts between therapist and patient or between parents and child are negotiated in the session, and so forth). Practice is encouraged, interpretation rarely is used, and empathic listening is used as long as it promotes the accomplishment of behaviorally based treatment objectives.

A fifth and final major assumption of behavior therapy is that behavior change is best maintained through enlisting the help of key persons in the client's environment ([Herbert, 1988](#); [Kazdin, 1985a](#)). In the case of children, this usually means teaching behavioral principles to parents, teachers, and other family members and establishing a treatment plan that provides for the generalization or “transfer” of treatment from the clinic to the child's natural environment, such as the home or school. Underlying this assumption is the belief that much behavior is situation specific and that proximal environmental contingencies can best be addressed by training key persons in the child's environment who can help maintain therapeutic gains.

## BEHAVIOR THERAPY TECHNIQUES

The techniques of child and adolescent behavior therapy can be categorized as attempting to produce either of two kinds of behavior change: (a) to strengthen, develop, or maintain behavior; or (b) to reduce or eliminate behavior. Although these techniques can be used for a wide range of problem behaviors, only the most common applications are summarized in the following sections.

### Techniques to Strengthen, Develop, or Maintain Behavior

In operant conditioning, *reinforcement* is the process by which behavior is strengthened by its consequences. In the case of *positive reinforcement*, a reward (or reinforcer) is presented after the occurrence of the desired behavior; in *negative reinforcement*, the reward involves removal of an aversive stimulus after the desired behavior occurs. Both positive and negative reinforcement differ from punishment because their purpose is to *increase* the likelihood that a particular behavior will occur. Punishment, on the other hand, is aimed at *reducing* the incidence of a particular behavior. Reinforcers can be either tangible (i.e., involving concrete, material items, such as food, money, privileges, opportunities to engage in specific activities or behaviors, and removal of sanctions) or intangible (i.e., involving social or related items, such as encouragement, praise, and smiles) ([Herbert, 1988](#)). In addition, reinforcers can be external (i.e., obtained from others) or internal (i.e., provided to oneself). An important property of reinforcement is that behavior is strengthened differentially by the schedule of reinforcement used. Reinforcement that is administered immediately after each time a desired response occurs is known as *continuous reinforcement*. Other types of reinforcement schedules involve some form of *intermittent reinforcement*. In a *fixed interval* schedule, the child is reinforced after a specific time, regardless of what response is emitted, whereas in a *variable interval* schedule, the rate at which reinforcement is administered varies randomly around a specific average. A *fixed ratio* schedule administers reinforcement after a specified number of the child's desirable responses, whereas a *variable ratio* schedule administers a reinforcer randomly around a specific average of desirable responses on the part of the child. In general, learning that results from intermittent schedules of reinforcement—and, in particular, variable interval or variable ratio schedules—is more stable and difficult to change than that acquired through continuous reinforcement. The treatment of compulsive gambling is an example of how an intermittent reinforcement schedule can lead to behavioral persistence and high rates of responding.

Positive and negative reinforcement are techniques frequently used to teach children skills to compensate for behavioral, learning, and other skill deficits. In addition, reinforcement often is used in combination with other techniques designed to strengthen or eliminate behaviors.

A second important behavioral change technique is *stimulus discrimination training*. This involves reinforcing a particular response in the presence of one stimulus while not reinforcing that response in the presence of another stimulus. Stimulus discrimination training enables the child to learn how to discriminate when and under what conditions it is most appropriate to emit a particular response, and when it is not. Three techniques are used in stimulus discrimination training: shaping, fading, and chaining ([Martin and Pear, 1983](#)). *Shaping* involves reinforcing closer and closer approximations of behavior to produce the final desired behavior. Thus, a

teacher of a severely mentally retarded child might initially reward the child for standing near a desk, then sitting in the desk, then engaging in playful behavior while sitting in the desk, then for on-task classroom behavior while sitting in the desk. This is accomplished by varying when and under what conditions reinforcement is provided. *Fading* involves gradually changing a stimulus that controls a response so that eventually a new, alternative stimulus produces the same response. Thus, an autistic child who only mimics the word *shoe* might be provided with a reinforcer (e.g., praise, hugs, tokens) every time he or she repeats “shoe” in the presence of an additional prompt, such as “What’s on your foot? Shoe.” Gradually the prompt “shoe” is faded until the child is able to respond directly to the question “What’s on your foot?” *Chaining* involves reinforcing more and more of the stimulus–response links that comprise a complex chain of behavior, such as using a fork to eat. This procedure usually involves the use of shaping or fading techniques to achieve stimulus control of the desired behavior. Thus, in chaining the therapist might demonstrate an entire behavior to be learned and then reinforce a child for his or her attempts to complete the entire behavior, as well as for specific successive approximations of the behavior, as is done in shaping. Shaping, fading, and chaining commonly are used in conjunction with other behavioral techniques, such as reinforcement, to teach children skills to compensate for behavioral, social, or other skill deficits.

*Conditioned reinforcement* also is used to strengthen, develop, or maintain behavior. In conditioned reinforcement, a particular stimulus—the conditioned reinforcer—signals the likelihood that reinforcement is forthcoming. Over time, the stimulus itself becomes reinforcing (i.e., it becomes conditioned) because of its association with the receipt of reinforcement. Thus, parental praise is a conditioned reinforcer because it signals the likelihood that other reinforcers, such as food, privileges, affection, and so on, are forthcoming. Tangible conditioned reinforcers that can be earned and exchanged for other reinforcers typically are referred to as *tokens*. A behavioral program that uses tokens systematically to produce behavior change is known as a *token economy*. Token economies have been used with considerable success in a wide variety of settings, such as schools, inpatient units, and group homes, as well as in the home by parents ( [Kazdin, 1977](#)).

*Contingency contracting* is another behavioral technique that is used primarily to increase specific behaviors, but also may be used to reduce inappropriate or unwanted behaviors (Herbert, 1987; [Kazdin, 1989](#); [Spiegler and Guevremont, 1993](#)). Contracts may be verbal or written and may be used in conjunction with conditioned reinforcers, such as tokens, to reinforce target behaviors. Written contingency contracts should specify the following in unambiguous terms: (a) the responsible parties involved (e.g., the parent(s) and the child); (b) the target behavior(s) to be increased (e.g., studying, school attendance) or eliminated (e.g., smoking, physical aggression toward a sibling); (c) the consequences for completing or failing to complete the target behavior (i.e., the behavioral contingencies); and (d) the time interval during which the contract is in effect (e.g., weekly, monthly). For some contracts, it also may be necessary to specify who will monitor some target behaviors (e.g., a teacher) or how those behaviors will be monitored (e.g., daily school report). An example of a written behavioral contract that parents might use to increase several specific target behaviors of an adolescent is found in [Fig. 81.1](#).

Child agrees to do	Parent agrees to do
1. Get ready for school (wake up on the alarm, get dressed, eat breakfast, brush teeth, and get out to the school bus on time every day).	1. Make breakfast, get ready, and send child off to school on time every day. If child is late, parent will bring to school every day and a reward of \$10 or the value of the week.
2. Complete homework. Complete daily homework, complete all projects on time, and complete all projects on time.	2. Give child \$10 if the child completes all homework on time. If the child does not complete all homework on time, parent will give the child a reward of \$10 or the value of the week.
3. Complete chores. Take out trash on Tuesday nights, clean shower on Wednesday and Thursday, and clean the kitchen on Friday.	3. Pay weekly allowance of \$10 on Friday if child completes all chores on time.
4. Engage in "family" time (reading with parent, watching TV, playing board games, etc.)	4. Engage in "family" time (reading with parent, watching TV, playing board games, etc.)

Notes: 1. If more than one child is involved, the contract will be modified for each child.  
2. If the child fails to complete a task, the parent will be grounded for 1 week (not to be used as a punishment).  
3. I agree to abide by the above contract to the best of my ability.

Modeling represents a behavioral change technique that involves having a child observe a model engage in a particular sequence of behavior for the purpose of producing behavior change. Three types of modeling have been identified: live, symbolic, and participant ( [Bandura, 1969](#)). In *live modeling*, a child observes a model engaging in the target behavior *in vivo*; in *symbolic modeling*, a child views the model on film or videotape or imagines himself or herself engaging in the behavior; and in *participant modeling*, a child observes a model engaging in the target behavior *in vivo* and then attempts that same behavior. Modeling can have a number of different effects: acquisition of a new behavior, social facilitation of observed behavior, enhancement of environmental influences, arousal of specific emotions, disinhibition of behaviors that previously were avoided, and extinction of behaviors associated with persons or objects that were observed ( [Bandura, 1986](#)). (The latter two involve effects that reduce or eliminate problem behaviors.)

A final set of behavioral change techniques that can be used to strengthen, develop, or maintain behavior, as well as reduce or eliminate behavior, is skills training approaches. Two types of skills training approaches are described most commonly: *social skills training* and *cognitive skills training*. The aim of social skills training approaches is to teach children the skills necessary to interact in socially appropriate ways with peers and adults. Typically, skills are taught in an analog or laboratory setting through a combination of behavioral techniques, such as positive reinforcement, modeling, coaching, instruction, role playing, and behavioral rehearsal ( [Hops et al., 1985](#)). For example, an extremely shy boy may be taught how to interact more assertively with peers by first viewing a model perform the target behavior and then being praised for each successive approximation of that behavior during role play. Therapist and child then rehearse this procedure until the child is ready to interact assertively with peers. Such techniques have been used extensively to teach appropriate social skills to socially isolated and withdrawn children, to mentally retarded and autistic children, and to children who are overly aggressive and antisocial ( [Dumas, 1989](#); [Hansen et al., 1989](#); [O’Leary and Wilson, 1987](#)).

Cognitive skills training approaches are a related type of technique that emphasizes teaching children cognitive skills that are presumed to mediate successful task performance. Also known as *self-instructional training*, *problem-solving training*, or *self-control training* (depending on the goals of the treatment), cognitive approaches are based on the cognitive–behavioral assumption discussed earlier, in which faulty cognitions mediate maladaptive behavior. As opposed to social skills training approaches, which emphasize teaching behavioral skills, these approaches focus on teaching children covert cognitive mediational techniques, such as corrective self-statements and covert verbalizations, to help regulate their behavior in various situations. In most training programs, the children use self-statements to identify the problem, generate alternative solutions, decide on one solution, evaluate the outcome of their choice, and provide covert positive self-reinforcement ( [Dumas, 1989](#)). This approach has been used successfully to promote adjustment to a wide variety of behavior problems in very young children, as well as in older children and adolescents. Although summarized here as a technique to strengthen, develop, or maintain behavior, cognitive skills training approaches often are used to reduce or eliminate childhood impulsivity, aggression, or fears ( [Christoff and Myatt, 1987](#); [Dumas, 1989](#); [Kendall and Braswell, 1985](#); [Meyers and Craighead, 1983](#)).

### Techniques to Reduce or Eliminate Behavior

In operant conditioning, *extinction* refers to the process in which reinforcement is withheld after an operant response so as to reduce the frequency of its occurrence. Ironically, undesirable behaviors usually *increase* in frequency for a brief period immediately after the introduction of an extinction procedure, although gradually they disappear in the absence of reinforcement. A common example of extinction is when parents attempt to help their young infant sleep for longer periods through the night. If a parent responds immediately to the infant’s cries after it is put to bed by holding it, the infant learns to associate crying at bedtime and being held. To unlearn or extinguish this operant response, a parent allows the infant to cry a few minutes before responding. If this practice is followed on successive nights by gradually increasing the parent’s response delay intervals by 5 minutes on each occasion, the infant’s crying will slowly be extinguished, so that he or she learns to fall asleep alone. Although useful as a procedure to reduce or eliminate some undesirable behaviors, extinction usually is not appropriate for the elimination of destructive or disruptive behaviors, which may require more direct intervention ( [Johnson et al., 1986](#)).

A technique for the reduction of problem behaviors that combines some of the properties of extinction with those of reinforcement is *differential reinforcement*. In this technique, reinforcement is given for the nonoccurrence or low rate of occurrence of the problem behavior. Three types of differential reinforcement have been identified: *differential reinforcement of other behavior* (DRO), *differential reinforcement of incompatible behavior* (DRI), and *differential reinforcement of low rates of behavior* (DRL). In a DRO procedure, a child is reinforced for not emitting the problem behavior during a specified time or response interval. In effect, what is being reinforced is every behavior *other* than the problem behavior. In a DRI procedure, a child is reinforced for emitting an appropriate behavior that is topographically incompatible with the problem behavior during a specified time or response interval. For example, a child who has trouble remaining on-task during class is reinforced for completing a specified number of assignments or for working on an assignment for a specified length of time. In a DRL procedure, a child is reinforced for emitting low rates of the problem behavior during a specified time or response interval. Thus, a child who frequently leaves his or her seat during class is reinforced for leaving the seat only twice during a specified time interval. DRO and DRL procedures provide the least amount of stimulus control in that alternative problem behaviors may be reinforced during a specified interval, along with appropriate behaviors. This is not the case with a DRI procedure because the emission of appropriate or prosocial

behaviors is required for reinforcement to occur. Differential reinforcement procedures are readily incorporated into school or institutional settings and are particularly effective in the reduction of disruptive, aggressive, and self-injurious behaviors ( [O'Leary and Wilson, 1987](#); [Martin and Pear, 1983](#); [Repp and Deitz, 1979](#)).

*Punishment* is a technique used to reduce or eliminate undesirable behavior through the introduction of an aversive stimulus or removal of a positive stimulus after an operant response. Scolding, spanking, or removal of privileges (e.g., watching television, going outside to play) are examples of punishment, if these are presented contingent on a child's behavior and reduce the frequency of that behavior. Punishment procedures differ from extinction procedures because they usually bring about a rapid decrease in the frequency of problem behaviors, thus making them particularly effective techniques for the reduction of self-injurious and aggressive behaviors and certain kinds of disruptive behaviors. Nevertheless, punishment also has many disadvantages that recommend against its regular use. It tends to suppress behavior temporarily rather than actually change it and may produce serious and unwanted side effects ( [Johnson et al., 1986](#); [Johnston, 1972](#); [Kazdin, 1982](#)), such as (a) the elicitation of fear responses that may become conditioned to the punisher or punishing situation; (b) the promotion of escape responses, such as physical or emotional withdrawal, after punishment is terminated; (c) the strengthening of behaviors that motivate the child to avoid the aversive situation and thus reduce the chance that more desirable behaviors can be learned; (d) reinforcement (and thus strengthening) of the undesirable behavior through negative attention the child receives during punishment; and (e) observational learning of other undesirable behaviors that may be modeled by the punisher for the child, such as aggressive physical or verbal behavior and disrespect for the rights of others.

Three common punishment procedures are time out, response cost, and overcorrection. In a *time out* procedure, the child is removed from the setting in which the misbehavior occurs and is placed in a restrictive environment for a brief period. The lack of opportunity to obtain reinforcers by having to remain in such an environment usually results in a rapid suppression of misbehavior. In the typical application of this procedure, the child is warned that a time out will follow if the misbehavior continues. If the child does not heed the warning, he or she is sent to the time out room (or area) and asked to remain there for 10 minutes (3 to 5 minutes for very young children). At the end of the designated time, the child is allowed to return to the previous setting. Time out has been widely used with success in classroom and institutional settings, as well as in the home. It has been found to be a particularly effective punishment technique for the reduction of disruptive or aggressive behavior, which is easily reinforced by peers ( [Foxy and Shapiro, 1978](#); [Hobbs and Forehand, 1977](#)).

*Response cost* is another common punishment procedure in which a reinforcer is removed contingent on misbehavior so as to reduce the future probability of its occurrence. Typically, response cost procedures are used in conjunction with a token economy program, but they also may be used in the home by parents who have established contingency contracts with their child, usually an adolescent. In such contracts, the parents agree to provide the child with rewards or privileges (e.g., use of the family car, extended use of the telephone) in return for completion of specific behaviors on the part of the child (e.g., coming home before curfew, cleaning one's bedroom). If the child does not keep the contract, payment is made by removal of agreed-on rewards or privileges. In the appropriate use of this procedure, the child is informed in advance that he or she will be penalized a specified amount of rewards, privileges, or tokens for a particular misbehavior. When a misbehavior occurs, rewards, privileges, or tokens are removed. This procedure has been used to reduce the incidence of a wide range of problem behaviors, such as disruptions in the classroom, crying, perseverative speech, aggressiveness, and hyperactivity ( [Rimm and Masters, 1979](#)). Response cost differs from time out because the child is not removed from the opportunity to gain reinforcers, making it particularly effective in promoting self-control and self-management.

A final, frequently used punishment procedure is *overcorrection*. Overcorrection involves having the misbehaving child correct the consequences of the misbehavior. In *restitutional overcorrection*, the child is required not only to restore the environment to its original state before the misbehavior but to improve it (e.g., a child who defaces a roommate's poster may be required to save enough money to replace the poster, as well as to do the roommate a particular favor). In *positive practice overcorrection*, the child is required to practice positive behaviors that are incompatible with the misbehavior (e.g., a messy eater may be required to practice eating correctly). Although these two procedures usually are not used in combination, for some problem behaviors, such as bed wetting, their combined use has met with success (e.g., a bed wetter is required to remove wet linen, remake the bed, and then repeatedly practice leaving the bed, walking to the toilet, and returning to the bed) ( [Azrin et al., 1974](#)). Major characteristics of overcorrection procedures are (a) they relate directly to the misbehavior by requiring the child to complete a chain of behavioral responses that are topographically similar to a correct response; (b) they are intended to have the child experience the effort required by others to correct the consequences of the misbehavior; (c) they are instituted immediately after the misbehavior so as to reduce the likelihood that positive reinforcement from the behavior can occur; and (d) "graduated guidance" is used to enforce completion of the overcorrection requirement, whereby the enforcing adult manually assists the child through completion of the overcorrection response ( [Foxy and Bechtel, 1982](#)). Although overcorrection has been shown to be effective in reducing the incidence of a wide range of aggressive, self-injurious, and self-stimulatory behaviors, as well as inappropriate toileting and oral behaviors (e.g., vomiting, drooling), it is an aversive procedure that holds considerable potential for abuse if not used with caution and discretion.

*Desensitization* refers to a broad class of related "exposure training" behavioral techniques that are based on classical conditioning principles and used to reduce children's fears. In desensitization, a child is gradually exposed to a conditioned stimulus (e.g., a dog, taking a test, being separated from one's mother) until the fear is extinguished. *Participant modeling* and *symbolic modeling* have each been used to desensitize a child from a conditioned stimulus. In participant modeling, the child observes another person (usually a child) in the presence of the feared stimulus and then is reinforced for gradually approaching the stimulus until the fear disappears. In symbolic modeling, the conditioned fear is extinguished by having a fearful child view a film in which an initially fearful child gradually overcomes the fear.

The most common form of exposure training to reduce fears is *systematic desensitization*. In this technique, the child first works with the therapist to establish a hierarchy of fears about the anxiety-provoking stimulus. For desensitization to have the potential for success, this hierarchy must be as detailed as possible. A sample hierarchy is presented in [Table 81.1](#) for a child with test anxiety.

---

10	Attending class
20	Hearing the teacher announce that there will be a test at the end of the week
30	Attending class the day after the test has been announced
40	Doing homework in that same subject the day after the test has been announced
50	Attending class 3 days before the test
60	Studying for the test at home 3 nights before the test
70	Attending class 2 days before the test
80	Studying for the test at home 2 nights before the test
85	Attending class the day before the test
90	Talking to classmates about the test 2 days before the test
100	Sitting in class just before the exam is passed out

---

<sup>a</sup>Items are ordered according to the amount of subjective anxiety they elicit from 10 (lowest) to 100 (highest).

**Table 81.1. Sample Items of a Desensitization Hierarchy for Test Anxiety for a 14-Year-Old Student<sup>a</sup>**

Once the fear hierarchy is established, the child is helped to feel relaxed by talking to the therapist or a parent, playing quietly with peers, or eating a favorite food. An alternative approach used regularly in systematic desensitization with adults is to have the child engage in deep muscle relaxation before exposure training ( [Cautela and Groden, 1978](#)). Relaxation is intended to function as an incompatible response to anxiety. Once the child is relaxed, the therapist asks the child to imagine the least distressing scene in the fear hierarchy and to indicate if the scene remains distressing (e.g., if the child is seated in an armchair, he or she may be instructed to lift an index finger to indicate distress). If the scene continues to elicit anxiety, the child is instructed to relax for a few seconds, and then the procedure is repeated with the same scene until it no longer elicits anxiety on three successive presentations. The therapist repeats this procedure with each successive distressing scene in the hierarchy until the child no longer reports being distressed by the feared stimulus. Typically, no more than three to five scenes can be presented per session.

A variation of this technique called *in vivo desensitization* has been developed, in which the child undergoes exposure training to the hierarchy *in vivo* rather than through imaginal responses ( [Morris and Kratochwill, 1983](#)). The effectiveness of both systematic and *in vivo* desensitization is enhanced when the therapist has the child practice between sessions those items that no longer elicit anxiety and when practice is accompanied by positive reinforcement ( [Johnson et al., 1986](#)).

A related exposure training technique that may be used as an alternative to desensitization is *flooding* (also known as *implosion therapy* when applied *in vivo*). Widely used with adults, flooding involves having the child come in contact with the most feared item in the hierarchy, either *in vivo* or in imagination, until the fear is extinguished. Although flooding has been effective with children when graded desensitization procedures have not met with success ( [Yule et al., 1974](#)), its use with

children raises ethical concerns about children's informed consent and voluntariness of participation in such a potentially upsetting procedure.

In addition to other behavioral reduction techniques discussed previously, a number of the techniques described earlier have met with considerable success in reducing or eliminating problem behaviors in children. Techniques such as modeling, self-instructional training, problem solving, and contingency contracting have been used extensively to treat problems such as aggressiveness, impulsivity, antisocial behavior, fears, and substance abuse.

## BEHAVIORAL ASSESSMENT

Behavioral assessment is the process of identifying target behaviors and their controlling conditions by several different methods to assist the clinician in developing an appropriate treatment plan. Traditional assessment approaches hypothesize the operation of traits or personality constructs from *within* the individual. Behavioral assessment approaches hypothesize the operation of specific behavior patterns or states *outside* of the individual. Although the distinction between these two approaches may be extremely subtle in practice (e.g., in the assessment of a child's cognitions and affects), conceptually it is an important one because it focuses the assessment on current circumstances in the client's environment rather than on enduring underlying traits or states.

Traditional assessment approaches attempt to uncover the individual's personality structure, arrive at a diagnosis, and, finally, offer a prognosis. In contrast, behavioral assessment methods gather data that are directly, rather than inferentially, related to a treatment program and its evaluation. Behavioral assessment can be viewed as a dynamic process that involves (a) problem identification and target behavior selection, (b) choice and design of a treatment program, (c) periodic measurement of results during treatment, and (d) evaluation of the final treatment outcome ([Bornstein et al., 1984](#)). Because all treatments are not equally effective and vary in their efficacy according to several client–therapist factors, such as the client's age and potential for compliance, family support, and the therapist's expertise in behavioral assessment, the choice and design of a treatment program is based, as much as possible, on the relevant therapy outcome literature. Once a treatment program has been selected, periodic reassessment of its efficacy and suitability throughout the treatment phase is essential.

### Models of Assessment

There are several widely used models of behavioral assessment. Kanfer and Saslow's S-O-R-K-C model ([Kanfer et al., 1969](#)) is a comprehensive method that assesses the stimulus (S), the organism's biological conditions (O) and behavioral response (R), the contingencies and schedules of reinforcement (K), and relevant consequences (C). The BASIC ID model of [Lazarus \(1973\)](#) is a multimodal assessment of behaviors (B), affects (A), sensations (S), imagery (I), cognitions (C), interpersonal relationships (I), and drugs and general physical state (D). [Peterson \(1968\)](#) has proposed a functional analysis of behavior model that involves systematic observations of the problem behavior and the stimulus conditions (antecedents and consequences) that give rise to it, followed by experimental manipulation of a functionally related condition that causes the behavior.

One particularly useful and comprehensive model for behavioral assessment is the Behavioral Assessment Grid (BAG) developed by [Cone \(1978\)](#). This model divides assessment into a tripartite conceptual scheme of behavioral contents, methods of assessment, and types of generalizability. The behavioral *contents* area of the BAG refers to the three domains that behavior therapists typically assess for behavioral responses: cognitive (subjective), motor, and physiologic. For example, a child's fear may be assessed as a worry in the cognitive domain, as behavioral avoidance in the motor domain, or as a biochemical response to a stimulus in the physiologic domain. These are believed to be distinct yet potentially overlapping areas of behavioral functioning. The *methods* component of the BAG refers to the many types of indirect and direct measurement techniques that can be used to make a behavioral assessment. Indirect methods include behavioral interviews, self-reports, and ratings by others. Direct methods include self-observations or observations by others in analog or naturalistic situations under free play conditions or role play instructions. Last, the *universes of generalizations* component of the BAG refers to the extent to which measurements obtained are generalizable across multiple contexts. Specifically, six “universes” of generalizability have been identified as particularly relevant to consider when making a behavioral assessment: dimension (of behavior that is assessed), method (used to make the assessment), setting (in which the assessment is made), time (when the assessment is made), item (which aspect of a dimension is assessed), and scorer (who makes the assessment). Thus, the BAG model allows for three domains of behavioral contents by eight methods of data collection by six universes of generalization, resulting in a theoretically possible matrix of 144 different combinations of behavioral assessments. Although existing assessment measures do not fit into each of these 144 categories, the BAG model provides a useful framework in which the clinician can conceptualize and classify behavioral assessment instruments and measures.

### Assessment Strategies

There are a variety of behavioral assessment strategies that range from the least to the most direct in terms of the method of data collection ([Cone, 1978](#)).

#### INTERVIEWS

Behavioral interviews are an integral element of the assessment process ([Morganstern, 1988](#)). The objective during the initial phase of the behavioral interview is to establish rapport with the child, regarded as a necessary but not sufficient ingredient for successful treatment. During this phase, the child is assured of the confidential nature of the relationship and informed of under what conditions of danger to self or others that confidentiality will be broken. After the child presents the problem, the therapist probes for additional information regarding the initiation, frequency, and controlling conditions surrounding the problem behaviors. In the case of very young children, it is common to conduct a verbal interview with the parents and a play interview with the child to obtain a sample of the child's behavior.

Structured interviews are another type of indirect assessment strategy and a relatively recent addition to the classic behavioral assessment protocol for children ([Morrison, 1988](#)). There are three major structured interview measures in use with children: the Diagnostic Interview for Children and Adolescents (DICA) ([Herjanic et al., 1975](#)), the Diagnostic Interview Schedule for Children (DISC) ([Costello et al., 1984](#)), and the Schedule for Affective Disorder and Schizophrenia for School-Age Children, Present Episode Version (K-SADS-P) ([Chambers et al., 1985](#)). The DICA is a 60- to 90-minute interview of both the child and parent in three parts, conducted by trained interviewers. The DISC involves two 45- to 60-minute separate interviews with both the child and parent by trained interviewers and provides a *Diagnostic and Statistical Manual of Mental Disorders* (DSM) diagnosis. Last, the K-SADS-P is a semistructured interview of both the parent and child that assesses four areas (affect, anxiety, conduct, and psychosis) in two time periods (the past week and when the current episode was at its worst). It takes approximately 60 minutes to complete each interview.

#### SELF-REPORTS AND RATINGS BY OTHERS

Self-reports and ratings by others can be obtained through the use of various rating scales, which vary in terms of their validity and reliability ([Morrison, 1988](#)). Such self-report scales increasingly are being used by behavior therapists to assess symptom severity and also to monitor treatment effects. Some of the most widely used self-report instruments are discussed here.

The Children's Depression Inventory (CDI) is a 27-item scale adapted from the Beck Depression Inventory that provides information on a child's cognitive, affective, and behavioral signs of depression ([Kovacs and Beck, 1977](#)). It can be self-administered or read to children, as well as completed by parents. The Child Behavior Checklist (CBCL) is an empirically derived questionnaire that asks respondents to rate the occurrence of 118 problem behaviors of childhood or adolescence on a 3-point scale ([Achenbach, 1978](#); [Achenbach and Edelbrock, 1979](#)). Although the version that is the most widely used is the parent form, teacher and youth self-report forms also have been developed. The CBCL is one of the most carefully designed, empirically sound, and comprehensive instruments available for the assessment of children's problems. It includes additional items that provide a gross assessment of a child's social competencies. The Conners Teacher Rating Scale ([Conners, 1973](#)) is a 39-item self-report measure whose items are rated on a 4-point scale. It is used most commonly in the assessment and treatment of hyperactivity because it is sensitive to changes due to both behavioral interventions and psychopharmacologic treatment. The Conners Parent Rating Scale ([Conners, 1970](#)) is also available for parent reports, and both scales come in short-form versions. The Fear Survey Schedule for Children—Revised ([Ollendick, 1983](#)) is an 80-item self-report measure that is rated on a 3-point scale. It differentiates phobic from nonphobic children and also identifies etiologic factors such as separation anxiety, school phobia, and recent physical illness.

#### SELF-OBSERVATION

Self-observation, one of the oldest methods of direct behavioral assessment, includes the simple tabulation of behaviors by check marks or counters as well as behavioral monitoring by more sophisticated electronic devices that measure physiologic responses such as heart rate and blood pressure. These measures are used in several self-control procedures, such as weight reduction, tic control, and nail-biting cessation. Self-observation is less expensive and intrusive than the use of outside observers, allows monitoring to occur for longer periods and across a greater number of settings, and is particularly appropriate when monitoring infrequently

occurring behaviors. Self-monitoring can be a highly reactive process for clients, one that can precipitate dramatic behavior change in a favorable direction.

### DIRECT OBSERVATION

Direct observation can be conducted in the natural environment as well as in analog situations. An example of the use of direct observation in an analog situation is the use of the Behavioral Avoidance Test (BAT) to measure phobic behavior in children. The BAT is the most commonly used direct observational procedure to assess specific fears ([Wells and Vitulano, 1984](#)). During the BAT, the clinician records the distance from and time a client spends with a feared object. Although this procedure is very useful in providing concrete evidence of the nature and extent of a specific fear under controlled conditions, it can be quite reactive to demand characteristics, such as telling a child to try harder.

Direct observation of role plays also is used in behavioral assessment, in either naturalistic or analog situations. During a role play, clients are asked to imagine themselves in various situations and then to respond in their typical manner. Role plays in naturalistic and analog situations are used frequently in the assessment of social skills deficits in children.

## TREATMENT APPLICATIONS

### Anxiety Disorders

Anxiety disorders include that group of disorders whose symptoms are characterized primarily by anxiety and avoidance behavior. This category of disturbances includes phobic disorders, panic disorders, generalized anxiety disorders, and obsessive-compulsive disorders. Although fears and anxieties are common and transitory throughout childhood ([Lapouse and Monk, 1959](#)), more severe and persistent phobic reactions in childhood that are not considered to be age or stage specific require the attention and treatment of professionals. Thorough assessment of children's fears should include an evaluation of the three-channel response system of subjective feelings and thoughts, behavioral avoidance, and physiologic activity ([Graziano et al., 1979](#)).

Assessment in all three channels facilitates treatment planning and enhances treatment efficacy. For example, for a child who exhibits avoidance behavior (i.e., the motor system or channel), reinforced practice would be an essential component of the treatment; for a child who reports considerable subjective anxiety (i.e., the cognitive channel), self-control strategies would be recommended; and, finally, for a child who experiences somatic symptoms when confronted with the feared stimulus (i.e., the physiologic channel), relaxation training would be indicated. Typically, however, treatment plans for anxiety disturbances usually are more complex because they involve two or three different channels of behavioral disruption. For example, a treatment plan for a child who experiences fear in all three channels might begin with relaxation training (physiologic), move to self-instructional training (cognitive), and then advance to the use of participant modeling (motor) in combination with self-instructional training. Thorough reviews of the use of various behavioral techniques, such as relaxation training, systematic desensitization, flooding, implosion, modeling, self-control training, and operant procedures to treat childhood anxiety disorders are available ([Siegel and Ridley-Johnson, 1985](#); [Straus, 1987](#); [Wells and Vitulano, 1984](#)). [Kendall and colleagues \(1992\)](#) describe a cognitive-behavioral treatment program in detail for use with anxious children, and [Kendall \(1994\)](#) demonstrates its effectiveness with school-age children in a randomized clinical study. [Flannery-Schrieder and Kendall \(2000\)](#) compare group and individual cognitive-behavioral approaches for anxious youth.

Despite the controversy over the etiology and definition of school phobia, behavior therapy usually has been successful in its remediation. Techniques such as systematic desensitization, participant modeling, and contingency contracting have been particularly efficacious ([Ollendick and Mayer, 1984](#)). Obsessive-compulsive disorders, on the other hand, have been shown to be responsive to *in vivo* exposure procedures when combined with response prevention techniques ([Baer and Minichiello, 1990](#); [Grayson et al., 1982](#); [Scahill et al., 1996](#)). For example, compulsive hand washers are encouraged to touch contaminated objects and then refrain from washing to break the negative reinforcement chain. Although there has been less success in the treatment of obsessional behaviors, the most promising strategy appears to be imaginal exposure to obsessional thinking for a prolonged period of 30 minutes or more (i.e., avoidance response prevention) to extinguish the anxiety response ([Rachman and Hodgson, 1980](#)). The treatment of obsessive-compulsive disorder symptoms in children and adolescents with Tourette's syndrome is best approached as part of a comprehensive, multimodal therapeutic plan ([King et al., 1993](#)). Finally, much of childhood anxiety may in fact be secondary to social skill deficits in anxious children. Such children initially may lack the necessary skills to interact in a feared situation and fail to acquire those skills because of successful avoidance behaviors, while their peers continue to learn interaction skills ([Wells, 1981](#)). The obvious treatment program for these children is to augment fear reduction techniques with social skills training ([Christoff and Myatt, 1987](#)).

### Depression

Behavioral researchers and clinicians maintain that childhood depression represents a complex amalgam of symptoms that vary in degree and kind according to a child's developmental level. Thus, children who are depressed in early childhood may show evidence of excessive crying, loss of appetite, and temper tantrums, whereas those of middle childhood (6 to 8 years of age) may exhibit dysphoria, somatization, and impulsive behaviors, and those of late childhood (8 to 12 years of age) may display poor self-esteem, social isolation, self-deprecating behaviors, and hopelessness ([Kaslow and Rehm, 1985](#); [Kovacs and Beck, 1977](#)). The complexity of this symptom picture, coupled with the considerable overlap between these and other symptoms of disorder in childhood and adolescence ([Kendall et al., 1989](#)), has led behavioral investigators to argue that the most effective intervention for childhood depression is to treat specific symptoms of the disorder, such as self-deprecating behaviors, social withdrawal, and low activity level ([Kaslow and Rehm, 1983](#); [Puig-Antich, 1982](#)).

There is growing evidence that this strategy is effective ([Reynolds and Coats, 1986](#); [Stark et al., 1987, 1990, 1991](#)). Among the various behavioral techniques, self-control training has demonstrated the greatest efficacy in the treatment of depression for children (9 to 12 years of age) and adolescents. Self-control training in the treatment of depression involves teaching the child to monitor negative self-attributions, evaluate the validity of those attributions, and reinforce positive alternative attributions. Children also are taught to set realistic goals and standards for performance, refrain from punitive self-statements, and use positive self-statements as reinforcers. Finally, to compensate for the tendency of depressed children to attribute success to luck or chance, children are taught to view success as resulting from their own stable and internal competencies and to view failure as emanating from external factors outside of their control ([Hughes, 1988](#); [Rehm, 1977](#)). Controlled outcome studies using these techniques in either 10- or 12-session interventions delivered over a 5-week period have resulted in significant reductions of depressive symptomatology immediately after treatment as well as at 5 to 8 weeks' follow-up, compared with waiting list control groups ([Reynolds and Coats, 1986](#); [Stark et al., 1987](#)).

Two other behavioral approaches also have been successful in the treatment of depression: problem-solving training and relaxation training. Problem-solving training has emphasized teaching children problem-solving skills for use in social and interpersonal situations, such as identifying and expressing feelings appropriately, generating alternative courses of action and considering their consequences, and implementing the solution that best fits the situation ([Stark et al., 1987](#)). Relaxation training, on the other hand, has been found to be successful in reducing depressive symptoms in adolescents ([Reynolds and Coats, 1986](#)). Adolescents are taught to identify the link among stressors, muscle tension, and depressive symptomatology and then are trained in relaxation techniques.

The success of self-control and problem-solving training with children and of relaxation and self-control training with adolescents attests to the considerable promise of behavioral treatments for childhood and adolescent depression. At present, however, the key ingredients of behavior change remain unknown. Among the cognitive-behavioral treatments (i.e., self-control training and problem-solving training), there is a common emphasis on having the child engage in more pleasant activities and use self-monitoring to track depressive symptoms ([Hughes, 1988](#)). Among all three treatments, there is a common emphasis on providing the child with an enhanced sense of control over symptoms.

### Conduct Disorder and Antisocial Behavior

Conduct disorder and antisocial behavior in children are characterized by externalizing behaviors such as aggression, truancy, firesetting, stealing, and other social rule violations. The level of dysfunction it entails is extensive, involving significant disruption in the home, at school, in peer relations, and in cognitive processes (Kazdin and Wassell, 2000). Its prevalence in community samples is relatively high, and its demand on clinical services is great, accounting for up to one-third to one-half of clinic referrals ([Kazdin et al., 1989](#)). In addition to its significant social and personal costs in the short run, the effects of conduct disorder and antisocial behavior frequently extend well into adulthood, manifested in such problems as criminal behavior, alcoholism, problems at work or school, significant disruptions in interpersonal relations, and other psychosocial difficulties ([Kazdin, 1987](#); [Robins, 1981](#); [Rutter and Giller, 1983](#)).

Two types of behavioral interventions have demonstrated success in the treatment of conduct disorder and antisocial behavior: problem-solving skills training (PSST) and parent training. PSST uses behavioral rehearsal, role playing, modeling, corrective feedback, and social reinforcement to teach children interpersonal cognitive

problem-solving skills, such as generating solutions, means–ends and consequential thinking, and perspective taking ( [Kazdin et al., 1987](#)). The intervention is delivered in 20 to 25 sessions once or twice per week. Controlled studies have demonstrated that PSST, as opposed to relationship therapy or an attention placebo control intervention, is effective in reducing antisocial behavior in severely disturbed, clinic-referred children 7 to 13 years of age at posttreatment as well as after a 1-year follow-up ( [Kazdin et al., 1987, 1989](#)). Despite these reductions in antisocial behavior, the incidence of problem behaviors of children who had undergone PSST remained significantly higher than that found in community samples ( [Kazdin et al., 1989](#)).

A second approach to the treatment of conduct disorder and antisocial behavior in children and adolescents is behavioral parent training. A variety of such treatment programs have been developed and have demonstrated considerable success in reducing antisocial behavior compared with no treatment or alternative interventions ( [Ducharme et al., 2000](#); [Wells and Forehand, 1985](#)). The most widely evaluated parent training approach is the program developed by Patterson and colleagues ( [Patterson, 1975, 1982](#); [Patterson and Guillion, 1968](#); [Patterson and Reid, 1973](#); [Patterson et al., 1982](#); [Vuchinick et al., 1992](#); [Wiltz and Patterson, 1974](#)). In this program, parents are taught basic behavioral principles and techniques (e.g., reinforcement, time out, response cost, conditioned reinforcement, contingency contracting) and how to apply these to specific interactions with their child. Next, parents are trained extensively through program manuals and weekly training sessions to observe, identify, track, and record deviant and prosocial behaviors on the part of their child. As part of this training, parents are asked to identify two prosocial and two problem behaviors to track and monitor over a 3-day period. To facilitate monitoring, it is not uncommon for the therapist to call parents daily to assist in the completion of this task. Finally, the therapist works directly with parents to help them design and implement a token reinforcement system for use in the home. Children are praised for appropriate behavior as well as provided with points that can be exchanged daily for reinforcers. Noncompliance or misbehavior is managed through the use of a time out (from reinforcement) or response cost (loss of points) procedure. The therapist uses a variety of behavioral procedures to teach parents necessary skills, such as modeling, behavioral rehearsal, and role playing.

Related behavioral parent training programs also have been developed for use with younger clinic-referred children, 2 to 8 years of age ( [Forehand and McMahon, 1981](#); [Webster-Stratton et al., 1988](#)). Such programs usually teach parents how to (a) observe, identify, and monitor their child's behavior; (b) reinforce prosocial and appropriate behavior; (c) extinguish minor aggressive or destructive behavior through ignoring; (d) give clear and concise one-time commands on the appearance of misbehavior; (e) provide a single warning of impending consequences for failure to comply with a command; and (f) use a 3- to 5-minute time out to punish noncompliance ( [Wells and Forehand, 1985](#)). In general, because positive reinforcement for prosocial behavior often is quite successful in reducing aggressive and destructive behavior in younger children, it is recommended that these techniques be implemented first before more punitive techniques are applied.

Overall, behavioral parent training programs for children and adolescents with conduct disorder or antisocial behavior have been very effective in reducing the problem behaviors of referred children to levels observed in nonreferred peers. These effects are maintained up to 1 year posttreatment ( [Fleischman and Szykula, 1981](#)), with some benefits persisting for over 10 years ( [Baum and Forehand, 1981](#); [Forehand and Long, 1988](#)). Such programs also appear to have some impact on reducing maternal depression and enhancing the prosocial behavior of other children in the family ( [Kazdin, 1985b](#)). Importantly, these programs have been found to be least effective when implemented in brief, time-limited treatment (10 hours or less rather than 50 to 60 hours) or by an inexperienced therapist, or with families who have significant marital, psychological, or social adjustment difficulties ( [Kazdin, 1988](#); [Wells and Forehand, 1985](#)). When such difficulties are observed during the course of treatment, the therapist is advised to deal with marital conflicts and other potential barriers to effective treatment implementation directly, as part of a more comprehensive intervention strategy ( [Griest and Wells, 1983](#)). Studies have shown that a combined approach of PSST and parent training is most effective in the treatment of antisocial behavior in children ( [Kazdin et al., 1992](#)).

### Attention Deficit/Hyperactivity Disorder

Evidence is compelling that behavior therapy in combination with psychostimulant medication is the treatment of choice for attention deficit/hyperactivity disorder (ADHD) ( [Hinshaw, 2000](#); [Rapport, 1987](#)). In studies comparing these two treatments, neither alone has been found to demonstrate efficacy consistently across relevant outcomes, such as reduced impulsivity and motor activity and improved attention, concentration, academic performance, and social relations ( [Barkley, 1985, 1990](#); [O'Leary and Wilson, 1987](#); [Rapport, 1987](#)). Although this may be due in part to the complexity inherent in diagnosing this disorder accurately ( [Barkley, 1981, 1991](#); [Rapport and Ismond, 1984](#)), a picture is beginning to emerge that suggests that these two treatments may each have a differential impact and thus be most effective when used in combination.

The psychostimulant medications most frequently prescribed for the treatment of children with ADHD are methylphenidate, dextroamphetamine, and pemoline, with methylphenidate by far the most commonly used and investigated of these in the United States ( [Safer and Krager, 1983](#)). Controlled outcome studies have shown methylphenidate to be effective in reducing impulsivity ( [Ayllon et al., 1975](#); [Brown and Sleator, 1979](#); [Rapport et al., 1985](#)) and motor activity level ( [Porrino et al., 1983](#)), improving attention, concentration, and on-task behavior ( [Rapport et al., 1986, 1987](#)), and enhancing social relations with adults and peers ( [Barkley, 1977](#); [Barkley et al., 1984](#); [Whalen et al., 1981, 1989](#)). Despite widespread positive effects in these domains, psychostimulant medication in general has fared poorly in demonstrating short- or long-term effectiveness on learning and performance on academic tasks ( [Barkley and Cunningham, 1978](#); [Hechtman, 1985](#); [O'Leary, 1980](#)), although there is evidence that some kinds of learning may be responsive to methylphenidate at higher dosage levels than are commonly used ( [Rapport, 1987](#); [Rapport et al., 1982](#); [Vyse and Rapport, 1989](#)).

Behavioral treatments for children with ADHD, on the other hand, consistently have demonstrated efficacy in enhancing learning and improving academic performance ( [Ayllon et al., 1975](#); [Barkley, 1985](#); [O'Leary, 1980](#); [Pelham et al., 1980](#)), in some cases by as much as 1.6 years of growth over the course of 1 year of treatment ( [Satterfield et al., 1979](#)). Behavioral treatments also have been shown to be effective in reducing impulsivity and motor activity and enhancing attention and concentration, although findings from these studies are less clear and at times contradictory ( [Barkley, 1985](#); [Gittelman-Klein et al., 1976](#); [O'Leary and Wilson, 1987](#)).

Behavioral interventions are most effective when implemented in three arenas: the home, the classroom, and with the individual child. Home interventions usually involve teaching parents observational and behavior management skills for use in rewarding appropriate behavior and extinguishing inappropriate behavior. Typically, parents are taught to use positive as well as conditioned (token) reinforcement to strengthen their child's ability to play independently and to engage in prosocial interactions with others. In addition, parents are trained in the use of time out and response cost procedures so that they can provide mild punishment for misbehavior and noncompliance with house rules. Successful school interventions have emphasized similar techniques, although a token economy system used in combination with response cost usually is an essential component of such programs. Finally, self-control techniques, such as self-monitoring, self-evaluation, and goal setting, have also been used with children with ADHD ( [Binder et al., 2000](#); [Davies and Witte, 2000](#)). Although these techniques have demonstrated only limited effectiveness, when used alone or in combination with psychostimulant medication they hold promise when combined with the parent or teacher components of a comprehensive behavioral treatment program ( [O'Leary and Wilson, 1987](#); [Whalen et al., 1985](#)).

### Pervasive Developmental Disorders and Autism

Pervasive developmental disorders (PDDs) consist of infantile autism and pervasive developmental disorders (not otherwise specified). The essential features of effective treatment of PDD include a thorough assessment of functional behaviors and their controlling variables. Because PDD involves impairment in social interaction and communication skills, the selection of target behaviors for modification should focus on key deficits that have a generalizing effect on several areas of functioning. Attentional and social skills training are two such areas that appear to have far-reaching educational and interpersonal ramifications.

Behavioral treatment techniques for these disorders generally fall into two categories: suppressing unwanted behaviors and teaching new skills. Early attempts at perceptual and sensory processing and integration training ( [Ornitz and Ritvo, 1968](#)) based on a neurologic theory of deficits have shown inconsistent results. Several different techniques have been used since with success to reduce unwanted behaviors, such as time out ( [Foxy and Shapiro, 1978](#)), overcorrection ( [Foxy and Azrin, 1973](#)), and punishment ( [Rincover et al., 1979](#)). New skills are taught by using reinforcement, stimulus discrimination training, and social skills training, and by providing clear instructions ( [Harris and Handleman, 1987](#)). For example, a child who has difficulty responding to social cues might respond to shaping and prompting techniques that can be used to teach such basic skills as making eye contact and sitting still. Once these skills are acquired, they can be used to teach the more complex and related skills of attention and observation ( [Koegel and Schreibman, 1977](#)). Parent training and sibling involvement in behavioral interventions also have been used to enhance the effectiveness of such training programs ( [Harris, 1983, 1984](#); [Lovaas et al., 1973](#); [Schreibman et al., 1983](#)).

Historically, the long-term prognosis for a return to normal functioning in children with PDD or autism has been very poor. However, a controlled outcome study by [Lovaas and colleagues \(1987, 1989; McEachin et al., 1993\)](#) on the intensive treatment of autistic children younger than 4 years of age is very encouraging. The treatment involved a minimum of 40 hours per week of one-to-one adult contact with the child for a period of over 2 years. Student therapists as well as the child's parents were trained to provide the intensive home-based treatment, which consisted of operant procedures aimed at promoting cognitive, verbal, and social skills. At the conclusion of the controlled trial, 47% (9 of 19) of the children who participated in the treatment were enrolled in regular first grade classrooms and were reported as "indistinguishable" from their classroom peers by school personnel. None of the children in a nonintervention group were enrolled in regular first grade classes. In addition, the nine children attending first grade classes exhibited dramatic gains in IQ from pretreatment to posttreatment. This pattern of differences between

experimental and control groups was maintained at a subsequent follow-up of these children when they reached a mean age of 11.5 years ( [McEachin et al., 1993](#)).

## **Mental Retardation**

The dramatic expansion of behavior therapy techniques has revolutionized the field of mental retardation therapy since the early 1970s ( [Reber, 1992](#); [Whitman and Johnston, 1987](#)). The most effective behavioral interventions have been developed for the mildly and moderately retarded, a group that comprises approximately 98% of the total population of retarded persons ( [Grossman, 1983](#)). In general, the goals of behavior therapy with the mentally retarded do not involve treatment for psychiatric disorders but rather focus on promoting adaptation in three major areas of skill deficits: self-control, social skills, and academic performance.

Self-control problems have been treated with a wide variety of techniques, such as overcorrection for self-stimulatory behavior ( [Foxy and Azrin, 1973](#)), differential reinforcement of other behaviors for the reduction of stereotypies ( [Eason et al., 1982](#)), and a variety of other operant techniques ( [Berkson, 1983](#)). As a last resort, punishment has been used effectively to reduce unwanted behaviors ( [Barrett et al., 1981](#)). Remarkable success also has been demonstrated in the acquisition of social skills among the mentally retarded, especially in the areas of communication skills and daily living skills. In general, reinforcement techniques have been applied in programs designed to improve expressive language skills ( [Handleman et al., 1984](#)), to foster understanding and ability to follow directions ( [Lancioni et al., 1984](#)), and to acquire basic personal and home living skills ( [Schadlock et al., 1984](#)). Finally, academic performance has been enhanced through the implementation of behavioral interventions. Basic classroom learning skills have been taught with the help of interventions that promote eye contact and increase on-task behavior ( [Bornstein and Quevillon, 1976](#); [Zigler and Hodapp, 1985](#)).

## **Enuresis and Encopresis**

Behavior therapy has been found to be particularly effective in the treatment of enuresis and encopresis. Of the two kinds of enuresis, diurnal (daytime) and nocturnal (nighttime), the latter usually is more persistent and troublesome to parents and child. Two types of behavioral treatment have been used with success in the treatment of nocturnal enuresis: the urine alarm and dry bed training (DBT). The urine alarm was first popularized as the bell and pad treatment for enuresis in 1938 by Mowrer and Mowrer. Although a number of modifications of the original bell and pad procedure have been developed over the years, the essential procedure remains the same. The child sleeps with a pad under a sheet that has been wired with an electrical current and serves as a urine sensor. When urine wets the pad, an alarm goes off and wakes parents and child. After using the toilet, the child makes the bed and resets the alarm before returning to sleep. Conditioning is believed to occur through either one or both of the following mechanisms: (a) the repeated pairing of the alarm and voiding (i.e., classically conditioned reinforcement), such that the child comes to inhibit voiding and sleep through the night; or (b) stimulus discrimination training, whereby the child is awakened when bladder distension cues are near their peak (i.e., when there is a full bladder) and, as a result, learns to wake and void when these cues are present.

Reviews have found this technique to be effective in 75% to 80% of cases, with relapse rates of 30% to 41% ( [Doleys, 1977, 1985](#); [O'Leary and Wilson, 1987](#)). Of those children who relapse, just over two-thirds remain continent after reinitiation of the procedure. Typically, training is completed in 5 to 12 weeks.

Two modifications of the standard urine alarm treatment have been found to reduce relapse considerably ( [Doleys, 1985](#)). The first involves use of an intermittent reinforcement schedule in which the child is awakened on only 50% to 70% of wetting episodes. The second involves use of an overlearning procedure in which the child is asked to consume liquid 1 hour before bedtime, usually beginning with 10 ounces and building up to 32 ounces over a few weeks. Overlearning is believed to promote generalization of learning to an increased range of bladder capacity and distention ( [Young and Morgan, 1972](#)).

A second behavioral treatment found to be effective in eliminating nocturnal enuresis is DBT ( [Azrin et al., 1974](#); [Said et al., 1991](#)). This treatment incorporates a number of behavioral techniques: positive practice, positive reinforcement, punishment, and the urine alarm. In DBT, the child is awakened during the night, asked to go to the toilet if any urge to void is present (positive practice), and then allowed to return to bed with praise for completing this onerous task (positive reinforcement). The urine alarm also is used as part of the treatment, and in the usual manner, the child is required to clean and change wet sheets in the event of an accident (punishment). Usually the child also is verbally reprimanded for a wet bed (punishment) and praised for staying dry (positive reinforcement). This procedure is followed on successive nights (and, in some applications, repeatedly throughout a single night) until the child remains dry for 2 weeks. Parent training manuals have been written to make this treatment accessible to the public ( [Azrin and Besalel, 1979](#); [Azrin and Foxx, 1974](#)).

There is some evidence that DBT is slightly more effective than the urine alarm, particularly in reducing relapse and achieving faster results, although evidence from various studies is inconclusive ( [O'Leary and Wilson, 1987](#); [Ronen et al., 1992](#); [Young and Morgan, 1972](#)). Because this procedure requires considerable effort on the part of parents and child, clinicians must determine whether the additional benefits of DBT over and above those of the urine alarm outweigh the very real possibility of treatment noncompliance.

Behavior therapy also has been shown to be effective in the treatment of functional encopresis, which is defined in DSM-IV as the repeated passage of feces in inappropriate places more than once per month after the age of 4 years and occurring for a period of 6 consecutive months ( [American Psychiatric Association, 1994](#)). Recommended effective behavioral treatments for encopresis involve the use of (a) positive and conditioned reinforcement, sometimes in combination with mild punishment; or (b) regular pants checks in combination with positive and conditioned reinforcement plus full cleanliness training (FCT). Laxatives or suppositories also often are used as an adjunct to treatment to promote the passage of fecal material. Treatments based on reinforcement (with or without mild punishment) involve training the parent to praise the child or deliver a conditioned reinforcer contingent on the child's passage of feces on the commode ( [Ashkenazi, 1975](#); [Wright and Walker, 1976](#); [Young and Goldsmith, 1972](#)). In the initial stages of this treatment, sometimes it is necessary to provide reinforcement for successive approximations of the appropriate behavior, for example, rewarding the child for passing feces in the pants while in the bathroom. This treatment usually eliminates encopresis within 15 to 20 weeks in most cases.

A second, slightly more efficient treatment for encopresis, which is also carried out by parents and supplemented by laxatives or suppositories as necessary, consists of three components: (a) periodic pants checks (usually 1 to 2 hours apart), (b) FCT after soiling, and (c) positive reinforcement for clean pants checks ( [Young and Morgan, 1972](#)). FCT is implemented when soiling is discovered during a pants check. After a show of displeasure by the parent, the child is required to wash the soiled underpants for 20 minutes and then must take a 20-minute bath in cool water. Successful pants checks result in praise as well as the awarding of conditioned reinforcers, such as tokens or points, which can be accumulated and exchanged for privileges, treats, or special activity time with one or both parents. This technique usually results in the elimination of functional encopresis in 10 to 15 weeks and is effective with most cases ( [Young and Morgan, 1972](#)).

## **Applications of Behavior Therapy in Diverse Settings**

One of the major advantages of behavior therapy is its applicability to a wide range of settings. Behavior therapy has been used with success in family interventions, school and community interventions, residential settings, and in the delivery of pediatric services. These diverse applications of behavioral approaches have promoted the delivery of services and treatments to previously underserved populations.

### **FAMILY INTERVENTIONS**

Two types of behavioral interventions have been widely used with families: behavioral parent training and behavioral family therapy. Parent behavioral training programs differ according to the behavioral skills emphasized (e.g., contingency management, conflict resolution, problem solving, positive parent-child interactions, contingency contracting) and the problem behavior being addressed (e.g., fostering independence for a mentally retarded child, reducing a child's fears, decreasing a parent's likelihood to engage in physically abusive behavior, promoting effective parent-child communication, and reducing parent-adolescent power struggles) ( [Graziano, 1977](#); [Twardosz and Nordquist, 1987](#)). Despite this wide-ranging focus, behavioral parent training programs have shown a promising record of efficacy relative to other forms of treatment.

Behavioral family therapy, on the other hand, is an emerging area of family intervention that combines family systems theory with learning theory. Family systems theory is used to formulate the presenting problem in the context of key parameters of family functioning, such as family communication, boundaries, power, affectivity, and family life cycle status. Learning theory is used to formulate the presenting problem in terms of behavioral contingencies that maintain or exacerbate the problem or that function to block effective problem solving. These perspectives are then combined in a treatment plan that may include teaching family members to identify feelings and thoughts during family interactions; reinforcing effective communication in the session; pointing out behavioral contingencies that inadvertently strengthen problem behaviors in the family; using modeling, role plays, and behavioral rehearsal in the session to teach contingency contracting or behavioral management skills (e.g., time out); and assigning homework for family members to practice skills taught in the session.

## SCHOOL AND COMMUNITY INTERVENTIONS

School and community interventions are another rapidly growing arena for behavioral interventions. Behavioral treatments are well suited for implementation in school settings because they often can be delivered effectively in a group context. The school, in particular, provides an excellent opportunity for implementing behavioral interventions at multiple levels. Children referred for treatment often can be seen individually or in groups in the school setting by a school psychologist, social worker, or counselor (Hughes, 1988). In addition, high-risk or normal children can participate in behaviorally based classroom interventions that seek to promote competencies or prevent problem behaviors, such as substance abuse (Snow et al., 1987). These programs frequently are compatible with other types of behavioral interventions, such as parent training programs, delivered in the same setting (Tebes et al., 1989). Community interventions provide further opportunities for behavioral interventions implemented at multiple levels. Such programs can augment school-based or parent training programs, can involve a variety of community organizations in their implementation, and can use the popular media to enhance the impact of the intervention (Pentz et al., 1989).

## RESIDENTIAL SETTINGS

Behavioral interventions also are common in residential treatment programs for children and youth. The most common form of behavioral intervention in these settings is the use of a token economy system as part of the treatment milieu. Such interventions typically provide steps in which children can gain more and greater privileges as they progress through the program. Token economies have been implemented with success in a variety of settings, such as those used to treat delinquent youths and mentally retarded children and adolescents (Kazdin, 1977).

## PEDIATRIC BEHAVIORAL MEDICINE

Finally, since the early 1980s, behavior therapy has been expanding its applications to pediatric settings in hospitals. Pediatric behavioral medicine is the new, rapidly expanding, interdisciplinary field involved with the prevention and treatment of emotional and behavioral problems related to child and adolescent health and illness. Although there is no specific theoretical orientation to the field of pediatric behavioral medicine, in practice it is the application of behavior modification principles in the medical arena. Pediatric behavioral medicine and its parent field of behavioral medicine usually are characterized by three types of interventions: (a) direct treatment of medical problems such as pain (Varney et al., 1982) and hypertension (Lutzker and Martin, 1981); (b) the development of programs to enhance compliance to medical procedures and regimens, such as fear reduction programs before surgery (Lutzker and Martin, 1981) and compliance programs for juvenile patients with diabetes (Lowe and Lutzker, 1979); and (c) health education, in which knowledge and skills training are provided in such areas of health behavior as accident prevention, nutritional compliance, and medical advice (Finney and Christopherson, 1984). The emergence of the relatively new field of behavioral medicine has expanded traditional medicine beliefs to include a more important role for the emotional factors that influence the development and course of many physical disorders and their most efficacious treatment.

## RELATED APPROACHES

### Hypnosis

#### HISTORY

A field related to child and adolescent behavior therapy is *hypnotherapy*. Although hypnosis has been practiced for thousands of years, much skepticism remains regarding the legitimacy of its therapeutic use (Kroger, 1977; Olness and Gardner, 1988). The history of modern hypnosis begins with Franz Anton Mesmer (1734–1815), who in the late 18th century claimed that magnetic fluid imbalances in the human body were the cause of many somatic and psychological diseases. His dramatic “cures” involved staring into his patients’ eyes while they held onto iron rods attached to a large tub of iron filings and allegedly were demagnetized of their illnesses (Tinterow, 1970). Mesmer was discredited by the distinguished Franklin Commission, which had been established by King Louis XVI to investigate mesmerism. Several of Mesmer’s followers tried to defend mesmerism, but not until the late 19th century did Jean-Martin Charcot (1835-1893), the French neurologist, give hypnosis a new measure of scientific credibility by describing it in neurologic terms. James Braid (1795-1869) coined the term *hypnosis* from the Greek word for “sleep,” *hypnos*, and he is now remembered as “the father of hypnosis.” Finally, Freud initially was interested in Charcot’s work with hysteria through hypnosis but abandoned this interest in favor of free association in psychoanalysis.

#### DEFINITION

The definition of hypnotherapy is complicated because it encompasses a wide variety of theories and techniques. Basically, hypnotherapy is a treatment modality that uses an altered state of consciousness (i.e., hypnosis) in its overall treatment plan. Much of the work in hypnotherapy is viewed as instilling “an attitude of hope in the context of mastery” (Olness and Gardner, 1988, p. 89). Most popular theories define hypnosis as an altered state of consciousness involving some combination of heightened awareness, increased suggestibility, intense interpersonal relationship, or direct unconscious access. These theories are primarily physiologic, psychological, or some combination of the two. The physiologic theories suggest selective inhibition of brain centers, whereas the psychological theories emphasize the subject’s hypersuggestibility. It is clear, however, that the process of undergoing hypnotic trance can affect physiology through altering autonomic nervous system responses, such as lowering blood pressure or reducing muscle tone. However, the studies of physiologic responsivity are unreliable because a person’s exact physiologic response also is related to the level of arousal developed by the imagery of the specific hypnotic trance. Not all hypnosis induces the same response.

#### TECHNIQUE

Formal hypnotic trance induction can be achieved in a variety of ways. In general, the child is first offered an explanation of the process that includes a methodology for relaxing and imagining, while therapeutic rapport is established. During the induction phase, the child often is asked to concentrate and focus on a visual fixation point on the ceiling until his or her eyelids became heavy and he or she closes them. Then, a deepening technique would enhance relaxation by means of any simple counting or breathing procedure, for example. Obviously, there is a limitless number of hypnotic induction techniques using visual imagery, auditory imagery, movement imagery, storytelling, ideomotor techniques, progressive relaxation, eye fixation, distraction, and other individual and group variations (Olness and Gardner, 1988). Although children younger than 7 years of age have a limited responsiveness to standard techniques, children between 7 and 14 years of age reach their peak in hypnotic susceptibility (Place, 1984). Often there is a temporary decline during adolescence, when trust in adults typically is diminished, until the pattern is stabilized again during adulthood. Olness and Gardner (1988) report the use of tactile and kinesthetic stimulation techniques with very young, preverbal children. There appear to be no significant sex differences during childhood regarding susceptibility (Cooper and London, 1966). However, the data are confounded when we consider informal hypnosis in the style of Milton Erickson and his followers (Erickson and Rossi, 1981). These methods involve indirect unconscious suggestion without the use of a bona fide trance induction. The child may not even know that a hypnotic technique was used because the doctor appears simply to be talking in some strange metaphor or asking the child to imagine something silly and absurd. These techniques can become quite sophisticated and appear subtle to the untrained eye. Some of the best professional training programs in hypnotherapy are organized by the American Society of Clinical Hypnosis in Des Plaines, Illinois, and the Society for Clinical and Experimental Hypnosis in Liverpool, New York.

#### APPLICATIONS

The clinical uses of hypnotherapy are limited only by the creativity of the therapist. In general, hypnotherapy is underused in the treatment of children, but it often is considered valuable in the areas of pain and habit control, pediatric medical problems, and stress reduction. As long as hypnosis is not used as an exclusive technique outside of a professional therapeutic context, there is little danger involved in its use. The major contraindications are situations where its use aggravates existing problems (ignoring acute pain, which is a warning signal) or avoids more effective treatment of the problem (medication or surgery). Hypnotherapy can be helpful in the treatment of headache (Olness and MacDonald, 1981, 1987; Olness et al., 1987), chronic and acute pain (Crasilneck and Hall, 1973; Hilgard and Hilgard, 1975; Russo and Varni, 1982), severe burns (Wakeman and Kaplan, 1978), obesity (Haber et al., 1979), compliance and pain control during medical procedures (Olness and Gardner, 1988), asthma (Kohen, 1986), dermatologic problems (Mirvish, 1978; Olness, 1977), enuresis (Mirvish, 1978; Stanton, 1979), nausea associated with chemotherapy (Cotanch et al., 1985; Hockenberry and Cotanch, 1985; Kohen et al., 1984; Zeltzer et al., 1984), stress reduction, and other problems of childhood and adolescence. There have been several dramatic claims of clinical cures of terminal disease through the use of hypnosis and positive imagery, but there are no properly controlled studies to support these claims (Lucas, 1985). In the broader context of good treatment, hypnosis can be a useful adjunct to behavioral treatment. The reader is referred to *Hypnosis and Hypnotherapy with Children* (Olness and Gardner, 1988) for a further review and excellent discussion of this topic.

## Biofeedback

Biofeedback is a treatment method that uses physiologic feedback instrumentation to train individuals in the regulation of their body responses, such as muscle tone, heart rate, blood pressure, and cortical brain activity ([Blumenthal, 1985](#)). Originally, biofeedback technology developed out of experimental attempts to operantly condition autonomic nervous system responses ([Miller, 1969](#)). Several models since the late 1970s have attempted to explain the process of biofeedback: learning theory, body awareness, cybernetics, hypnosis, and others. Some of the major applications of biofeedback are (a) electromyography feedback for muscle relaxation in the treatment of tension headaches ([Budzynski, 1978](#)), hypertension ([Patel, 1977](#)), cardiovascular disease ([Cheatle and Weiss, 1982](#)), muscular rehabilitation ([Basmajian, 1981](#)), and temporomandibular joint pain ([Scott and Gregg, 1980](#)); (b) thermal feedback of skin temperature in the treatment of migraine headaches ([Blanchard and Andrasik, 1982](#)) and Raynaud's disease ([Surwit et al., 1978](#)); (c) feedback of electrodermal activity for treatment of hyperhidrosis; and (d) electroencephalographic feedback of cortical brain arousal in the treatment of neurologic disorders. Because of the cost and inconvenience of the equipment, biofeedback has lost some relative popularity among the vast array of relaxation therapies, yet it still remains helpful for some clients.

## ISSUES IN CHILD AND ADOLESCENT BEHAVIOR THERAPY

### Common Criticisms

Two of the most common criticisms of behavior therapy is that it results in symptom substitution as opposed to lasting therapeutic change and that it fails adequately to take into account clinical process issues that arise during the course of treatment.

#### *SYMPTOM SUBSTITUTION*

Perhaps the best-known criticism of behavior therapy is that it results in symptom substitution. This criticism is based on the belief, grounded in psychoanalytic theory, that the goal of behavior therapy is to provide symptomatic relief as opposed to treatment for a symptom's underlying cause. According to this view, the alleviation of a particular symptom will result in the appearance of a new symptom until the underlying cause is addressed.

A number of behavior therapists have questioned the logical basis for this view ([Bandura, 1969](#); [Kazdin, 1982](#); [Sloane et al., 1975](#); [Wolpe, 1978](#)). For example, because critics who argue for the inevitability of symptom substitution after behavioral treatment do not specify which symptom will appear, when, and under what conditions, how can a valid test ever be made of the charge? Furthermore, how would one know whether a symptom arising after behavior therapy was a consequence of the treatment and not merely a new symptom? And finally, because all types of intervention—behavioral or otherwise—inevitably result in both intended and unintended positive and negative effects, why should behavior therapy be singled out for criticism when such effects are endemic to therapy *per se*? Logical considerations aside, evidence is lacking for symptom substitution after behavioral interventions ([Kazdin, 1982](#)), although there is considerable evidence that behavioral interventions have wide-ranging beneficial effects beyond specific target symptoms ([Casey and Berman, 1985](#); [Durlak et al., 1991](#); [Herbert, 1988](#); [Hersen and Bellack, 1985](#); [Weisz et al., 1987](#)).

#### *CLINICAL PROCESS*

Another frequent criticism of behavioral interventions is that clinical process factors that emerge over the course of treatment are not taken into account. Factors such as the therapist–client relationship and the nature of the therapeutic interaction are focal examples of such processes. Critics have asserted that this is because behavior therapists do not adequately attend to these issues in treatment, or even eschew the clinical value of doing so.

To some extent, these criticisms are accurate. For many years, behavior therapists spent much of their time emphasizing the need to attend more to the *tasks* of treatment than to process issues. An example of this can be found in the early behavior therapy literature, in which the therapist was described essentially as a “social reinforcement machine” ([Krasner, 1962](#)). Someone with only a cursory knowledge of actual behavior therapy practice could easily be led to believe that behavior therapists regard themselves merely as technicians who find little merit in fostering the therapeutic alliance and responding genuinely and with empathy to their clients. Although the reasons for this early emphasis are not entirely clear, a prevailing experience among behavior therapists in the 1950s and 1960s was excitement over the emerging technologies being used in treatment and a belief that this represented significant strides away from previous approaches. The cost of embracing this “techno-therapist” vision, however, was that much of the writing about behavior therapy excluded some of the *essentials* of successful treatment, behavioral or otherwise: the need to build a strong working alliance with one's client and to use that alliance to weather disruptions (i.e., resistances) in the treatment so as to facilitate therapeutic gains.

More recently, behavior therapists have begun to focus on the merits of the clinical process in promoting the therapist–client relationship and in facilitating effective clinical interactions ([Fishman and Lubetkin, 1983](#); [Herbert, 1988](#); [Hersen and Bellack, 1985](#); [Kazdin, 1988](#); [Sloane et al., 1975](#)). Ironically, some behavior therapists have argued that such factors are even more important to the success of behavioral interventions because the therapist usually is more actively engaged with the client over the course of treatment in setting goals collaboratively and in implementing them through the use of a variety of interactive techniques ([Fishman and Lubetkin, 1983](#)).

### Ethical Issues

The ethical concerns of child and adolescent behavior therapy are no different, in principle, from those found in any other area of psychotherapeutic practice ([Keith-Spiegel and Koocher, 1985](#)). The 1970s saw a growing legal and public demand for increased accountability on the part of all therapists for their clinical practices. This led to a published report on the ethical practice of behavior therapy by the Association for the Advancement of Behavior Therapy ([Azrin et al., 1977](#)). The report sought to protect clients' rights in such areas as therapeutic goal setting, quality and appropriateness of treatment, voluntary participation, confidentiality, and the competency of the therapist.

Ideally, behavior therapists encourage young clients together with their parents to set their own goals for treatment in consultation with their therapist. This minimizes the chance for the treatment to be unduly influenced by the therapist's personal biases. Behavior therapy practice insists that therapists make clear their biases to their clients, establish an explicit treatment contract, and monitor progress periodically to determine whether continued treatment is warranted. Alternative methods of treatment always should be considered, and clients must remain aware of their treatment options as well as their voluntary and confidential participation in any treatment program.

Because so much of behavior therapy occurs in the context of research to evaluate treatment efficacy, these standards apply to clinical as well as research protocols. Special guidelines also have been developed for use whenever more aversive techniques of punishment are implemented as part of the treatment ([American Psychological Association, 1981](#)). Although interventions based on such techniques can affect incidental behavior not targeted for change, they are justifiable as a final treatment of choice for self-injurious and otherwise unmanageable children exhibiting dangerous behaviors. Finally, behavior therapists believe that the ethical practice of therapy involves selecting an intervention strategy well suited to the presenting problem. Such a choice should be based on empirical evidence of the treatment's long-term effectiveness, relative efficiency, likely side effects and response covariation, overall safety, the potential for compliance, and the potential consequences of not offering treatment.

### New Directions

Since the early 1980s, behavior therapy has clearly established itself as a major force in mental health treatment, prompting a reconsideration of previous approaches to practice. Two examples of this changing view are the current value placed on the use of integrative approaches to practice and the considerable interest in more and better treatment outcome studies. Currently, the trend in mental health care is toward a greater integration of proven therapeutic approaches. Therapists of all persuasions are moving toward a pragmatic eclecticism rooted in empirical evidence ([Bornstein et al., 1985](#)), rather than defending their own turf. This open-mindedness is prompted by the reality that most clinical data are equivocal and that therapeutic behavior change is difficult to achieve. Such a perspective will permit clinical researchers to begin to specify which treatments work with which persons and under what conditions ([Kazdin, 1988](#)).

The emphasis on treatment specificity is a major issue in the field of child and adolescent behavior therapy and is one that underlies the current interest in more and better treatment outcome studies. Such studies need to use more adequate controls, use larger sample sizes to be able to detect true differences among sample groups (not only between treatment versus placebo or waiting list control groups, but among groups that receive differing treatments), and examine more comparable

treatments to determine relative differences in their effectiveness on similar disorders. At present, clinical researchers in general have failed to use samples that are large enough to detect the small differences that presumably exist between two or more treatments (Kazdin and Bass, 1989) and usually have compared a heterogeneous mix of treatments for widely varying clinical populations (Kazdin et al., 1992). In addition, treatment outcome studies need to include three-channel assessments of children's functioning as well as assessment of other relevant domains in the child's life, such as family functioning, school performance and adjustment, and peer relations.

Another promising direction for behavior therapy is the increased design and implementation of self-control and self-management interventions. Not only are these approaches efficacious (Durlak et al., 1991; Dush et al., 1989), but they foster the development of such basic competencies as independence and self-control, are relatively easy to use, and are readily accessible through self-help books and tapes that can serve as an adjunct to treatment and, in some cases, produce equivalent results (Webster-Stratton et al., 1989).

Pediatric behavioral medicine is another exciting and growing field in child and adolescent behavior therapy that holds future promise (Lewis and Vitulano, 1988). As one of the fastest-growing interdisciplinary fields, its potential to improve the care and treatment of children with health-related problems is great, particularly in such areas as stress management, pain reduction, treatment compliance, and the care of chronically ill children. Many of these innovative applications will need to be community based to reach the populations for whom they are intended.

Finally, the development of preventive and promotive interventions also is likely to be a major arena for behavioral approaches. Such interventions often include common behavioral techniques (e.g., skills training, role playing, behavioral rehearsal, self-monitoring) that can easily be incorporated into natural settings for children, such as schools (Weissberg et al., 1991). The recent implementation of life skills training programs in schools in which children are taught social skills, self-control, and other behaviorally based skills to reduce high-risk behavior that may lead to human immunodeficiency virus infection and other problems faced by children and youth is one example of a preventive behavioral intervention (Barth, 1993). Behavioral approaches also figure prominently in interventions aimed at promoting resilience among children at risk, such as those surviving a natural disaster, being regularly exposed to community or family violence, growing up in extreme poverty, or being reared by a severely mentally ill parent (Rolf and Johnson, 1994; Tebes, 1994).

Behavior therapy's emphasis on an empirically based science of behavior, coupled with its applicability to a wide range of settings, has enabled it to grow into a field that addresses many of the problems of childhood and adolescence and offers efficacious innovative interventions for their prevention and treatment.

Cognitive therapy (CT), rational-emotive therapy (RET), and cognitive-behavioral therapy (CBT) are among the leading empirically tested psychosocial treatments of child and adolescent psychiatric disorders. Clinicians can significantly increase their assessment and treatment skills by learning the basic theory and strategic techniques of CT, RET, and CBT. RET and CT both focus on the role of cognitive distortions in the development and maintenance of psychopathologies. Differences include CT's emphasis on modifying underlying dysfunctional beliefs, whereas RET aims to change specific and dysfunctional self-statements ( [Meyers and Craighead, 1984b](#)). CBT is a hybrid of cognitive, behavioral, affective, and social strategies in which behavior and feelings are altered through changes in thinking patterns. The focus is on behavior and the cognitions needed for controlling and guiding feelings and behavior ( [Reinecke et al., 1996](#)).

### COGNITIVE THERAPY

#### Background and Conceptual Framework

The contributions of such diverse theorists as A. Adler, F. Alexander, K. Horney, S. Freud, G. Kelly, M. Arnold, R. Lazarus, A. Ellis, C. Rogers, and J. Piaget have been acknowledged in the development of CT ( [Weishaar and Beck, 1987](#)). The empirical nature of the approach is ascribed to developments in behavior modification, especially those related to collaboratively developing an agenda for each session, operationalizing problems, testing hypotheses, eliciting feedback, assigning homework, and using problem-solving techniques. In the CT model, feelings and behavior are determined largely by how people structure situations or events in their own minds. Thoughts or images of an event are *cognitions*, which are shaped by classifying, interpreting, evaluating, and assigning meaning to the event based on underlying attitudes or assumptions (schemata) derived from earlier experiences. When, for example, danger is perceived, egocentric (i.e., Piagetian preoperational stage) mechanisms are activated, and primitive thinking is used. Objective reality cannot be clearly distinguished from subjective thoughts and feelings. Cognitions also have been described as stream-of-consciousness awareness for verbal or pictorial events ( [Beck, 1967](#); [Beck et al., 1979](#)). Personal schemata usually develop early in life and can be either adaptive or maladaptive, universal or idiosyncratic, positive or negative ( [Harter, 1977](#); [Wright, 1988](#)).

The schemata are influenced by the child's developmental history before the onset of psychological distress. In stressful situations, latent negative schemata can be activated by circumstances similar to the original event or by an overwhelming of the child's coping abilities. *Automatic thoughts*, cognitions that tend to be repetitious and to occur without deliberation, are then invoked. The normal corrective process—refinement of the perception through testing against reality and prior experience, and then modification to reflect reality—fails to function in these instances. The result is the person's responding with exaggerated affect and deviant behavior. The automatic thoughts, only partially available to consciousness, are accepted as plausible without question. Closer scrutiny of these thoughts can reveal distortions and errors in logic. Psychiatric disorders result when the patient is sensitized to situations that evoke such *cognitive distortions* (systematic errors in reasoning). The consequent dysfunctional beliefs, attitudes, and assumptions become “silent” regulators of behavior. They override common sense and realistic responses, resulting instead in pathologic and disturbing emotional reactions ( [Beck, 1967](#); [Beck et al., 1979](#)). The negative cognitive triad of a negative view of the self, world, and future illustrates this principle ( [Beck, 1967](#); [Beck et al., 1979](#)).

The related depressogenic schemata (e.g., “I am really dumb. Nothing is ever going to go right for me.”) are latent and may be activated by a situation.

---

#### CASE ILLUSTRATION

Don, an 8-year-old boy with dysthymic and developmental reading disorders, felt overloaded with homework because of procrastination in completing assignments and not understanding a key concept needed to complete an English paper. As his depression deepened, Don lost the ability objectively to assess his negative thoughts and adaptively process incoming information. Cognitive distortions then followed. Don believed that, because he had problems with one concept for one paper, he was stupid and would never learn English. His automatic thoughts precluded his seeking clarification in his textbook or from class notes. As a result his performance suffered.

---

Several types of cognitive distortions or systematic errors in reasoning are associated with depression and require attention in therapy ( [Beck, 1967](#); [Beck et al., 1979](#); [Weishaar and Beck, 1987](#)).

1. *Arbitrary inference*: Specific conclusions are made contrary to or without confirming evidence (e.g., even though Don had always submitted papers in a timely fashion, he began to tell himself, “This material is so complicated that I will never get it and may as well give up now.”).
2. *Selective abstraction*: Details are taken out of context, and relevant data are ignored in conceptualizing an entire experience (e.g., Don thought, “The teacher doesn't like me at all. So I'll probably get a bad grade anyway.” This was based on the teacher's not calling on Don when he had the answer to a question.)
3. *Personalization*: Responsibility for external events is attributed to the self, with no basis for a connection (e.g., “I'm to blame for my parents' fighting.” This caused Don to daydream considerably, to not concentrate, and to miss class material or assignments.)
4. *Absolutistic, dichotomous thinking*: All experiences are placed in extreme categories, and the patient selects the most negative one (e.g., “I'll never learn to do that.”).

Anxiety disorders, agoraphobia, and other phobias likewise are conceptualized as responses to incorrect processing of situations ( [Kendall et al., 1991](#)). CT has been used in treating a number of childhood disorders and usually is combined with other cognitive and behavioral methods ( [Robins and Hayes, 1993](#)).

#### Strategies and Techniques

The goal of CT is to relieve symptoms and prevent future disorder. The therapist is active and directive. Questioning opens the belief system to scrutiny, with behavioral “experiments” serving as means to determine the validity of the underlying dysfunctional assumptions or beliefs. The behavioral experiments usually are developed and agreed on in the session. This process has been labeled a *collaborative empiricism*, with the patient's active involvement being a critical feature. The patient must understand the rationale and objectives of each assignment or experiment and agree to its implementation. The collaborative relationship is enhanced through active elicitation of feedback from the patient regarding his or her perceptions of therapy-related issues, and it aids in handling transference and resistance issues.

Initial treatment strategies are directed at clarifying the model and its theory, defining the problem, and relieving symptoms. Training patients to identify their automatic thoughts and to treat them as testable hypotheses is crucial. Also central is a listing of problems and priorities for treatment, which is incorporated into an overall treatment plan and used to set agendas for each session. *Guided discovery* is a term denoting the process by which Socratic dialogue is used in helping the patient learn to identify maladaptive conditions and underlying assumptions and to test them through consideration of alternatives. Behavioral change is expected to occur

through the testing of these hypotheses, the subsequent development of more realistic, adaptive assumptions, and the increased use of congruent behaviors ([Weishaar and Beck, 1987](#)).

“Cognitive” techniques allow for identifying, testing, and correcting specific distortions in thinking through monitoring negative automatic thoughts; recognizing the interrelatedness of cognitions, affect, and behavior; examining evidence supporting the distorted cognitions; substituting reality-based interpretations for the distorted ones; and changing the dysfunctional, distorting beliefs ([Beck, 1967](#)). They explore the basis of faulty assumptions by operationally defining the assumptions, refining terms, developing measures of probability, and reassigning attribution. Other useful techniques include charting the occurrence of automatic thoughts and disturbed affects, exploring worst-case scenarios, and using imaging to convey self-concepts and fantasies. [A listing of additional cognitive or verbal techniques is available elsewhere ([Beck, 1967](#)).] Once an assumption is identified, the patient and therapist engage in a process of validity testing: determining its universal application, listing supporting evidence, and considering the pros and cons of modifying the assumption or implementing an experiment contrary to the expected result.

“Behavioral” techniques help patients bring forth and test their dysfunctional cognitions and change their behavior. Homework assignments are used in practicing social skills, increasing activity, time structuring, and carrying out exercises targeted to specific situations. Monitoring activity through mastery and pleasure ratings, behavioral rehearsals and role playing, cognitive rehearsals, self-reliance training, graded task assignments, use of “diversion techniques,” exposure to dreaded situations, and relaxation training are additional behavioral techniques of value in conducting CT ([Beck, 1967](#); [Petti et al., 1982](#); [Robins and Hayes, 1993](#)).

### Application to Children and Adolescents

Several strategies to facilitate the successful use of CT in adolescents have been described ([Bedrosian, 1981](#); [Bowers et al., 1996](#); [Leahy, 1988](#); [Petti et al., 1982](#); [Wilkes and Rush, 1988](#)). The need to interview the whole family to learn the context within which the symptoms occur and to get the family involved in treatment distinctly differs in all three models from standard work with adults. [Bedrosian \(1981\)](#) outlines a series of questions useful in addressing this issue. Often the parents, who have brought the youth for treatment, have their own distorted perceptions related to developmental issues of adolescence, which require modification. Similar distortions exist in teenagers (e.g., regarding physical appearance, sexuality, autonomy and control, competency, and peer status).

### SPECIAL ISSUES

As in all psychotherapies, the nature of the therapeutic alliance with children and adolescents differs from that with adults. It is difficult to evaluate and test automatic thoughts in children, even after they have been acknowledged. The alliance can be jeopardized by premature confrontation of the dysfunctional cognitions. The youngsters may not perceive a need for treatment, believing that it is the parents' problem. Modifications to address these issues include examining everyone's view of the problem and acknowledging and accepting the teen's negative view of treatment. A more symptom-focused plan can be developed once the relationship jells. [Wilkes and Rush \(1988\)](#) suggest that offering to teach teens alternative ways of perceiving events is preferable to identifying and correcting logical errors. Use of a triple-column technique, with the headings “fear,” “automatic thought,” and “rational response” placed at the top of the columns, to deal with specific areas (e.g., noncompliance in keeping appointments), is recommended as well.

The techniques and principles of establishing rapport differ little from those applied in adult practice; conflict and threats to the relationship are minimized by modeling a style of information processing that contrasts significantly with that experienced in relation to the parents. For adolescents, the therapist must clarify that he or she cannot control his or her behavior, and that the therapist's evaluation of the teen is quite separate from their reaction to the adolescent's behaviors. The adolescent must feel in control of the flow of information considered and be involved at least in helping to set the agenda for the session ([Bedrosian, 1981](#)). Juveniles frequently have difficulty with lengthy, hour-long sessions; durations of 30 minutes supplemented by meetings with family members usually are better tolerated. Accepting teens' wish to end therapy on cessation of symptoms often is necessary unless a risk of danger is evident ([Bedrosian, 1981](#)). Likewise, expectations for homework assignments are less than those for adults. Flexibly set standards and concrete assignments are necessary. Recordings of activities and behavioral experiments should be expected to be completed more often than cognitive tasks, which can provoke performance anxiety. Some children have difficulty learning to use the techniques. Determining their cognitive capacity to complete the assignments is critical ([Forehand and Wierson, 1993](#)).

### DEVELOPMENTAL PERSPECTIVE

[Leahy \(1988\)](#) highlights the importance of taking a developmental perspective in the use of cognitive approaches with children and describes levels of depression related to development. For example, the therapist could use a blackboard to illustrate concepts such as the “Bad Thought Monster” and the “Smart Thought Man (or Woman)” and to depict examples of types of thoughts for each, have them fight, and so forth, to illustrate conflict, maladaptive and adaptive cognitions, and the relationship between thoughts, feelings, and actions. He also suggests creating an exciting persona such as a “Zen warrior” with the “force” for correct thinking and gaining competence. [Stark and Kendall \(1996\)](#) use similar methods to bring childhood interest to the challenge of automatic thoughts. They suggest that the child be like a detective when challenging maladaptive thoughts that cause depression. Teaming up with “Detective Dan,” the child tests assumptions and beliefs to see if they are realistic. Thus, the same treatment principles used with adults are creatively implemented in socializing youngsters to treatment (e.g., accepting behavioral assignments), identifying and changing underlying assumptions, and setting up experiments to challenge dysfunctional cognitions, commensurate with the cognitive–developmental level of the child. Facilitative modeling is a modification of treatment in which a parent is invited to some sessions to demonstrate interrelationships between thoughts and feelings and to serve as a role model for such behaviors as the sharing of negative self-statements and their correction.

Challenging assumptions is difficult with children, and the therapist may need to draw inferences from limited verbalizations. The Bad Thought Monster, Smart Thought Man (Woman), and Detective Dan are particularly useful in providing examples. Puppets that easily look the part of such representations also can be useful. For children younger than 12 years or those lacking formal operational thinking and the ability to abstract, [Leahy \(1988\)](#) recommends having the child commit adaptive thoughts to rote memory, with the therapist modeling such during the sessions. Less emphasis is placed on Socratic dialogue and more on role playing and reverse role playing in rational responding. Rational thoughts can be carried on flashcards and practiced as self-verbalizations during the day, with the parents being involved with this type of homework. In the initial socialization of the youngster to principles of the cognitive approach, the therapist may be usefully portrayed as “like a teacher” ([Leahy, 1988](#)). Drawing the analogy of therapist as coach also may assist in this process.

The following case represents an attempt to demonstrate the direct application of Beck's CT principles to the treatment of a disturbed child ([Petti et al., 1982](#)).

---

#### CASE ILLUSTRATION

John, age 12 years, was referred for suicidal ideation, recurrent depression, and refusal to eat or to go to school. We agreed that these problems, particularly his fear of eating outside his home, had contributed markedly to his dysphoria and would be the focus of our work. He developed an understanding of the interrelatedness of thoughts, feelings, and behaviors through the use of diagrams depicting his own feelings in positive and negative situations. We exposed several major cognitive distortions through role playing, assessing probabilities, monitoring predicted outcomes, homework (“experiments”), and other techniques. Our handling of an invitation he received for holiday dinner at a favorite relative's home illustrates some of these techniques. John's first response was to refuse adamantly to go or even to discuss the possibility. Exploration of this during the session revealed the underlying dysfunctional belief: “I'll get sick and puke all over. I'll be very embarrassed, and everyone will be upset with me.” Thus the resulting automatic thought, “No! I am not going,” and the block to further discussion became more understandable. John then estimated the probability or likelihood that any of the feared events expressed in his dysfunctional thoughts might actually occur (i.e., someone getting sick, getting scared of becoming ill, getting a nauseated feeling, being extremely embarrassed) on a scale from 0% to 100%. The estimated probabilities ranged from 80% to 100%. These were substantially reduced as we discussed his actual past related experiences. Probabilities for pleasant experiences on the visit likewise were analyzed and modified. We then role played the visit and ultimately devised a set of thoughts that could be used when the automatic thought occurred. He practiced them during the session and agreed to do further practice at home and to record the actual outcome as part of our “experiment.” John carried out his homework and reported that no one, including himself, had gotten sick, and he compared this outcome with his early and modified predictions. This became another part of our developing a more complete picture of his distorted cognitions and the means to address situations causing his fears and dysphoria. The parents also were involved in supporting his positive cognitions, adaptive responses, and overall program. Systematically collected data revealed progress in all areas.

---

## RATIONAL–EMOTIVE THERAPY

### Background and Conceptual Framework

Rational–emotive therapy or rational–emotive behavior therapy (REBT) ([Ellis and Dryden, 1997](#)) represents a bridge between CT and CBT. RET has been used with children since the 1950s and was among the first cognitive approaches in the psychotherapy of disturbed youth ([Bernard and Joyce, 1984](#); [Ellis and Bernard, 1983](#); [Waters, 1982](#)). As with CT, RET focuses on cognitions and on the identification, then elimination, of sources causing symptoms. Unlike CT, it seeks profound and lasting personality change, emphasizes active disputation with the patient concerning fundamental dysfunctional thoughts, and teaches evaluation of actions. It focuses on the core of the underlying dysfunctional belief system within the structure of an interactional theory of personality and personality disorder, and may be used with developmentally advanced teens but requires levels of cognitive functioning generally beyond those of younger youth. For these younger children, general

RET, "virtually synonymous with CBT," is used ([Ellis and Bernard, 1983](#)).

Rational–emotive therapy applies a panoply of action-oriented activities. In RET, *beliefs* express values and consist of one's appraisal and evaluation of the interpretation of reality and not the interpretation itself. *Assumptions* comprise both interpretations made about reality that can be assessed as true or false and the actual appraisal and evaluation of the interpretations, which also can be evaluated regarding extent of validity. *Irrational beliefs* in the RET framework are antiempirical assumptions held about the self or surrounding world that are formed early in life and often are fixed. In the RET model, emotional disorders are considered to occur following cognitive errors, either from (a) the interpretation of one's perceptions of a situation through empirical distortions of reality, or (b) the faulty *appraisal of the interpretation* through a negative evaluation of the inference with respect to one's life ([DiGiuseppe and Bernard, 1983](#); [Ellis and Bernard, 1983](#); [Waters, 1982](#)). The faulty appraisal of interpretations is considered the key to most emotional disturbance and to treatment. Distortions of reality can be corrected by adequate appraisal. A distorted perception will not result in significant levels of extreme arousal and pathology if it is appropriately appraised ([Bernard, 1988](#)).

Rational–emotive therapy, like CT, aims to modify or replace dysfunctional cognitive–emotive links and thus ameliorate specific emotional and behavioral problems, and to provide broad-based skills and strategies for solving diverse problems during and after treatment ([Ellis and Bernard, 1983](#)). Labeled "ABC(DE)," the therapeutic process is as follows: An activating event (A) is interpreted and analyzed in view of the person's belief (B) about what happened, which creates the emotional or behavioral consequence (C). In and after treatment, disputation (D) uses systematic challenge and question of the untenable hypotheses or irrational beliefs of absolutistic and imperative assumptions held about self, the world, and others in the environment. The new trust in the resulting cognitive–emotive and behavioral changes (E) occurs when the unrealistic assumptions and beliefs are reformatted into more sound and empirically valid statements.

Targeting distortions of inferences drawn during interpretation is a limited, less elegant, and short-lived solution (nonpreferential RET), whereas challenging the appraisal or evaluation of the interpretation (preferential RET) is the approach of choice if the child is capable of and willing to engage in such an effort. RET assumes that children and adolescents are especially influenced by affective and behavioral interventions and susceptible to cognitive appeals through didactic teaching, persuasion, and information giving ([Ellis and Bernard, 1983](#); [Waters, 1982](#)). The basic goal for both preferential and nonpreferential RET is the internalizing of a "philosophy of life/cognitive strategy that is more rational and realistic than the one [patients] commonly abide by when they get into difficulties" ([Ellis and Bernard, 1983](#)).

Adolescents and older children may in addition have the following as goals of treatment ([Young, 1983](#)): learning self-acceptance; learning to dispute personal imperatives (e.g., "musts," "shoulds," and "oughts" and "awfulizing"); and correcting misperceptions of reality. Young also suggests that adolescents can most easily grasp the irrationality of "I can't stand it" thinking and learn to challenge their conviction of being unable to handle inconvenience or discomfort.

[Waters \(1982\)](#) has listed seven goals of RET for younger children: identifying emotions correctly, establishing a vocabulary of terms to describe emotions accurately, distinguishing harmful from constructive feelings, distinguishing thoughts from feelings, being alert to self-talk, connecting self-talk and feelings, and developing rational coping statements.

### Strategies and Techniques

The stages of RET consist of relationship building, assessment, skill building, and application of skills. A high level of rapport may not be required for successful treatment with children and adolescents ([Bernard, 1988](#)). The factors for developing a working relationship are similar to those for CT.

### ASSESSMENT

Problem identification is the first phase of assessment. In this stage, determination is made of the actual existence of a problem and whether it belongs to the child or to individuals in the environment (e.g., parents, teachers) ([DiGiuseppe and Bernard, 1983](#)). The problem analysis phase follows and continues as an ongoing part of therapy. The dysfunctional cognitions, emotions, and behavior contributing to the disorder are determined and the subsequent insights integrated into the evolving treatment plan. Central concerns are expected to be revealed after higher levels of rapport are achieved in the therapeutic relationship. The assessment also addresses the child's cognitive strengths and weaknesses, the extent to which language may control the child's behavior, and the child's capacity to gain distance from the problem. The assessment should identify the antecedent and consequent conditions of the target behavior and the type and severity of maladaptive emotions before the analysis of such dysfunctional cognitions as (a) irrational self-statements and beliefs—self-defeating and irrational appraisal ("awfulizing," self-downing); and (b) causal attributions—appropriateness of beliefs regarding negative and positive events (e.g., negative outcomes are caused by factors related to the self; positive events are attributed to external factors). Additional components of the analysis are areas of strengths and skills, including coping self-statements and practical problem-solving skills—for example, generating several solutions to an interpersonal problem (alternative solution thinking) and predicting consequences of specific behavior (consequential thinking) ([DiGiuseppe and Bernard, 1983](#)).

Direct assessment measures, elaborated by [DiGiuseppe and Bernard \(1983\)](#) to access the self-talk of children and teens, are of great practical use in helping youngsters access their own thoughts and feelings, as well as in providing a mechanism for reporting self-talk. For the RET practitioner, they provide a window into the child's perceptions and verbal-language range and a basis for cognitive restructuring efforts. The following techniques may be of value for conducting most types of psychotherapy with children and some teens ([DiGiuseppe and Bernard, 1983](#)):

1. *Subjective Units of Discomfort Scale* ([Wolpe, 1982](#)): The child is asked to think of the worst feeling he or she has had or can imagine. This feeling is given a 100 rating and then compared with absolute calm, rating 0. The child is then asked, "From this scale, for (situation), how do you rate yourself at this moment, or when you are exposed to—?"
2. *Emotional (feeling) scales*: Children are asked to rate the impact of a particular emotion experienced in a given situation on a 10-point scale. This enhances the child's ability to quantify the strengths of feeling states and to perceive the experience of several emotions from weak to strong.
3. *Emotional flashcards*: The therapist and child take turns play acting the emotion named on the card, while the other guesses at it or tells stories about the emotion. This increases emotional awareness.
4. *Emotional detective*: The child is asked to work on a "case" by investigating how the child or others handle feelings, with the report due at the next session.
5. *Peeling the onion*: The therapist keeps offering verbal prompts until the level of thought activating the dysfunctional thinking is exposed.
6. *Feeling charts*: Descriptors (e.g., pleasant–unpleasant, weak–strong, short–long) are used by the child to depict feelings.
7. *Emotional vocabulary building*: Children list the names of all the feelings they know, then are asked to consider a situation in which a particular feeling was experienced and, if possible, the preceding thoughts. This allows labeling each feeling with a definition and sensitizes children to a wider range of emotions. It also demonstrates the level of emotional understanding and provides an introduction to RET ([Waters, 1982](#)).
8. *Thought bubbles*: The aim here is to convey the notion of thoughts creating feelings and to assist children in making the connections. This can be done with a series of cartoons depicting temporally related scenes of a problem. The cartoons contain characters with dramatic expressions, and the child is asked to fill the accompanying bubble with thoughts of the character.
9. *Sentence completion*: Incomplete sentences concerning problem areas are presented, which the child is requested to complete. These elicit the presence or absence of coping self-statements, beliefs, and practical and emotional problem-solving skills (e.g., "When the girl gets teased before class, she thinks ...").
10. *Think aloud*: Children are asked to think aloud as they attempt to complete a task. This provides a picture of the affective quality of their self-talk (e.g., fear of visiting the dentist for an examination).
11. *Thematic Apperception Test–like approach*: Pictures of ambiguous situations are shown, and the child is asked to create a story about the thoughts and feelings of the characters and explore alternative options in that situation.
12. *Expansion*: Verbal prompts expand abbreviated self-talk; for example, as the child expresses thoughts experienced in a problematic situation, the therapist asks questions and gives verbal instruction to expand the content ("What thoughts came after . . .?" "Tell me more about ...").
13. *Words "and," "but," and "because"*: These are used to facilitate tuning in to and reporting automatic self-talk when the child ends an incomplete sentence about a thought.
14. *Instant replay*: Developed for parents and children to keep track of unpleasant emotions arising from specific situations and events occurring during the prior week, the "rerun" asks them to play back their related thoughts and feelings.
15. *Guided imagery*: The child is asked to relax, to imagine vividly a problem situation, and to describe feelings and related self-talk.

### SKILL BUILDING

The third stage, skill acquisition and skill building, consists of training to use problem-solving skills and help the child or adult take responsibility for their emotions by controlling their feelings through rational thinking and use of such skills. Teaching youngsters to change inappropriate to appropriate feelings frequently involves changing irrational, extreme responses to moderate and more realistically appropriate feelings and actions (e.g., changing rageful anger to annoyance or changing

panic to apprehension) to allow more goal-oriented actions ( [Waters, 1982](#)).

[DiGiuseppe \(1981\)](#) suggests that initial efforts with children should be directed to helping them build a schema with a vocabulary of feelings and responses and a framework for their application. To illustrate how changes in feelings and behavior are possible, the contrasting differences in results between a child's usual negative behavior and what can be expected from more appropriate, less disturbing behavior, achieved by use of alternate strategies, should be discussed. The need to get out of an "emotional fog" and to calm down before taking action is another principle to discuss early on in the process of problem solving.

Teaching the specifics of "ABC," the next step, focuses on awareness of self-talk and the connections between beliefs, feelings, and antecedent events. Older children are taught the difference between rational and irrational beliefs and other critical thinking skills (e.g., absolute vs. conditional thinking; consequential thinking; discriminating fact from opinion, inference, and assumption; learning to take a perspective on a situation; and disputing irrational thinking). Younger children practice coping self-statements in learning how cognitive change can occur and influence B and C in the ABC paradigm ( [DiGiuseppe and Bernard, 1983](#); [Waters, 1982](#)).

Because younger children may have difficulty with the terms *rational* and *irrational*, [Waters \(1982\)](#) suggests substituting *helpful* and *harmful*, respectively. Helpful beliefs are based in reality and result in more acceptable feelings and actions and in getting what you want. Harmful beliefs result in self-defeating thoughts, destructive and nonacceptable feelings, and failure to attain one's desires. A set of questions based on the question, "Is there enough evidence to conclude that this thought is true?" allows the child reasonably to challenge beliefs.

---

#### CASE ILLUSTRATION

Fred, a verbal young teen with borderline and schizotypal features, is overly attached and dependent on his grandmother. He asked her to help monitor his homework. Learning disabled but very bright, he frequently makes errors. When she suggests that a word may be misspelled or a sentence incomplete, an argument ensues because he inevitably challenges her point. Fred was finally able to share his underlying belief that being wrong was a sign of weakness and defeat. To accept her correction meant "submitting" and defeat. He learned to challenge the rationality or helpfulness of the belief by questioning the correctness of the appraisal and seeking evidence to try to support it. He decided that it was not so awful to have her point out errors, that he was really strong enough to accept such assistance, and that it could be much worse if she corrected in a belittling fashion or not at all. He learned that the harmful belief ran counter to his own needs and desires. Most critically, he came to understand that making errors did not make him any less worthwhile and that accepting corrective feedback could improve rather than diminish his stature as a person of worth.

Fred's case also illustrates a more sophisticated intervention. He had just received a poor grade from a recent examination. Beyond learning to dispute the concepts of "ain't it awful" or "I'm just stupid" with regard to that particular episode, he was able to look at the more general issue of what needs to be done when you have a learning handicap, and that it is different from being stupid or not having any control over the situation. He discussed what might be done differently in the future. The next step was to apply empirical analysis, a strategy to modify dysfunctional interpretations. As in CT, therapist and child agreed to design an experiment to evaluate his belief of being stupid. Fred agreed to pay closer attention to the teacher and write assignments and tests down in a notebook that would be kept up and brought home daily. We then compared the results of the next examination with his earlier experience. He tested whether he (a) would do poorly again, to see if he did have some control over the situation, and (b) could do well, contrary to his belief that he was always doomed to fail. His belief was that he had done everything possible and that he had no control over his grades. Fortunately, the behavioral structure he imposed on his schoolwork demonstrated that organizational skills and not stupidity accounted for his poor performance.

---

Rational-emotive imagery ([Ellis and Bernard, 1983](#); [Waters, 1982](#)) is another strategy that asks the child to imagine a picture depicting a situation that generates an extreme emotion. The child is asked to change the feeling to a milder form (e.g., from hating and greatly fearing a bully to a strong dislike and worry about the bully). Once this is done, the link between thought and emotional change is highlighted for present and future use.

#### APPLICATION OF SKILLS

Implementation of the newly learned rational thinking skills outside the therapy session is the final stage of RET. Homework assignments are the major vehicle in effecting this task. This involves, for example, practicing the skills; monitoring their effect and associated feelings; listing personal demands; listing thoughts, feelings, and behaviors related to specific events; completing a self-concept inventory; and using positive self-talk as a reinforcer ( [Bernard, 1988](#)). This phase requires considerable effort by both therapist and child because major changes in thinking, feeling, and acting are being attempted. The relationship must be sufficiently established to weather the expectations placed on the child. Developing a system of reinforcers in cooperation and collaboration with the parents can be useful in overcoming resistance to completing the homework or in overcoming a well entrenched set of bad habits. The therapist also can focus on irrational beliefs in the session to deal with this difficult issue ( [Bernard, 1988](#)). In children with cognitive deficits rather than distortions, training in such CBT models as interpersonal cognitive problem solving (ICPS) ( [Spivack and Shure, 1974](#)) is most appropriate.

#### ROLE OF PARENTS

Involvement of the parents in all stages of assessment and treatment facilitates a successful outcome. Assessment provides a guide to the extent to which parental behaviors and beliefs influence the child's problems. Goals and principles to use in work with the parents have been developed ( [Bernard, 1988](#)), and the same four stages are applicable, from the development of rapport to practice of skills outside the sessions. Likewise, problem identification and analysis of difficulties that exist in the family are analogous to those for the children. The focus is to assist the parents in overcoming their own and the child's difficulties by developing an understanding of their basic dysfunctional beliefs and an awareness of more constructive alternatives. Participation in their own homework also is expected, including better control of emotions, distinguishing rational from irrational ideas, implementing behavioral changes, and use of child-related literature ( [Bernard, 1988](#)). The RET approach of [Block \(1978\)](#) has been found to be one of the probably efficacious treatments for adolescents with conduct problem behaviors ( [Brestan and Eyberg, 1998](#)). The use of RET in the family context is articulated by [Ellis and Dryden \(1997, pp. 152-161\)](#) in their case example of family therapy for a family of five, including a disturbed and disturbing 15-year-old daughter.

## COGNITIVE-BEHAVIORAL THERAPY

### Background and Conceptual Framework

Cognitive-behavioral therapy, a major force in the treatment of children, is based on developments from the behavior therapy movement of the late 1960s and the thrust of psychology in a "cognitive" direction. A number of workers have been credited for their major contributions to this growth ( [Kendall, 1993](#); [Mahoney, 1993](#); [Petti, 1989](#)). The evolution occurred along three paths: (a) advances in cognitive and developmental psychology ( [Bandura, 1977](#); [Meichenbaum, 1977](#); [Shirk, 1988](#)); (b) evolution of self-control procedures from the operant model, including [Bandura's \(1977\)](#) concept of reciprocal interaction between individuals and their environment; and (c) the contributions of CT and RET, as noted previously. CBT reflects an integrative approach that incorporates CT and RET. As such, it has become the primary cognitive therapy approach used with children and adolescents. In addition to being widely used, CBT has been shown to be efficacious in studies of several disorders ( [Kazdin and Weisz, 1998](#)). Empirical research has shown CBT to be superior to no treatment and to some other types of psychotherapy (including placebo support) for depression (Clarke et al, 1999; [Kaslow and Thompson, 1998](#)), anxiety ( [Ollendick and King, 1998](#)), obsessive-compulsive disorder ( [March and Mulle, 1996](#)), and conduct/oppositional disorders ( [Brestan and Eyberg, 1998](#); [Kazdin and Wassell, 2000](#)). Many CBT interventions are considered probable empirically supported treatments (ESTs). ESTs are defined as "clearly specified psychological treatments" shown to have their efficacy "established" or "as probably efficacious" in controlled research with a delineated population ( [Chambless and Hollon, 1998](#)). To be designated an EST, a treatment must meet rigorous research efficacy criteria ( [Chambless and Hollon, 1998](#); [Lonigan et al., 1998](#)) that are roughly analogous to those required of medications for clinical indication. ESTs are becoming one of the major standards of care for psychotherapeutic intervention. Hence, consistent findings of empirical support for the use of CBT with diverse disorders suggest that CBT interventions are some of the most effective modalities of psychotherapy.

Primary CBT goals are concordant development of efficient and adaptive modes of perceiving, interpreting, solving, and responding to problematic situations, leading to an increase in adaptive thinking and behavior and the elimination or reduction of maladaptive and inappropriate behaviors. This is accomplished by developing and internalizing self-control skills and reflective problem-solving strategies. CBT integrates the concept from behavior therapy that antecedent and consequent environmental factors contribute to overt behaviors, with concepts from cognitive and rational-emotive therapies that emphasize the role cognitions play in dealing with environmental stimulation and changing overt behavior ( [Craighead et al., 1985](#)). Cognitive distortions and deficiencies associated with deviant or dysfunctional behavior are the focus of concern ( [Kendall, 1993](#)). A multimodal approach to treatment is considered necessary to address the multidimensional factors that contribute to and maintain the psychopathology. Underlying assumptions have been summarized by [Cohen and Schleser \(1984\)](#): (a) active problem solving is expected in childhood; (b) discrimination, extraction, and analysis of data and subsequent planning are characteristic of problem solving; and (c) styles of problem solving change with developmental progression. The child is assumed to be an active participant in and interpreter and recorder of experiences. The developmental implications and skill levels of the child are considered essential to planning treatment strategies. Cognitive therapies with adults can successfully focus on their subjects' distorted processing of information and world views. In most children and many adolescents, however, the issue of distorted cognitions is considered of less importance than the lack of effective strategies for controlling behavior ( [Braswell and Kendall, 1988](#)) and the prominence of impulsive cognitive styles over more reflective styles ( [Cohen and Schleser, 1984](#)). The need to differentiate between the presence of cognitive deficiencies, distortions, or both is critical in helping the

child build a new “cognitive template” to identify and solve problems ( [Kendall, 1993](#)).

With age, children become more reflective ( [Leahy, 1988](#); [Roberts and Nelson, 1984](#)). Strategies for implementing CBT interventions also must consider the developmental level of the child’s cognitive skills ( [Durlak et al., 1991](#)) and attentional, memory, and related skills. Achieving a level of formal operations allows the teen to attend selectively to tasks, to use deductive reasoning and problem solving, and to learn strategies that can be applied in a flexible manner. Those who have attained the concrete level of operations can appreciate the usefulness of a strategic approach to problem solving, but may not be able to focus their attention or may get excessively involved in the problematic situation and thus may lose details in the process. They need to be made aware of the value of using a mnemonic strategy. Preoperational and preschool children function on a here-and-now basis. They are incapable of planning for a problem-solving situation ( [Cohen and Schleser, 1984](#)).

Generalization of change to other situations, settings, or environments is a major consideration in conceptualizing strategy. Problem identification, goals of treatment, and sequence of planned intervention strategies depend on the child’s level of development ( [Roberts and Nelson, 1984](#)). Increasing a child’s ability to report experiences accurately, evaluate his or her own performance situation, and self-monitor mood is considered a major objective of CBT interventions.

## Strategies and Techniques

Many types of CBT models exist; the names of these approaches include *cognitive–developmental* ( [Harter, 1977](#)), *cognitive training*, *cognitive behavior modification* ( [Meichenbaum, 1977](#)), *cognitive–behavioral–psychosituational* ( [Griegeer and Boyd, 1983](#)), and others ( [Dobson, 1988](#); [Dryden and Golden, 1987](#); [Meyers and Craighead, 1984a](#)). The basic strategies in general are similar. Most of the variants emphasize one facet of CT, RET, or CBT over another, depending on the developmental level of the child, the targeted behavior, and the techniques to be used.

## ASSESSMENT AND TREATMENT

[Roberts and Nelson \(1984\)](#) review assessment issues for general use with CBT. These include the role of developmental processes, identification of target behaviors, evaluating outcome, and relationships between measures for verbal and motor behavior. They also outline cognitive and behavioral assessment strategies related to academic and social problem solving and consider rating scales, checklists, measurement of academic performance, and behavioral observations.

Several standardized scales and approaches have been devised to assess the family structure in CBT with conduct-disordered children and teens ( [DiGiuseppe, 1988](#)). Understanding the extent to which children have the cognitive repertoire needed to understand therapeutic interpretations and their causal/attributional/locus of control style is considered a critical aspect of assessment ( [Shirk, 1988](#)). [Braswell and Kendall \(1988\)](#) list a number of other behavior rating scales, performance measures, and self-report instruments used to assess children’s self-talk, expectancies, and attributional style.

Differentiation between internalizing and externalizing disorders is one way to select treatment strategies. Internalizing disorders (e.g., depression and anxiety disorders in older children and teens) might best be treated through recognizing and testing “mistaken misperceptions, expectations, and/or attributional preferences,” whereas externalizing conduct-disordered children with deficiencies in effectively mediating their behavior might be approached through training in verbal mediation techniques (e.g., self-control and more reflective problem-solving approaches) ( [Braswell and Kendall, 1988](#); [Kazdin and Weisz, 1998](#)). Even within the same diagnostic category, several different CBT methods and strategies might be considered. Multiple approaches to particular types of disorders are available. [Kendall \(1993\)](#) lists general treatment strategies of CBT as modeling, building a coping template, rewards, enactive procedures, affective education, and training tasks, and provides specific methods for each. The following describes representative CBT models.

## MODELS

### Verbal Self-Instruction Training

Among the most widely used CBT procedures, verbal self-instruction training (SIT) has been demonstrated to be efficacious in assisting children with self-control and self-monitoring problems ranging from anger outbursts to social skills deficits and impulsive behavior. SIT involves learning and practicing a set of procedures for interpreting situations, guiding behavior, and solving problems. Initially, the procedures are practiced by saying them aloud as problems are solved. Later, the child learns to use SIT procedures with internalized talk and well rehearsed responses to problem situations.

[Kendall \(1992\)](#), for example, uses SIT as part of a manual of CBT treatment for impulsive behavior called *Stop and Think*. The Stop and Think treatment program begins with the child learning a five-step problem-solving plan for slowing impulsive behavior: (a) identify the problem (“What am I supposed to do?”); (b) generate alternatives (“Look at all the possibilities”); (c) select the best solution (“Pick an answer”); (d) evaluate the solution (“Check out your answer”); and (e) self-praise or redirection back to task (“I did a good job” or “I’ll pick another answer and do better next time”). Children initially say these problem-solving steps aloud as they solve a variety of word and math problems for practice. Later in treatment, they practice the problem-solving steps with increasingly difficult and realistic situations (such as social interaction). Homework assignments encourage children to practice their problem-solving steps at home and to learn to monitor their feelings and behavior. Other components of Stop and Think teach children to anticipate feelings, control emotional responses, and understand what others might be thinking or feeling. The ultimate goal of Stop and Think is to teach the child to use the SIT problem-solving steps in complex, provocative (e.g., emotional, social) situations to produce more planned, careful behavior.

Self-instruction training also is a part of programs that address depression ( [Stark and Kendall, 1996](#)) and anxiety ( [Kendall, 1990](#)). These interventions use SIT (as well as several other CBT techniques) as a part of problem solving and learning new patterns of interpreting situations. They help because negative cognitive appraisal of (e.g., making sense out of) situations often leads to depressed or anxious symptoms. Although SIT programs for depression, anxiety, and impulsivity differ somewhat in content, they share in common the use of internal cognitive and behavioral directions to carry out the goals of treatment.

There is strong evidence that SIT improves children’s problem-solving ability and coping skills ( [Kendall and Braswell, 1993](#)). Research has shown Stark’s cognitive–behavioral treatment for depression and Kendall’s cognitive–behavioral treatment for anxiety to be efficacious in reducing symptoms of these disorders in children ( [Kaslow and Thompson, 1998](#); [Ollendick and King, 1998](#)), although SIT is only one component of these interventions. Treatments for attention deficit/hyperactivity disorder (ADHD) that use SIT alone have not been found to be very effective for the core inattention–disorganization and hyperactive–impulsive symptoms of the disorder ( [Hinshaw, 1996](#)). However, SIT may be more effective for impulsivity and aggressive behavior related to social and anger control problems ( [Hinshaw, 1996](#); [Kendall and Braswell, 1993](#)).

---

## CASE ILLUSTRATION

Nine-year-old Joe was referred for severe hyperactivity and oppositional behavior present from the time of his adoption at 6 years of age. His dysthymia was successfully treated with imipramine, but his impulsive and negative behavior persisted. His adoptive parents were most concerned about his ravenous “stealing, wolfing, and secreting” of sweets. He and his parents agreed to target this behavior for treatment. After collecting baselines for missing goodies, a self-control program was initiated. First Joe’s thoughts, feelings, and actions were explored using the thought, “I want/need a cookie.” A written sequence was developed, which was practiced out loud in the sessions for Joe to learn to use at home:

I want cookies!  
What AM I supposed to do? (Think of available choices.)  
I need to look at all my alternatives!  
Grab it and take a chance on being punished, feeling guilty, etc.  
Ask my mom or dad and expect ...  
Wait till later to ask and expect ...  
Which is my best choice?  
How should I do it? and, later to discuss in therapy ...  
How well did I do? [Petti, 1989](#).

Joe refused to keep a log monitoring his thoughts, feelings, and success in maintaining control when faced with the urge. He did report verbally what occurred, and this compared well with parents’ reports. His probability estimate for how successful he would be in controlling his behavior around sweets was less than 50%. Both he and his parents were therefore delighted at his close to 100% success rate. A similar approach was taken with other impulsive behaviors.

---

Interpersonal cognitive problem solving is an approach that mixes problem-solving skills with interpersonal challenges. ICPS makes intuitive sense because good social behavior is based on processes such as means–end thinking, accurate appraisal, evaluating alternative responses, and choosing an appropriate response for a problem. Conversely, fixation on a goal and failure to think through the means to reach the goal can lead to problems in social behavior. When problems in social behavior occur, the child may resort to less skilled means of achieving or avoiding social goals, such as aggression and withdrawal. By carefully appraising, planning, and choosing problem-solving behaviors, children can therefore improve their social behavior.

Children are taught ICPS by first learning that many alternative behaviors may occur in a given social situation and that their behavior is their choice. Next, means–end thinking, connecting behavior and social consequence, is encouraged ( [Spivack and Shure, 1974](#)). Later, children are taught problem-solving steps, using SIT techniques. A typical progression of problem-solving steps involves identification (accurate appraisal) of the problem, generating possible solutions, evaluating the solutions, choosing a solution, and evaluating the adequacy of the solution (if the solution fails, the problem-solving steps are used again). The child practices the problem-solving steps on increasingly difficult social problems. Role playing is used to make the practice more realistic and to anticipate difficulties. Most ICPS programs include a reinforcement component in which children can earn rewards for adequate performance of ICPS steps and goals ( [Kendall, 1992](#); [Kazdin, 1996](#)).

Interpersonal cognitive problem solving has been shown to be an efficacious preventive intervention in poor urban preschools ( [Shure, 1999](#)), although the relationship between ICPS skills and later social behavior has been questioned ( [Braswell and Kendall, 1988](#)). ICPS, especially when combined with parent management training, has been shown to lead to decreased aggressive and externalizing behavior, as well as to improved prosocial behavior ( [Kazdin, 1996](#)). ICPS also involves developing the skills to name unconnected, alternative solutions (alternative solution thinking), to weigh pros and cons of those solutions to a situation, and to think of the different outcomes that might occur (consequential thinking). Implementation of ICPS by teachers and parents of preschool and early school-age children has been shown to prevent violence and high-risk behaviors. Manuals and books are available for this purpose ( [Shure, 1999](#)).

---

#### CASE ILLUSTRATION

In the treatment of a depressed, impulsive 12-year-old ([Petti and Wells, 1980](#)), situations provoking anxiety or anger were hierarchically arranged from least to most arousing. Scenes evoking the lowest level of arousal were addressed first through role playing of appropriate cognitive, behavioral, and verbal responses. The responses were first modeled by the therapist. The youngster was then coached in their use and provided positive feedback as he role played each situation. The emotion-arousing situations were practiced until the patient's responses were satisfactory to both patient and therapist. Follow-up indicated better than adequate functioning.

---

#### CASE ILLUSTRATION

Jean is a 14-year-old girl with low-average intelligence and a long history of being sexually abused in a chaotic "family" setting. Her episodic dyscontrol became prominent after placement in a supportive preadoptive home. During an inpatient stay, her lack of interpersonal skills was evident. She had developed a knowledge of the basic language concepts required for this approach and had some appreciation for the feelings of herself and others. However, she was wedded to "satisficing"—taking the first available option that came to mind, which was usually based on long-standing distrust of others and was predominantly hostile, aggressive, and negative in nature. Several episodes on the unit were used to develop the concept of seeking alternative explanations and responses, then to tie the options to possible consequences, and finally to anticipate the consequences of her actions when confronted with conflict. She then practiced this evolving skill around her desire to do what she wanted on an outing, in conflict with the desires of her caretaker. She was able to negotiate a compromise acceptable to all. This allowed her then to trust and learn to discuss conflicting views and desires without assuming the worst before she even began the process. She ultimately felt more confident in relating to peers, staff, and family members. Initial preparation of significant others in the environment to be receptive to these changes can be the critical factor predicting the degree of successful outcome.

---

#### Self-Evaluation and Self-Management Skills

Self-evaluation skills consist of learning accurately to recognize and label internal states and external behaviors. Typically, a self-evaluation protocol begins with a discussion of the behavior or internal state to be identified. Concrete, specific examples of the behavior are given to teach the child to recognize it. [Kendall \(1990\)](#), for example, uses facial expressions and bodily reactions to teach children to understand anxiety states. The child's improved self-evaluation allows him or her both to identify anxiety states and understand the impact of anxiety states on expression and physical functioning. After discussing the characteristics of the behavior or the internal state, the child then practices accurately identifying it in the normal course of daily life. [Hinshaw \(1996\)](#), for example, uses a gamelike format to teach children with ADHD about their behavior. Both therapist and child rate the child's target behavior on a scale of 1 (worst) to 5 (best). If therapist and child ratings match, the child receives a reward. Self-evaluation is a part of many cognitive–behavioral programs that require the child consistently to monitor target behaviors. Used in isolation, it may promote better control over behavior by making the child more aware of the target behavior itself or the precursors of the behavior.

Self-management skills apply the knowledge gained in self-evaluation in the service of modifying behavior. One type of self-management skill, self-regulation, involves (a) self-evaluation, (b) setting acceptable objectives, (c) evaluating the response, and (d) reinforcing oneself if the standard is met. [Williamson and associates \(1981\)](#) describe a modification of this approach with an extremely hyperactive, distractible young boy and the subsequent dramatic decrease in his need for stimulant medication. Correspondence training, on the other hand, is a self-management intervention that operates by rewarding children for doing what they say they will, for accurately describing what they did, or for showing an appropriate response to a targeted situation described by the therapist. [Hinshaw \(1996\)](#) describes an anger self-management program that consists of self-evaluation/monitoring followed by use of strategies to reduce anger/aggression and practice of the skills during mock provocation by peers in a group. [Hinshaw \(1996\)](#) has shown in a series of studies that self-evaluation/self-management training for anger control results in improvements in angry-aggressive behavior.

## CONCLUSIONS

The cognitive therapies are varied and comprise amalgams of diverse contributions. It has been argued that they are simply extensions of the behavior therapies ([Wolpe, 1982](#)). However, collectively they do address in a systematic manner virtually all nine of the skills axes and methods to promote these skills considered by [Strayhorn \(1983\)](#) to be relevant to psychotherapy and preventive mental health. Combinations of treatment components usually are used in most studies ( [Durlak et al., 1991](#)).

Overall, the cognitive therapies are recognized as research-validated, efficacious psychotherapeutic approaches for depressive, anxious, and some disruptive behavior disorders ([Kazdin and Weisz, 1998](#); [Kendall, 1991, 1993](#); [Lochman, 1992](#)). They provide opportunities for briefer, empirically supported, cost-effective interventions and allow developmentally appropriate, multimodal assessment and intervention. Combined treatments developed for specific disorders ( [Bernstein et al., 2000](#)) can be expected. Manuals (e.g., [March and Mulle, 1998](#)) to train therapists in implementing CBT represent a major advance in the field. They provide researchers with the means to ensure uniformity of techniques across investigators and individual clinicians. CBT often is used in a group format, especially in early intervention in schools ( [Clarke et al., 2001](#)). Limitations ascribed to CBT research related to its evaluation with nonreferred populations fail to consider the major value of this efficacious approach to early intervention and the secondary prevention of more severe forms of psychiatric illness when delivered in schools and related settings ([Petti, 1999](#)).

[Chapter References](#)

Between 1995 and 2000, somewhat more than 500 articles, chapters, books, and dissertations were written about group psychotherapy with children and adolescents. From the clinical perspective, there have been advances in the treatment of previously contraindicated populations (low intelligence, organic cases, the very young, and the very difficult, acting-out child.) This chapter updates the previous review ( [Azima, 1996](#)) and includes new group applications to high-risk psychiatric disorders, focusing specifically on research advances in these areas. It is clear that there has been a marked shift in theoretical orientations from psychodynamic/psychoanalytic to cognitive-behavioral/interactive ones, especially for short-term modalities. This shift has encouraged structured and manualized approaches that can be operationalized and subjected to research investigations.

Increasingly, child group psychotherapy is becoming part of a multimodal integrative approach for outpatient and inpatient, day hospital, and residential facilities. Psychoeducational approaches with children and parents have become more prevalent, as has their use in schools and communities. As is illustrated, the emerging problems of our society that have affected youth have dictated the increased use of groups for anxiety, depression, suicide, violence, oppositional defiance, drug addiction, posttraumatic stress, social phobia, medical disorders, family separation, and sexual abuse.

An early report by [Toseland and Siporin \(1986\)](#) that group psychotherapy is an efficient and cost-effective treatment has been further confirmed by the meta-analysis of [Hoag and Burlingame \(1997\)](#). These authors analyzed 56 outcome studies published between 1974 and 1997 on the effect of group treatment with children and adolescents (4 to 18 years of age). A variety of types of group treatment were assessed, including preventive programs, psychotherapy, and guidance, counseling, and training groups. The results indicated that group treatment was significantly more effective for children than wait-list and placebo-controlled groups (effect size = .61), with the average child or adolescent treated in groups better off than 73% of those in control groups. Some findings were challenging and surprising, in that variables that were significantly related to improvement included socioeconomic status of the patient, the allegiance of the therapist, setting of the therapy, and publication year of the study. Variables not related to improvement included diagnosis and content and source of the outcome measures. Future meta-analyses are necessary to confirm these findings. The current clinical and research overview corroborates positive outcomes in most cases for both clinical and research reports.

Clinicians have continued to be enthusiastic that group psychotherapy for children and adolescents is a treatment of choice. Young, active children can communicate with one another, often without words or symbolic reasoning, as if they have a private language. Therapists have the opportunity to observe the actual behavior of the children, to clarify the diagnosis, and gradually to interpret the meaning of their play and interactions. Psychotherapeutic and educational goals are provided in a safe, supportive, empathic setting where boundaries and rules are established by the therapists. As for adolescents, group settings are particularly advantageous because of their specific need for relationships with their peers. Reciprocal exchange of thoughts and feelings permits self-disclosure in the group that often is not possible in individual therapy, where rebellious silences pervade the transference to parental authority figures. In the group, the adolescents themselves are clear about what is acceptable and proper for others in their age group. Learning that problems are not unique and that they are shared by peers can promote faster sharing of information.

## APPROACHES

Current group psychotherapeutic approaches for children stem from modifications of traditional activity therapy ( [Schiffer, 1977](#); [Slavson, 1952](#)) and group analytic models ( [Anthony, 1965](#)). For young children, these approaches are blended with psychoanalytically oriented play therapy ( [Ginnott, 1961](#); [Phillips, 1985](#); [Winnicott, 1971](#)).

### Activity Group Therapy

This approach, introduced by [Slavson \(1952\)](#), focuses on observation of the children's behavioral and motoric communications and is carried out in a permissive, empathic, supportive setting. The focus is on seeing how the child relates to and copes with other children and physical objects in the group context. Transference interpretation is minimized. The therapist provides little structured activity and intervenes only when a child is in danger, is hurt, or threatens another child. Toward the end of the session, refreshments are provided.

### Activity-Interview Therapy

This modification was formulated by [Schiffer \(1977\)](#) to provide additional structure to the original technique. The first part of the session allows group play with peers, followed by a structured discussion period. The fantasy produced in the play period is explored, with the therapist imparting meaning, insight, and transference interpretation. In addition, the group dynamics and bonding with peers and the therapist solidify over time and provide the vehicle for the therapeutic change.

### Group-Analytic Psychotherapy

Current activity models are more integrative with psychodynamic theory. [Johnson et al. \(1998\)](#) outlined a guide of activities useful in many settings. This model was adapted by [Anthony \(1965\)](#) for nursery, latency, and adolescent groups. The therapist intervenes rarely with the nursery children, keeps to the background, and fits interpretation into the play themes. A specified "small table" technique was evolved, which concretized the space or territory of the table and room for each child and therapist and permitted observation of changes over time. For the latency group, a "small room" technique was used, in which a discussion group was followed by an activity phase. Repeated themes identify the children's conflicts, whether they are expressed in symbolic play, free associations, or fantasies and dreams. The older latency children begin to demonstrate more of the specific group analytic factors introduced by Foulkes, such as socialization, mirroring, the condenser, and chain phenomena. The condenser is a sudden reaction to the group that is discharged by a particular event. The chain phenomenon is likened to the group's free-floating discussions, in which the topic is carried forward by each individual's response, followed by a condenser outburst. The specific roles of the scapegoat, stranger, and historian in the latency-age group are still highly relevant today. Although the technical aspects of the approach may be modified, the therapist's psychodynamic understanding remains central.

Some 60 years later, current group approaches include pure or blended psychoanalytic, psychodynamic, behavioral, and cognitive models, combined with family and network interventions. The precise applications appear to be the result of the group therapist's theoretical training, the particular setting's philosophy, and the type of population that is in need of treatment.

Most therapists working in the field today use a developmental framework involving parents in parallel treatment for the younger children. The two major theoretical trends are psychoanalytically oriented and behavioral–cognitive approaches, both emphasizing here-and-now interactions. Unfortunately, in this age range there has been insufficient attention paid to the actual interactions in the matrix, the reciprocity patterns, and the changes over time in leader dominance and submissive followers within the group ([Azima, 1982](#)).

The group therapy area in the past suffered from an undue borrowing from individual therapy theory. For group theorists, the historical premise is that the infant is embedded in a symbiotic group fusion and, developmentally, only gradually becomes individuated. There has been a revival of interest in interpersonal ([Sullivan, 1953](#)) and peer theories. [Grunebaum and Solomon \(1987\)](#) concluded that the ability to master peer relationships and define friendship patterns involves a separate line of development from that of the mother–child dyad. These authors do not negate the importance of the parent–child relationship, but emphasize the independence of peer competency. These authors have postulated that self-esteem and peer relationships are such interconnected phenomena that self-evaluation may be viewed in large measure as the inner experience of the esteem in which one is held by one's peers. Nowhere is the study of peer relationships more important than in child and adolescent group therapy.

As in all therapies, the essential ingredient is the analysis of content and process, which over time allows the unfolding and recapitulation of the past in the present context. The group affords an increased expression of thoughts and feelings, including projective biases that allow each member to be understood from many more points of view than a single therapist can hypothesize. Further, the projections open a window into the speaker's own pathologic process. The allies and dissidents actively demonstrate the variation in projective identifications, as if it were a system of revolving mirrors, reflecting intrapsychic and interpersonal coordinates for each member. The differing responses to the individual speakers promote the working-through process and constitute a corrective monitoring system for the group therapist. Among other important features of multiperson therapy is the provision of a social context and the rebuilding of more accurate interpersonal relationships; the development of bonding, an esprit de corps or group climate that motivates and energizes the loyalty, intimacy, openness, and cohesion of the membership; the development of a group composition that permits stronger, better-functioning members to interact therapeutically with ego-weak, more pathologic children; and the working through of dominant/submissive, independent/dependent roles ([Garland, 1992](#); [Pfeifer, 1992](#); [Spinner, 1992](#)).

### APPLICATIONS AND TECHNIQUES FOR CHILDREN'S GROUPS

Increasingly, community demands have led to the introduction of short-term models ([Epstein, 1976](#); [Scheidlinger, 1984](#)) and the introduction of structure and innovative techniques to focus the attention of the emotionally disturbed child to allow self-disclosure. [Frank \(1983\)](#) introduced the concept of dramatic play for greater structure and therapeutic support for ego-weak children. Central to the controversy was the dilemma of whether the children's verbalizations were necessary for an interpretive approach ([Charach, 1983](#); [Sugar, 1974](#)). Not only were many of the children nonverbal, but they lacked the symbolic ability to communicate their thoughts and feelings.

Significant sociocultural changes have altered the concepts of latency and adolescence and have led to a modification in group composition, the roles of the members, and the functions and countertransferences facing the therapist ([Azima, 1977](#)). The bulk of referrals for clinic and day hospitals are for defiant, acting-out children from single-parent families in which the father is absent or plays a minor role. These children often are both witnesses and victims of psychological and physical abuse. Simultaneously, they are encouraged by television, music, and dance to act out more of their sexual and aggressive fantasies. These youngsters in the group are boisterous and outspoken, and use sexualized language and behavior.

[Aronson and Scheidlinger \(1997\)](#) demonstrate the current trend to integrate psychoanalytic and psychodynamic and developmental theories in therapy groups. [Canham and Emanuel \(2000\)](#) and [Privat \(1999\)](#) both use concepts from Bion as a basis for their approach. The former authors describe a 1-year psychoanalytic psychotherapy group for young children (4 to 8 years of age). Privat outlines a strict, "closed," classic monotherapy for seven children, aged 9 to 11 years.

The literature review demonstrates a decrease in the use of the psychoanalytic model and a significant increase in cognitive-behavioral, psychoeducational and multimodal approaches. In contrast, cognitive–behavioral and psychoeducational models have proliferated, with accompanying clinical research. These trends have encouraged the goals of short-term, managed care, and the integration of parents, community, and psychopharmacologic treatments. Psychoanalytically oriented theory remains central for long-term groups, and more traditionally trained clinicians whose goals may be more significant ego changes for their patients.

### COMPOSITION AND STRUCTURE

A major task facing the therapist is the selection and balancing of the composition of the group, orchestrating the number of acting-out children with the quieter, less demanding, more compliant ones, and deciding on the play, activities, or toys used to engage and interest the children. The reality is that there is no such thing as an ideal composition, and a group is formed with the available referred candidates. The stronger the group, the more very disturbed children can be included.

As a rule, the children are seen and evaluated with their parents. Often, observing the children over time helps clarify the diagnosis ([Anthony, 1965](#); [Liebowitz and Kernberg, 1986](#)).

#### Age Groupings, Heterogeneity, Homogeneity, and Frequency

Preschool children, boys and girls 3 to 5 years of age, are seen in small groups of three, four, or five and usually by two therapists in a play or activity group. The more active or pathologic the children, the greater the need for auxiliary personnel.

The latency therapy group usually is separated into early (5 to 7 years of age), middle (8 to 10 years of age), and late (10 to 12 years of age) groups. Frequently these age groups are intertwined, and more attention is placed on the composition of the range of intelligence, physical size, and diagnoses of the children. In treatment groups, latency boys outnumber girls, at a ratio of 4:1 to 8:1, depending on the population being serviced. There is some current indication of a rise in girl referrals, however. The preponderance of boys in the groups necessitates that one of the therapists or special care counselors be male to provide a role model and to diminish acting-out behavior. Some of the children from single-parent families are threatened by the presence of both male and female therapists.

At times, the late latency group is combined with the preadolescent group. The older boys and girls usually do better in homogeneous groups with the same-sex

therapist ([Kennedy, 1989](#)).

Frequency of sessions varies from once or twice a week to every day in a day hospital. A beginning group may tolerate only 15 minutes and gradually work up to 45 minutes or an hour.

### Play, Toys, and Activities

Play and activities are the natural vehicles for child therapy ([Bratton and Ferebee, 1999](#); [Sweeney and Homeyer, 1999](#)) and, in general, the less complicated and fewer the toys, the better fantasy play is encouraged. The fundamentals are a portable table and chairs, paper, pencil, crayons, playhouse, dolls, and play telephones. The toys should not be unduly stimulating but rather should focus on the projective nature of the action and production. Among the techniques useful in getting the children focused and "grouped" are the following: creating large murals or collages and playing the game of "Guess What I Have Made." Art therapy and psychodramatic techniques ([Skaife and Huet, 1999](#)) are useful procedures, both when the children invent the characters and when the therapists provide a fishbowl from which a variety of themes outlined on paper slips may be drawn. This technique is especially helpful when a theme is being avoided, for example, dealing with the group bully, the sexually provocative child, a child who feels responsible for a divorce, or a child in the group who faces residential placement.

Through the play, the therapist and children begin to understand the meaning of the disclosures. Preparing the children to express themselves is antecedent to further working through of their problems.

### Specialized Group Approaches

Humor adds a special, and necessary, dimension to work with children (Dana, 1995). A *clown club* ([Smith et al., 1985](#)) has been introduced to provide a structured fantasy approach. The therapists dress up and play clowns, to the delight of the children. The psychodrama can be expanded to include the playing of good and bad witches, angry teachers or parents, and the like.

A variety of *video techniques* ([Gardano, 1994](#); [Mallery and Novas, 1982](#)) have been used with school-age children. Children can produce and watch their own videos. Replaying and redoing scenes allow the children actually to see their behavior and attempt to correct it by activities that strengthen organizational skills and memory. The video camera is an invaluable tool for diagnosis, research, training, and follow-up ([Smead, 1996](#); [Tellerman, 1998](#)).

*Kinetic group psychotherapy* ([Schachter, 1984](#)) is a technique involving an activity period of exercises or games, followed by a verbal discussion period. The technique has been used with a wide range of children's problems, including childhood autism and depression.

The use of *genograms* ([Davis et al., 1988](#)) is a technique borrowed from family therapy with latency-age children. The children, aided by the therapist, map out the family constellation, which helps them to focus on and question the events of the parents' marriage or separation, new alliances, and catastrophic events. The genograms are shared in the group and encourage each member to divulge hidden fears and learn to distinguish between reality and fantasy.

Other innovative techniques include storytelling ([Gersie, 1997](#)), group sandplay, ([De Domenico, 1999](#)), music therapy ([Plach, 1996](#)), and use of masks, puppet plays, and group emblems ([Prokoviev, 1999](#)). All such projective activities allow the children to reveal their problems in a nonthreatening manner. A sign of a maturing group process is when the children need less prepared structure from the therapists and suggest and create their own object world. Older, more verbal, intelligent, and stable children are capable of using a talking group as opposed to a holding group for the ego-weak children.

For impulse-ridden children ([Crawford-Brobyn and White, 1986](#)), changes in the traditional models may be necessary. Some children can progress from working with another child in a dyad for a time to joining the group. The acting-out child may be able to tolerate only one of four group sessions, until tolerance is slowly built up. [Evans \(1998\)](#) uses an individual therapy session before the group for children (and adolescents) who act out, are defiant, or fearful of their peers. This author terms this approach *active analytic*. [Strieder et al. \(1996\)](#) reviewed a wide variety of differential diagnoses and corresponding group structures operating in outpatient treatment of latency-age children.

## INTERACTIONAL PSYCHODYNAMIC GROUP PSYCHOTHERAPY

The model described in this chapter is applicable to all age groups. The specificities of the approach for children and adolescents include the provision of activity, play, and fantasy according to developmental level, temperament, diagnosis, and goals of the treatment. The interactive context in the here and now, among the peers and the therapists, amplifies the precise nature of the communication difficulties and conveys over time the dysfunctional intrapsychic conflicts within the group paradigm. The degree of permissiveness, structure, and limit setting depends on the activity level and explosiveness of the group and the degree to which regressive acting out is desired or can be tolerated. Greater vigilance is necessary with children who are overly aggressive than with shy children. The thrust of the model is to define the emerging object relations, symbolized by the choice of play objects, and the actual interactions with other group members. The psychodynamics of the group activities are partially translated into meaningful dialogues and understanding by the children. As the therapy progresses, modifications of the explanations and interpretations are appropriately made.

---

### CASE ILLUSTRATION

David was a husky, attractive 7-year-old bully when he first came to the day hospital. He kicked the therapist and refused to have anything to do with the other children. His bravado covered his horrifying nightmares, his daily nausea in the car, and his inability to function in the classroom. When he started in the group, the members were working on a large world mural. One youngster was drawing the clinic, another the roadway, and another the school car. At this point David became very agitated and wanted to scribble over the drawing. The group members became somewhat intimidated, and the therapists attempted to calm him down, but to no avail. He was then told that, unfortunately, he could not manage the group that day and was asked to leave, with the comment "When you feel you are able to return and join the activity, please tell Sally [the Special Care Counselor who escorted the child from the room], knock at the door, and let us know when you are ready." It took several weeks before David was able to return to the group; when he did, he announced, "I'll try it out." The other children greeted him with understanding. The group members were drawing different emotions on faces. David first drew an angry face with teeth; when he noticed that others were drawing happy or sad faces, he remarked that he often had such feelings himself. In a subsequent session two or three of the members played with hand puppets and through the play told David that they did not like to be hit. Two years later David was present when a new child joined the group. By chance he and this child again chose the puppets. When the younger child kept smashing the head of the puppet on the table, David said in a soothing voice, "I know what it is like when you are so mad that your head feels like thunder." David worked through a considerable amount of rage. His somatic symptoms, including car sickness, largely disappeared, as did his repetitive drawing of cars. Such a child needed a gradual progression from dyadic to group therapy. His mother profited from parenting management. She was not a psychologically minded individual, but was motivated to help her child and cooperated well with the program.

---

## APPLICATIONS FOR SPECIAL POPULATIONS (CHILDREN)

### Anxiety Disorders

Increasing attention has been paid to the group treatment and outcome assessment of anxiety in children. [Dadds et al. \(1997\)](#) evaluated the effectiveness of a cognitive-behavioral and family-based group intervention for preventing the onset and development of anxiety problems in children. In this study, 1,756 children, 7 to 14 years of age, were screened for anxiety problems using teacher nominations and children's self-reports. After recruitment and diagnostic interviews, 128 children were assigned to a 10-week, school-based, child-and-parent-focused psychosocial intervention or to a monitoring group. Both groups showed improvements immediately postintervention. However, at 6 months' follow-up, improvement was maintained in the intervention group only, with reduction in the rate of existing anxiety disorders and prevention of the onset of new anxiety disorders. These results indicated that anxiety problems and disorders identified by child and teacher reports can be successfully targeted through an early intervention school-based program.

[Barrett \(1998\)](#) evaluated a cognitive-behavioral, family-based group intervention with 60 children, ranging in age from 7 to 14 years, with a diagnosis of anxiety. The study divided the sample into three treatment groups: group cognitive-behavioral therapy (CBT), group CBT plus family management, and wait list. Posttreatment, 64.8% of children no longer fulfilled diagnostic criteria for an anxiety disorder, compared with 25.2% of children on the wait list, and the treatment groups maintained the gain at 12-month follow-up. Comparisons of self-report measures and clinician ratings of children receiving group CBT with those receiving group CBT plus family management indicated marginal benefits from the addition of family management to the group CBT.

A randomized clinical trial by [Silverman et al. \(1999\)](#) evaluated the efficacy of group CBT with concurrent parent sessions versus a wait-list control. The treatment group of children showed substantial improvement on the main outcome measures posttreatment and at 3-, 6-, and 12-month follow-ups, compared with no gains on the wait list. A group CBT treatment of childhood anxiety focusing on the role of parental involvement was carried out by [Mendlowitz et al. \(1999\)](#) in a study of 62

parents and children. One group was subdivided and randomly assigned to one of three 12-week treatment conditions: parent and child intervention, child-only intervention, and parent-only intervention. A battery of tests was used to assess child anxiety, depression, and coping strategies before and after treatment. The results showed that all treatment groups reported fewer symptoms of anxiety and depression posttreatment, but children in the parent and child intervention used more active coping strategies post treatment compared with the other two treatment conditions. Parents in the parent and child intervention group reported significantly greater improvement in their children's emotional well-being compared with the other treatment conditions. The short-term effectiveness of this group CBT intervention was demonstrated. Comparison of these three studies assessing the effectiveness of parental involvement is difficult, but suggests this issue needs further classification.

### **Social Incompetence and Phobia**

Groups for children emphasizing cognitive-behavioral and educational models demonstrate effectiveness in reducing social anxiety, shyness, and incompetence. [Blonk et al. \(1996\)](#) studied the short-term effect of group CBT for 72 socially incompetent children (8 to 12 years of age) who were experiencing poor peer relationships. The sample was divided into treatment groups (six children per group) and a wait-list control. Treatment outcome was assessed by teacher and parent reports on social behavior, sociometrics, and self-reported anxiety and self-evaluation. Posttreatment groups showed more appropriate social behavior and an increase in peer acceptance and number of friendships. These effects were sustained at 4- and 5-month follow-up assessments.

[Shechtman \(1993\)](#) reported increased self-esteem and close friendship in 52 elementary school children placed in 6 small counseling groups compared with matched control subjects. As might have been predicted, there was an intercorrelation between intimate friendship and self-esteem.

### **Depressive Disorders**

There has been an increase in the use of groups to alleviate mourning in children. [Schoeman and Kreitzman \(1997\)](#) used 12 parallel sessions for caretakers and children, and a joint session to work through the death of a parent. [MacLennan \(1998\)](#) reported on the use of children's groups for both expected and sudden death of family or friends. [Glazer and Clark \(1999\)](#) describe a family-centered intervention for grieving preschool children, and a multifamily and psychoeducation group was described as helpful by [Fristad et al. \(1998\)](#). A group play and activities therapy was described by [LeVieux \(1999\)](#), and an overview of loss and grief groups was provided by [Keitel et al. \(1998\)](#).

An outcome study by [Tonkins and Lambert \(1996\)](#) demonstrated the effectiveness of a short-term, 8-week bereavement psychotherapy group of 16 children, aged 7 to 11 years, divided into a treatment group and a wait-list control group. In the treatment group that shared feelings about the death of a parent or sibling, there was a significant decrease in symptomatology on multiple measures from multiple sources, and participants were able to develop new coping strategies.

[Clark et al. \(1993\)](#) introduced a group for mothers exhibiting postpartum depression and their newborns. Mother and infants participated in 12 weekly group sessions, 2 of which included spouses or partners. The authors' report is based on 5 years of time-limited groups, which showed improvement in the mothers' depression, problem solving, mutual support, and empathy.

[Trad \(1994\)](#) elaborated a sequential model of mother-infant psychotherapy, integrating the mother's individual therapy with the mother's observation of her infant's behavior with the therapist, participation in a mother's group, and family therapy. These last two studies suggest a preventive intervention for high-risk infants.

### **Groups for Abused and Traumatized Children**

Trauma groups have multiplied since the early reports of [Green \(1978\)](#), [Cunningham and Mathews \(1982\)](#), and [Mara and Winston \(1990\)](#).

In 1994, Reichert reported on the use of play and animal-assisted therapy for sexually abused Appalachian children. The focus was on the use of play and fantasy for the children to reverse their role from victims to survivors. [DeLuca et al. \(1995\)](#) evaluated the effectiveness of brief (9 to 12 weeks) structured therapy groups with 35 girls, 7 to 12 years of age, with a history of sexual abuse, showing an increase in self-esteem and a decrease in anxiety and behavior problems. Parents also felt that the treatment was helpful at 9- to 12-month follow-up. [Zamanian and Adams \(1997\)](#), using a time-limited (16-week) psychotherapy group with four sexually abused boys, describe the loss of power, helplessness, and the defenses of identification with the aggressor, splitting, dissociation, and so forth. The therapist's conflictual countertransference is discussed.

[Strieder et al. \(1996\)](#) outline a comprehensive ego-enhancing program of 10 session psychotherapy groups for cumulatively and repetitively traumatized children. As part of an elementary school-based violence prevention/intervention program [Murphy et al. \(1997\)](#) introduced trauma/grief-focused psychotherapy groups for children exposed to intrafamilial and extrafamilial violence. The multimodal, interdisciplinary team's goals were both psychological repair and social adjustment.

A comparison between a psychodrama group with young girls and a control group showed significant decreases in self-reported difficulties, withdrawn behavior, and anxiety/depression ([Carbonell and Partelano-Barehmi, 1999](#)).

[Peled and Edelson \(1992\)](#) reported on a 10-session group format for children of battered women. Children who are witnesses to violence and abuse of their mothers sustain significant trauma. The ability to speak about these events with their peers and therapists provides significant support in short-term, manually guided psychoeducational groups. Activity groups ([Nisivoccia and Lynn, 1999](#)) and play therapy ([Gallo-Lopez, 2000](#)), as well as a multimodal programs, have been used with children who have witnessed abuse. [Crockford et al. \(1993\)](#) introduced an integrated program, "Play Friendly and Safe," in which there were separate and combined groups for children and abused parents, as well as the inclusion of a nonoffending parent support group. A psychoeducational group for grandmothers raising inner city, abused, helpless, and depressed children focused on practical issues of school, home maintenance, and daily problem solving ([Vardi and Bucholz, 1994](#)).

Child victims of extrafamilial sexual abuse have been treated in separate, combined, group, and family approaches ([Grosz et al., 1999](#)). Group play therapy combined with psychoeducational techniques, drawing, and story telling have been used for family traumatized latency-age children ([Leavitt et al., 1997](#); [de Ridder, 1999](#)).

Children who were abused by a school employee were treated individually, in play groups, and with the family ([Pelcovitz, 1999](#)). Children and adolescents who have abused others have been treated in trauma-alleviating groups ([Erooga and Masson, 1999](#)).

Working with these abused children in all settings is difficult because they are fearful of divulging secrets about their abusive parents ([Schacht et al., 1990](#)). In residential settings, they are treated in homogeneous groups, whereas in outpatient clinics and day centers they more frequently are seen in heterogeneous groups. Negative countertransference feelings toward the parents must be faced. Often these abused children become the perpetrators, and tend to victimize weaker children. In play groups, several cotherapists often are necessary to control and moderate the acting out.

### **Learning Disorders and Underachievement: Clinic- and School-Based Groups**

[Gaines \(1986\)](#) outlines a variety of strategies helpful in the treatment of the retarded children and those with attention deficit disorders, including computer games, videotaping, and expressive arts. The use of structured, time-limited activities is critical with this group ([Azima, 1986](#)). Various group models for these underachievers have been used in various settings. [Mishna \(1996\)](#) used a psychodynamic interpersonal model stressing mutual recognition and trust in an outpatient setting. [Slavin \(1997\)](#), using a psychoanalysis-based approach in schools, addressed both academic and behavior problems.

[Gupta et al. \(1995\)](#) used a method of classification and diagnosis of school-age children seen in clinic groups. Working with ego-impaired groups in a residential program, [Winek and Faulkner \(1994\)](#) used a psychoanalytic, insight-oriented group, conceptualized as a collective superego, to encourage maturation. In school settings, groups using art therapy ([Prokoviev, 1999](#)) and psychotherapy ([Merydith, 1999](#)) have been used with underachieving students.

In an assessment of brief group therapy with low-achieving elementary school children, [Shechtman \(1996\)](#) examined 142 low achievers, in grades 2 to 6, who were randomly divided into an experimental and a control group. In addition to receiving assistance with school work 4 to 6 hours per week, the experimental children participated in a weekly psychotherapy group. The results indicated significant gains for the psychotherapy group in both academic progress and social well-being, which increased over time.

[Montello and Coons \(1998\)](#) compared the behavioral effects of an active, rhythm-based group music therapy with a passive, listening-based group music therapy with 11- to 14-year-olds in special classes for emotional, learning, and behavioral disorders. The Achenbach's Teacher Report Form showed that both music therapy interventions (not only the hypothesized active music groups) produced a lowering of scores on the aggression/hostility scale. It was suggested that music was a helpful modality for increasing creativity and self-mastery.

### Medical and Neurologic Conditions

Increasingly, medical and neurologic conditions are being treated in groups for children, adolescents, and parents. Some of the following subgroups overlap with former ones in the review (e.g., learning disorders, school, trauma). *Hyperactive* children were treated in a semistructured activity group to enhance self-esteem and social competence, diminish sense of shame, and work through unmet exhibitionistic needs ([Gnoulati, 1999](#)).

Group therapy with *siblings of autistic children* increased knowledge of the disorder and allowed the expression of thoughts and feelings related to despair, guilt, and alienation from society ([Carmi, 1997](#)). Children with *Aspergers' syndrome* have been treated in a social skills group for boys ([Marriage et al., 1995](#)), and in a 2-year interpersonal group stressing peer interaction ([Mishna and Muskat, 1998](#)).

A parents' psychoeducational and experiential group for *developmentally disabled adolescents* was integrated into a total treatment program ([Lynn, 1994](#)).

A structured group intervention for siblings of children with *cancer* was conducted for a younger (7 to 11 years of age) and an older (12 to 17 years of age) group. The 6-week program revealed statistical and clinical improvement on posttreatment measures in interpersonal and intrapsychic problems, improved mood and communication, and greater cancer-related knowledge ([Dolgin et al., 1997](#)).

A 3-year play group for three *hearing-impaired* latency-age boys showed improvement in school, home, and community posttreatment and 2 years after termination ([Troester, 1996](#)). A social skills group for boys with *Gilles de la Tourette's syndrome* showed small improvements in self-esteem and ability to voice social and academic problems with each other and families. Subsequently, a monthly support group was formed for parents and children ([Lambert and Christie, 1998](#)).

Habit reversal training for *trichotillomania* in a group format showed decreases in measures of global severity of obsessions and hair-pulling behavior at 1- and 5-month follow-ups ([Mouton and Stanley, 1996](#)).

*Epileptic* adolescents were treated in psychoanalytically oriented group therapy for 2 years. The goals were a better understanding of the illness and provision of information on questions such as the effects on sexuality, pregnancy, and work. The goals included psychological support, comprehension, acceptance, and coping with the disorder ([Rossi et al., 1997](#)). A cognitive-behavioral group for adolescents and adults with *spinal cord injuries* led to improved feelings of self-control compared with a control group at a 2-year follow up ([Craig et al., 1998](#)).

The results of these studies of various group models suggest important group applications to these long-standing, chronic medical and neurologic illnesses.

### Family Issues

Groups for *children of divorce* are used in various formats, including psychoeducational, cognitive-behavioral, drawing, and story-telling activities. [Epstein and Bordium's game \(1985\)](#), "Could This Happen," helps focus disclosures of anxiety about angry, "bad" parents.

[Roseby and Johnston \(1997\)](#) introduced a group treatment manual for school-age children dealing with violent separating families. The manual includes drawings, cartoons, and specified themes and activities.

A group intervention for *children and separated families* revealed differences posttreatment and 6 weeks later. [Durkin and Mesie \(1999\)](#) suggest that children should not be regulated as to with whom they communicate, or how, but rather that caution be used to allow children to make their own choices regarding visitation rights and the like.

*Parent, family, and multifamily groups* have used psychoeducational, psychotherapeutic, parallel combined, or integrated programs ([Epstein, 1976](#); [Hoffman et al., 1981](#); [Paramenter, 1976](#)).

A comparison of multifamily group therapy (42 families) with traditional family therapy (39 families) in the treatment of abusive and neglectful caregivers showed that the children in the multifamily therapy group become more assertive, had fewer behavior problems, and showed greater self-confidence ([Meezan and O'Keefe, 1998](#)).

## ADOLESCENT GROUP PSYCHOTHERAPY

### Young Adolescent Group

The techniques used with the pubertal group (12 to 14 years of age) approximate those used with latency-age children, namely, a combination of activities, play, drawing, psychodrama, and discussion periods. Most therapists tend to treat pubertal children in homogeneous groups with a same-sex therapist. These adolescents often are gauche and active and have difficulty in verbalization, especially the more pathologic, who are hospitalized or live in residential care. This age group works best on structured themes related to dependency, attachment, separation, and competition, among others. Sessions in general are a maximum of 45 to 50 minutes in length. Both short-term and long-term models are used. In the latter category, [Gordon \(1989\)](#) has reported a 2-year group with aggressive boys that used the model of working through symbiotic attachment and gradually working toward individuation. Interpretations were made to the group as a whole, dealing with ongoing interpersonal themes, rather than on the intrapsychic material of any one member. Videotaping, music, projective art techniques, and board games ([Kraft, 1986](#)) often are stimulating for children of this age, who often are too timid to talk openly about their sexual abuse, drug use, inferiority fears, and marked ambivalence to parents.

### Middle and Late Adolescent Groups

The age group of 15 to 19 years is most amenable to verbal psychotherapy. Outpatient models usually group the 15- to 18-year-olds. Increasingly, the adolescents referred for group psychotherapy are characterized by depressive reactions, suicidal attempts, and borderline symptomatology, in addition to the usual range of behavior disorders linked to delinquency, rebellion against parents, school dropout, and drug and alcohol use. The more severely disturbed adolescents are hospitalized and placed in residential and treatment centers. School groups focus on learning disorders, low motivation, disruptive behavior, and the like. Outpatient clinic groups treat the largest number of adolescents, whereas private practice groups tend to cluster in the more affluent areas.

The average psychotherapy group size ranges from six to eight and includes both sexes (with the exception of the pubertal group); where possible, heterogeneous composition is preferable. Acutely psychotic, autistic, or very handicapped borderline youngsters are suitable for outpatient groups but may be placed in modified group forms in hospital and residential settings ([Speers and Lansing, 1965](#); [Stengel, 1987](#)). The inclusion of borderline and very fragile adolescents depends on the strength of the total membership, which acts as a type of absorption filter and control mechanism. Group sessions vary from 1 to 1½ hours, at the rate of once or twice a week, and may be either short or long term.

## THEORETICAL CONSTRUCTS

Theories and techniques include psychoanalytic, psychodynamic, psychodramatic, gestalt, transactional analysis, behavioral, cognitive, and system approaches. The choice of methods appears to be made by a combination of the therapist's theoretical orientation and the specificities of the adolescents being treated.

In the psychoanalytically oriented framework, the approaches of Freud, Bion, and Kohut have been adapted to the group protocol. By and large, the developmental, interactive, and cohesive processes dictate whether individual or group address is used.

## Identity Group Psychotherapy

[Rachman \(1989\)](#) proposes a theoretical model based on the resolution of the adolescent's identity crisis in the group context and uses a blend of creative introspection, free thought, verbal and fantasy experimentation, and active techniques. The latter include role play, psychodrama, and dream interpretation, as well as specially devised scenarios to permit adequate self-disclosure and working through of problems.

## Interactional Psychodynamic Adolescent Group Psychotherapy

It is proposed that confrontation, empathy, and interpretation are the therapeutic triad underlying this approach, and that all three stem from a common source ([Azima, 1989](#)). Confrontation accentuates the verbal enunciation of thoughts and feelings, whereas empathy involves the experiential process incorporating the other person's feelings and thoughts. It is postulated that the peers in the group are representative of varying confrontational and empathic styles. Some personalities are in need of a more confrontational approach, whereas others need longer nurturance and silent understanding. Interpretation occurs at the point in the therapeutic process when there has been sufficient empathic confrontation and clarification to uncover and give meaning to the underlying unconscious conflicts, and it should occur in synchrony with the individual and the group process.

---

### CASE ILLUSTRATION

John was a 15½-year-old with marked narcissistic and grandiose features. For many sessions, he boasted that he could live on his own, that he did not want to be in school, and that he had many friends. The other five group members could hardly get a word in, as he pontificated and analyzed everyone. Gradually, certain members began to confront and question him and to express their annoyance. He soon revealed that his mother had divorced his alcoholic, abusive father and later married an older, quiet man. This man could not tolerate the patient, and he was moved into a small apartment with one of his brothers, who soon left, and he continued there alone. As these facts and feelings came out, he was amazed to regain the empathy of many group members. The therapist in the early stages had assumed an empathic, understanding approach with John and only gradually began to confront the narcissistic defenses. Although the patient was willing to interpret everybody else's problems, he could not accept other people intruding into his inner life. Many sessions later, a pretty adolescent to whom John was clearly attracted told him in a direct, confronting manner that he would have a hard time making friends, especially with girls, because he was not truly interested in them, and that he was sure to make others very angry by his know-it-all manner. John was stunned, averted his gaze, bent over, and remained silent. He slowly lifted his head, and holding back his tears, he said, "I think you are right, and that's what I am afraid of."

### Comment

It may be necessary to confront the silence of adolescent members very early, in an understanding way. The psychodynamic significance of intrapsychic and interpersonal communications and interactions remains the cornerstone of the interactional psychodynamic group psychotherapy approach. As in all psychotherapies, the goal is for the adolescent to develop self-understanding, independence, self-esteem, and interpersonal competence.

---

The preceding clinical example was taken from an outpatient, open-ended, heterogeneous group with an average patient attendance of 2 years. In this model, the goal is the development of autonomy and independence. Parents are seen only at intake and at the end of each year's group, with the adolescents' consent. Confidentiality is highly protected in this model, and this in turn promotes faster divulgence of material. This approach is facilitated in a country (such as Canada) that provides funds so that parents do not have to pay the bills. In addition, in the Canadian system of health care, any adolescent older than 14 years of age can request treatment without the parents' knowledge. Outpatient clinics and private practice group psychotherapy often involve a combination of psychopharmacology, combined individual and group therapy, and parallel or conjoint parent or family therapy. In long-term treatment necessitated by regressions or traumatic events, a combined network approach has been used effectively ([Richmond, 1989](#)).

## Inpatient and Residential Treatment Groups

Inpatient and residential treatment groups form an integral part of most adolescent units and residential treatment centers ([Chase, 1991](#); Kleiger and Helmig, 2000; [Stein and Kymissis, 1989](#)). The group format varies indefinitely according to the degree of pathology, intellectual level, and longevity of the group, and number of absences of group members. Inpatient psychotherapy groups ([Kymissis, 1996](#)) are advantageous in that they can focus on ongoing resistances and acting out in the group and the hospital network. Conformity and compliance as to weekend passes, attendance at meetings, and taking of medication are strengthened in the group context. The handling of confidentiality in inpatient groups is a delicate issue, and it seems wise to explain at the outset the team's sharing of information. In ward situations where adolescents are assigned to certain staff members, there often is conflict between the patients and different staff teams.

## APPLICATIONS FOR SPECIAL POPULATIONS (ADOLESCENTS)

### Depression

Parentally bereaved adolescents were treated in a large discussion group format using other parentally bereaved adolescents as therapeutic assistants to help reduce the resistance to talking and giving feedback ([Levy and Zelman, 1996](#)). A 7-week antidepressant, antisuicide group was conducted with seven teenage women using a collaborative feminist and narrative approach to externalize, empower, support and define the depression ([Johnson, 1994](#)). [Clarke et al. \(1995\)](#) assessed a prevention program targeted for 150 adolescents at risk for future depressive disorder. A randomized 15-session trial of group cognitive intervention was compared with a usual case-control group. Survival analysis indicated a 12-month advantage for the prevention program and a decrease in depressive indices. In a further study, [Clarke et al. \(1999\)](#) compared maintenance cognitive behavioral with acute CBT groups with booster sessions. One hundred twenty-three adolescents with major depression or dysthymia were assigned to one of three 8-week acute conditions: adolescent group CBT (16 2-hour sessions), separate parent group, or a wait-list control. Subsequently, the members completing the CBT groups were randomly reassigned to one of three conditions for the 24-month follow-up period, namely, assessments every 4 months with booster sessions, assessments only every 4 months, or assessments every 12 months. Results indicated that acute CBT groups yielded higher depression recovery rates (66.7%) than the wait list (48.1%) and greater reductions in self-reported depression. Outcomes for the adolescent-only and adolescent plus parent conditions were not significantly different. Rates of recurrence in the 2-year follow-up were lower than in treated adult depression. The booster sessions did not reduce the rate of recurrence in the follow-up period but appeared to accelerate recovery among the subjects who were still depressed at the end of the acute phase. The authors concluded that CBT was an effective intervention for adolescent depression. It is of some interest that the parallel parent group did not add significantly to the reduction in depression. This confirms this author's belief that for adolescents, separate treatment that protects confidentiality and allows separation from parents may be the treatment of choice, whereas young children profit more from parallel, integrated modalities.

[Fine et al. \(1991\)](#) reported on the comparison of two forms of short-term group therapy for 66 outpatient adolescents clinically diagnosed as depressed. Subjects were randomly assigned to either a therapeutic support group or a social skills group. Posttreatment, adolescents in the therapeutic support group showed a greater decrease in depressive symptoms and significant increases in self-concept. At the 9-month follow-up, adolescents in the therapeutic support groups maintained their improvements, but adolescents in the social skills group had now caught up in their improvement between the posttreatment group and follow-up assessments. The authors postulated that the original gains made in the therapeutic support group were necessary to alleviate the depression before members were able to profit from the problem-solving strategies taught in the social skills groups. The manic defenses in the mourning process were described for an adolescent group, using a Kleinian analytic framework. The group as a whole focused on the process and the dynamics of the relationship between the adolescents, staff, and family ([Toder-Golden, 1999](#)).

### Self-Mutilation and Self-Destructive Behavior

Self-mutilation and self-destructive behavior have received scant attention in the group literature for children and adolescence. [Sansone et al. \(1996\)](#) have described an integrated psychotherapeutic approach in the management of self-destructive behavior in eating-disordered patients with borderline personality disorder. A group psychotherapy approach was found useful for a reasonable resolution over time of self-destructive behavior.

[Hartman \(1996\)](#) discusses deliberate self-cutting by adolescents in psychiatric inpatient units. The author suggests that the interpersonal aspects of the cutting are neglected, with undue attention given to the individual patient, who may be acting out the group's conflicts and discontents as well as protesting against inadequate staff supervision.

### Social Phobia

Cognitive-behavioral group therapy for social phobia in female adolescents was described by [Albano et al. in 1995](#). The results of a pilot study ([Hayward et al., 2000](#)) compared the outcome results for 35 girls with social phobia at high risk for major depression, 12 of whom were assigned to a treatment group and 23 to a

nontreatment group. Of the 11 subjects who completed treatment, there was a significant improvement and reduction in the symptoms of social anxiety and depression. However, at the 1-year follow-up there were no significant differences by treatment condition, but there was suggestive evidence that the treatment of social phobia lowers the risk for relapse of major depression among the subjects with a history of major depression. Combining the decline scores for social phobia and depression produced more robust treatment effects for the 1-year follow-up. The results indicate that there was a moderate short-term effect of group CBT for female adolescents, and that a decrease in social phobia also may reduce the criteria for major depression. This latter finding suggests the usefulness of group-based prevention programs for shy, socially incompetent children. The question of adjuvant pharmacotherapy for social phobia was raised because there have been positive findings with its use in adult social phobia ([Heimberg et al., 1998](#)).

### Anger, Violence, and Conduct Disorder

Groups for the control of anger, violence, and conduct and criminal disorder have increased in response to the rise in rebellious, destructive behavior in society. The following studies are included because of their innovative clinical and research approaches.

A structured group for undersocialized, acting-out adolescents that used a pretherapy training program and an initial therapy contract showed positive clinical outcomes ([Corder, 1996](#)).

Cognitive-behavioral anger management groups showed improved arousal control, cognitive restructuring, and prosocial skills ([Feindler and Scalley, 1998](#)). A CBT group of 11 adolescents showed statistically significant changes in aggressive behavior, attentional problems, self-esteem, anxiety, depression, and somatic complaints, as shown on posttreatment scores on the Youth Self-Report, the Achenbach Child Behavior Checklist, and the Piers-Harris Children's Self-Concept Scales ([Kastner, 1998](#)). A brief anger management therapy group of 10 to 12 sessions showed improved functioning in 25 adolescents in hospitalized groups, compared with 25 in control groups ([Snyder et al., 1999](#)).

A teen abuse group using a CBT model targeted socioeconomically depressed black and white adolescents. The 10-week program was part of a Master's-level social worker's training module. The approach appeared clinically promising. [Carlin \(1996\)](#) describes a large group treatment of 25 severely disturbed, conduct-disordered adolescents. Needs for effective leadership, acceptance of the members' cultural differences, and insurance of maximum safety influenced more positive interpersonal relations. [Byrnes et al. \(1999\)](#) compared reductions in criminality in three different formats—group, individual, and family therapy—in a sample of 532 adolescents in a residential and day-treatment program over a 4-year period. The major finding were (a) the number of hours in group therapy explained the greatest variance in the reduction of criminal charges, followed closely by hours in individual therapy, whereas hours in family therapy was not a significant predictor; and (b) residential treatment was associated with greater reductions in adult correctional commitments than was day treatment.

The findings that group therapies are effective treatment for delinquent adolescents confirm the early findings of [Bratter \(1989\)](#), [Friedman and Glickman \(1986\)](#), and [Raubolt \(1983\)](#).

### Trauma and Abuse

Trauma groups for a variety of disorders have been described for children and adolescents who have become the victims of natural disasters, sexual abuse, violence, and atrocities of war. Classifications of posttraumatic disorders in the third (revised) and fourth editions of the *Diagnostic and Statistical Manual of Mental Disorders* emphasize significant cognitive, behavioral, and physiologic somatic effects after the trauma. A variety of group interventions, including supportive, CBT strategies have been used to reduce posttraumatic stress disorder symptoms to expose the trauma and to work toward improved coping skills ([Foy et al., 2000](#); [Kopala and Keitel, 1998](#)). [Glodich and Allen \(1998\)](#) reviewed the group therapy literature on preventing trauma reenactment in adolescents. Group CBT and psychoeducational strategies are considered important ways of interrupting the pernicious cycle of reenactment and further risk-taking behavior. [Everly et al. \(1999\)](#) compiled a meta-analysis of the effectiveness of psychological debriefing with vicarious trauma. An outline study of 41 sexually abused adolescent girls (13 to 18 years of age) were divided into small, structured groups. Each of the seven treatment sessions consisted of a didactic presentation, an art activity, and the development of a positive associational cue. Posttest assessment revealed improved adaptive functioning and skill mastery.

Female adolescent survivors of sexual abuse responded to a goal-oriented therapy group ([Backos and Pagon, 1999](#); [Furniss et al., 1988](#)). Adolescent girls facing the loss of their parents through acquired immunodeficiency syndrome were treated in a 2-year psychoanalytic group. [Cohen \(1996\)](#) analyzed the transference-countertransference in this angry, depressed group of girls. It is likely that through the countertransference, the therapist was able to empathize with the adolescents' plight and work through a treatment plan. [Henry \(1996\)](#) explored human immunodeficiency virus-related risk taking in a psychodynamic group for adolescents.

### Alcohol and Substance Abuse

The number of groups for adolescents addicted to alcohol and drugs has increased to meet treatment and prevention needs. A variety of models exist, including multimodal programs ([Bratter, 1989](#); [Friedman and Glickman, 1986](#)) in residential and outpatient clinics ([Bogdaniak and Piercy 1987](#); [Gonet, 1998](#); [Nastasi, 1998](#)). The use of multifamily play groups for families in addiction recovery was effective in promoting parent-child communication, the development of a nonblaming attitude, and an understanding of children's reactions to their addiction ([Cwiakala and Mordock, 1997](#)). A therapeutic community drug treatment program that studied 938 adolescents (15 to 17 years of age) who were admitted to residential treatment for substance abuse revealed that one-third of the sample showed histories of sexual abuse. A Cox regression analysis showed that a history of sexual abuse is related to earlier onset of alcohol and illicit drug use. It was suggested that drug use may function to ameliorate feelings of depression and poor self-esteem that accompany childhood abuse ([Hawke et al., 2000](#)).

[Kaminer and colleagues \(1998\)](#), using manual-guided interventions, measured the treatment process in CBT and interactional group therapies for adolescent substance abusers. In a 15-month follow-up of a pilot study, [Kaminer and Burlison \(1999\)](#) reported on the comparison of 32 dually diagnosed adolescents, randomized into 2 short-term outpatient group psychotherapy groups, one using CBT and the other an interactional treatment (IT). At the 3-month follow-up, no patient treatment matching effects were shown. However, adolescents in the CBT group showed a significant reduction in severity of substance abuse compared with those assigned to the IT group. At the 15 month follow-up, there were no differential improvements as a function of therapy type. However, subjects maintained significant treatment gains in the substance abuse, family function, and psychiatric status domains of the Teen-Addiction Severity Index, and both CBT and IT were associated with similar long-term gains. This study is the only one to date that demonstrates no superiority for short-term group CBT compared with short-term group IT.

[Pressman and Brook \(1999\)](#) have described a multiple group psychotherapy approach with adolescents with psychiatric and substance abuse comorbidity, treated in an inpatient psychiatric setting. The involvement of a multidisciplinary team using an integrative approach showed promising results.

A five-phase group model for outpatient adolescents who abuse substances was described by Spitz and Spitz (1955). It includes the following phases (a) evaluation and orientation, (b) entry into the group, (c) establishing a working climate, (d) a middle or working stage, and (e) transition out of the group. The authors conclude that group therapy is the treatment of choice.

### Eating Disorders

[Azima \(1992\)](#) described an intensive group psychotherapeutic interactional model for outpatients seen in a heterogeneous group. Parental involvement was indicated for the younger but not the older teen group. A variety of techniques and activities, including drama therapy and guided imagery, are used in short- and long-term eating disorder groups ([Moreno, 1998](#); [Wurr and Pope-Carter, 1998](#)).

[Mitchell and collaborators \(1990\)](#) compared the efficacy of antidepressant drug therapy with structural, manual-guided group therapy for a total of 12 weeks. The overall finding was that the addition of the antidepressant to the group psychotherapy did not significantly improve the eating disorder, but did ameliorate the features of depression and anxiety. At 6-month follow-up ([Pyle et al., 1990](#)), 30% of the sample had relapsed; however, group psychotherapy alone or combined with drug therapy showed lower relapse rates than treatment with medication alone. It also was found that neither attendance at the maintenance group sessions nor imipramine maintenance was associated with a better outcome.

[Leung et al. \(1999\)](#) evaluated 10-week group CBT with 20 women diagnosed with anorexia nervosa, aged 17 to 58 years. At posttreatment, group CBT was found to be ineffective in symptom reduction, and basic core beliefs were irrelevant to outcome. The authors concluded that group CBT in the current short form is insufficient

to induce changes, and suggested further group treatments to address the issues of poor motivation, lack of insight, and ambivalence toward treatment.

A clinical study of an expressive group therapy eating disorders program reported positive behavioral change in this adolescent group, but there was no research to support these impressions ([Shander and Orbanic, 1995](#)).

It can only be concluded that eating disorders, especially anorexia nervosa, are resistant to change with short-term formats. Further research is needed to assess multimodal programs, including motivational preparation before group treatment. The links of eating disorders to sexual abuse and borderline and self-destructive behavior need to be noted ([Sansone et al., 1996](#)).

### Other Disorders and Issues

The subject of *learning-disabled adolescents* overlaps with the previous children's section in this review. Residential, outpatient, and school programs offer specialized groups often integrated with other academic modules. Investigators agree that both the learning disability and social/emotional problems must be attended to in the group format. ([Coché and Fisher, 1989](#); [Mishna and Muskat, 1998](#)). Computers and videos are helpful adjuncts to the group treatment ([Cox and Lothstein, 1989](#); [Gardano, 1994](#)).

[Bernstein et al. \(2000\)](#) investigated the use of imipramine plus CBT in the treatment of 63 *school-refusing* adolescents with comorbid anxiety and major depressive disorders. The findings were that imipramine plus CBT is significantly more efficacious than placebo plus CBT in improving school attendance and decreasing symptoms of depression in school-refusing adolescents.

*Parent and family group therapy* are combined more frequently in the treatment of younger children; parallel and combined groups appear indicated with acutely ill, traumatized adolescents, and where a return to living in the family is indicated.

The use of *multifamily group therapy* has been recommended in the treatment of dually diagnosed adolescents ([Kymissis et al., 1995](#)), and with abusive and neglectful caregivers ([Meezan and O'Keefe, 1998](#)).

A *father-adolescent son group* was described by [Ginsberg \(1996\)](#). The goal of these groups was the developments of insight, closer communication, and understanding. A combined experimental/psychoeducational format was used as part of a group therapy program called the *Parent-Adolescent Relationship Development Program*.

A multimodal group program for *pregnant and parenting* adolescents involved collaboration with parents, school, and community ([Stoiber et al., 1998](#)).

### Culture

The influence of *culture and society* on therapy groups has been the subject of increasing investigation ([Serrano and Hou, 1995](#)). Culture-focused group therapy has been reported as enhancing bonding with both the shy and introverted adolescent, as well as dealing with identity issues in gang-motivated youth ([Vargas and DiPilato, 1999](#)).

Psychotherapy groups were carried out with youth experiencing war (Schneider and Cohen, 1996) and refugee trauma ([Brumen-Budanko, 1998](#); [Foigel, 1997](#)). [Azima \(2002\)](#) has reported on the use of groups with immigrant and refugee children and their families, and has outlined a training model for mental health professionals.

## THE GROUP PSYCHOTHERAPIST: FUNCTIONS, REALITY ISSUES, AND COUNTERTRANSFERENCE

Aside from the obvious managerial duties of selecting, composing, and deciding on time and place, the major focus of the group therapist is to forge a *therapeutic alliance* appropriate to the age level of the patient. It must be made clear to the group that the common goal is the understanding and solving of painful thoughts and behavior. Increasingly, patients are being prepared, before and in the initial group sessions, to understand the functioning of the mind and the ability to analyze the self, and to be responsible for uncovering and talking about conflicts hidden in their inner worlds. A parallel task for the therapist is to orient the group members to be aware of their behavior with each other, to share thoughts and feelings, and to offer suggestions about how to deal with these problems.

Functioning in the group context puts greater stress on the therapist, especially with children who act out physically and regress rapidly ([Azima, 1986](#)). With adolescents, there is the accompanying disrespect and rebellion against authority figures ([Azima, 1973](#)). The reports of homogeneous groups for young patients with bulimia, anorexia, diabetes, migraine, thalassemia, and cancer indicate improvement in motivation and compliance with prescribed diets, exercise, and the use of medication.

A leader must solve the quandary of how to be a competent therapist and a respected authority figure, and not an admonishing disciplinarian. The reality is that therapists working with adolescents may experience sudden eruptions of anger at and fear of some members, as well as show undue sympathy and overprotectiveness to others. Consider the following examples: A sudden brawl breaks out; a member swears at and insults the therapist; an adolescent produces a gun or a knife; one of the group members breaks into the therapist's car. Should the therapist's disturbed reactions to any of these episodes be classified as countertransference, or realistic? It is clear that more punitive rage can be activated in the group therapist working with children and adolescents than with adults. Furthermore, the scoffing, belittling attitudes of adolescents often cause narcissistic injury to the doctor's status.

There is general agreement that today's child and adolescent group therapists have become more actively involved, less permissive, more spontaneous in their play, more confronting, and in general less distant in their relationship with group members. With adolescents, the therapist tries to assume an emotional/cognitive role model midway between the adolescent and the parent. Therapists with overclose identification with adolescents are put at risk of collusion, passivity, or acting out, whereas therapists with too distant an identification are rendered vulnerable to possible rebellion against parental figures. A good practice with adolescents is to assume an attitude of controlled curiosity and sophisticated ignorance, especially in the early stages of the group. An overintellectual approach on the part of the therapist is likely to produce silence, fear, withdrawal, and withholding in the group members.

Adding to the therapist's countertransference is the pressure from parents for the therapist to see the child from the parents' point of view. The therapist must be realistically empathic and not overjudgmental. In the clinic or day-hospital setting, the therapist often is caught in a tug of war between team members who side with or against the parent, teacher, or judge.

In many cases, the therapist's reaction should not be classified as countertransference unless there is evidence of ongoing behavior patterns that block or are destructive to the group process. Therapists who do not do well with this age group usually are unable to deal with the acting out, overplayfulness, and disregard for the status of authority figures. But it is precisely these defensive resistances that provide the first insight into the group members' problems. Therapists who have been raised in a strict, obedient fashion, with strong moral and ethical standards, may be more vulnerable to the adolescent age group. Fearing loss of control of their own anger, they become overly silent and permissive in their leadership.

Group psychotherapists who do not overcentralize their position are more likely to be perceptive of the interactive psychodynamics and to reflect on the variety of positive and negative feelings and thoughts that corroborate or differ from their own. The interactive interpersonal variations become a therapeutic tool for the therapist and in many instances dilute or eliminate countertransference responses by clarifying and comparing the responses of other group members.

Some helpful qualities of the group therapist working with children and adolescents include comfort in a group, spontaneity, flexibility, playful creativity, and the ability to set adequate limits as a rational, empathic role model. Continuing clinical research in the area of child and adolescent group psychotherapy will, it is hoped, clarify and identify which therapeutic models are most effective with specified age groups, intelligence levels, and diagnoses.

## CONTRAINDICATIONS

The question of contraindications to group psychotherapy for children depends not so much on the diagnoses, symptoms, or deviant behavior, but on the total

composition of the group, the competence of the staff, the availability of support staff, and whether the treatment is carried out in residential or outpatient settings.

Special problems and hazards are presented by children who are explosive, cruel and vindictive, sexually acting out, overly autistic, seclusive, and depressed. Children with physical stigmata often are scapegoated. When children are enuretic or encopretic, entry into the group usually is postponed until adequate controls are developed. Children of very low intelligence do poorly in verbal psychotherapeutic groups but profit from socialization, compliance, and support groups. Homogeneous groups in residential treatments report better outcomes with retarded and delinquent populations.

Some children entering day-hospital programs initially may not be ready for or capable of entering a psychotherapy group until they have adequate controls and are capable of listening to others and expressing themselves. Younger children usually must be involved in multimodal therapeutic school programs with a gradual transition to triadic therapies with another child or parent before group psychotherapy is possible. Short preparatory groups are necessary for children with poor frustration tolerance.

For adolescents, the basic contraindications outlined previously apply as well. For outpatient treatment of adolescents 15 to 18 years of age, contraindications include acute psychosis, heavy medication, drug addiction, and delinquent acting out. Again, it appears that motivation, psychological mindedness, and attraction to the norms of the adolescent peer group are the more critical variables. In addition, an alliance must be articulated that sets the therapeutic goals for the group.

The selection of the specific therapeutic modality for children and adolescents should be made in a more sequential fashion, considering the developmental stage, the type of problem, and the degree of intrapsychic or interpersonal deficit. It may be that one child may need individual play therapy first, whereas another requires integration into a group. In addition, the combination of individual, family, or group becomes realistic only if time and expense are not factors. It is likely that some patients are held in one fixed therapeutic modality too long before another is tried.

This review shows that clinicians have been increasingly challenged to do groups with children who previously have been considered contraindicated (e.g., children with autism or Asperger's syndrome, the developmentally and intellectually handicapped, and the traumatized and abused child). Expressive therapies and structural play activities have been introduced for the nonverbal or less verbal child.

## CLINICAL AND RESEARCH TRENDS

Group as a therapeutic modality has been increasingly confirmed by both clinical and research investigation, in a wide variety of areas. Clinics as well as inpatient, residential, private practice, and community programs have expanded rapidly. Applications to psychiatric, medical, neurologic, community, and social issues have grown at an unprecedented pace.

The trend is toward short-term, cognitive-behavioral, interactive models often using manualized guides. These approaches are much more conducive to applying statistical research designs. The goal is to find ways of carrying out research with long-term psychodynamic groups and specifying criteria for change. There is acknowledgment that some short-term models are not effective with very resistant disorders (e.g. eating disorders, severe depression, and substance abuse). In such cases, multimodal models integrating group therapies with pharmacotherapy may be indicated. Partnership in contributing to government policy is needed for broader-based intervention and prevention for the major psychiatric disorders, the socioeconomically deprived, and for alcohol, drug, and cigarette consumption. The involvement of the media has contributed positively in addressing mental health issues. The expansion of information on the Internet and the growth of chat groups has moved us into the area of prevention and group therapy on-line.

A predictive trend is for the use of parent-infant/child groups for healthy development. Schools are becoming increasingly involved in doing groups with the underachievers, the aggressive bullies, and the creative thinkers, as well as research studies.

Increasingly, research has expanded and answered the past paucity ([Azima and Dies, 1989](#); [Azima, 1996](#); [Dies and Riester, 1986](#)). Meta-analysis confirms the efficacy and efficiency of group psychotherapy for children and adolescents ([Hoag and Burlingame, 1997](#)).

Clarification is needed as to the inclusion or exclusion of parents and family in treatment. For adolescents at the stage of separation, family therapy may be contraindicated. Studies that have found little therapeutic input with family therapy require replication. For day therapy centers, parent involvement appears a necessity. At follow-up, parents rarely are included in booster sessions, and the decline in their participation likely has a negative impact on the results.

Further investigation of the interactive process of the peers in the group matrix continues to be neglected, partly because of the lack of satisfactory group measures, and the cost of these investigations.

Current and future outcome research will likely be easier to carry out with the introduction of more efficient and sophisticated instrumentation. The field lacks long-term follow-up studies. Outcome results could help specify what length of therapy, short or long term, and what style of therapy, cognitive-behavioral, interactional, or psychodynamic, is indicated for specific disorders. Where results show little clinical effectiveness for the group intervention, other therapeutic modalities should be considered (e.g. individual or pharmacotherapy) in combination or sequentially. The current trend is toward inpatient multimodal models, involving school and community. The efficacy of outcome is now considered not only in terms of self-esteem, pleasure, and improvement in functioning in the home, school, and work, but in terms of cost of the delivery of mental health care. Here, group therapy has the advantage in that more children can be treated at less cost. It is clear that research supports group therapy effectiveness, and children and adolescents are decidedly excellent candidates for this interpersonal treatment modality.

The term *family therapy* refers to interventions that attempt to alter interactions among family members and thereby improve the functioning of the family as a unit and the functioning of individual family members. Family therapy interrupts interactional patterns that cause distress between individuals and, correspondingly, within individuals. Family therapy eventually addresses the concerns of all family members, but most commonly begins by focusing on the clinical needs of a symptomatic child.

Family therapy denotes a conceptual framework guiding interventions and a specific psychosocial intervention. For a generation, family therapy has been guided by the concept of the family as a system. In this view, psychopathology resides in the system, not in individuals, and interventions are designed to change family relationships because symptoms are seen as regulating family relationships. Symptoms in a child are necessary for the system, and behavioral dysfunctions are seen as dysfunctions of the entire system. The influence of the systemic approach, although generative of numerous hypotheses and new ways of looking at the problems of children, has lessened. This chapter emphasizes that although symptoms can *maintain* interactional problems, these interactional problems also *generate* problems for children. Family therapy that changes relationships ultimately changes the internal lives of individuals, particularly those of developing children.

As an intervention modality, family therapy is more accurately termed *family treatment* because this denotes different ways in which clinicians can work with families—with the entire system, with dyadic subgroups, and with individual family members. Any intervention that specifically improves the functioning of the family can legitimately be seen as an aspect of family treatment. Traditionally, family therapy implied that all family members were present for treatment. For many practitioners, eclectic family therapy approaches that encompass behavioral, educational, and psychological interventions are seen as family treatments. Further, specific interventions focusing on parental dysfunctions and facilitating parental support can legitimately be seen as a subset of family interventions. Because parents perform executive functions for the family, increased parental stability will have a salutary effect on all aspects of family functioning. *Family therapy* and *family treatment* are used interchangeably in this chapter.

Family therapy uses key elements of the other psychosocial therapies. Family therapy uses a behavioral emphasis in that clinicians observe behaviors and design plans to alter them by intervening in the interactional patterns associated with problematic behaviors. This often is done in session through therapist directives and out of session through homework assignments. Family therapy uses concepts of individual therapy such as developing an alliance with the family, assessing familial resistance, and considering therapist countertransference to the family's behavior. Perhaps most clearly, family therapy shares characteristics of group therapy. Individuals in the family perform functions for the family as a whole, but these functions are not just derived from family sessions. Roles assigned by biological relationship of parent to child and sibling to sibling, as well as the shared history of each of the family members, have an impact outside the consulting room (Josephson, 2000a).

Any contemporary effort to define family therapy must recognize a relatively recent phenomenon: there is increasingly less consensus on what actually constitutes normal family experience. Early systemic family therapy was based on the concept of the family as a stable nuclear unit with extended family support. Many of the transitional experiences of the contemporary family are receiving increased attention and these include, but are not limited to, stepfamilies, single-parent families, and serial cohabitation (Barnes, 1994). Achieving consensus on a definition of family therapy is now more complicated because of this apparent shift in the definition of the family.

### FAMILY INFLUENCES ON PSYCHOPATHOLOGY

It is self-evident that experiences in the family comprise an important, perhaps major, influence on children's emotional development and in the causation of psychological and psychiatric disorders. This intuitive position is substantiated by significant empirical evidence (Garnezy and Masten, 1994; Rutter, 1991). There should be little debate about the need for a systematic evaluation of family functioning in any child or adolescent being assessed for psychiatric disorder. Research in

psychopathology reveals that family discord, disruption, and disorganization are strongly associated with psychiatric disorder ( Jenkins, 1994). Psychiatric risks appear to arise more from specific interpersonal relationships rather than general family milieu characteristics. This is supported by behavior genetic analyses that separate the effects of shared and nonshared environmental effects ( Plomin and Daniels, 1987), and by detailed clinical studies ( Buchanan et al., 1991). In spite of this evidence indicating the family's importance in the etiology of children's problems, the field of family therapy has had to grapple with views in child and adolescent psychiatry that suggest that family interaction never causes individual psychopathology but merely responds to it ( Koplewicz, 1996; Sargent, 1997). These views appear influenced by historical factors, not the least of which were the inaccurate attributions of the etiologic role of familial and parental dysfunction in major mental disorders ( Fromm-Reichmann, 1948). The unfortunate blaming of parents appears to have given way to the field's reluctance to implicate familial problems as etiologically relevant to child and adolescent psychiatric disorders.

This chapter emphasizes the bidirectional nature of the influence of families. If families nurture and assist children, which they surely do, they also can hinder the developmental and clinical status of children. Family therapy practiced at its highest levels empathically relates to the family and vigorously attempts to discern the role the family plays in the disorders under investigation and treatment. Family therapy recognizes that parents and families shape children, and children shape parents and families ( Leventhal and Conroy, 1991; Rutter and Cox, 1985). Family therapy must empathically relate to family difficulties and, at the same time, urge families to change patterns of interaction where this is indicated.

## HISTORY

The history of family therapy throughout the past century is fascinating and convoluted, with numerous reviews of this history available ( Broderick and Schrader, 1991; Ravenscroft, 1996; Sholevar, 1997). There are several historical themes that illuminate the current status of family therapy in the treatment of child and adolescent psychiatric disorders. Ironically, much of the early family therapy literature did not emphasize children or adolescents. Without children, there is no family. Family therapy often emphasized systemic principles that frequently did not take into account the differential effects of the age of a family's children and related aspects of developmental psychopathology. Clinicians treated the family system as a game of checkers, when the analogy of chess was much closer to the clinical reality. To further the chess analogy, the presence of individual psychopathology meant certain family members were restricted in some of their moves. This relative avoidance of children in family therapy has shown encouraging signs of changing ( Combrinck-Graham, 1989; Zilbach, 1986).

It is ironic that the systemic approach minimized the role of children because most observers agree that the beginnings of family therapy occurred in the early 1900s as child guidance clinics treated the problems of children in a family context. The orientation of these clinics at the time was influenced by the psychoanalytic ideal of separate, confidential, individual treatment. Even though Freud had pointed out the interplay of family forces in intrapsychic development, the primary clinical intervention focused on the mind of the child. In these clinics, the psychiatrist treated the child and the parents were seen by the social worker. This approach reflected the primacy of the individual approach, a situation that continued through the first half of the century. Even though clinicians were beginning to report relationships between parental dysfunctions and conduct disorder ( Johnson, 1949) and schizophrenia ( Fromm-Reichmann, 1948), most psychiatrists still continued to see family interviews and conflicts as ancillary to the treatment of the child's internal conflicts. John Bowlby (1949) stated that he found family interviews useful "before treatment is inaugurated." This statement by an influential psychiatrist simultaneously encouraged clinicians to think of family influence yet underscored that the definitive treatment was with the individual.

## Pioneers

Many of the early pioneers of family therapy became involved in family therapy because of their disenchantment with psychoanalysis or their opposition to the hegemony of the medical model, or both. Nathan Ackerman, arguably the father of family therapy, was a child psychiatrist and psychoanalyst. He was typical of the analytically trained early family therapy leaders who believed their individual treatments were less effective because they were undermined by families who had difficulty adjusting to therapeutically induced changes in their children. Ackerman saw that individual dynamics appeared to arise from similar dynamics in parents. His commitment to thinking about families, coupled with his influential position in the psychiatric community, did much to win acceptance for family therapy. In 1960 he founded the Ackerman Family Institute in New York City.

At the same time, modifications of psychoanalytic theory began to emphasize social forces: Heinz Hartmann's adaptive ego psychology, Harry Stack Sullivan's interpersonal psychiatry, and Eric Erikson's epigenetic developmentalism. Concomitantly, psychoanalytic object relations theory was being developed by Melanie Klein, D. W. Winnicott, and others in England. These clinicians and theorists took into consideration the interactional nature and relational matrix that appeared to give rise to intrapsychic process. In doing so, they indirectly fostered the development of family therapy. Parallel activity between psychosocially aware, individually oriented therapists and family therapists continued into the 1950s and 1960s. As an example, empirical research by Margaret Mahler and her colleagues on the separation-individuation process furthered the concept that development does not occur apart from a social matrix. Mahler's seminal work supports family therapy interventions, yet it rarely is mentioned in family therapy literature ( Mahler et al., 1975).

## Radical Environmentalism and Family System Theory

The next era in the development of family therapy was revolutionary. In the 1950s, 1960s, and 1970s, the family was defined as a system, and for many clinicians the only way to intervene with a family was through systems therapy. This perspective dominated family therapy for a generation, and its impact is still being felt. The biologist, Ludwig Von Bertalanffy (1968), had significant recurring impact as perhaps the major theoretician of general systems theory.

Similar to the development of psychoanalytic concepts after their introduction by Freud, the concept of the system soon was developed further by a number of different clinicians. Their different emphases became subsumed under various schools of family therapy ( Table 84.1). Carl Whitaker, known for his unique, idiosyncratic style and creative clinical abilities, founded the *experiential family therapy* school (Whitaker and Keith, 1981). Whitaker used an antihistorical, antitheoretical, here-and-now approach that emphasized emotional expression and self-actualization.

**Table 84.1. Varieties of Family Therapy**

*Strategic family therapy* emphasized communications between family members and used paradoxical techniques. Gregory Bateson, Jay Haley, and Don Jackson were early leaders in this group that described the "double-bind" communication ( Bateson et al., 1956). In 1958, Jackson established the Mental Research Institute, which fostered much generativity in strategic therapy. Finally, *structural family therapy* was developed by Salvador Minuchin, initially derived from his work with poor families during the 1960s (Minuchin et al., 1967). In contrast to many early family therapists who worked with middle class families, Minuchin's direct, pragmatic approaches in a difficult-to-treat population soon captured the imagination of many in the field. Other clinicians who maintained interest in developmental theory and analytical processes while working with families included John Bell (1961), Murray Bowen (1966), and Ivan Boszormenyi-Nagy (Boszormenyi-Nagy and Ulrich, 1987).

This was an exciting era because early systems proponents believed, not unlike earlier proponents of psychoanalysis, that mental illness could be cured through this new approach. Along with this radical view came a rigid adherence to the approaches of the systemic perspective that became conflictual for the field. For example, it was not uncommon for a family to present for a psychotherapy session without one member and have the session canceled because it was believed that the entire family had to be present for the process to be effective. Systems therapists were trying to make the point that the family is a system and it is impossible to deal with

the entire system with members absent.

Systems therapists moved away from individual psychodynamic approaches, yet remained vigorous environmentalists. The here-and-now focus of family systems treatment was frequently demonstrated through live clinical interviews in formal and informal educational settings. A generation of family therapists was spawned through attending workshops and observing the techniques of charismatic figures. The advent of video technology allowed practitioners to demonstrate their work, which added visual learning to the traditional process note method of psychotherapy education. Contrastingly, direct observation appeared to encourage further the emphasis on techniques and the dramatization of the change process. It was not uncommon for clinicians to teach that strategic interventions in a “stuck system” could produce results within one session.

Family therapy techniques became the order of the day. Some were creative and generative of new hypotheses of family functioning. As an example, disruptive children in a family would be asked, in a *paradoxical intervention*, to become increasingly disruptive at the first sign of a parental disagreement, and by this action would keep the parents escalating to open conflict. By prescribing the hidden function of such systemic problems, the therapeutic process rendered them explicit and voluntary. If a family complied with the paradoxical directive, these elements of mental functioning were brought under conscious control. If the family resisted accepting the directive, the dysfunctional structure changed and the problem resolved. Developing newer and newer techniques began to drive the field, a field that lacked a unified theory of family functioning. A generation of family therapists mixed elements of systems theory with a collection of techniques, as the field of family therapy became technique driven.

Given this trend, it was not surprising that polarization began to occur between family therapists and certainly between family therapy and the field of child and adolescent psychiatry (McDermott and Char, 1974). Child and adolescent psychiatrists and family systems therapists interacted less frequently. Ravenscroft (1996) has described the separatist climate of therapists who practiced outside the mainstream of psychiatry, including child and adolescent psychiatry. The attitudes taken were frequently “anti” the following: medical model, designated patient, individual symptoms, differential diagnosis and differential therapeutics, and individual therapy, especially psychoanalysis. Systems therapists eschewed history and the explanation of specific etiologic factors, often derisively referring to these linear explanations as archaic and antisystemic. The developmental needs and perspectives of children were not a focus of systems therapy. By ignoring individual psychology and broader social networks, this narrow, rigid systemic view was similar to earlier developments in psychoanalysis where, for example, all behavior was seen as unconsciously derived and, therefore, interpretable. The pervasiveness of these ideas led some family therapists to bemoan the loss of the “self in the system” (Nichols, 1987).

### Rapprochement and Integration

Numerous advances in psychiatry in the 1980s and 1990s, as well as specific research on developmental psychopathology, led to the integration and rapprochement of family therapy with child and adolescent psychiatry. The current status of family treatment, and the orientation of this chapter, is that a family therapy approach that integrates systems, individual psychodynamic, and behavioral concepts most effectively treats the psychiatric disorders of children and adolescents. Such family treatment is cognizant of biological vulnerabilities and is flexible enough to include parent training and education, as well as individual therapy with children, adolescents, and parents, and to work with the broader social networks that are involved with disturbed children. Integrated family treatments typically include aspects of several different schools of family therapy. Family therapy approaches differ with specific psychiatric disorders, and clinicians increasingly tailor approaches to the unique characteristics of each disorder (Table 84.2).

**Table 84.2. Clinical Issues in the Family Treatment of Specific psychiatric Disorders**

A confluence of several areas supports the integration of family treatments with other interventions, particularly interventions with individual children and parents (Josephson, 2000a).

1. Child development studies (Emde, 1983; Main and Goldwyn, 1984; Stern, 1985; Zeanah and Zeanah, 1989) emphasize that the relational family context generates the inner mental world of a child, also termed *internal working models of relationships*.
2. Clinical psychiatry emphasizes an interactive mosaic of risk and protective factors (Kagan, 1988). Child psychiatry uses “goodness of fit” to describe biological vulnerability interacting with environmental demands to determine clinical outcome (Thomas and Chess, 1980). Biopsychosocial psychiatry uses a stress-diathesis model (Engel, 1980; Rosenthal, 1970) in that the stressfulness of an event depends on the unique biological and psychological characteristics of the individual experiencing the event. In this model, the family may be a risk factor or a protective factor.
3. Family researchers (Reiss, 1989) emphasize factors that reside in the individual as well as factors that reside in the system.
4. Psychodynamic psychiatry continues to include interactive concepts in its theoretical base. Object relations theory is based on the internalized object relations derived from life experience (Scharff and Scharff, 1987), and self psychology describes parents as “self objects,” providing mirroring and idealizing functions necessary for healthy child development (Kohut, 1971).
5. Outcomes of specific medical disorders are increasingly seen as influenced by family processes (Reiss et al., 1986). This fact is underscored with the development of a new journal, *Family Systems Medicine*, devoted to this topic.

### Current Trends

Even as many forces have led to an integration of family treatment with other therapeutic approaches, dissatisfaction with systems approaches has been associated with a new development in family therapy, the use of *narrative therapy* as an organizing construct (Freedman and Combs, 1996). This movement is encouraging but harbors a potentially divisive element in the trend toward integrating therapies. On the one hand, this approach appears to be a return to the developmental perspective, that each individual life is lived in stages and in each stage, one's life story unfolds. Respect for the individual perspective of each person in the family is engendered by the clinician's careful, empathic listening responses. This change seems a clear response to the technicism and hierarchical approaches of many systemic family therapies, wherein the clinician issued various change directives to the family. Although there is a similarity to a historically based, developmental perspective, there also is a distinct difference. This trend in family therapy is heavily influenced by social constructivism, the “postmodern” idea that there are no essential truths except the ones individuals construct for themselves. As a result, the therapist conducts family therapy without *a priori* assumptions regarding healthy family life and normal child development, but rather joins the family through interpreting their experience.

The problem in integrating this approach to child and adolescent psychiatry is obvious. The child psychiatrist attempts to identify generalizable, if not universal, principles of families and child development based on clinical and research perspectives. The narrative therapist brings no such structure, or perspective, to therapy and attempts through “therapeutic conversations” to help the family construct a new story or a current reality. Although not explicitly antimicrobial, this approach appears to run the risk of marginalizing family therapy. In its attempt to regain the subjective, it dismisses concepts important to the experience of child and adolescent psychiatrists. The emphasis on the family's creation of reality makes the approach difficult to research as well.

Encouragingly, some clinicians see the possibility of rapprochement here as well (Malone, 2001). The medical model was misunderstood by many systems therapists who did not recognize that the idea of recursive feedback loops is consistent with a medical model. As blood pressure drops, the heart rate increases to maintain constant perfusion throughout the circulatory system. Similarly, the notion that an individual child, or parent, has a specific disorder does not exclude the importance

of family narrative and individual experience. Subjective experience can be maintained while empathically eliciting and categorizing symptoms that individuals and families are experiencing. By decreasing the emphasis on pathology, by denying generalizable principles of individual or systemic functioning, and by emphasizing “conversations” as a core element of treatment, the family therapy as envisioned by narrative therapists again runs the risk of being placed outside the mainstream of medicine and psychiatry.

Narrative family therapy will contribute most significantly to child and adolescent psychiatry by simultaneously enhancing the reemphasis on the patient's story while not dismissing core concepts in medicine and psychiatry. Narrative therapy is strongly tied to a specific, “postmodern” philosophy and, as such, is vulnerable to cultural shifts.

Contemporary psychiatry emphasizes biological mechanisms of disorder, often coming close to *biological reductionism*. A natural correlate of this trend is a deemphasis on family contributions to psychopathology. Although families may not always *cause* psychopathology, they can increase the *risk* for disorder. Family factors do not differ from biological and other psychological and social factors that increase risk for disorder, but rarely are powerful enough to be the sole determinants of disorders. Risk factors, such as genetic vulnerability to depression (biological), inability to trust others (psychological), and unemployment (social), *predispose* individuals to disorders but do not *cause* them. The tendency of contemporary psychiatry to translate biological risk into biological cause is a significant challenge for family therapy. As a result, families increasingly pursue pharmacologic interventions for many child behavior problems ( [Sprengr and Josephson, 1998](#)). Reimbursement systems that cover only the brief, infrequent clinical sessions of pharmacologic treatments further exacerbate the challenge to the practice of family therapy.

## AN INTEGRATED PERSPECTIVE ON FAMILY THERAPY

The contemporary approach to family therapy in the treatment of child and adolescent psychiatric disorders emphasizes integration. Systems theory has had a significant impact by offering valuable new perspectives on family treatments. The pendulum has now swung to reassert the importance of individual history and narrative. The integrated approach must consider systemic, psychodynamic/developmental, and behavioral perspectives. There is some difficulty in finding a term for the family therapy approach that deals with the relationship between family processes and intrapsychic development without the term being unwieldy. For example, Malone has used the term *psychoanalytic object relations attachment theory* (Malone, 1991). To facilitate readability, *psychodynamic* and *developmental* are used interchangeably in the remainder of this chapter to denote that particular family therapy perspective.

In the systems view, individuals in the family are interdependent. No change occurs in a family system without other things changing accordingly and, as change proceeds, the family acts to maintain equilibrium or homeostasis. Symptoms are not seen as residing in the child or adolescent but as serving a purpose, or function, for the family system. A child's physical symptoms, which result in his father canceling a business trip, appear to strengthen a tenuous attachment to this father and, at the same time, decrease the child's anxiety about ongoing marital conflict related to his father's frequent absences. Each family member is presumed to act in a way that would oppose symptomatic improvement in the child. The family interaction becomes a shared coping mechanism and, by this mechanism, members avoid distressing affects associated with change. This perspective often gives the clinician the ability to anticipate what events would transpire if a child's symptoms were ameliorated. Therapeutic interventions attempt to manage tension inherent in change and to prevent families from reverting to old patterns of interaction. In this instance, the family may achieve a new equilibrium and the child's symptoms remit as father adjusts his work demands and the marriage bond is renegotiated. Family therapy approaches that possess some of the characteristics of a systemic view are the structural approach and the strategic approach.

The integrated view of family treatment also emphasizes the unique life experience and individual development of each family member. The emphasis on life experience integrates the concepts of developmental and psychodynamic psychiatry with some of the current notions of narrative in family therapy. This perspective also suggests mechanisms of transmission. It presumes that a child's life experience in family relationships becomes internalized as a psychological structure. In adulthood, these internalizations prepare the way for choice of a partner and new family formation. When a parent's developmental experiences are negative, such as sexual abuse, parental harshness, or parental indulgence, they predispose the parents to initiating pathologic family interaction. To some extent, these developmental experiences predict how a parent negotiates the transitions of the family life cycle in the next generation. The family's passage through the life cycle and the interactions that are associated with this passage contribute to the definition of the inner world of the developing child. Family treatments that have elements of this approach are intergenerational family therapy ( [Bowen, 1978](#)), contextual family therapy ( [Boszormenyi-Nagy and Ulrich, 1991](#)), and object relations family therapy ( [Scharff and Scharff, 1987](#)).

Finally, the integrated approach to family therapy must include an understanding of behavioral elements based on social learning theory. This eminently practical approach teaches parents how to apply environmental contingencies such as positive and negative reinforcement, punishment, and extinguishing responses, all of which shape children's behavior. Remarkably, many parents do not know how to apply basic behavioral management techniques. These techniques can be taught directly and through their application, parents can see dramatic changes in their child's behavior. Behavioral approaches to family treatment include functional family therapy ( [Barton and Alexander, 1981](#)), parent management training ( [Forehand and McMahon, 1981](#)), and behavioral family therapy ( [Griest and Wells, 1983](#)).

An integrated approach to family therapy does not diminish the uniqueness of each school. The definition of schools of family therapy has been useful in the advancement of the field, and there may be some training advantages in learning one specific approach before practicing eclecticism. In our current state of knowledge, one school has not been shown to be more efficacious than another. The general orientation of each school is summarized (see [Table 84.1](#)), but this chapter does not review each school in depth, apart from a brief discussion regarding the most useful techniques of several of the schools.

The integrated approach to family therapy draws support from three areas: clinical practice, research in developmental psychopathology, and contemporary psychiatry's interactive model of symptom development.

### Clinical Practice

Several individuals have been attempting the integration of individual/psychodynamic and systems perspectives in clinical practice for a number of years ( [Kantor, 1985](#); [Malone, 1983](#); [Pinsof, 1995](#); [Scharff and Scharff, 1987](#); [Slipp, 1984](#)). Two common clinical problems illustrate the importance of simultaneously considering these two perspectives.

In a family with an adolescent with anorexia nervosa, excessive attention to the child's eating serves the function of diverting attention from a marriage that lacks intimacy, and serves to *maintain* the eating disorder. As this interaction proceeds, however, the excessive attention and solicitous parenting toward the adolescent begin to *generate* problems in her. Specifically, her sense of specialness, entitlement, and dependency, all derived from the experience of parental figures watching her every move, are maladaptive in social situations. As this young girl begins to negotiate adolescent relationships, she finds others are not nearly as solicitous and attentive as her parents. The experience of weight loss conveys a needed sense of identity, control, and self-efficacy. In this sense, family interactions not only have maintained her eating problem but have contributed to her own internal problems.

In like manner, adolescents who exhibit self-harming behavior draw concerned family members toward themselves. The systemic consequence of self-harm also is accompanied by the need for an assessment of the affective and perceptive state of the individual adolescent. Self-harming behavior affects others, yet also is a clear indication of inadequate individual coping with distressing, painful affects.

### Research Supporting Integration

A number of family researchers and child development researchers have provided empirical support for integrating systemic and psychodynamic/developmental perspectives. [Reiss \(1989\)](#) conceptualizes family continuity in terms of the *representea* family and the *practicing* family. According to this categorization, in the represented family not only are relationships represented by inner working models of self, but the coherence and stability of the relationships themselves are located in, and conserved over time, by such internal structures. In the practicing family, the coherence and stability of family relationships do not reside in individuals but rather in the coordinated practices of the family as a whole. At least four specific lines of research are concerned with family factors in the mechanisms of intergenerational transmission of psychopathology. Several studies ( [Belsky and Pensky, 1988](#); [Main, 1984](#)) have demonstrated that the transmission of patterns across generations of abuse and child maltreatment are mediated by the parents' internal working models. This research does not consider how a parent's internal working model becomes translated into actual abusive relationships with his or her child. To understand this aspect of transmission, the practicing family perspective must be considered. Studies on alcoholism ( [Steinglass et al., 1987](#)) indicate that its transmission across generations is influenced to the extent the alcoholic individual's drinking behavior is included in family rituals. The “coercive family” engages in a pattern of coordinated family sequences that, according to [Patterson \(1982\)](#), maintains conduct disorder in boys. Finally, [Goldstein \(1987\)](#) has confirmed with adolescent patients what adult studies have shown: a strong association

between the presence of high expressed emotion and the development of schizophrenia spectrum disorders.

Other studies documenting the relationship of individual psychological development to life experience include those of Emde and colleagues ( [Klinnert, 1986](#)), who describe the concept of “social referencing.” In these studies, infant and toddler behavior is shaped by the behavioral responses of parents. Similarly, [Anders \(1989\)](#) has described the process of development as requiring the regulatory functions of caretakers to proceed smoothly.

### Family Therapy, Neurosciences, and Integration

Although biological reductionism seems to be on the rise, the stress-diathesis model ( [Rosenthal, 1970](#)) and the biopsychosocial model ( [Engel, 1980](#)) allow for an integration of family, developmental, and biological factors. Psychiatric disorders currently are viewed as the result of a mosaic of biological, psychological, and social risk and protective factors. Not all families with interactional difficulties are associated with child and adolescent psychiatric disorders (e.g., overprotectiveness is not always associated with an anxiety disorder). On the other hand, many individuals at biological risk for disorder do not develop the disorder in question (e.g., monozygotic twins are not uncommonly discordant for schizophrenia). This mosaic of risk factors suggests that psychiatrists can make a diagnostic statement regarding an individual child, yet appreciate the importance of family interaction. The psychiatric mainstream has recognized that psychiatric disorders can cause disturbed family relationships, but disturbed relationships can be associated with the onset of child and adolescent psychiatric disorders ( [American Psychiatric Association, 1994](#), pp. 681–690). An integrated family therapy model that integrates the findings of biological and developmental research is the model that best serves the field because it will be the model most likely accepted by practicing child and adolescent psychiatrists.

## CLINICAL PROCESSES: ASSESSMENT

Effective family therapy is based on a thorough assessment of the family, which provides data for the clinical formulation. It is the formulation that delineates the family's role, if any, in the onset and maintenance of psychopathology and the relative effect of individual child psychopathology on the family. Although numerous sources are devoted to general family assessment ( [Nichols and Everett, 1986](#)) and family therapy techniques ( [Minuchin and Fishman, 1981](#)), the following delineates the relevant clinical processes involved in assessing and treating a family of a child and adolescent with a psychiatric disorder. Consistent with the integrative approach of this chapter, these processes are those that have the consensus of the field and have been developed by multiple contributors. The following section identifies the goals and objectives of family assessment, the clinical data of assessment, and the typical sequences of family treatment, and provides a clinical example to illustrate treatment principles.

### The Family Interview

The assessment of the family is based primarily on the clinical interview. Rating scales and self-report measures can contribute increased detail to an assessment but typically are used for research ( [Fredman and Sherman, 1987](#)). The family interview should obtain history of the immediate clinical problem, or presenting complaint, and history relevant to general, pervasive family functioning. The interview should observe interactions between family members and assess the thoughts and emotions of individual members in the family. The interview must gather enough data to develop a formulation of family problems that allows the clinician to determine if, and how, these family factors relate to the clinical disorder. The data of the family interview serve the goal of developing a formulation and, thereby, a rational intervention strategy. Interventions may directly attempt to alter family relationships or solicit family support for other specific interventions. An essential goal of the family interview is to develop an alliance with each family member that facilitates future contact.

In addition to general goals, the family interview should achieve specific objectives ( [Josephson and Moncher, 1998c](#)). A well conducted family interview (a) indicates areas of family interaction requiring behavioral intervention; (b) identifies marital and individual impediments to systemic and behavioral interventions; (c) reveals which areas of a child or adolescent's development have been affected by family interaction; (d) identifies problems and areas of concern of other family members; (e) suggests which areas of delayed parental development have predisposed to family interactional problems; and (f) helps determine whether the family is compensating for a child's disorder or is contributing to the child's disorder.

#### PREPARING FOR THE FAMILY INTERVIEW

Before the interview, the clinician should review all available clinical data, determine the referral source, identify who has recognized the need for change, and understand whether other agencies and professionals are, or have been, involved with the family. The most common presentation requiring a family interview is a symptomatic child, but on occasion a family may present with an identified family problem and request a family intervention.

There are two basic approaches to the initial interview. Some clinicians request that the entire family be present for the first session and focus this session on family interactional factors, the meaning of symptoms for the family system, and how the symptoms are maintained by the family system. Other clinicians adopt a more eclectic, flexible approach and do not request that the entire family be present initially. This approach tends to make families less defensive because the clinician uses separate interviews with child and parents to gather extensive history before observing the family as a unit. When parents are interviewed alone, important facts about the child's development and symptoms emerge. An adequate diagnostic appraisal requires the gathering of factual information about the child and about the family. Individual interviews with parents tend to be superior for this purpose. The detection of family psychopathology is adequately detected through individual interviews with parents and child, yet such interviews are less effective in the assessment of how pathology arises and is maintained ( [Jenkins, 1994](#)).

Individual parental interviews emphasize traditional elements of the psychiatric evaluation such as transference, countertransference, and resistance, as they relate to parents. They also allow the clinician to assess parental temperament and personality so that the clinical data can be placed in context ( [Greenspan, 1991](#)). Parents also provide their perceptions regarding discipline techniques and communication in the family.

The clinician must determine who will participate in the family interview. All first-degree biological relatives who reside with the identified patient should attend the initial family interview. This interview also should include those who have influential regular interactions with the identified patient, such as grandparents who have daily contact or parenting responsibilities. It may be necessary to have several meetings with such individuals to observe fully patterns of interaction. Children of divorced parents should be interviewed with the biological parent who has regular physical custody and, where relevant, a new partner. Wherever possible, separate interviews with the noncustodial biological parent are indicated to provide a complete perspective on the child's problems. It is not uncommon that some family members fail to attend when requested to do so. When this occurs, it frequently is due to some family interactional problems that are contributing to the presenting complaint.

#### STAGES OF THE INTERVIEW

There is some consensus about the specific stages in the family interview: a social stage, a problem stage, an observation stage, and a summation stage ( [Goldner, 1987](#); [Haley, 1976](#); [Josephson and Moncher, 1998a, 1998c](#)).

As in any meeting of strangers, the beginning of family therapy requires a greeting and the introduction of each person, tailoring these interactions to the developmental level of each child present. This *social stage* quickly gives way to the *problem stage*. Although most of the participants have some idea of the problems that have led to presentation to the clinic, the initial inquiry into these problems begins with the parents, acknowledging their executive function in the family. Subsequently, the clinician explores the problem with each family member. It is not uncommon to leave the identified patient, child or adolescent, until the end to convey support and decrease defensiveness.

It is important to gather a history of acute events and a sequential account of particularly troubling interactions that are associated with the clinical presentation. The process of therapy actually begins with this aspect of assessment. As the interviewer elicits information from family members, the style and structure of questions introduce new information into the family system. This has been termed *interventive interviewing* ( [Tomm, 1987, 1988](#)). Another relevant interview technique is *circular questioning*. By this method, the clinician does not directly confront symptomatic individuals about their behavior, but explores patterns of communication within the family as problems are sequentially discussed with each family member. Each participant in the interview is invited to express his or her perspective on the behaviors and interactions of others. This type of interviewing often produces new material for families to consider, which can be threatening and, at the same time, very relevant.

The *observation* stage occurs throughout the interview and, because relationships are better understood by observation than by report, is an essential element of the assessment. This stage begins by observing choices of seating arrangement. At any point in the family interview, as a family member is sharing his or her perspective

on family problems, the family may begin to interact in ways that demonstrate the presenting complaint or other problems. Once an important family interaction is set in motion, the assessment of this interaction takes precedence over further historical data gathering, which can be reinitiated after the spontaneous interaction has subsided. The observation stage forces the interviewer to decide whether to continue to focus on the presenting problem of a child, gather associated aspects of family history, or focus on immediate interactions that have interrupted the flow of the interview. The clinician should pursue the most pressing issue for the family, being ever mindful of the presenting complaint.

When a child's dependent behavior is part of the presenting complaint and the clinician observes the father answering questions for the child and the child looking to the mother for direction, the clinician has the benefit of living with the problem as opposed to merely hearing it described. Such observations have great clinical utility in that, once they are comfortable, families tend to behave in the clinic as they do in natural settings. It is important in the observation stage to be every mindful of the possibility that in broadening the interview to general aspects of family life, family members can become defensive at this apparent intrusion by the interviewer. Because one of the key goals is to develop an alliance with the family and have them return to be involved in the treatment of their child, it is a sensitive and important decision when to probe less directly into family life.

There are significant challenges for the child and adolescent psychiatrist in family interviewing compared with individual interviewing. The basic challenge in conducting a family interview involves simultaneously gathering the facts of history and observing family interaction. It requires a certain degree of clinical skill to deal simultaneously with the apparent lack of organization in the presentation of clinical material, distracting noise and spontaneous discussion by various family members, and the concerns of multiple individuals.

Finally, the *summation stage* includes the clinician's brief comments regarding which changes appear to be needed, typically starting with elimination of the presenting problem. This stage may describe the need for other assessments of the individual child and further family interviewing, including family members not present initially. The clinician should clarify with the family whether their ongoing presence is necessary merely to support their child or whether there is evidence of family interactional problems that need to be addressed to benefit the child.

Although the many schools of family therapy and approaches to treatment offer unique perspectives on family therapy, there is an emerging consensus that the data on which interventions are based can be summarized in four categories: family history, family structure, family communication, and family regulatory functions. [Davidson et al. \(2001\)](#) have reviewed the content to be covered, providing a clinician's guide to relevant lines of questioning in assessing these four areas.

### Data of the Assessment: Family History

The data of history can be further categorized into four areas: (a) the family interactional history related to the presenting complaint and, if different, the history of pervasive family functioning; (b) parents' developmental history; (c) the history of the marital relationship; and (d) the history of the family as a unit (i.e., family life cycle). The approach to gathering family history differs according to the experience of the parents. Parents who have more than one child draw on a comparative, developmental database unavailable to first-time parents.

#### INTERACTIONAL HISTORY

It is not uncommon for the history of a child's presenting problems to be associated with specific interactional sequences. For instance, aggression, self-harm, and refusal to eat may arise after interaction between family members. The acute interactional history is very useful in understanding the precipitation of clinical problems. Clinicians must determine if the descriptions of family interactions associated with acute events are similar to family interactions that have occurred on a chronic basis. The interactional history helps distinguish between adjustment problems and those chronic interactions that have a more enduring impact on child development.

#### PARENT HISTORY

Whereas the onset of children defines a family, family history is informed by an understanding of the developmental histories of each of the parents and the history of the marital relationship. The clinician asks, "What type of person is this parent?" A systematic developmental history of each parent, derived from the descriptions of family-of-origin experiences, informs an understanding of parental strengths and weaknesses and parental personality functioning that mediates parental role functioning. Most parents' adaptive and maladaptive parenting strategies have been influenced significantly by how they were parented. Formal psychiatric and medical history is a standard part of this history.

#### MARITAL HISTORY

The marital history is a logical continuation of the individual parent history. The choice of partner significantly reveals aspects of individual functioning, both conscious and unconscious, that predispose to family health or family difficulty (e.g., the dependent woman who marries a tyrannical, controlling man). The clinician asks, "What drew these two individuals together?" The family's successful negotiation of life cycle tasks is the main task of the marital unit, the executive unit of the family ([Wamboldt and Reiss, 1989](#)).

#### HISTORY OF THE FAMILY AS A UNIT

Effective family interviewing requires knowledge of the stages of the family life cycle ([Carter and McGoldrick, 1999](#); [Combrinck-Graham, 1985](#); [Walsh, 1993](#)). Families with infants are dealing with issues of nurturance and attachment; those with toddlers are confronting issues of limit setting and the draining demands of constant observation; those with school-age children are addressing issues of socialization and achievement; and families with adolescents deal with the dilemmas of the imminent independence of their child and the accompanying evidence that she is not quite ready for complete emancipation. Finally, families deal with the complete emancipation of all their children, with couples facing renegotiating their relationship in middle age. Mastering stages of the life cycle includes mastering anticipated challenges, such as children entering formal schooling, and unanticipated challenges, such as a child's life-threatening illness. A unique aspect of the history of the family life cycle is a search for enduring, unique family beliefs and recurring themes in family life. Themes that endure in the family unit (e.g., the men in the family will assume leadership roles in the community) may be associated with puzzling patterns of family interaction that have existed from generation to generation. The family unit history often is schematically summarized in the genogram ([McGoldrick and Gerson, 1989](#); [Fig. 84.1](#)).

Figure 84.1. The Family Genogram as of 1999.

### Data of the Assessment: Family Structure

Family structure refers to the typical organizational and transactional patterns and hierarchies that exist between individuals in the family ([Minuchin, 1974](#)). The family interview, through historical data and observation, produces information from which the clinician can assess family structure. The important components of family

structure are adaptability, cohesion, and boundaries.

#### *ADAPTABILITY*

The healthy family has a flexible structure with stable transactional patterns that shift when circumstances dictate the need for change. Clinical families may be too chaotic, with interactional patterns and individual family roles constantly changing, or too rigid, with the family unable to change typical ways of interacting, even as life circumstances demand such changes.

#### *COHESION*

The healthy family demonstrates a balance between connectedness and separateness, whereas clinical families may be too emotionally close (i.e., enmeshed) or too disengaged.

#### *BOUNDARIES*

The healthy family has emotional boundaries between subsystems (e.g., parent–child) that are permeable but clear (e.g., an adolescent teasing father while father remains an authority figure), whereas clinical families often have boundaries that are rigid, diffuse, or misaligned (e.g., a child serving as the primary source of emotional support for a parent).

### **Data of the Assessment: Communication**

Family communication refers to verbal and behavioral interactions by which family members impart information to each other about their individual needs and their perceptions of others in the family. Components of family communication are clarity, emotional expression, and problem solving.

#### *CLARITY*

Healthy families communicate clearly and consistently with affect that is congruent to the message conveyed. Clinical families tend to communicate ambiguously about both minor transactions and those of major importance.

#### *EMOTIONAL EXPRESSION*

Healthy families communicate with an open expression of affect congruent with the message conveyed, whereas clinical families may either block the expression of feelings, express affect incongruent with life experience, or both.

#### *PROBLEM SOLVING*

Healthy families agree that problems exist, negotiate differences in conflicts, and are able to use new information. Clinical families tend to have multiple individual perceptions of the problem, are unable to sacrifice toward common family goals, and are unable or unwilling to perform the tasks necessary to assist family coping. Clinical families are ineffective at problem solving and have a decision maker who is either a poor communicator, authoritarian, or indecisive.

### **Data of the Assessment: Family Regulatory Function**

The physical, social, and emotional development of children evolves in an interactional context that facilitates the mastery of developmental tasks. The family is perhaps the most powerful regulator of the developmental process. Regulation has been described as implying an equilibrium or balance between inhibiting and facilitating interactions between caretaker and child ( [Anders, 1989](#)). Families that appropriately regulate a child's development are attuned to developmental needs and adapt their behaviors accordingly. These needs vary according to a child's developmental stage and temperament, as well as a family's particular life situation. In some situations, for example, children need a limit or restriction, and in other contexts they need encouragement of autonomous functioning. Children may need to be protected and, at other times, may need to fend for themselves. Families who are in clinical difficulty often have several patterns of regulatory dysfunction, exacerbated by skews between the different approaches of mothers and fathers ( [Josephson and Moncher, 1998c](#)).

## **CLINICAL PROCESSES: FAMILY TREATMENT**

Once family interviews are completed, the data gathered in the four domains—history, structure, communication, and regulatory function—reveal what family factors are related to clinical problems, what factors serve as a general context for the problems, and what factors are unrelated to the problems. This formulation serves as the basis for family intervention. With some symptomatic children, the family is viewed as etiologically important in the onset and evolution of the child's problems. Here, the clinician sensitively explores and elucidates the role of family conflict in the child's disorder. At other times, family interaction is seen as a response to illness or disorder in the child. In such cases, the clinician educates and empathically supports the family as they endure difficult circumstances. Complex family situations may involve both approaches. Although there is no widely accepted classification of families, the clinician through these efforts at formulation gains a sense of the type of family with which he or she is dealing and tailors the approach to family treatment accordingly (see [Table 84.2](#)).

In contemporary child and adolescent psychiatry, it is rare that family therapy is initiated at the onset of a clinical encounter. It is much more common for an evolution of interventions with the family to take place, from more simple to complex ( [Josephson and Moncher, 1998b](#); [Ravenscroft, 1996](#)). Systemic and dynamic/developmental formulations lead to a sequential integrated approach to family therapy. The question is not whether to do family therapy, but when to do so. The family always must be involved in the treatment of a child or adolescent psychiatric disorder. When to involve the family directly and which specific elements of family treatment to use become the critical determinations for the clinician.

The following description presents a typical clinical process in which family therapy becomes embedded. The process described includes phases *before* the formal family therapy and *after* a family intervention may take place. Each phase described often unfolds chronologically, but not necessarily so. This general process includes a number of different features of many schools. Specific formulations of clinical problems and their related approaches may be of use in certain clinical situations, leading to some variation in this pattern.

### **Immediate Problem Solving**

Clinical disorders present as the gradual culmination of pervasive, ongoing problems that lead to referral or present acutely as the onset of crisis. Families present with problems that require immediate interventions, often behavioral and pharmacologic. To stabilize a crisis, a child may need to be removed from the immediate family environment, including psychiatric hospitalization for emergency evaluation and treatment of life-threatening situations. Clinicians may need to use community resources such as shelters for runaway children or emergency foster care. In less acute situations, families are given brief, problem-focused advice on child management to decrease family distress.

### **Parent Education**

After stabilization and immediate problem solving, education is the focus of the next stage of family intervention. Here, the clinician offers directives about the management of child and adolescent behavior that are explicit, easily understood, and quickly implemented by many parents. Parent management training and education often suffice to interrupt behavioral problems, particularly when the problems are mild or parents are merely inexperienced. Parents often benefit by learning how to set limits, learning to foster a child's independence, and acquiring relevant facts about child development. When education is only partially effective, or completely ineffective, the clinician typically has observed parental psychopathology or marital conflict underlying the inability of parents to respond to direct educational efforts. The clinician begins to develop questions—Why can't these parents set limits? What prevents them from nurturing?—that prepare for intervention in family interaction.

## Intervention in Family Process

At this point, the point of traditional family therapy, the clinician sees the entire family and notes patterns of interaction that are maintaining the clinical problem. Conjoint family therapy refers to sessions in which all family members are treated by a single therapist or cotherapists. Concurrent family therapy refers to family therapy and individual therapy conducted at the same time, usually with different clinicians. A final modality, the multiple family group, refers to meetings of several families, all of whom have an individual family member with similar problems (e.g., the disruptive child) or developmental challenges (e.g., the emancipating adolescent). In each of these varieties of intervention, family therapy sessions are held regularly, with variations in frequency, and can last as long as 2 hours.

The clinician challenges patterns of interaction using techniques such as those developed by the various schools of family therapy (see [Table 84.1](#)). Predictably, as the field has advanced since the time when technicism predominated, the most useful interventions have found their appropriate place in the family therapist's practice. This is not unlike the historical development of psychoanalysis, which had many of its most useful constructs—the unconscious, resistance, and transference—appropriated by other forms of psychotherapy. Now, the phenomenon of transference is an accepted aspect of general psychotherapeutic practice. In like manner, each family therapy school has contributed specific interventions that now are part of general family therapy practice. There are numerous, extensive descriptions of these interventions ([Gurman and Kniskern, 1991](#); [Minuchin, 1974](#)).

Family therapy interventions share many of the basic therapeutic tenets of individual psychotherapy. These include developing an alliance with the family, working through family resistance, and recognizing a type of “family transference” to the therapist. In addition, factors common to all successful psychosocial interventions are congruent with the techniques of family therapy: the healing context; a confiding relationship with a helper; a plausible causal explanation; the provision of optimism; and the provision of success experiences ([Frank, 1973](#)). Once the clinical formulation is clear in the clinician's mind, any number of different techniques can address problems in family functioning. This is an essential point: When the clinician discerns what needs to occur in a family, he or she can quite rationally determine how to do it.

As a general rule, structural and strategic approaches are most relevant for “here-and-now” problems, whereas intergenerational models address more chronic, pervasive family issues. Specific formulations for certain disorders can be very helpful in developing intervention sequences. When [Minuchin et al. \(1975\)](#) described core features of the “psychosomatic family” as enmeshment, rigidity, overprotectiveness, and lack of conflict resolution, they also implied ways to intervene with these families. In like manner, [Johnson's \(1949\)](#) classic description of “superego lacuna,” as it applied to some families with a conduct-disordered youth, was generative of new therapeutic approaches. Such special formulations are the exception, not the rule, yet when they exist, their striking presentations suggest specific targets for family therapy interventions.

*Structural family therapy* interventions include reframing, family enactment, and realigning boundaries. *Reframing* is an intervention by which the therapist attempts to give a positive, adaptive connotation to problematic behaviors. As the therapist provides an alternative way to perceive a behavior, he or she has the same intent of the individual therapist who clarifies and interprets. For example, a family therapist hears of a wife's anger and apparent disinterest in her husband's business trips. The therapist states, to the husband, “Your wife sure has an interesting way of saying ‘I love you’ and ‘I want to be with you.’” In family *enactment*, the family therapist promotes the replication of a family problem to understand its interactional and structural aspects. By directing a dependent adolescent to make decisions regarding his or her summer plans, the therapist can observe pathologic responses such as the overinvolvement of a controlling parent. At times, the therapist does not need to promote an enactment of a problem but merely pursue a detailed discussion of several interactional family problems that have occurred since the last session. In *realigning boundaries*, the therapist shores up boundaries that are diffuse and permeable or attempts to diminish rigid boundaries. For example, a family consultation reveals both parents are having difficulty controlling their three children. Their egalitarian beliefs include the ideal that listening to children is very important. They often conduct family votes on various issues. The family therapist educates the parents that they are in the executive position in the family and that, although they need to listen to their children, they do not need to have family boundaries so permeable that the children decide, by their majority vote, how to run the family. The direct nature of strategic interventions has immediate learning potential for families and can provide dramatic change experiences. The family therapist with a structural orientation often resembles a “traffic cop”—encouraging some to speak, directing others to stop speaking, getting participants to sit in different parts of the room, and changing chairs with parents.

Strategic family therapy interventions include paradoxical intervention and circular questioning. In a *paradoxical intervention*, the clinician makes a demand contrary to expectation, such as the request to exaggerate a symptomatic family pattern. In the family of a young girl with anorexia nervosa, the clinician encourages the mother to spend more time with her daughter and to help her daughter more often, while encouraging the father to remove himself from family life and develop his own pursuits. Prescribing the covert function of these family interactions renders them explicit and voluntary. If the family complies with the clinician, the interactions are brought under conscious control, antecedents to the overprotectiveness are explored, and a desire for liberation from this behavioral pattern is verbalized, usually by all involved. If the family resists the directive, the dysfunctional interaction changes. This technique may be less successful in the family therapy where members are cognitively or emotionally unable to process subtlety, and may be less useful in treating families with young children.

In *circular questioning*, the therapist does not directly confront the symptomatic individual but explores patterns of family communication. The clinician does not challenge the adolescent boy about his aggressive, noncompliant behavior. The family therapist elaborates the problems through interaction with the boy's mother, who describes its effects on her, her concerns of its effects on other children, and her anger at her husband's apparent unwillingness to attempt to control their son.

In *extended family intervention*, intergenerational processes in the broader kinship are the focus rather than events in the immediate nuclear family. Although it often is not practical to involve these extended family members on a regular basis, a well timed consultation can open up past interactional experience that has prevented the individuation of parents who are having trouble facilitating their children's emancipation.

Object relations intervention approaches deal frequently with projective identification. The family therapist notes a family member projecting parts of the self into another person, followed by identification with, and reaction to, these perceived attributes. This process is problematic enough in marital conflict, but is extremely toxic to children, whose sense of self is still developing and dependent on external validation. For example, the father of a teenage boy is extremely upset when his son becomes noncompliant and begins to experiment with behaviors that challenge the father's moral code. The father believes the son is going to develop sexual and drug-related problems, yet his rigid parenting seems to be provoking his son to engage in the forbidden activities. Later in therapy, the father, the son of a minister, reveals that he had impregnated a girl when he was a teen and had a significant alcohol problem in young adult life. Here, the family therapist intervenes through clarification and interpretation of the family interaction, and facilitates the father's recognition that his behavior toward his son is fueled by his own life experience and related internalized object relations.

*Narrative therapy* attempts to *externalize the problem* ([White, 1990](#)). This intervention involves two sets of questions. The first set of questions asks family members to describe the influence of the problem on their lives and relationships. In the second set of questions, the therapist asks the same individuals to describe their own influence on the “life of the problem.” Through this “influence questioning,” the problem is separated from the person and neither the family member nor the relationship between family members is blamed. Through externalizing the problem, family members gain some distance from problems that have been shaping their lives.

Altering family interactions may eliminate the problem and provide opportunities for improved adaptation in the family. Yet, these interventions often are resisted and unsuccessful. In these instances, individual family members often have their own reasons for resisting change.

## Considering the Individual Perspective

Intervention in family interaction patterns frequently are unsuccessful because of the individual motivations of family members. It seems that problematic family interactions often prevent individual intrapsychic conflicts from being expressed and, correspondingly, being treated. For example, in trying to interrupt an overly close mother–adolescent daughter dyad, the family therapist becomes aware of the mother's helplessness and sense of affective of distress at the thought of “losing her daughter.” Preexisting developmental factors that placed her at risk to overprotect her daughter begin to be exposed, and this exposure is resisted. The adolescent's dependency and selflessness seem the effects of mother–daughter symbiosis. The mother's conflict cannot be addressed while the family interactive processes of overenmeshment and overinvolvement is continuing. As family therapy attempts to help the daughter individuate, the mother's intense affects associated with this intervention place her at risk for becoming overinvolved, once again, in her daughter's life. By considering the internalized world of specific family members and using individual interviews to explore these worlds, the family therapist can intervene effectively with such resistance.

Family treatment can thus lead to individual interventions with either parent or the symptomatic child and can prepare for a marital intervention. It is important that this

process naturally unfold because there can be complications. For example, a clinician must not be drawn into “scapegoating” an individual family member through individual therapy and its implication of internalized pathology. Work with an individual family member may suggest the individual is the primary problem and could maintain family pathology rather than interrupt it.

## Marital Therapy

In a natural progression of family interventions and individual work, couples often consider their marital relationship some time after initial family interventions. Parents more easily reflect on their own contributions to clinical problems when their child's disorder is stable. Except in cases of imminent marital disruption, this stage usually occurs later in family treatment and indicates a deepening and maturing of the therapeutic process. Past issues surrounding the choice of a partner, and specific problems in the family life cycle, come into perspective for couples who are considering the difficulties of their child.

## Intervention with Siblings

Problematic family interactions typically affect more than one child. Symptomatic expression can be modified by a child's intelligence, temperament, or birth order, among other factors. As intervention in family process stabilizes one child, the needs of other children often become manifest. The clinician must assess whether the onset of symptoms in a sibling is a diverting mechanism away from another problem, such as father's alcoholism (systems view), or a statement of the sibling's individual vulnerability, such as low self-esteem (dynamic/developmental view).

## Termination

Some problems, which are phase specific, respond well to parent management training and brief family therapy interventions. In these instances, cases can be terminated. With multiproblem families, family interactions need periodic, ongoing monitoring. As children move through various stages of the life cycle, families may need to have renewed contact with a clinician who knows them well. The duration of family treatment varies from brief interventions for specific problems, to longer-term treatments with intermittent clinical contacts around different problems, often posed by different family members.

This sequential, integrated approach to family treatment is supplemented with other supports and interventions. Specific socialization difficulties often respond to group therapy. Educational supports often are necessary for children who have emotional difficulties, and parents who collaborate with schools maximize the chances of educational success for their children. Children with disruptive behavior disorders frequently are involved with the courts. This involvement, although always stressful, often contributes to the limit-setting efforts of parents who are having difficulty in this area. Families who are attempting to control their children can have their efforts strengthened when the behavioral consequences for breaking the law are applied by a legal agency.

---

### CASE ILLUSTRATION<sup>1</sup>

Merrilee, a 15-year-old girl, was referred by her maternal grandmother, with whom she was living. She had been expelled from school, become increasingly oppositional, and experienced depressive symptoms with vague suicidal ideation. Merrilee would return to her mother's home for periods of time, only to get into conflicts with Mandy, her mother, and Bob, her mother's live-in boyfriend of 8 years' duration. Merrilee's father and Mandy had divorced when Merrilee was 3 years old (Fig. 84.1).

The initial *formulation* of family problems included a mother dependent on her daughter for affection, an immature “stepfather” with limited vocational skills and low self-esteem, and a maternal grandmother viewed by the mother as intrusive. Merrilee's adolescent behavior disturbance seemed the culmination of persistent developmental problems. Her two younger half-siblings, Bob's sons, aged 6 and 4 years, also were suspected of having difficulty.

Merrilee was hospitalized to ensure safety, complete a diagnostic evaluation, and initiate pharmacotherapy. *stabilized the crisis*, and resulted in a thorough assessment of familial strengths and liabilities. Contacts with community resources—mental health agency, court, and school—helped prepare for outpatient treatment. Merrilee was noncommunicative in individual and group therapies, but did comply with the behavioral expectations of the unit. She was discharged with noticeably improved affect, although she remained defiant.

*Parent education* in behavioral management techniques was an early focus in the outpatient course of treatment that followed hospitalization. Bob and Mandy were taught how to provide Merrilee with consistent discipline, and the family therapist discussed how a nurturant, nonpunitive stance could facilitate Merrilee's acceptance of limits. Mandy related to her daughter as a sister would, indulging her when consistent discipline was indicated. Efforts to get Mandy and Bob to work together to set limits on Merrilee were unsuccessful because she accurately perceived that Bob had no sanctioned role in the family. Merrilee's tyrannical, aggressive behavior toward her 6-year-old half-brother necessitated *intervention in family process*.

Merrilee's rejection of Bob's authority revealed problems in family structure. Bob was not supported by Mandy, and Merrilee took advantage of this fact, often commenting, “You are not my father.” Mandy frequently joined her daughter in berating Bob, exacerbating family tension. This structural problem made effective behavioral control of Merrilee impossible. It appeared that commitment in the couple's relationship was tenuous and that perhaps Mandy was continuing the relationship only because of the income she received from Bob's Social Security disability benefits.

A family intervention attempted to strengthen the parents' relationship and decrease the control of the grandmother, who not only allowed Merrilee to stay in her home but was caring for Jacob, the 4-year-old half-brother. Efforts were made to have both Jacob and Merrilee return home, with Bob and Mandy working together to provide nurture and discipline. Parent education and intervention in family process were frustrated by the *sig* *individual needs of parents*.

Mandy was a self-preoccupied woman who had experienced a severe burn when she was a young child. Some facial disfigurement and a father who spent all of her developmental years incarcerated seemed important factors in her low self-esteem. Mandy's choice of husbands further reflected a low self-concept. Merrilee's father, Mandy's first husband, abandoned the family, and Bob, 8 years her junior, had cognitive impairments that were associated with employment difficulties. Individual sessions with each parent revealed their feelings of being overwhelmed with raising three children. The role of grandmother took on a new perspective. Individual contacts with the grandmother revealed her to be less intrusive and more the family safety net, providing support and structure for a couple that desperately needed it. Merrilee refused individual therapy but received some support from a group intervention. Merrilee became increasingly aggressive toward John, the 6-year-old. It became apparent that the reunification of the family, with all three children in the home, taxed the parents as individuals and their relationship.

Bob fled from the responsibilities of parenting while Mandy undermined Bob, refusing to marry him. This inadequate parental coalition precluded effective parenting. Family process interventions, thus, became secondary to an evaluation of Bob and Mandy's relationship and its future. Little hope was offered for the children's stability without clarification of their relationship. Several episodes occurred in which Bob impulsively left the home or was asked by Mandy *Marital therapy* reviewed these conflicts and their antecedents, with the goal of enhancing Bob's and Mandy's skills in resolving conflict.

School personnel initiated contacts with the family therapists (a cotherapy team) to *iden* *problems with sibling*, John and Jacob. John was seen as an aggressive, noncompliant boy, whereas Jacob was seen as distractible, preoccupied, and impulsive. They appeared to be in competition with each other for the affections of teachers. Individual assessments and psychotherapy were offered to the boys, with Bob and Mandy receiving further, developmentally oriented parent management training.

The treatment of this disorganized family was fraught with difficulty, and the process described had several recursive loops. Well into treatment, Merrilee required rehospitalization for aggressive behavior and experienced legal detention for destruction of property. The family received in-home, behavioral parent training for several months. Ultimately, Merrilee could not be integrated into her mother's home, and when residential placement was unavailable, she was permanently placed with her grandmother. This boundary clarification seemed to help Mandy and Bob to focus on the needs of John and Jacob, who remained with them. John's and Jacob's behavior improved in the school setting, although in individual sessions they both manifested indications of insecurity related to their father's impermanence in the family. The parents made some progress with their individual conflicts but continued to have difficulty with a long-term commitment in their relationship and experienced another physical separation.

The continuing availability of the family therapists, who identified the needs of individual family members and the need for family system alterations, served an organizing function for this multiproblem family. When the therapists identified *theadjunctive supports outside clinical session*, they coordinated family therapy with the activities of other agencies.

---

## CLINICAL ISSUES

### Indications for Family Therapy

Family treatment, in some form, always is indicated in treating children, and usually indicated in treating adolescents ( [McDermott, 1981](#)). The family is the developmental context of each child's life and can powerfully impede a child's development or dramatically aid it. Although families always must be involved, the specific target of intervention—individual parent or child, marital unit, or entire group—varies. With some disorders, the family is viewed as etiologically important in the onset and evolution of disorder (e.g., conduct disorder). Here, the clinician empathically explores family conflict and educates the family about their role in the child's disorder. With other disorders (e.g., autism), family interactions and responses are seen as the response to illness in the child. In these instances, the therapist empathically supports the family and provides sources of referral for further support. [Table 84.3](#) offers some guidance to the clinician in making this difficult, yet important, distinction.

Family health is suggested when some of the following characteristics are present. The more characteristics are evident, the more confidence the family therapist can have that observed family interactions are the cause of a child's disorder and therapy should emphatically support the family.
1. Parents understand developmental norms.
2. Parents are free of major psychiatric disorders.
3. Parents are committed to their children's well-being.
4. Parents have been exposed to their child's needs.
5. The family has members (includes grandparent) who have mastered developmental tasks.
6. The family does not have a child with demonstrable organic deficit.
7. Parents are mutually supportive.
8. Child's behavior is not demonstrably sensitive to environmental change (e.g., conflict with family and other family).
9. Parents have demonstrated effectiveness with other children and settings (i.e., discipline).
10. The identified child has (a) differential responses to the family environment compared with other environments (e.g., "center of home," "corner of home," "room"),
11. Mental disorders occur in other siblings.

### Table 84.3. A Clinical Guide to Determining the Directional Effects of Family Influence

Empathic exploration of family issues is indicated when parental psychopathology complicates parenting efforts; there is empirical and clinical support for the efficacy of family approaches; a clinical problem presents as an interactional problem (e.g., physical conflict between son and father); or a child fails to respond to repeated medication trials.

Empathic support of families is indicated in the treatment of medical disorders such as diabetes, psychiatric disorders with a strong biological component such as schizophrenia, and neurologic disorders such as mental retardation and autism. The overwhelming stresses faced by families of such ill children require the mobilization of individual and community support. Education, respite care for children, and linkage with support agencies are all important adjuncts to family treatment.

#### Contraindications to Family Therapy

The main areas of contraindication involve legal and ethical issues. In family treatment it is contraindicated to:

1. Repeatedly involve individuals who are not regularly involved in a child's life.
2. Continue to work jointly with parents who are divorced. Ongoing work with each parent and new family unit should occur, but in separate sessions. This decreases confusion for the young child and minimizes the chances of reawakening old conflicts in the adolescent.
3. Conduct family therapy that increases the potential for harm to family members. The family therapist may find that intense affects emerge during the exploration of family conflicts. Careful monitoring of these affects is imperative and, at times, a cessation of this type of uncovering work is indicated.

#### Complications

Family therapy can have dramatic effects relatively quickly. When progress does not occur, the clinician should be alert to several of the common impediments to successful treatment.

1. Minimal father involvement. Mothers often bring children by themselves for treatment. Fathers either resist the process of intervention or are physically unavailable. When fathers do get involved in treatment, progress still may be difficult, but the chances of success are increased.
2. Lack of clinician objectivity. Family problems mobilize strong countertransference responses. Affect-laden areas such as child-rearing practices, divorce, human sexuality, and gender role may be areas that clinicians are dealing with in their own lives. Unconscious clinician attitudes may negatively affect treatment.
3. Inattention to nonnuclear family relationships. Some relationships may have significant potential to be a resource for the child (e.g., a mother's boyfriend), whereas others may be counteracting the positive effects of therapy (e.g., an intrusive grandparent). These factors must be accounted for in planning family therapy.
4. Lack of appreciation of the cultural context of the family. Norms of expected family development and child development vary according to culture and socioeconomic level. Treatment approaches should be adjusted accordingly.
5. An inaccurate formulation of the family's role in the child's disorder. Progress is frustrated when families are inappropriately held responsible for a child's biologically based disorder. On the other hand, progress is delayed when a family receives support when its conflicts should be explored and change expected. When the latter is operative, it often is complicated by excessive reliance on medication interventions ( [Sprengr and Josephson, 1998](#)).

#### Ethical Issues

Most ethical issues in family therapy are related to issues of confidentiality and the clinician–patient relationship ( [Jensen et al., 1989](#)). In family therapy, the therapist relates simultaneously to other members of the family, in addition to the identified patient. The family therapist can comfortably discuss, with any family member, material that previously emerged in family sessions. Dilemmas arise when information that a family member shares with the therapist, in the absence of certain family members, has relevance to those members. In this instance, the therapist must encourage the individual to bring this information into future family sessions. With discerning clinical judgment and permission of the individual, the clinician may initiate sharing the information with the family.

Family therapy initially may focus on an identified patient, but it is not uncommon that as therapy progresses, the concerns, and perhaps disorders, of other family members become a focus for treatment. The therapist is at risk of coming into conflict with the needs of other family members as therapy proceeds. Family members who have not met each other's needs may become less invested in therapy when one member appears to be benefiting most directly from the clinician's intervention. The family therapist must be aware of this issue and make a deliberate attempt to relate to all family members. As the family therapist develops a therapeutic alliance with the whole family, all will accrue benefit. The clinician should make it clear that over time, each family member will be heard and each perspective will be taken into account, even though some sessions may seem to be weighted more toward one member's self-interest than another's.

#### Developmental Considerations

Family therapy differs dramatically according to the constellation of ages presented by the family in treatment. The younger the child, the more likely it is that the nature of the parent–child relationship will determine presentation. Excluding definite organic disease (e.g., autism), caregiving practices are the prime determinant of presentation in infants and toddlers. Parental availability and capability to nurture are important considerations. With toddler and preschool children, parents must be consistent and have significant energy to respond to their consistent demands and provide the structure they require. As the child enters formal schooling, families must facilitate success and competence in academic endeavors. Mastery of these endeavors is heightened through consistent, structuring efforts of an available parent. It is at this stage that parents usually recognize the strengths of their children and try to maximize them, as well as minimize weaknesses. Adolescent children present numerous dilemmas because they often request independence without demonstrating the competence to handle such independence. Emotions involved with physical and geographic moving away from the family are significant for both the parent and adolescent. The increased contemporary potential for negative consequences of high-risk behaviors involving drugs, motor vehicles, and sexuality brings a sense of urgency to many family therapy approaches to adolescent disorders.

#### Cultural Issues

In the family therapy literature, there is an increased exploration of the relationship of family dynamics to social class. Some of the relevant issues include the phenomenology of class-specific family dynamics, cultural differences in normative family processes and values, consequences of social class prejudice and discrimination, and clinician–patient interactional difficulties when social class and cultural differences exist ( [Canino and Inclan, 2001](#)). Families dropping out of therapy may be due to therapist lack of cultural awareness or therapist countertransference problems. It is not uncommon for clinicians to have difficulty accepting family styles and interactions that are not part of their own cultural tradition (e.g., the egalitarian therapist confronting a conservative, controlling father).

The family's cultural background influences beliefs about normative family structure, communication style, and child development. With respect to family structure, cultures differ regarding the appropriate level of involvement of the extended family. In some cultures, it is not uncommon for the extended family to be significantly involved in family life, including extended family members living in the same domicile. In contrast, most North American families are typecast as nuclear without intimate extended family involvements, with blended families and single-parent families becoming increasingly common variants. Despite differences in family structure, families in each culture must meet the many developmental needs of children.

Culture influences the range of emotional expression acceptable in typical family communication. For example, family emotional outbursts may appear out of control to some ethnic groups, but may be the norm for others. In like fashion, the clinician may believe a family to show blunted and defensive expression of affect when a narrow range of emotional expression is common in the cultural background of the patient's family. Whatever the stylistic difference, however, clarity and competent problem solving are necessary elements of successful communication of families in all cultures.

## WORLD VIEW

Many family beliefs and values with respect to child rearing are directly influenced by a family's religion, world view, or philosophy of life ( [Josephson, 2000b](#)). It is important for the clinician to understand the characteristics of a family's world view, an underappreciated component of cultural influence. If this world view is distinctly different from that of the clinician, it is important to have the family explain these aspects of their culture to the clinician, who should respond in an open manner. Joining with the family in a discussion of their world view can clarify some diagnostic issues and potentially increase treatment alliance. On occasion, family therapy may need to be conducted with the aid of someone from the family's culture or religion for the clinician to understand clearly the family milieu that is influencing the developing child.

## ALTERED FORMS OF FAMILY STRUCTURE

In contemporary culture, altered forms of family structure are increasingly common. This includes same-sex parents raising children and multiracial adoptions, with blended families and single-parent families being the two that most frequently affect clinical practice. Blended families refer to a family reconstitution, most commonly after a divorce or the death of a parent. These situations share similarities in that one biological parent is actively removed from day-to-day contact with the child. The key difference is that the divorced parent usually is involved with his or her child's development in an ongoing, albeit intermittent, basis, whereas the absence of a parent through death is an unalterable loss. Consequently, the acceptance of the reality of parental absence is more straightforward, even though the circumstances of death can affect its impact on the family.

When a child's biological parent forms a new union with a stepparent, the family therapist must consider the numerous challenges such families face in realigning their relationships. It is important for the family therapist to understand how the children were prepared for their parent's remarriage, as well as whether the biological parent and the stepparent reviewed the unique needs of each child involved in the transition. Did the biological parent make clear what was expected of his or her new partner? Did the stepparent have the opportunity to express concerns he or she had about the new union and its attendant parenting tasks?

Family therapy of the children of divorce must consider that children, consciously and unconsciously, often long for reunification of the biological parents. This can continue many years after a remarriage and the formation of the new, blended family. Such a persistent desire often explains hostility toward the stepparent that frustrates the development of family harmony.

When the blending of families results in children of two previous families becoming step-siblings, the complexity of interactions increases. Intense affects can be generated by such things as favoritism between a biological parent and a biological child and frank competition between step-siblings and biological siblings for the affection of parents. Practical matters such as arranging visitation schedules and dealing with child support often take a significant amount of family time, particularly if they are associated with ongoing conflict. ( [Visher and Visher, 1988](#)).

Single parents include those previously married and those widowed, as well as those never married. The family therapist must be aware that because the demands of single parenting are significant, there often are surrogate caretakers and other adults who are involved with children. The family therapist must make every effort to inquire whether such individuals exert a significant influence on the child being treated and, if so, they should be included as part of the assessment. It is important for the therapist to consider the single parent's resources, time and financial, the number of children in the household, and the sex of the children. There are unique challenges for the single parent associated with raising a same-sex child and an opposite-sex child ( [Josephson, 1998c](#)).

## Training

There remains debate regarding the appropriate approach to family therapy training for child and adolescent psychiatrists. This debate is embedded in the larger question of how much and what type of psychotherapy training a child and adolescent psychiatrist should receive. An information explosion has inundated child and adolescent psychiatry curricula with significant amounts of new information, typically in the area of neurobiology. This is occurring at the same time that family fragmentation and other social difficulties are stressing children increasingly ( [Achenbach and Howell, 1993](#)).

The classic approach to family therapy training focuses on the trainee learning one approach, or school, thoroughly as a foundation for the subsequent incorporation of new knowledge. The educational premise is that through learning one family therapy approach, the family therapist internalizes the systemic perspective. This approach is likely more effective than residents trying to master several schools of therapy and collecting knowledge of various techniques but acquiring limited conceptual integration. On the other hand, competing schools' claims for uniqueness have given way to consensus on the important areas of family assessment and intervention. It now seems clear that family therapy needs to integrate both systemic and psychodynamic perspectives. The next generation of training in family therapy will likely be more eclectic and pragmatic, and more easily assimilated by child and adolescent psychiatry residents. The ongoing challenge will remain, as it does for any psychosocial treatment, to continue to have family treatment as a vital part of the child and adolescent psychiatrist's therapeutic armamentarium.

## RESEARCH AND FAMILY THERAPY

[Gurman et al. \(1986\)](#) made the direct pronouncement, based on their monumental review of the marital and family therapy literature, that "family therapy no longer needs to justify itself on empirical grounds." Since then, however, there have been further reviews that have indicated gradual and substantive research advances in demonstrating positive family therapy outcomes ( [Asen et al., 1991](#); [Combrinck-Graham, 1990](#); [Diamond, 2001](#); [Diamond et al., 1996](#)).

There remain significant challenges in that many studies have been difficult to assess because they use heterogeneous patient samples, including patients with different diagnoses and at different developmental levels. In addition, studies of family therapy outcome continue to be more frequent in the population of adult psychiatric patients than in the child and adolescent population.

Not surprisingly, the marginalization of family therapy from the field of psychiatry affected family therapy research. The scientific method clashed with the systems approach of many early family therapists. The systems view, that pathology was maintained by recursive feedback loops and did not reside in the patient, rendered traditional methods of research inappropriate for assessing the family. As an example, research that focused on measures of individual patient outcome was discouraged. Over the last several decades, however, new developments in developmental psychopathology research and increased eclecticism in clinical practice, including the use of behavioral and educational approaches in family therapy, have opened up research avenues. Research in family treatment now assesses behavioral approaches, educational approaches, as well as systemic and psychodynamic approaches. As a result, it is increasingly acceptable to use individual patient characteristics as research outcome measures.

There is general consensus that family therapy approaches have been shown to be effective for treating schizophrenia (i.e. adolescent patients), conduct disorder, and substance abuse. There are some data to support its effectiveness in treating eating disorders, although this has been controversial. The extant research literature in the family therapy of externalizing disorders significantly outweighs the literature on the family treatment of internalizing disorders. The family treatment of internalizing disorders, such as anxiety disorders and depressive disorders, shows promise in that family risk factors are quite prominent in these disorders. This discussion of research follows the approach of [Diamond et al. \(1996\)](#), who discussed family risk factors for disorder as a prelude to reviewing the research on outcomes of family treatments for specific disorders.

The rationale for discussion of family risk factors is important. Given the difficulties in family therapy outcome and process research, it is important that epidemiologic research can first establish that family risk factors are, indeed, associated with disorder. Designing family interventions to diminish risk factors is consistent with medical research in disorders of unknown etiology but with known risk factors (e.g., cardiovascular disease). Although the risk factor for a pathologic family process (e.g., parental harshness) may be a focus for family intervention, this does not imply the process is specific to a particular disorder. In addition, it is incumbent on the clinician to maintain a bidirectional perspective, considering that an apparent family risk factor may be a cause, or effect, of the disorder in question.

## Schizophrenia

The interaction patterns of negative attributions about a patient's illness and high levels of parental overinvolvement, hostility, and criticism have been shown to increase rates of relapse of adult schizophrenic patients ( [Vaughn and Leff, 1976](#)) and to predict adolescent onset of schizophrenia ( [Doane et al., 1981](#)). This line of research, originally focusing on adult psychiatric patients in Britain ( [Brown et al., 1972](#)), was followed up by American research by Goldstein et al. in 1978 that

showed that a reduction of expressed emotion during treatment reduced the likelihood of relapse in adolescent patients.

At this point, several psychoeducational approaches have been well studied and shown to be successful. These programs focus on reducing expressed emotion and increasing positive family interaction and coping. Numerous intervention trials in adolescents as well as adults ( [Diamond, 1996](#)) have demonstrated that medication and family intervention provide better prophylaxis against rehospitalization than medication alone. Although questions remain regarding the contribution of family environment to this disorder, there is no longer a question whether family treatment for this population is effective.

### **Conduct Disorder**

Conduct disorder is the child and adolescent psychiatric condition that has the clearest documentation of family risk factors. Numerous reviews ( [Diamond et al., 1996](#); [Kazdin, 1987](#)) have shown that such factors as harsh and inconsistent discipline, marital discord, single parenthood, and parental psychopathology (e.g., substance abuse) have all been linked to conduct disorder. One widely discussed family interactional pattern is that of [Patterson \(1982\)](#), who described the cycle of reciprocal, coercive processes in families that reinforce aggressive child behavior and inconsistent parenting responses.

Parent management training, which teaches parents to be more consistent with their behavioral contingencies, more clear in their communication of behavioral expectations, and more available to nurture their children, has shown positive results. Follow-up studies have found parent management training to have long-term benefits ([McMahon, 1994](#)). Several studies of functional family therapy ([Alexander, 1988](#)) have shown that improvement in family interaction is associated with treatment gains and lower relapse rates in juvenile delinquents. Functional family therapy sees conduct disorder symptoms as maladaptive, yet legitimate in their overall functional significance. In this approach, therapists attempt to “relevance” behavior as a way of decreasing defensiveness and blame by reframing the child's conduct problems as a way of getting his or her needs met. Several variations of family-based treatments of conduct disorder have been shown to be effective, including augmentation with individual and group treatments. Individual treatments have been shown to be more effective when used in conjunction with marital and family interventions ([Dadds et al., 1987](#)).

Family treatments of conduct disorder recently have gone beyond family to include other systems. [Henggeler et al. \(1998\)](#) have extensively studied multisystemic therapy (MST), an intensive family- and community-based treatment that addresses multiple systemic determinants of serious antisocial behavior. The intervention is based on the premise that, in addition to family, conduct-disordered adolescents are involved in a complex network of interconnected systems that includes peers, school, and neighborhood. MST uses a home-based model of service delivery that attempts to improve parenting skills and increase parental emotional resources needed to raise teenage children. Correspondingly, the intervention attempts to empower youth to cope with serious social problems in their neighborhoods. The MST program has demonstrated the reduction in long-term rate of criminal offending in serious juvenile offenders, reduced rates of out-of-home placement, improvement in family functioning, and, most recently, reduction of days in hospital when hospitalization is needed.

### **Attention Deficit/Hyperactivity Disorder**

Family risk factors for attention deficit/hyperactivity disorder (ADHD) often are confounded by the significant comorbid presentation of conduct problems and oppositional defiant disorder. When a child with ADHD has symptoms of oppositional defiant disorder, families typically have greater conflict, anger, and rebelliousness, along with more aversive and negative communications ([Barkley et al., 1992](#)).

Most studies of treatment outcome in the ADHD population focus on pharmacotherapy and behavioral treatments. The National Institutes of Health Consensus Development Conference ([National Institutes of Health, 2000](#)) indicated that pharmacotherapy treatments of ADHD demonstrated better outcome than behavioral approaches. There was some suggestion that combined behavioral and pharmacotherapy approaches had some advantages over sole approaches, but the advantages were deemed modest. This study recommended the need for longer-term studies, beyond 14 months, to assess outcome better. Family therapy has not been formally studied in this population, yet, clearly, any implementation of behavioral paradigms must involve parents. One longitudinal study ([Satterfield et al., 1987](#)) demonstrated that stimulant medication in combination with long-term, multimodal psychosocial treatment had better outcome, with respect to the presence of conduct problems, than did long-term medication treatment alone. These results were maintained at a 9-year follow-up assessment.

### **Substance Abuse**

Adolescent substance abuse is associated with chronic family conflict, parental substance abuse, inadequate parent–child attachment, and coercive, inconsistent parenting ([Liddle and Dakof, 1994](#)). These factors are similar to the family risk factors for conduct disorder, which is not surprising in light of the significant comorbidity of the two conditions.

In widely quoted work, [Stanton and Todd \(1982\)](#) effectively applied structural and strategic family therapy to patients receiving methadone. Since that work, numerous studies ([Diamond et al., 1996](#)) have demonstrated the superiority of brief family treatments over individual and group treatments for reducing drug use. Family treatments had lower attrition rates, and it also has been demonstrated ([Szapocznik et al., 1988](#)) that family treatment approaches significantly increased the likelihood of adolescents attending the first treatment session. A significant development in the empirical assessment of family-based treatments in 1992 was the establishment of the Center For Research on Adolescent Drug Abuse at Temple University (CRADA), which was dedicated to family-based treatment research.

### **Depression**

Four family factors have been repeatedly associated with the onset of a depressive disorder in children and adolescents. These include neglect and poor parent–child attachment, hostility between parent and child, parental psychopathology, and ineffective parenting practices. Although these factors obviously are not specific, and associated with other psychopathology, they are highly predictive of depression ([Beardslee et al., 1996](#); [Sexson et al., 2001](#)).

Treatment studies of depressed youth continue to be relatively sparse. Few have targeted family relationships as primary treatment foci ([Brent et al., 1997](#)). This appears likely to change because several innovative approaches in the family therapy for the treatment of depressed adolescents are evolving ([Diamond and Siqueland, 1995](#)).

### **Anxiety Disorders**

Family risk factors for anxiety disorders are not as clearly delineated, and treatment studies on anxiety also are lacking. Current studies suggest that a parent with an anxiety disorder increases the likelihood that his or her offspring will also have a similar disorder. Parental anxieties toward fear-producing situations appear to be communicated to the child in explicit or implicit ways ([King and Noshpitz, 1991](#)). An epidemiologic study suggests that family difficulties in the areas of role performance, values, and norms were identified in the families of school-refusing, anxious children ([Bernstein et al., 1990](#)). Family risk factors appear to covary for both anxious and depressed children.

Family-based treatment research is focused on parents administering cognitively based interventions for the treatment of fears and general anxiety. Although cognitive–behavioral treatment approaches have gained ascendance, one study suggests that when family intervention is coupled with cognitive–behavioral treatment, treatment effectiveness is enhanced ([Barrett et al, 1993](#)).

### **Eating Disorders: Anorexia Nervosa and Bulimia Nervosa**

[Humphrey \(1994\)](#) has differentiated subgroups of families in which a child has an eating disorder. A review of these studies suggests that families with a bulimic child, or a child with both bulimic and anorectic symptoms, show more hostility, chaos, isolation, and impulse disorders. Families of children who have only the symptoms of anorexia nervosa demonstrate less externalizing behaviors, yet show evidence of rigidity, dependency, and emotional restrictiveness.

Family therapy has, for some time, been seen as a core component in the treatment of eating disorders ([Lange et al., 1993](#)). This tradition was stimulated by research on the use of structural family therapy by [Minuchin and colleagues \(1975\)](#) in the treatment of families of anorectic patients and other “psychosomatic families.” Subsequent studies have not confirmed a specific anorexigenic family structure ([Ravenscroft, 1996](#)). There continues to be evidence, however, that family factors do influence the emergence and maintenance of eating disorders and that a flexible treatment approach, using family treatment with other modalities, is clearly indicated and likely effective. [Russell et al. \(1987\)](#) found, and confirmed in 5-year follow-up ([Russell et al., 1994](#)), that family therapy produced better maintenance of weight gains and improved menstrual functioning for adolescents when clinical problems had developed within 3 years of the initiation of treatment. Russell et al. found that

older patients improved more from individual therapy compared with family therapy. The assessment and treatment of family interaction continues to be important for patients with eating disorders, particularly younger patients.

## Metaanalytic Reviews

[Diamond \(1996\)](#) has reported on three metaanalytic studies of family therapy. Metaanalysis is a statistical method by which results from several different studies are standardized and then combined to yield an average effect size. The three studies reported by Diamond suggested that family-based therapies were as effective as other models of intervention. This review suggested that more valid estimates of efficacy can be derived only from larger samples of well designed studies. Several problems exist in this methodology, including the overrepresentation of externalizing disorders in family metaanalytic studies.

## Family Treatment Process Research

Since 1990, family process research has made modest, but steady, advances. In contrast to outcome studies that determine the results of an overall treatment intervention, process research goes into greater detail on how specific processes of therapy contribute to outcome. A key concern of process research is the study of patterns of patient–therapist interaction that lead to intrasession change. This methodology attempts to operationalize and validate basic techniques of family therapy. Techniques studied have included assessing the effects of cross-generational coalitions between parent and child; reframing; contributing to a more positive attributional set about a problem; and paradoxical interventions. Clearly, mapping in session therapy sequences and tying them to outcome represents an advance in the ability to understand the mechanisms of change in family therapy ([Diamond, 1996](#)).

In summary, there is an evolving empirical tradition in family treatments. Outcome studies suggest positive results when family therapy is used in conduct disorders, schizophrenia, and substance abuse, with encouraging findings in eating disorders. Based on family risk research, there appears to be potential in using family therapy approaches for the internalizing disorders. Research in family therapy will benefit from (a) replications of previous studies; (b) more studies in the area of internalizing disorders such as anxiety and depression; (c) treatment models developed from basic psychopathology and process research; (d) increased development of reliable, valid, and treatment-sensitive family assessment tools; (e) assessment of treatment models in community (i.e. “real world”) settings; and (f) focus on parental psychopathology and marital conflict ([Diamond, 2001](#); [Diamond et al., 1996](#)).

## THE FUTURE

The future of family therapy remains bright, while at the same time the field faces numerous challenges. Family therapy will always maintain an intuitive advantage compared with other psychosocial therapies. Simply, without families children would not exist. Parents create children and either facilitate their journey into adulthood or frustrate this natural developmental passage. As our science proceeds and child and adolescent psychiatrists can discern when, and how, to intervene more effectively with families, children will benefit. Yet, there remain limitations to implementing family therapy effectively in today’s child and adolescent psychiatry.

Systems-oriented clinicians still are reluctant to accept current psychiatric diagnostic nomenclature. Although the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* includes Axis IV, delineating psychosocial problems, this has not satisfied many family therapists. In the absence of a relational disorders classification, the existing nomenclature still describes disorders in an individual, contrary to the basic systems postulate that symptoms do not reside in individuals but result from family context. There is hope that this controversy will recede as integrated approaches to treatment emphasize the compatibility of individual dynamic, developmental, and systems approaches.

The explosive development of the neurosciences has broadened the diagnostic and treatment capability of the contemporary child and adolescent psychiatrist. Contrarily, its emphasis has obscured the clinical reality that most disorders result from a combination of biological, psychological, and social vulnerabilities. Psychosocial variables can protect children from expressing disorders with biological contributions, whereas psychosocial stresses can foster the clinical expression of a biological vulnerability. The clinical correlate of this fact is that families have strengths and weaknesses with broad implications for family therapy. Many psychiatric training programs are having difficulty conveying this broad picture of psychiatry.

If the revolution in neurosciences was not enough, an economic revolution in health care has added to the challenges of the family-oriented clinician. Many third-party payors resist reimbursing for family therapy because it is seen as psychosocial support and not a defined medical treatment. The changes in health care delivery greatly influence the characteristics of psychiatric treatment and the roles of the respective mental health disciplines. It is not uncommon for the child and adolescent psychiatrist to be reimbursed solely for providing biological treatments and the nonmedical therapist for providing psychosocial treatments, such as family therapy.

Within a generation, the definition of the family has shifted to the point where it is often a matter of contentious debate. It has become difficult to enter into a rational discourse about the family, even if it includes factual data, without offending some constituency. Are there better ways to raise children than others? Are some forms of family structure healthier than others? These straightforward questions can become inflammatory and difficult to discuss, even in some academic settings. What does seem clear is that the developmental needs of the children have not changed. The family of the future, however defined, must continue to meet these developmental needs.

## CONCLUSION

Any brief review of family therapy in child and adolescent psychiatry only scratches the surface. This chapter has reviewed historical antecedents, current status of the field, a review of basic clinical processes and issues, a discussion of the disorders that appear to be helped most directly by family therapy, and a summary of future challenges. There is much yet to be learned. Working with the family of the child or adolescent psychiatric patient is of critical relevance. Child and adolescent psychiatrists remain mental health practitioners with a broad perspective on working with individuals at all stages of development and at all levels of the biopsychosocial continuum. The family is at the heart of a developmental, biopsychosocial perspective that remains the core of our field.

[Summary](#)  
[Chapter References](#)

The purpose of this chapter is to describe psychotherapeutic work with parents as a means of helping the child who is being seen in psychiatric outpatient settings. The discussion begins with the rationale for engaging parents in the child's treatment, proceeds to issues to be considered in the assessment evaluation processes, and reports on primarily evidence-based interventions with parents relevant to the child's difficulties. Parent work is described here, using multiple program examples, as an integrated model of therapy that uses many approaches, including cognitive-behavioral and psychodynamic methods, as determined by the needs of the child and family.

Parent work rests on a model that is child centered and family focused ([Stroul and Friedman, 1996](#)). This implies that the types and combination of services provided must be driven by the needs of the child and his or her family. It also means a commitment to adapting the services to suit the child and family, not the other way around. Also implicit is providing services to the child within the context of the family and maintaining the integrity of the family wherever possible. Children must not be served by a bifurcated system, one that separates them from the significant adults in their life. In most cases, parents are primary caregivers, and according to the system of care philosophy they must be supported, assisted, and involved in every decision regarding service delivery ([Stroul and Friedman, 1996](#)). Professionals and families need to work together in relationships of respect and mutual support in all aspects of planning, program development, service delivery, and evaluation. Families need to have the lead voice, as well as choice, in decisions regarding treatment plans for their children. Our charge is to operationalize this inclusive model in both training and practice.

[Jones \(1999\)](#) tracked the evolution of the child guidance movement from its roots in the Juvenile Psychopathic Institute in the last decade of the 19th century to its expansion in the 1920s and 1930s and into the present. This movement was characterized by an ecologic perspective that focused on the role of the family and society in the child's development. However, Jones proposes that along with this growth, problems emerged that propelled the field of child mental health into a problematic situation, namely an erosion of the team concept of psychiatrist, social worker, and psychologist in which psychotherapy was in the domain of any of the three disciplines. Jones argued that the role of society and family in the practice of child mental health and such factors as culture, economics, and education have not received enough attention. The lack of attention in training programs given to working with parents also has been emphasized by [Jellinek \(1986\)](#). The early philosophy of the child guidance movement was reintroduced in September 2000 when the Surgeon General proposed a paradigm shift—in effect, a return to an ecologic approach in the delivery of child mental health services ([U.S. Public Health Service, 1999](#)). A federal initiative, The Child and Adolescent Service System Program (CASSP), has, in fact, for over a decade tried to implement such a model in the service system ([Stroul and Friedman, 1996](#)). We believe it is important to integrate both the medical model, with its contribution to diagnostic understanding of a problem, with the ecologic model, which supports the team approach and recognizes the multiple factors in a child's life.

The same social factors that gave impetus to the child guidance model in the 1920s, when parents were in a quandary over how to deal with their “flapper”-influenced children, is mirrored today as our society confronts a mobile lifestyle and varied family structure with few precedents to offer guidance, support, or preparation. The rationale for working with parents should be obvious. However, the diminishment of the team approach and the ecologic model alluded to earlier, as well as the limitations set by managed care, have created barriers to engaging parents in child treatment.

### RATIONALE FOR PARENT WORK

Poor parenting can create, maintain, and exacerbate child behavioral problems through a number of negative patterns (see also [Chapter 86](#)) and negative reinforcement. [Patterson \(1982\)](#) described a “cycle of reciprocal coercion” whereby parents inadvertently encourage bad behavior. In turn, difficult children can place heavy burdens on parents and families.

Child behavior and parents' relationships with their children are partially rooted in the affective life and in the parents' unconscious issues and conflicts ([Freud, 1960](#)). Because of the tendency of humans to replicate behavior patterns unconsciously over time, the parent-child relationship often becomes the arena in which parents reenact with their children aspects of relationships with their own parents ([Fraiberg, 1954](#)). In theory, once the parents' intrapsychic issues and conflicts are identified, worked through, and resolved at some higher level of integration, the child should be less burdened with the parent's emotional legacies.

Hence, parent work that is psychodynamically informed relies primarily on principles that encourage parents to understand the ways in which they have repeated their own childhood experiences in patterns of behavior as adults, and especially where they have consciously or unconsciously reenacted these experiences with their child. In practice, parent work rests on the assumption of the validity of psychodynamic, behavioral, and cognitive theories. Thus, prerequisites for doing parent work are skills in individual, marital, family, and group interventions based on these theories, as well as knowledge of child and adult development. Awareness of indications for psychoanalysis, psychopharmacologic therapy, and psychological testing also is required for purposes of referral. In addition, clinicians need to be familiar with services provided by schools, pediatricians, day care centers, and other community agencies that touch the lives of the child and his or her family.

### ASSESSMENT OF PARENTAL INFLUENCES

Before determining what type of intervention is needed, an assessment of the parent should be completed. This assessment should include (a) the nature of the parents' difficulties with the child, (b) individual attributes of each parent, and (c) motivation for treatment. A guideline for the assessment of the parent is shown in [Table 85.1](#).

<b>Reason for referral</b>
By whom, and for what reason
Parents' concerns, their "diagnosis," and their prediction of the outcome
<b>Family history</b>
Family constellation: identifying essential descriptive data regarding members of the household such as age, employment, cultural and religious affiliations, living conditions
Parent presentation: impressions, including relevant physical presentation, degree of comfort or anxiety in interview situation, affective presentation, relative contribution of each parent, agreement or disagreement in describing the child
Individual history of each parent
Marital history: Describe adjustment in current marriage/ previous marriages as significant
<b>Family style</b>
Summary of personal, social, environmental, academic, psychiatric, and medical history: relevant peer and family relationships, should include strengths and weaknesses
Discipline style of parents: How does the parents' (co)parental perspective compare with the child and siblings (if any) and with parents when they were child's age?
Developmental history: Significant history of pregnancy, labor and delivery, infancy, sleeping, eating, talking, motor development, language, play interests, attitudes and fears, aggression, relationships
Medical history/psychological testing
Medical/psychiatric history of child as relevant
Genetic consultation of family
Recommendations/disposition (indicate if recommendation accepted)

**Table 85.1. Parent Evaluation Outline**

The complete family history is indispensable for understanding the complexities of the child and his or her family. In the family constellation, it is important to know who are the people in the life of the child. Their age, cultural and religious influences, employment, education, socioeconomic status, and living conditions need to be explored.

The marital history and individual history of each parent are key components of the parent assessment. In taking a history, the clinician often learns that an adult's relationship with his or her child mirrors the one he or she had with a parental figure. The interviewer may find that the child and his or her siblings are replicating the marital conflict. During history taking, dynamics such as repetition compulsion and primitive defenses (e.g., projective identification), which are having a deleterious effect on the child, may be revealed. The parents' own histories influence how each of them cope with a child who is handicapped with pervasive developmental disorder, autism, Tourette's disorder, retardation, and other serious impairments (Lefley, 1987; McLoughlin, 1992). The family style, including the degree of affection and support available to family members, the degree of conflict and anger in the family, and how conflict and anger are managed, is crucial to assess. Whether the child is reacting to parental/family dynamics or bears his or her own serious mental illness, the individual history of each parent, the marital history, and the family style all are crucial elements in understanding the child in the context of the family.

As we have mentioned, possibly the most important issue to explore when evaluating parents is whether they appear to be projecting their own conscious or unconscious conflicts onto the child or are in some other way using the child as a vehicle through which they reenact an aspect of their own emotional histories or current life problems. If so, it must be further determined whether this conflict is limited to a relatively small area of the relationship or if it is all-inclusive. "Good enough" parents can identify and maintain parental, marital, and generational boundaries. Sometimes the parents' difficulties in maintaining such boundaries are part of a characterologic problem. In this case, individual psychotherapy may be indicated for the parent.

If the assessment determines that the parent is ready to continue and if the situation is a suitable one for outpatient clinic treatment, regular, usually weekly or semiweekly, appointments with both parent and child are scheduled. Optimally, although it is not always possible, the child should see his or her own therapist, while the parents work simultaneously with their therapist. The process that takes place is referred to as *parent work* rather than *parent guidance*, *parent training*, *counseling*, *parent psychotherapy*, or some other denominator because these other terms are restrictive and usually are subsets of the larger domain of the interventions used with parents.

## SPECTRUM OF INTERVENTIONS IN PARENT WORK

The services offered in the course of parent work after the evaluation are selected from a spectrum of potential interventions (Armbruster and Fallon, 1994). It is not unusual to use a psychodynamic approach with one set of parents, and to use a cognitive-behavioral approach with another, or both, during the course of a given treatment. Even among that group of parents with whom the psychodynamic model is appropriate, the clinician might determine that marital therapy (Scarf, 1987) is the best way of treating one couple, whereas in the case of another family, she or he might make the assessment that intensive psychodynamic psychotherapy with only one member of the marital dyad is the intervention that is most likely to be effective (Chethick, 1976, 1989; Fromm-Reichmann, 1950). The goal is to free the child from the conflict that has been displaced from the marital to the parent-child relationship. If, in the course of this work, an issue arises that suggests a more educative or informational approach, the work can shift from psychotherapy to parent guidance. In Hollis and Woods' (1981) topology, a dynamic intervention shifts to a didactic one. If parents do not have the capacity for reflection and their observing ego functioning is limited, a cognitive-behavioral approach may be the most useful. However, the cognitive-behavioral approach has been shown to be very successful for working with a variety of parents of children with externalizing behaviors (Kazdin, 1997a; McMahan, 1999). The parent work may rest with such approaches or return to a more insight-oriented intervention. The clinician also needs to interact with others in the child's environment, such as noncustodial parents, stepparents, relatives, teachers, and other school personnel.

The flexible, selective use of different, clinically indicated treatment modalities characterizes parent work. These modalities can vary in depth, intensity, and duration, depending on the internal or external situation of the parent at a particular time. This spectrum of intervention includes but is not limited to parent guidance, supportive therapy, and psychoanalysis. Marital, individual, group, and family therapy also may be used, depending on the clinical issue. At times, the parents may be seen exclusively or more frequently than the child. This is true particularly if parents have unresolved issues from their own childhood or mental health problems, or need help in structuring the home environment and disciplining the child.

To determine an appropriate treatment modality, the goal of the parent work always must be kept in mind: to help the child by helping the parent. The challenge of parent work is to facilitate parents' understanding of their relationship with their child and to help them achieve some resolution of their own conflicts manifested in their behavior, especially when these behaviors are specific to the interactions with the child (Armbruster and Fallon, 1994).

## TREATMENT CHOICES FOR SPECIFIC DISORDERS IN CHILDREN

### Profusion of Treatment Choices

There are over 200 different treatment approaches in child and adolescent therapy (Kazdin, 1997). However, as mentioned earlier, it is common for therapists to integrate different interventions in response to the needs of parents and their children at different stages in the treatment process (Armbruster and Fallon, 1994; Diamond, 1996; Sargent, 1997). Because it is unlikely that any single method will be able to solve the multifactorial problems that have emerged in today's social climate, parent work may be used in combination with individual, family, or group therapy. In the following text, examples of successful intervention for parents whose children present with a variety of disorders are discussed. Although many of the interventions presented demonstrate positive outcomes for child symptoms, before describing them there are some common limitations of research that need highlighting:

- Few studies investigate the impact of parent outcome on child treatment, and much needs to be learned about how such investigations should be done.
- Little is known about the processes by which change occurs. For example, when treatment groups are compared to wait-list control subjects, is change due to regularly meeting with a therapist, to specific intervention, or to the developmental process?
- Sampling bias in effectiveness studies may affect outcome where subjects are not randomly allocated and there often is a high rate of attrition before treatment begins.
- Positive outcomes may be partly due to more motivated parents remaining in treatment.
- Most studies have short-term or no follow-up to treatment because of the difficulty of finding long-term funding for projects. Therefore, it is not possible to determine the longer-term gains of intervention.
- Few efficacy studies demonstrate clinical significance or generalizability to real-world contexts.
- Studies rarely address which treatments do not work.

### Developmental Issues

In working with parents, it is critical that the developmental context of the child be at the forefront of helping the parent understand the child. Parents' expectations

often are unrealistic given the child's age. Understanding the child's developmental stages may mitigate a potentially complicated situation leading to parent–child discord. In such situations, the child may feel inappropriately pressured and develop poor self-esteem, and the parents may be chronically disappointed. These feelings are expressed by anger on both sides. Frequently, both didactic and insight approaches are useful in such situations because a parent may have been the recipient of unrealistic expectations and be perpetuating his or her experience. In our experience, the most effective treatment is when two clinicians are engaged, one for the child and one for the parent. However, as stated earlier, specialization and managed care have made this unrealistic in most settings. At present, one clinician usually sees both parent and child. However, in the case of the adolescent, the parent in most instances is seen by a separate therapist, except when family therapy is indicated.

### Cultural Context

In our increasingly diverse society, developmental phases vary in different cultures. Clinicians need to be sensitive to such issues and not attempt to impose the biases derived from their own experience and training onto families where cultural norms may be antithetical to the therapist's perceptions and knowledge base. This is particularly true for immigrant families from traditional societies, as well as for subcultures outside the American mainstream, in which child-rearing practices and parental expectations may be very different from the clinician's. In the past, waves of immigrant families tried to assimilate as quickly as possible. However, this is no longer true, and various cultures are encouraged to maintain their practices rather than relinquish them. For example, our emphasis on separation and individuation in adolescents is particularly perplexing for families where the extended family is housed in a single residence and where adult children are expected to live until married or even have their spouse move into the parental home. The same is true for corporal punishment, such as spanking. Rather than confront a family head on, the therapist might explore (a) the parent's upbringing, (b) the family's cultural norms, and (c) whether such punishment has been effective. Often this type of discipline has not corrected the problem and the clinician may be given an opportunity to segue into alternative disciplinary approaches. (Obviously, in the case of injury to the child the clinician as a mandated reporter must contact the appropriate state child protection agency.) In this era of diversity, it is particularly important that the cultural as well as socioeconomic contexts be considered and respected.

After this background, specific behavior and emotional disorders associated with parent treatments now are discussed.

### Behavioral Problems and Disorders

Family characteristics that are associated with conduct problems in children are similar to the characteristics that predict premature dropout or treatment failure. These characteristics include low income, low educational attainment, teenage pregnancy, isolation, high stress, single parenthood, parental psychopathology, criminal history, substance misuse, marital discord, and depression ([Webster-Stratton, 1998](#)). Children who are vulnerable to conduct problems typically have academic problems, poor social skills, and poor problem-solving skills ([Webster-Stratton, 1998](#)). Identification of these risk factors helps in designing preventative strategies in vulnerable populations.

Although parent behaviors alone do not cause child psychopathology, parents can reinforce and exacerbate overt conduct disturbances in their children through their maladaptive interactions ([Diamond, 1996](#)). Harmful parenting styles such as inconsistent discipline, physical abuse, excessive criticism, hostility, disengagement from school, and lack of stimulation are all correlated with behavioral problems in children ([Webster-Stratton, 1998](#)). In [Woodward and colleagues' \(1998\)](#) study, after controlling for conduct disorder (CD) and parental psychopathology, the strongest predictor of hyperactivity was disciplinary aggression by a parent.

Children with behavior problems place particular strains on parents ([Diamond, 1996](#)). For example, boys with hyperactivity were found to be less compliant and more off task, negative, attention seeking, talkative, and demanding of parents than control children ([Woodward et al., 1998](#)). Parents of children with overt conduct problems experience greater stress, see themselves as less skilled and knowledgeable, and are at risk for depression, other personal distress, and marital discord ([Anastopoulos et al., 1993](#)).

Most outpatient psychiatric clinic referrals are for externalized behavior such as attention deficit/hyperactivity disorder (ADHD), CD, and oppositional defiant disorder (ODD). Externalized behaviors are referred more often for treatment because children tend to be referred for treatment of behavior that is problematic for others as well as themselves ([Kazdin and Weisz, 1998](#)). As a result, work with parents that has received considerable attention over the past few decades has focused on teaching parents particular procedures that modify interactions with their child, with the goal of encouraging positive behavior and reducing deviant behavior of the child ([McMahon, 1999](#)). This cognitive–behavioral approach is referred to as *parent training* (PT), and it is used preeminently in the treatment of preadolescent children who exhibit overt conduct problems, the arena in which it has the most empirical support ([McMahon, 1999](#)).

Parent training programs use social learning principles to develop positive prosocial behaviors and decrease deviant behavior through positive reinforcement. The primary theoretical bases are operant conditioning ([Skinner, 1938](#)) and research of parent discipline practices ([Patterson, 1982](#)). There are numerous studies of parent management training programs (PMT) or PT using behavioral approaches for use with children with CD, ODD, and ADHD ([Kazdin, 1997a](#)). Examples include:

- A program for 34 children with ADHD aged 6 to 11 years ([Anastopoulos et al., 1993](#)). Children and parents in this program showed improvements in symptoms and functioning (reduced stress and increased self-esteem) in contrast to a wait-list control group that showed no improvement.
- A parenting program targeting behavioral problems in children 3 to 8 years of age ([Scott, 1998](#)). The program had three parts: teaching techniques to increase desired behavior; reducing unwanted behavior; and developing strategies for avoiding troublesome situations.
- [Webster-Stratton \(1989\)](#) conducted many studies to examine her PT program for children with CD. Variations of the program (for 3- to 8-year-olds) include videotape modeling and group discussion ([Webster-Stratton, 1989](#)). Positive outcomes were demonstrated in a study designed to strengthen the protective factors in a population vulnerable to CD. With a sample of 394 Head Start mothers, interventions in the experimental group focused on parenting competence, child social competence, and home–school connections. There were positive outcomes for the first and second measures, but not for the third. The study demonstrates that low-income parents can be engaged in and benefit from parenting programs ([Webster-Stratton, 1998](#)).
- [Pfiffner and McBurnett \(1997\)](#) measured the outcome of a parent generalization-training component, which was added to a social skills training (SST) program for 27 parents of children 8 to 10 years of age with ADHD. These parents were trained to support their children's transfer of social skills from the program to everyday use. A different group of similar parents received SST alone, and there was a wait-list control group. The results showed that both groups receiving SST improved compared with the control subjects, but that the PT component did not yield additional gains.

Although these studies are not conclusive, they demonstrate clinically significant improvements achieved by PMT and PT approaches on a wide range of measures, often bringing half of the sample into the normative range. Gains were maintained 1 to 3 years after treatment in most cases, and the impact was found to generalize to other areas such as sibling behavior and marital relationships ([Diamond, 1996](#); [Kazdin and Weisz, 1998](#)).

Studies also have attempted to delineate the important mechanisms of support for parents of conduct-disordered children. [Prinz and Miller \(1994\)](#) focused on opportunities for parents to discuss nonbehavior management problems such as job stress, health problems, family disputes, and other personal worries in a group setting. In a comparison of parent groups, those in the experimental group (“enhanced family therapy”) had a lower dropout rate, suggesting that the additional support may have helped them cope more effectively with the challenges of parenting a conduct-disordered child as well as other environmental stressors affecting the family. In globalizing this study, a need is identified for parents of children with CD to receive help with problems other than child management.

Another option in addressing this parental need is multisystemic therapy, which focuses on interrelated systems and how they affect each other. This form of therapy has been used with delinquent youths, resulting in reduced delinquency, decreased emotional and behavioral problems, and improved family functioning ([Henggeler et al., 1998](#)).

[Scott \(1998\)](#) advocates a combination of PT and emotional support for parents of children with behavioral problems because these families are more likely to be economically disadvantaged and in need of assistance with related financial, employment, and housing problems. He stresses that didactic work is unlikely to achieve positive outcomes without addressing other needs of parents, and general counseling by itself may not produce significant changes in behavior.

A prevention study in London evaluated the efficacy of increased parent support by front-line welfare workers. [Davis and Spurr \(1998\)](#) used health visitors and clinical medical officers to provide counseling to 55 parents of preschool children in a deprived area. The outcomes were compared with a control group that received standard community services. Parents who had received additional counseling on top of normal services showed increased self-esteem, decreased stress and emotional difficulties, more positive attitudes toward their children, improvements in their home environment, and decreased child behavior problems. However, many of the families referred never engaged with the service, so there may be sampling bias.

[Dadds and McHugh \(1992\)](#) designed a study aiming to improve parenting and child conduct behavior symptoms. Twenty-two single parents were assigned to one of two groups: The experimental group received parent training plus “ally support training” (where a named person agrees to offer support) and the control group received only parent training. Although having an ally did not produce significant results, the importance of support was demonstrated by the fact that maternal perception of a high level of available social support from friends was the best predictor of positive response to treatment.

Before improvements in parenting can be made through parent interventions, the engagement of the family in treatment is the first task of clinicians. A study of suicidal adolescents ([King et al., 1997](#)) showed low compliance with treatments involving parent guidance and family therapy compared with pharmacologic treatment and individual therapy. The difference in compliance was explained by the practical difficulty of mobilizing a family, resistance to the idea that the family is implicated in the problem, and perceptions about the relative effectiveness of different treatments. The study found that the inclusion of a family educational component assists in the engagement of parents in treatment.

In conclusion, engaging parents of behaviorally disordered children often is critical to addressing the child's difficulties and improving his or her functioning. Often the child is responding to problematic issues in the family. However, a variety of interventions exist, and it is the clinician's responsibility to access the most effective in a particular case.

As the following discussion of parent interventions for disorders other than behavioral ones illustrates, similarly effective results have occurred when parents have been actively enlisted in the treatment.

### **Mood Disorders**

A study on parental intervention for mood-disordered children used a 90-minute psychoeducational workshop to discuss mood disorder symptoms; etiology, course, and prognosis; and treatment and family factors that affect outcome ([Fristad et al., 1998](#)). The Understanding Mood Disorders Checklist was administered before and immediately after the workshop. Results indicated that parents' knowledge of mood disorders increased significantly after the workshop. This increase was greater for the fathers, whose lower baseline knowledge before the workshop progressed so that it equaled that of the mother. Further, the Expressed Emotion Adjective Checklist was administered before and 4 months after the workshop. This revealed improved expressed emotion scores in parents, who also reported decreased negative and increased positive emotions. Again, fathers' scores were raised to levels similar to those of mothers' after the workshop. The authors suggested that these two results potentially could improve the home environment by providing consistency in parenting. In this case, educating parents about mood disorders was helpful; parents were less vulnerable to perceiving their child's mood as a reflection of their poor interaction with their child and were less likely to blame themselves or feel diminished as parent. When parents feel inadequate, a negative cycle of interaction often is created between parents and child, with deleterious effects for both.

Interpersonal psychotherapy for depressed adolescents (IPT-A) is a brief, time-limited intervention based on the premise that no matter what the underlying cause, the depression is “inextricably intertwined” with interpersonal relationships ([Mufson et al., 1993](#), p. 3). IPT-A, which has been shown to be effective in various empirical studies for treating adolescent depression, brings into treatment the parents and siblings of the adolescent for either support or for direct intervention to change family patterns, which in turn often are replicated in relationships outside the family ([Mufson et al., 1993](#)).

### **Dissociative Disorder**

Parental involvement in the study of treatment of children with dissociative disorder was the most significant factor in a positive outcome ([Silberg and Walters, 1996](#)). Factors associated with treatment outcomes in 34 children (3 to 14 years of age) with dissociative identity disorder who were treated in two geographically different settings by the same three-phase treatment approach were examined. Dissociative children living with dissociative-disordered parents had outcomes just as positive as those in nondissociative outcomes.

### **Anorexia Nervosa**

A recent study was carried out to compare the efficacy of behavioral family systems therapy (parents are seen conjointly with the child) with that of ego-oriented individual therapy (parents are seen collaterally) as treatment for adolescents with anorexia nervosa ([Robin et al., 1999](#)). The results showed that although both treatments were effective, the behavioral family systems therapy produced a faster return to health. The results indicate the importance of parental involvement in the treatment of young adolescents with anorexia nervosa, but does not require all therapy to include conjoint child and family sessions. This intervention emphasized the premise that anorexia nervosa needed to be seen in the context of family, not simply focused on the child.

### **Pediatric Traumatic Brain Injury**

Behavioral dysfunction is a commonly reported outcome of pediatric traumatic brain injury (Knight et al., 1991 in [Kinsella et al., 1999](#)). This study assessed the behavioral outcome of a sample of children with traumatic brain injury up to 2 years after the initial incident. One finding of the study was that acute emotional reaction of the parents to the injury was predictive of child behavioral outcome (although not after 2 years), which suggests that the parents' coping resources may affect child behavior after the injury. The authors believe this emphasizes the role of the family in the child's response and the importance of supportive interventions. Again, evidence of the ecologic perspective emerges, along with the need to intervene in the context of the family system.

### **Autism**

When the design for behavior modification in the treatment of autism included parents as members of the treatment team, children showed higher IQ scores and rates of class placement in school, and the effects were maintained for a mean of 5 years (Lovaas, 1987 in [Kazdin and Weisz, 1998](#)). Here, again, the inclusion of parents in the child's treatment appears as a key factor in improved outcome.

In summary, the engagement of parents is a critical component of a multifaceted approach in the treatment of children with a variety of diagnoses. We have described an armamentarium of interventions for specific diagnoses; it is the clinician's task to assess the efficacy of the treatment for the particular child and family. Although diagnoses are an important aspect in the determination of interventions, consideration also must be given to parents. Given all the variables that exist in the ecology of the family, the child, his or her parents, and perhaps others, the clinician's training, skill, and experience are deciding factors in selecting the intervention in working with the parents that will have the most positive impact on the child. In the assessment of the parents, it is critical to identify both strengths and deficits, for the intervention selected may rely more on the parents' positive attributes than on their weaknesses.

## **TREATMENT CHOICES WHEN PARENTS HAVE SPECIFIC DISORDERS**

### **Pathogenesis**

Parents with their own psychiatric diagnoses introduce another level of complexity in both assessment and treatment. Children of psychiatrically ill as well as substance-abusing parents have an increased risk of psychopathology ([Andrews et al., 1990](#); [Beardslee et al., 1998](#); [Cummings and Davies, 1994](#); [Gondoli and Silverberg, 1997](#); [Hill and Muka, 1996](#); [Inoff-Germaine et al., 1997](#); [Klimes-Dougan et al., 1999](#); [Kuperman et al., 1999](#); [Lundy et al., 1997](#); [Warner et al., 1999](#); [Williams, 1998](#)). The transmission of mental illness from parent to child depends on a variety of mediating factors that are biological, psychosocial, and environmental. Although early studies examined the impact of maternal disorders on the development of the infant, current evidence emphasizes the risk to children and adolescents of all ages resulting from mental illness in either or both parents (biological or custodial) ([Hill and Muka, 1996](#); [Lundy et al., 1997](#)). Increasing evidence indicates that major depression runs in families and that children of depressed parents are at risk for this illness ([Beardslee et al., 1983](#); [Hammen et al., 1990](#); [Orvaschel, 1990](#); [Weissman et al., 1984, 1987](#)). Family, twin, and adoptive studies have indicated that there is a genetic connection between affective disorders in parents and their children ([Beardslee et al., 1998](#); [Cadoret, 1978](#); [Torgerson, 1986](#)). However, the link is stronger for bipolar than unipolar depression, and neither case undermines the important role of environmental factors in transmission ([Beardslee et al., 1998](#)).

[Beardslee and colleagues' \(1998\)](#) review of studies revealed that a child with an affectively ill parent has a 40% chance of experiencing an episode of major depression by the age of 20 years and is more likely to exhibit general difficulties in functioning, increased guilt, interpersonal difficulties, and attachment problems.

According to [Weissman and colleagues \(1987\)](#), children of depressed parents are at threefold increased risk for school problems and suicidal behavior, and have an increased prevalence rate for substance abuse and poor social functioning.

Conflict between parents has been identified as an important linking mechanism between parental and child psychopathology. Studies support the associations between high marital conflict and poor adjustment in toddlers and distressed families predicting child behavior problems ([Abidin et al., 1992](#); [Armbruster et al., 1996](#); Reid and Crisafulli, 1992). A “disturbed family system” will “likely take an early toll on the child”; conversely, problematic children often increase stress within families ([Donenberg and Baker, 1993](#)). [Cummings and Davies \(1994\)](#) observe that psychiatric illness may cause or be caused by marital problems, or that external stressors such as poverty may precipitate both. Children may be affected both by the observation of conflict and by impaired child management practices. Further, marital problems may decrease the parents' ability to provide the support that may have helped the child cope with the parental disorder ([Beardslee et al., 1998](#)). [Armbruster and colleagues \(1996\)](#) found marital conflict rather than divorce had a negative impact on children's behavior.

### **Impact of Parental Mental Illness on Children**

Associating with someone with mental illness is stressful for most people. However, having a parent whose illness may prevent him or her from providing nurturing, stability, structure, and consistency is particularly difficult for a child. Children may blame themselves for the parent's behavior and feel that they caused their situation, and as a result may suffer guilt and a poor self-image. Children need predictability; a mentally ill parent's erratic and emotionally labile behavior may result in extremely poor parenting skills, all of which may have a deleterious impact on the child's development. Studies suggest that the risk for children increases proportionately with the duration of the parent's disorder, the number of episodes, and their severity ([Hammen et al., 1990](#) in [Beardslee et al., 1998](#)).

The following studies illustrate the impact of psychiatrically impaired parents on children.

[Williams' \(1998\)](#) study of adult daughters describes the emotional trauma resulting from their experience as children of mentally ill mothers. The subjects remembered their mother's “disappearance” on admission to the hospital, parentification, and deficits in social skills. Common themes raised were hatred of themselves and their mothers, lack of support from their extended families, isolation, and envy of those with normal families. All children had current psychiatric diagnoses.

Another study of 20 mother–child dyads found a strong correlation between maternal depression and behaviors in children ([Lundy et al., 1997](#)). A link between ineffective discipline and externalizing behaviors in 6- to 11-year-olds was identified, and children with both internalized and externalized disorders showed fewer positive behaviors when their mothers were depressed.

[Inoff-Germaine et al. \(1997\)](#) examined how parental affective illness was related to family, dyadic, and individual functioning. Compared with 18 control families, the family functioning in the 41 experimental families with affective illness was limited in terms of organization, communication, and affect regulation. The mood and behavior of the children also were affected, and families with a unipolar parent functioned better than those with a bipolar parent.

### **Resilience, Prevention, and Treatment**

Despite the risks to children who grow up in families where a parent has a psychiatric diagnosis, many children fare well, indicating that a genetic predisposition to mental illness is not the only factor in determining child psychopathology, and that those interventions that address parenting behavior may help prevent more chronic disorders.

In response to an Institute of Medicine mandate ([Leckman et al., 1995](#)) encouraging research on the treatment and prevention of psychopathology in children at risk owing to parent mental illness, a study in Boston attempted to promote resilient traits in non-ill children ([Beardslee et al., 1998](#)). The researchers targeted eighteen 15-year-old children whose parents had an affective illness and intervened to teach parents how to increase their children's understanding of their illness. The children of parents who responded positively to the study reported better outcomes in terms of depressive symptoms and global functioning.

[Free et al. \(1996\)](#) examined the impact of psychotherapy for depressed mothers on affective language with their children. The study is based on the premise that affective language can produce a confusing environment where children are drawn into their mother's sadness and in which their empathy is exploited. The authors predicted that psychotherapy would help depressed mothers to be more responsive to their children, teach them about emotions, and offset the risk of developing difficulties. Three groups were used for the study: depressed mothers receiving no treatment, depressed mothers receiving treatment, and a control group of nondepressed mothers. The sample totaled 84 mothers. Depressed mothers who had received psychotherapy were able to interpret emotional expression with more accuracy (particularly negative emotions) than the no-treatment group. The authors concluded that depressed mothers who receive treatment are more accurate in their interpretation of emotional expression and may pass the same skills on to their children.

Positive outcomes of group therapy also were reported for the four adult daughters of psychiatrically ill mothers ([Williams, 1998](#)). After 10 sessions, all were able to cease individual therapy despite having presented with psychological problems. At a 12-month follow-up, all the women reported improvements in parenting of their own children in mood and self-perception.

In summary, psychiatrically ill parents are a major risk factor for their children's mental health. Early identification and treatment are important for both the child and his or her family. Improvement in the parent–child relationship can occur if the parent is emotionally available to understand the impact of his or her illness on the child and can be helped to communicate this to the child, as well as learn improved parent management skills. The child must be helped to understand that he or she did not cause the impairment, be educated about the illness, and be given guidance and support in how to cope with such issues. However, despite the burden on child and family, research suggests that effective interventions with positive outcomes do exist. Removal from a family may occur in extreme cases, and the clinician often is called on to provide an opinion or testimony.

### **Substance-Abusing Parents**

According to statistics, there are 28 million children of alcoholics in America, and almost 11 million are younger than 18 years of age. In addition, there are an unknown number of children of other substance abusers ([Adger et al., 1999](#); [Johnson and Leff, 1999](#)). The relationship between parental substance abuse and subsequent alcohol-related and other problems in children has been extensively documented. However, it is difficult to isolate substance abuse as the change variable because of the high prevalence of other stressors, including comorbidity with a psychiatric disorder ([Hill and Muka, 1996](#); [Kuperman et al., 1999](#)). In a study of 76 children, 8 to 18 years of age, of alcoholic parents (with no psychiatric diagnosis) and a control group, the children of alcoholic parents displayed more psychiatric diagnoses than the control children ([Hill and Muka, 1996](#)). The risk increased when the child was living with a biological mother and a custodial father who were alcoholics.

As with the psychiatric disorders discussed previously, there are biological, psychosocial, and environmental factors mediating substance abuse ([Johnson and Leff, 1999](#)). Familial and parenting factors include disruptions such as lack of family rituals and frequent conflict, poor home management, lack of communication skills, ineffective parenting strategies, physical violence, decreased family organization and cohesion, isolation and stress, and frequent family moves ([Johnson and Leff, 1999](#)). The results of these risk factors on the children of substance-abusing parents are adjustment problems, psychopathology, lack of awareness, insight, and empathy, anxiety, depression, low self-esteem, impaired emotional development, and externalizing behavior problems, including delinquency. In a study by [Kuperman and colleagues \(1999\)](#), poor parenting by adults with alcohol dependence and antisocial personality disorder was associated with conduct disorder, alcohol abuse, and cannabis abuse in children.

The recognition of the impact of alcoholic parents on children has increased the attention given to parent- and family-directed interventions ([Loveland-Cherry et al., 1999](#)). Some studies have found encouraging results with family and parental interventions as a means to prevent alcohol use and misuse, as well as a preventative measure to limit the effect alcoholic parents have on the development of their children. A study by [Loveland-Cherry and colleagues \(1999\)](#) used a parental intervention that aimed to (a) increase protective factors (factors that protect adolescents from alcohol use), such as a cohesive, supportive family environment, clear rules for expected behavior, and parental monitoring and knowledge of the predictors and consequences of alcohol use; and (b) decrease risk factors such as permissive or inconsistent parental discipline as well as parental alcohol use and approval of adolescent alcohol use. The family intervention focused on general parenting skills and family functioning as well as on factors specific to alcohol use and misuse. The study showed promising results for the efficacy of this family intervention as a universal prevention program to decrease initiation of alcohol use and subsequent misuse for most adolescents who do not report prior drinking. Additional interventions are needed for those adolescents who already have used alcohol.

Another study (Nye et al., 1991) implemented a family-based intervention program for the prevention of conduct problems among preschool-age sons of alcoholic fathers, in an attempt to change the potential risk structure. The study also examined the interplay between parent expectations and commitment to treatment in predicting change in child behavior and parenting style. Parent expectations at pretreatment were found to have influenced their early investment in the program, thus predicting treatment outcomes. Parent and therapist satisfaction ratings during treatment were associated with one another and with expectations that the program would continue to promote changes in the child. Parent investment was a particularly important influence on outcome because increased investment throughout the program was associated with improvement in child behavior and decreased authoritative parenting at termination.

For substance-abusing parents with children, the research again notes that interventions provided in the context of the family may auger well for good outcome. Many therapists will not treat individuals with substance-abusing problems unless they are involved in a 12-step program and regularly attend an Alcoholics Anonymous group. Often, support groups for such children, such as Al-Anon, are helpful in reducing a sense of isolation and blame, as well as offering coping strategies. As with psychiatrically ill parents, in extreme cases the child may have to be removed.

## OUTCOME RESEARCH

Numerous studies have indicated that parental involvement in the child's treatment is an important indicator of good outcome ( Hudson and Harrison, 1986; Rosenstock and Vincent, 1979; Tittler et al., 1982). Various issues that arise in outcome are discussed ( Table 85.2 and Table 85.3).

Reference	Issue	Outcome
Ulan and Langer, 1983; DeWitt, 1983	Assessment of problem and mutual goals between therapist and parent	Continuance in treatment
Cole and Magnusen, 1967; McAdoo and Gagne, 1972; Rosenstock et al., 1981; Gager et al., 1983; Rosenstock and Stephenson, 1988; Armbruster and Kazdin, 1994	Parental involvement in treatment and compliance	Increased compliance
Ulan and Langer, 1983; DeWitt, 1983; Gager et al., 1983; Rosenstock and Stephenson, 1988; Armbruster and Kazdin, 1994	High expectations for child and parent	Increased compliance

## Naturalistic versus Research Settings

General indicators of successful outcomes include improvement in child behavior, improvement in parental functioning, and maintenance of treatment gains ( Kazdin and Weisz, 1998). Most treatment outcome studies in outpatient children's mental health services have taken place in research clinics. Findings from research studies have been consistently positive. For example, of 150 child therapy outcome studies reviewed by Weisz and Weiss (1993), cognitive-behavioral interventions showed more positive outcomes compared with nonbehavioral treatments. Randomized, controlled trials have indicated improvements in the quality of parenting; success in bringing half the children with diagnosable disorders into the nonclinical range; and maintenance of gains 3 to 10 years later ( Scott, 1998). There remain questions about the magnitude and scope of change and durability of outcome effects, and the applicability of these treatments to naturalistic settings still is unclear ( Kazdin, 1997a; Kazdin and Weisz, 1998). In contrast, there are only a handful of published outcome studies based in "naturalistic" settings, with mixed and far less positive results. Weisz and Weiss (1993) address this problem with the "good news bad news joke," which states that "the good news is that child psychotherapy works; the bad news is, not in real life" (p. 96).

Contrasting procedures between research and "real world" clinics may explain these observed differences in treatment outcome. Werry and Andrews (1996) point out that "there is little resemblance between what researchers study and what practitioners do" (p. 879). Differences in procedures between the research and the naturalistic settings include the following: subject recruitment, parental involvement in treatment, stringent treatment protocols, exclusionary criteria, manualized treatment, and completion of measures by both therapist and patients ( Kazdin, 1991; Kendall and Southam-Gerow, 1995). Such procedures are often anathema to both clients and clinicians in naturalistic settings and likely result in different clinicians and different subject populations being seen at research- versus non-research-based clinics.

In the adult literature, Seligman (1995) describes this dialectic by distinguishing between "efficacy" studies in research clinics and "effectiveness" studies in naturalistic settings. Under tightly controlled conditions with sophisticated methodology, efficacy studies conducted in research clinics differ from effectiveness studies, which assess "how patients fare under the actual conditions of treatment in the field" ( Seligman, 1995, p. 966). Although both approaches contribute to our knowledge of treatment outcome, effectiveness studies may hold the greater potential to teach us about the majority of clients and clinicians who participate in the "real world" of mental health.

## Parent Attributes that Affect Outcome

There are a number of parent and practice characteristics that can contribute to selection of treatment intervention and are predictive of different outcomes in parent work. These include ethnicity, socioeconomic status, the parent's psychiatric history, parent-therapist relationships, flexible scheduling, and access and availability of preventative services. Some characteristics in parents and children have been shown to predict poor outcomes across a range of therapeutic approaches. Parent characteristics include denial of problems, refusal to cooperate, personality disorder, psychopathology, and a parental history of physical and sexual abuse. Child characteristics include severe antisocial behavior, hyperactivity, and learning difficulties. Other factors are related to social environment; disorganized, poor living conditions; lack of social support; and a hostile partner ( Scott, 1998). Preventative services to vulnerable families tend to be community based, taking resources into neighborhoods to make it easier for poor families to access services ( Davis and Spurr, 1998; Webster-Stratton, 1998).

Researchers have agreed that parental motivation and positive attitude toward treatment appear to be "crucial factors" and the "only reliable finding" in predicting continuance in a child guidance clinic ( Armbruster and Kazdin, 1994; Cole and Magnusen, 1967; Gager-Piacun, 1985; Gould et al., 1985; McAdoo and Roeske, 1973; Novick et al., 1981; Pekarik and Stephenson, 1988). Motivation is a key ingredient in the assessment of parents, as discussed earlier. In the interventions described earlier, motivation also was critical for compliance with the study protocols.

## Practice Attributes that Affect Outcome

Agreement on the problem and mutual goals between therapist and parent appears to augur well for treatment ( [Dechillo, 1993](#); [Lake and Levinger, 1960](#)). Improving communication between therapist and parents and understanding parental expectations, perceptions, and attitudes also have been identified as crucial to treatment continuance ( [Singh et al., 1982](#)). "In general, professionals seem reluctant to accept the concept of improvement" without their intervention ( [Madger and Werry, 1966](#), p. 716). In children's mental health, this resistance to the "parents' point of view" ( [Madger and Werry, 1966](#)) may be described as clinic centrism ( [Armbruster and Kazdin, 1994](#)), observer bias ( [Magder and Werry, 1966](#)), staff bias ( [Mirin and Namerow, 1991](#)), and blame ( [Early and Poertner, 1993](#)). Parents "vote with their feet" ( [Mirin and Namerow, 1991](#)) when the match with the clinician is not comfortable and the offered service does not meet their needs. [Chess and Thomas' \(1986\)](#) concept of "goodness of fit" is useful to consider in this context. Examining the match between the proffered service and the child and family, as well as the tension between patients' goals and expectations and those of clinicians ( [Armbruster and Kazdin, 1994](#)), is particularly important in parent work. Kazdin and colleagues have reported that when child treatment includes the parents, there are gains in both child and parent functioning ( [Kazdin, 1985](#); [Kazdin et al., 1992](#)). The recent MTA Collaborative Multi-modal Treatment Study of Children found that the combination of interventions that intensively engaged parents was more successful than the other interventions used ( [Wells et al., 2000](#)). Hence, findings underscore the importance of families and of working with them to support effective child treatment ( [Campbell et al., 1993](#); [Hibbs et al., 1993](#); [Yama et al., 1993](#)).

## Attrition and Its Relationship to Outcome

Fifty to 60% of children referred for therapy commonly drop out prematurely ( [Armbruster and Kazdin, 1994](#)). Dropping out limits both the benefits of treatment and, by introducing a sampling bias, the effectiveness of outcome studies ( [Prinz and Miller, 1994](#)). There are well established characteristics of families who drop out of treatment: socioeconomic disadvantage, minority status, high stress levels, family dysfunction, difficult living circumstances, parental psychopathology, and severity of child problems ( [Armbruster and Kazdin, 1994](#)).

[Kazdin \(1997b\)](#) demonstrated, in a 4-year, prospective study, that there are other barriers associated with treatment that are separate from the characteristics listed previously that increase the risk for dropping out. These are practical obstacles (e.g., transportation), perception of treatment as demanding or irrelevant, and poor relationship or alliance with therapist. Parents often enter into parent work with low self-esteem and little confidence in their parenting ability. If they are then made to feel blamed, criticized, and attacked, the likelihood of dropping out of treatment is increased ( [Sargent, 1997](#)). Alternatively, building a strong alliance between the therapist and parent with an attitude of working collaboratively facilitates a sense of responsibility and urgency on the part of the parent. The cooperation of parents is essential to the successful outcome of child therapy, and behavioral treatments require reinforcement from parents.

To reduce dropout from therapy, [Scott \(1998\)](#) recommends visiting the family in the home, trying to fit in with the daily routine of the family, and providing child-minding services for other children. [Prinz and Miller \(1994\)](#) also recommend providing transport, offering therapy at out-of-office hours, and demonstrating sensitivity to cultural issues. [Kazdin's study \(1997b\)](#) has further implications for practice because it suggests that individualized interventions during the therapy process can reduce the likelihood of early termination. Examples of these interventions are discussing parent expectations, building a stronger alliance with enhanced communication between therapist and parent, and addressing other life stressors ( [Prinz and Miller, 1994](#); [Singh et al., 1982](#)).

For the researcher, attrition harms the design and obfuscates the findings; for the clinician, attrition is an indication of patient noncompliance or dissatisfaction. Some studies have taken an alternative approach by acknowledging the parents' perspective as it relates to attrition. Parental dissatisfaction with the services includes lack of improvement in their children's behavior, dislike of the interpersonal aspects of the evaluation, dislike of group treatment for themselves, and unfulfilled expectations ( [Ewalt et al., 1972](#); [Farley et al., 1975](#); [Singh et al., 1982](#)).

Clinic-centrism does not acknowledge that the patient's goals, as opposed to the therapist's, may have been met, and that dropout may not be treatment failure ( [Armbruster and Kazdin, 1994](#); [Tuckman and Lavell, 1959](#); [Viale-Val et al., 1984](#)). Nor should the assumption be made that dropouts harbor a negative view of what mental health services may offer. Clinicians may find it useful to acknowledge that the admission of a problem—for example, a parent calling a clinic—is the first step in the process of change, and for some persons this may be all that is necessary. [Farley et al. \(1975\)](#) found that dropouts did not have a negative view of interventions received but, to the contrary, 88% of them would recommend the services to others. These authors did not depict dropouts as "rejecters" of therapy, and with others suggest that mental health professionals, as well as patients, share the responsibility for dropout ( [Farley et al., 1975](#); [Kourney et al., 1990](#)).

## Cultural Issues Related to Outcome Research

The clinic-centric perspective also may be related to issues of cultural/ethnic compatibility associated with attrition among minority patients. African Americans in general have significantly higher rates of dropout from therapy and use fewer services than nonminorities ( [Armstrong et al., 1984](#); [Goodman and Seigal, 1978](#); [Sue, 1977](#); [Vail, 1978](#); [Vernon and Roberts, 1982](#)). The finding may not be due to minority status *per se*, but rather may reflect a mismatch of services or incompatibility of cultural/ethnic views, a "cultural incongruity" between those who receive and those who provide services ( [Cheung and Snowden, 1990](#), p. 284). Indeed, [Flaskerud \(1986\)](#) found that ethnic/racial differences between clinician and client, and location of the agency outside the ethnic/racial community, all predict dropout. Given differences in behavioral problems and parenting between ethnic groups, authors emphasize that PT programs should not be assumed to be universally effective ( [Florsheim et al., 1996](#); [Forehand et al., 1997](#)). However, [Ho and colleagues \(1999\)](#) found that PMT worked well with a Chinese population despite anticipation of cultural incompatibilities. Disruptive behavior was reduced and improvements in parent-child interactions were maintained at a 4-month follow up. Ho et al. highlight the danger of stereotyping, but generally found PMT to be consonant with Chinese cultural norms, given the emphasis on discipline, obedience, and parental responsibility and structured interventions. However, lack of data and "little contribution from rigorous, formal research" (p. 289) are major concerns in examining mental health service use patterns for minorities ( [Cheung and Snowden, 1990](#)). Because most of the existing studies are of adult patients, these concerns are even more acute for child research.

## SUMMARY

There is a consensus that work with parents increases the positive outcomes for children in treatment, and future models of the child psychiatric services are urged to pay "close attention to variables other than children's psychiatric symptom levels," such as parent characteristics ( [Jensen et al., 1990](#)) and other environmental factors. In helping children overcome various problems, multiple perspectives are critical. The research interventions described in this chapter point to the importance of parent involvement in achieving effective results for children. Although engagement with parents has not been especially emphasized in the training of child mental health professionals, as noted at the outset, the Surgeon General in the first National Conference on Child Mental Health in September 2000 proposed a paradigm shift to an ecologic model that actively includes the parents and family in the treatment of the child ( [U.S. Public Health Service, 1999](#)). Policy makers, administrators, and others are seeking a new way of thinking about the relationship between families and service providers at both the individual family and the policy level. They have arrived at a philosophy that emphasizes the interdependence of all participants and the need to engage in interventions as allies in the challenge to improve the lives of children. Intrinsic to this philosophy is the recognition of the importance of moving from a hierarchical to a team model. Family members rarely are accorded the same respect as clinicians, policy makers, researchers, or administrators. Yet, in most situations they are the "experts" in regard to their children. When professionals begin to recognize what family members already know—that families are crucial participants in the ecosystem in which children grow—the challenge is reframed. Once everyone fully acknowledges and respects the membership parents already have, the task becomes one of how to develop and maintain connections between professional and familial members. Their inclusion as active partners in providing services for their children is necessary, responsible, and effective.

Most parents are “good enough,” although all parents at times lose empathy and do things that fail to meet their children's needs. However, many parents are not “good enough,” because they cause too much harm to one or more of their children as a result of the characteristic ways in which they think, feel, and behave. Although parents with parenting disorders often feel unreasonable anger and disappointment toward their children, these parents also are very much in love with those same children. Parents who are hurtful, even most of those who engage at times in overt abuse and neglect, sincerely want to be able to treat their children well. In addition, parents who are themselves victims of external forces and powerful mental experiences that are out of their control are still responsible for the hurtful behavior. Such paradoxes are the hallmark of parents' inner struggles to manage unwanted thoughts and feelings without acknowledging them, and they also reflect parents' often incompatible wishes to reduce their own pain without abandoning their obligation to foster the well-being of their own children.

Psychodynamic explorations of the inner lives of hurtful parents reveal in almost every case a disorder of the parents' enduring patterns of thoughts and feelings about the particular child they are hurting. The concept of the parental mental portrait of the child is introduced in this chapter as a framework for a psychodynamic understanding of the enduring patterns of parental thoughts and feelings that characterize every parent–child relationship. The concept of an unhealthy parental mental portrait of the child is at the center of the clinical approach recommended here, because it is the approach that best enables clinicians to secure enduring improvements in the parent–child relationship that are profound enough to promote the long-term well-being, autonomy, and healthy mental life of the child who is being hurt, the overriding goal of all parent therapy.

Many parenting interventions are not adequate to treat significant disorders of the parent–child relationship vigorously enough to improve the parental mental portrait of the child. First, when a disorder of the parental mental portrait of the child exists, there may or may not be hurtful child-rearing practices, but there is always a disruption in the constructive emotional tone and mutuality of the parent–child interactions. Consequently, parenting interventions designed to help parents to select socially appropriate child care practices are not sufficient, because the negative emotional tone and the lack of mutuality in the parent–child interactions almost always persist even after appropriate child-rearing practices have been adopted. Second, by the time parents seek help for parenting disorders, the destructive mental patterns that characterize the disorder of the mental portrait of the child have usually become self-sustaining. Thus, parenting interventions that aim primarily to alleviate the familial, social, economic, political, or biological factors that helped to create and sustain the disorder of the parental mental portrait of the child are often no longer sufficient to help a parent to change it. Third, most of the thoughts and feelings that characterize a disorder of the parental mental portrait are unconscious. Therefore, interventions that primarily help parents to improve their conscious knowledge of child development, children's needs, appropriate child care practices, and positive caregiving attitudes are also insufficient. Psychodynamic parent psychotherapy is often the best treatment option because it is a clinical approach, perhaps the only one in child psychiatry, that has as its primary goal relatively profound and enduring improvements in the content and regulation of the self-sustaining unconscious mental patterns that pressure parents to hurt their children repeatedly.

Effective diagnosis and treatment of parenting disorders are extremely difficult because of the extraordinarily powerful and disruptive psychological reactions that are stimulated in therapists when they are working closely with patients who are hurting their own children. It is most upsetting to clinicians to come to terms with the knowledge that their patients are good enough ordinary adults, not very different from the therapists themselves, and those same patients are also hurtful parents who make choices that are not compatible with their moral commitment to support the well-being of their own children, a commitment that is one of the most universally held and most important moral standards of our culture.

Engaging in a professional caregiving relationship with such parents forces therapists to think about their own very difficult unresolved moral issues and the hard choices they face every day that affect the spiritual center and meaning of their own lives. Even very experienced psychodynamic psychotherapists frequently fail to manage their psychological reactions to these difficult moral issues very well. As a result, therapists employ various unconscious and conscious defensive psychological strategies to avoid full awareness of the true nature of the moral dimension of the parents' problems.

Such defensive thinking disrupts the therapeutic stance profoundly and has a devastating impact on effective diagnosis and management of parenting disorders in the following ways. Therapists who work within a conventional psychoanalytically informed clinical approach may simply overlook the serious nature of the parenting problem. Other clinicians who work within a more medical clinical approach may fail to address the parenting problem because they allow themselves to set aside the long-term primary treatment goal of achieving lasting improvements in the parent–child relationship that promote the child's long-term mental health, well-being, and autonomy and instead adopt an exclusively narrow, short-term treatment approach. Such a narrow treatment approach is usually focused on improving the child's behavioral adjustment and symptoms, but sometimes it is focused on treating acute problems of the parent that are not directly related to parenting. The narrow treatment focus facilitates the therapists' own motivation to divert attention from the parenting disorder, the inner life of the parents, and especially the most troubling aspects of the parents' inner life, the thoughts and feelings associated with the moral dimension of the parenting disorder.

However, even when they identify a serious parenting disorder and sustain their attention to the inner life of the parent, therapists may still defensively ignore the most disturbing aspects of the true nature of the parent's responsibility for making ethical decisions that are harmful to the child. By engaging in unsystematic, unrealistic, dichotomous moral reasoning, therapists can protect themselves by granting a false blanket exoneration to hurtful parents or by dismissing the parents as very different from the therapists themselves or by exaggerating the patients' immorality and demonizing them. In addition, therapists may protect themselves with the self-deluding pretense of abstaining from any ethical judgment of the parent, by assuming a neutral therapeutic posture that is almost always a rationalization for the experience of exaggerated blaming or blanket exoneration that has been suppressed.

Such defensive moral reasoning is the most important cause of failure of even the best clinicians to diagnose and treat parenting disorders effectively ( [Siskind, 1997](#)). Of course, when clinicians do not identify or attend to significant parenting disorders, they cannot recommend parenting psychotherapy when the children and their parents need it. When they embrace a view of their patients based on exaggerated blaming or blanket exoneration, they undermine the therapeutic stance. When the therapeutic stance is undermined, clinicians cannot make sound clinical judgments, nor can they sustain the empathy, respect, and fidelity to both parent and child that are required to support the professional therapeutic relationship.

Strong psychological reactions, denial, and defensive moral reasoning are impossible for parent psychotherapists to avoid completely. Conversely, however, it is almost impossible for clinicians to sustain such destructive defenses if they discipline themselves to hold onto dual empathy for the parent and the child and an

appropriately complex, comprehensive understanding of the parents, the child, the parent–child relationship, and the psychotherapy. Therefore, the primary goal of this chapter is to suggest that clinicians prevent serious treatment problems by disciplining themselves to do the following: (a) formulate the clinical parenting disorder with the parental mental portrait at the center, by taking into account the complex dynamic interactions of the full range of biological, psychological, social, and moral factors; (b) achieve, monitor, and sustain dual empathy for parent and child; (c) explicitly assess and attribute to the parent a balanced and realistic determination of ethical responsibility for decisions that hurt the child; (d) sustain the primary long-term clinical goal of advocating for long-term improvement in the mental life of the child; (e) protect the determining role of individualized clinical judgment that is based on the primary goal of parent treatment in association with other appropriate values including the unique personal values of the child and family; and (f) adopt a body of clinical theory and scientific knowledge that is appropriate to encompass the moral dimension of professional medical care, that is, a body of knowledge and theory about profound suffering as well as severe pain, free choice as well as biological and environmental determinants, and the values that imbue the lives of individual patients with dignity and meaning, as well as the values that support the achievement of competence, mastery, adaptation, social success, and survival.

The chapter begins with a discussion of the concept of the parental mental portrait of a child, including the origin, pathogenesis, and impact of disorders of mental portrait and a comprehensive framework for formulating parenting disorders. A description of the powerful psychological reactions of therapists to the moral dimension of parenting disorders is followed by a presentation of additional practice guidelines designed expressly to help therapists to manage those responses better. The chapter concludes with some selected practical suggestions about how best to begin and perform parent psychotherapy and encouragement for clinicians to evaluate all the children they see clinically for defects in the parent–child relationship and to recommend psychodynamic parent therapy much more often than they do now. The presentation is directed toward clinicians who are already trained as competent psychodynamic therapists and who have an opportunity to work under conditions that are compatible with the performance of relationship-based psychotherapies.

## PARENTAL MENTAL PORTRAIT OF THE CHILD

The concept of the parental mental portrait of the child is introduced here as a framework for the psychodynamic understanding of the enduring patterns of parental thoughts and feelings about a particular child. The mental portrait concept is the central element in a modal formulation designed to help clinicians think about parenting problems in a way that is most likely to achieve the primary therapeutic goal of enhancing a child's long-term well-being, autonomy, and healthy mental life. In the following section, the concept of the parental mental portrait is defined, and then disorders of the mental portrait of the child are described, including their origin, their pathogenesis, and their relationship with parenting disorders, including the role of parental choice in their expression and the impact they have on the parent–child relationship and the development of the child.

### Defining the Parental Mental Portrait

All parents sustain a unique mental portrait of each of their children. The *parental mental portrait* of the child is a psychodynamic understanding of the enduring features of a parent's inner life that is focused on the thoughts and feelings associated with a particular child. It is an understanding that is informed by certain useful clinical concepts selected primarily from the interpersonal ([Gill, 1983](#)) and object relations ([Kernberg, 1982](#)) aspects of psychoanalytic theory. The mental portrait of the child refers primarily to a parent's enduring, global synthesis of all the remembered thoughts and feelings that are closely associated in that parent's mind with the subjective experience of a particular child ([Feraholt, 1976](#); [Feraholt et al., 1985](#)). These remembered thoughts and feelings, primarily unconscious, are more or less well organized, often hierarchically, to form a global mental synthesis that serves to represent a particular child in the mind of the parent. The global synthesis is best thought of as an enduring dynamic mental system, not simply a static composite or “average” memory. The mental portrait has both an enduring, current, structural dimension and a historical, developmental dimension.

The parental mental portrait includes what is commonly called the meaning of the child to the parent and is informed by what others have written about as the mental representation ([Kernberg, 1980](#); [Sutherland, 1980](#)), narrative story line ([Schafer, 1992](#)), working model ([Greenson, 1960](#); [Stern, 1985](#); [Zeanah et al., 1989](#)), and cognitive and developmental schema ([Bruner, 1990](#); [Piaget, 1953](#)). Because the mental portrait guides the perception, selection, and interpretation of new information and remembered thoughts and feelings about the child, it has a major impact on all the parent's behavior in relation to that child.

The mental portrait model for formulating parenting disorders is not limited to the psychoanalytic notions that constitute the mental portrait concept itself. The model for formulating parenting disorders is a theoretically pluralistic model, but not a syncretic or eclectic model; it depends on concepts drawn from a variety of theories. This variety of concepts is needed to take into account the many factors that may be important to treatment planning for any particular clinical case of an individual child in a family with parenting disorders. The important factors usually include the biological and psychological state of each family member, the nature of the family unit, and the social institutions, economic forces, and political forces that influence parents. However, the model presented in this chapter is unusual because it emphasizes the conscious value-based choices of the parent; this model includes the moral dimension in addition to the biological, social, and psychological dimensions of the clinical situation.

To encompass the moral dimension of the clinical situation, the model presented here includes the language and concepts that are required to organize data about the relevant values, life plans, ideals, and standards of the particular parents, as well as those of their families, religions, and ethical traditions. These personal and cultural factors are the ideals that guide important parental choices. This model also requires concepts, methods, and data that are suited to describe, in a way that is clinically useful, the moral courage and competence of a particular parent to uphold his or her own ideals by meeting the standards of conduct associated with them and by resisting strong impulses to betray ideals to seek gratification or avoid pain. The model of formulation also emphasizes the degree of autonomy of therapists and factors that inform their value-based choices. It includes the necessary language, concepts, and methods to make individualized clinical judgments that integrate a professional commitment to the ethics of traditional medicine in a Western rights-based democracy with respect for the particular values of each individual parent.

### Disorders of the Parental Mental Portrait

Because all parents lose empathy and hurt their children at times, disorders are distinguished from “good enough” parenting based on clinical judgments of the severity, pervasiveness, and chronicity of the disturbances in the parenting relationship. However, less severe disturbances in parenting are also identified as clinical problems deserving treatment if they are judged to be detrimental to a child with particular vulnerabilities. Disorders of parental experience of the child are characterized by insufficient empathy, denigration, or idealization, overinvolvement or remoteness, and a poor match with the actual characteristics of the child. The discrepancy between the parent's view of the child and reality stems from distorted perceptions, misinterpretations, confusions, overly simplistic interpretations, and even unconscious fabrications about the child. These cognitive distortions are associated with ego mechanisms of defense and are discussed later.

When there is a very severe defect in regulation within the portrait, parents unconsciously experience the child in a prejudiced way, almost all the time. They attribute exaggeratedly evil designs to the child, but sometimes their attributions involve unrealistic perfection ([Miller, 1981](#)). In the most serious cases, a parent may consciously experience a child as if he or she were someone or even something else (e.g., father, mother, sister, demon, monster, genius, angel, or god). Some parents, even when there is no other overt psychiatric disorder, have no doubt that their rigid, black-and-white characterizations of the child are completely true. The parental prejudices of disturbed parents portray the child in terms of a range of undesirable caricatures or stereotypes, including versions of the following: the coldly calculating, self-aggrandizing villain; the wild, unsocialized primitive; the irresponsible, lazy, manipulative tramp; the tragic, fragile, suffering invalid; and the generous, powerful, brilliantly intelligent, creative, invulnerable leader. The case of Jason M. (see later) illustrates such a defect in a parental portrait so severe that it could not be sufficiently repaired.

More commonly, the defective portrait manifests in more subtle ways. The parent repeatedly experiences brief episodes of exaggerated affect and inappropriate ideation and affect that occur in the course of difficult interactions with the child. Most of the time, the handicapped parent may sustain a reasonable attitude toward the child, often affectionate, but always with defects in empathy, that is, a failure to understand the child's point of view. The prejudices are not consciously held, but they can be elicited in the course of an intensive psychiatric interview. The second illustrative case in this chapter, Douglas T., describes a less severe defect in parenting that is responsive to treatment.

### Development of the Parental Mental Portrait

The mental portrait begins with the parent's fantasies before meeting the child. In the course of an adult's “healthy” development as a parent, the mental portrait of a child is repeatedly reworked to achieve higher levels of organization and complexity, best to protect and support the developing competence and autonomy of the child. Such ongoing development of the mental portrait is best viewed by parent therapists in terms of two interactive processes: (a) the process by which the components of the mental portrait are repeatedly reconciled with perceptions of the real child who is changing and (b) the process by which the parent's mental representations of the child, initially tightly entangled with the parent's self-representations, are gradually separated in the parent's mind from those representations of

the parent's self.

These two developmental processes in the development of the mental portrait depend on a sequence of parental experiences of loss, grieving, and restoration, which are understood best using concepts borrowed from the study of mourning after the death of a loved one ([Engel, 1962](#)). When, in the course of development, the parental mental image of the child is challenged by the parent's perceptions of the real child, the parent suffers a psychological loss that disrupts the integrity of that parent's experience of self. If the mourning processes are significantly obstructed or distorted, the mental portrait will be compromised. Thus, the same etiologic factors are present in both pathologic deviations in grieving and in defective development of the mental portrait.

### **Etiology of an Unhealthy Mental Portrait**

Viewed from the perspective of the mourning that the parent must achieve in the development of the healthy mental portrait, the causes of deviant, defective development of the portrait include the factors that interfere with mourning. Extreme ambivalence toward the child is a common cause. Ambivalence may develop because a healthy child comes at a very bad time, there is a painful, physically damaging pregnancy and birth, or care of the child is very difficult. Ambivalence may develop if a normal child fails to meet unrealistically high parental expectations, such as the capacity to repair a failing marriage, to achieve a reunion between a parent and a grandparent, to fulfill the parent's unmet needs for parental care, or to solve the parents' problems in social adjustment. Ambivalence may also result from the overwhelming intensity of the psychological loss associated with an unhealthy child, as may occur if a child is born deformed or handicapped severely or if a child almost dies during gestation, at birth, in an accident, or from a potentially fatal illness.

Many different biological, psychological, social, economic, and political factors can interfere with a parent's capacity to mourn a loss and in this way contribute to the development of defects in parenting. They include the following: psychiatric problems in the parent, such as parental depression and personality problems such as pathologic narcissism; memories of unresolved past losses after the death of a loved one, disrupted love relationships, or childhood neglect and abuse; lack of preparation for various difficult experiences of parenthood, including ignorance and misinformation about pregnancy, labor, delivery, child development, or child care; lack of emotional support from loved ones after the loss because of marital problems or social isolation; and compounding losses from additional stressors, including physical illnesses, the death or separation from a loved one, marital discord, family disorders, social isolation, unemployment, poverty, sexism, and racism. The interaction of various factors at any one time may trigger disturbances in the development of the mental portrait of one child even in a parent who sustains healthy portraits of other children.

### **Pathogenesis of an Unhealthy Mental Portrait**

Almost all the mental processes central to a defective mental portrait transiently distort the mental life of every parent. Again, problems are distinguished from "good enough" situations by degree, pervasiveness, and balance. In the intrapsychic sphere, problems in the mental portrait concern both content and regulation. Most commonly, there is a failure to manage adequately the boundary between the mental representation of the child, that of the parent's self, and that of each of the parent's own parents, although representations of other loved ones may sometimes play a role, too. Many psychodynamic concepts can help the therapist to generate a useful intrapsychic understanding of the nature of particular aspects of the psychological processes that underlie the defective regulation. The ego mechanisms of defense are indispensable to such psychodynamic formulations, especially projection, projective identification, and a set of related concepts that encompass both the intersubjective and the interpersonal perspectives on the parent-child relationship ([Bollas, 1987](#); [Bollas, 1992](#); [Masson, 1984](#); [Miller, 1981](#); [Miller, 1991](#); [Sperling, 1974](#); [Sutherland, 1980](#)). However, more comprehensive notions are also helpful in some cases, such as the child in the parent's mind as "self-object," "symbiotic object," "unacceptable self," and even "sexual fetish" ([Schreier, 1992](#)).

Two clinical concepts—identification and reactivation—are especially useful in describing intrapsychic dynamics. A healthy parent "identifies" strongly with a very young child. Various processes of internalization lead to intense and irrational identifications that are useful when they are properly regulated, because they help to sustain sufficient commitment and interest in the child. However, a pervasive, fixed, and irrational identification can be at the center of defective regulation when the mental representation of the parent's self and that of the child tend to become stuck in the fused state, stuck in a detached state, or to alternate erratically from extreme detachment to extreme fusion. In a state of extreme fusion, characteristics of the child that are significantly different from the parent are overlooked; in a state of extreme detachment, the identifications needed to sustain an essential intuitive empathic knowledge of the child are impossible.

A healthy parent also experiences the eruption of repressed memories of childhood in the context of his or her identifications with a child, because that child is at the same age, in the same stage of development, or is having experiences that are similar to those the parent had when the memory was created. This process, which is referred to as *reactivation*, is often a constructive impetus for continuing personality development in the parent. However, if the reactivated memories are too disturbing, then reactivation may contribute to defective regulation by causing tumultuous emotional responses or eliciting primitive defensive operations, especially denial and distortion of those aspects of the child that stimulated the intolerable reactivation ([Coleman et al., 1953](#)).

Some related concepts, including projective identification, extractive identification ([Bollas, 1987](#); [Bollas, 1992](#)), and introjective identification, are also useful in understanding certain aspects of the defective mental portrait. Although historically connected to terms describing intrapsychic processes such as *projective identification* ([Klein, 1946](#)), these concepts have been expanded in current psychoanalytic theory so they can be used to bridge the intrapsychic and interpersonal spheres ([Tansey and Burke, 1989](#)). In the *current* discussion of the parent-child relationship, these bridging concepts refer to an interactive psychological process by which the parent places an attribute from his or her unconscious mental portrait directly into the mental life of the child, specifically into the child's unconscious self-representation.

These interactive processes, like the intrapsychic processes referred to earlier in this section, are ubiquitous in the relationship of a child to a parent and are usually compatible with healthy personality development. However, projective or extractive identifications can interfere with healthy development and are important aspects of defective regulation in an unhealthy mental portrait associated with parenting disorders. They may contribute to the development of the child's experience of a false self, when too many important aspects of the child are removed from his or her authentic self-portrait and too many incompatible traits are placed into the child by the parent. In addition, particular unhealthy personality traits (e.g., defects in conscience—superego lacunae) may be unconsciously put into the child by a parent.

It is sometimes useful for the parent therapist to view the psychological processes of a defective portrait from the perspective of the family unit as a whole. At such times, concepts of group dynamics that apply only within the interpersonal sphere, such as delineations, designations, and scapegoating ([Ackerman, 1958](#); [Stierlin, 1977](#); [Vogel and Bell, 1960](#); [Zinner and Shapiro, 1972](#)), are most useful. When group dynamics are in focus, the individual intrapsychic mechanisms and bridging psychological mechanisms mentioned earlier are subsumed within the interpersonal group concepts that the therapist is using at that time.

### **Conscious Aspects, Including, Choice, Guilt, and Responsibility**

Some disturbed parents, even those who are socially well adjusted and free of overt psychiatric disorder, intentionally do very harmful things to a child in a vindictive or cynical frame of mind, at times with premeditation and planning. Most hurtful parents do not consciously intend to hurt their children. However, even parents who are basically well intentioned are never completely oblivious to hurtful actions; they are repeatedly aware, even if only transiently and peripherally, that something is wrong with the way they are thinking and feeling about the child as well as the way they are treating the child. Most hurtful parents lie to everyone including their doctors about what they know about their own parenting problems, before they are engaged in a treatment. However, in the course of describing to a trusted therapist in detail many specific interactions, they usually reveal at the least that they did realize, at times, that they were doing things to make a bad situation worse, neglecting to do things that they knew could make it better. These hurtful choices include suppressing appropriate or indulging inappropriate emotions, noticing that people outside the web of the colluding family suspected a parenting problem, or making only the minimal effort to change even when professionals identified the seriousness of the parenting disorder. Very disturbed parents often have elaborate rationalizations for their abusive behavior and may even experience a dissociative state during the short time that they are actually doing something awful to their child. However, even parents driven by the most powerful psychological drives are aware, to some degree, at some times, that something is very wrong. They almost all report, in the course of treatment, that they consciously decided to hide their actions even from those they trusted most, although they maintain paradoxically that they believed at the time that there was nothing wrong with what they were doing to their children.

Therefore, most parents with a defective mental portrait of a child decide many times to deceive themselves, to deceive their loved ones, and not to ask for help. These decisions are made although these parents have the freedom to act differently, if they exerted enough effort. Such parents decide to continue to hurt their children and indulge their desire to avoid various uncomfortable experiences that would result from revealing the problem to others to seek help. Such uncomfortable experiences include the following: (a) guilt, shame, and other psychological pain; (b) deprivation associated with giving up some important gratification; (c) shame associated with social rejection; and (d) tangible loss associated with economic and legal consequences. Such decisions to continue to hurt their children and not to seek help are, in fact, choices for which parents are responsible in the context of a variety of extenuating circumstances. When parents think they are vulnerable to

such self-accusation, they often try to escape from guilt, more or less consciously, by adopting a simplistic, one-dimensional image of themselves such as innocent victim, martyr, or handicapped person. To embrace such a caricature of themselves in relation to their children, parents must also adopt reciprocally extreme conscious characterizations of their children, such as abusing villain or “cross to bear,” thus increasing the child’s vulnerability to being mistreated.

### Consequences for the Parent–Child Relationship

A parent's conscious attitudes and feelings are communicated to the child in good part through planned, easily observable actions that include child-rearing practices. Overt assault, sexual abuse, or gross neglect is almost always associated with a severe defect in the parental mental portrait. However, the converse is not true; that is, serious defects in parenting are usually associated with child-rearing practices that are socially appropriate. In fact, a disorder of parenting often presents to the clinician as a problem in the child who is being raised in what appears to be an appropriately loving, concerned, stable, and well-adjusted family.

Although there may be no easily observed deviant child-rearing practices, unconscious thoughts and feelings, such as loss of empathy, rejection, idealization, sexualization, and other disturbed aspects of the parent's inner life, will still harm the child. Unconscious thoughts and feelings influence the child primarily through nonverbal communication and the emotional tone surrounding words and overt actions, that is, unintentional, “microscopic” aspects of the parent's behavior. These microcommunications include the subtext of the parent's verbal communications, the timing of intended actions, and body language. The subtext, or latent content, of verbal communication is expressed through tone of voice (pitch, melody, rhythm, and stress), sound patterns of selected words, slips, jokes, evoked images, connotations of words, and associative sequences. The timing of actions often communicates meaning in relation to the context of the action and state of reception in the child as a biological organism and psychological being. Body language communicates unconscious thoughts and feelings through facial expressions, patterns of direct eye gaze, posture, gesture, proximity modulation, style of movement in the presence of the child, and ways of touching, avoiding touching, or responding to being touched.

### Consequences for the Child

Even transient and mild disorders in the mental portrait may cause considerable mental anguish, but when there is an enduring and pervasive disorder, even a very resilient child will experience profound mental suffering associated with pervasive and enduring personality disturbances. A defective portrait may also induce the onset of a psychiatric disorder, even when a biological origin is primary, and the defective portrait will almost always worsen the course of a psychiatric disorder in the child. Similarly, defects in the parental mental portrait can precipitate and exacerbate many other medical and developmental problems. In fact, a disorder of parenting often presents only as a complaint about a child with developmental delay, disruptive behavior, mood disorder, or somatic symptom.

Although the deleterious impact of the defective parental mental portrait on a child's personality development can be understood in numerous ways, four are very useful: (a) every extremely painful experience that seriously disrupts the child's experience of safety and trust in the parent–child relationship has a profound and enduring traumatic impact; (b) the dysphoric experiences within parent–child interactions have an incremental impact; (c) the unique learning experiences associated with internalization in love relationships, including projective identification and extractive identification, impose specific unconscious parental expectations on the personality of the child; and (d) the unique learning experiences associated with the child's perception of parental self-indulgence and betrayal of parental fidelity to work very hard to do no harm and to promote the child's well-being disrupt the child's moral development.

It is tempting to speculate that, in some cases involving very bad parenting of a vulnerable infant, global disturbances of brain function may be associated with deviations in postnatal structural development of the brain as well, deviations that could have long-term psychiatric, educational, and psychophysiological implications. Such speculation is controversial among many research scientists, but it is supported by considerable indirect evidence. For example, disturbances in the parental mental portrait can interfere with a child's central nervous system functioning profoundly enough to stop growth and to precipitate asthma, diabetes, projectile vomiting, or dehydrating diarrhea. Further support comes from various data derived from pediatrics and animal investigations, which document deviations in postnatal brain development associated with permanent significant abnormalities of perceptual and synthetic psychological functioning as a result of early and prolonged sensory deprivation or perceptual challenges. Data associating child abuse, psychiatric disturbance, and neurobehavioral deviations in violent criminals are also suggestive, although it must not be forgotten that biologically damaged children are more likely to behave in ways that precipitate mistreatment by their caregivers ([Hoffer, 1995](#); [Perry, 1995](#); [Radic et al., 1994](#); [Singer 1986](#)).

---

#### CASE ILLUSTRATION

This case illustrates the devastating impact of a severe disorder of a parental mental portrait on a child in a family where child-rearing practices were by conventional standards “good enough.” The child suffered with severe psychiatric disorders, personality deviations, and physical problems as a result of serious ongoing disorders in the emotional tone of the interactions with his parents, even while overt, easily observable child-rearing practices were, for the most part, appropriate. Countertransference problems were responsible for the delay in diagnosing the parenting defect. The treatment reflects child advocacy and dual empathy for both the child and the parents. The father's defective mental portrait resolved, and the boy's situation was improved, but the mother's psychological disability was so severe that she could not tolerate the psychodynamic parent psychotherapy. She was unable to grieve her own losses even in the context of intensive outpatient psychotherapy, and the defective mental portrait of her son could not be repaired enough for them to continue to live together.

##### Case Presentation

Jason, age 7, was admitted to a combined medical and psychiatric research hospital ward for psychiatric evaluation and studies of his growth hormone regulation. He weighed 22 pounds and was 3 feet tall. (National averages for second graders are 50 pounds and 4 feet.) Before his admission to the hospital, Jason was spending long periods alone in his room, doing nothing but sitting on his bed, motionless and mute. He also had inconsolable screaming spells for no apparent reason, ate garbage, drank from toilet bowls, and ate his own vomitus. He rarely spoke at home, and he usually acted unfriendly, angry, and demanding with his family.

As an infant, Jason had cried incessantly, rejected comfort, recoiled when held, ate so much that he vomited, and slept only during the day. In his second year he clung to his mother and displayed frequent strong tempers with head banging and breath holding. During his third year, he became indifferent and listless, stopped growing, and developed the behavior problems that still were prominent 4 years later when he was hospitalized at age 7.

Jason's parents were middle-class, educated, intelligent adults without any formally diagnosed, psychiatric disorder. They were “good enough” parents to their other children, who were growing adequately and were well adjusted at home and at school. Before treatment, both mother and father accepted this bizarre situation almost without complaint. Supported by their pediatrician, they believed, without any supporting medical evidence, that Jason was brain damaged from birth and that, as a result, he could not help being self-centered, demanding, and unaffectionate. They did not physically abuse, sexually molest, or neglect Jason. After consulting their pediatrician, they had used child-rearing practices that were reasonable, considering their son's extreme behavior problems. In fact, they spent a lot of time trying to teach him self-help skills and appropriate social behavior.

##### Treatment Course

Once in the hospital, Jason was seen in individual psychotherapy, and his parents were seen in parent psychotherapy. Jason lived in a pediatric hospital environment with very intensive nursing, a school program, and a “child life” program. Jason's abnormal growth hormone metabolism corrected itself (without medication) in days, and he began to grow at the rate of 1 cm per month, with proportionate weight gain. His social adjustment was excellent from the outset, his school work improved, and he was free of all his previous bizarre behavioral symptoms. There was no evidence of psychosis or brain damage of any kind. Although his depression lifted enough to allow his body to function more normally, Jason's play therapy continued to reveal extensive abnormalities of his inner life, including intense depression, rage, and deviant personality development.

Jason's father at first was perplexed when his son improved so rapidly in hospital, but in treatment he gradually recognized the family problems, accepted a psychosomatic formulation of the growth failure, and became interested in improving family relationships by better understanding unconscious mental life. He began to like Jason and to notice the boy's feelings. His mental portrait of his son rapidly improved once the family patterns were identified and modified. Jason's mother, conversely, became depressed, angry, and anxious as her son improved. She could no longer displace and project her impulses onto her child. She desperately tried to insist that he was not really changing and even denied his measurable growth. As her anxiety escalated, she accused her husband and the medical staff of turning against her and lying about Jason's progress. She threatened to end the marriage. When she was not very angry, she was depressed, with suicidal thoughts. Jason's mother's mental portrait of her son was inflexible; she was not strong enough to allow it to change with the psychiatric care that was available to her.

It became evident as their history unfolded in treatment that the parents' detached, dehumanized view of their son as a brain-damaged retarded child had caused them to ignore Jason's loneliness and despair and their own sadness and anger. When Jason no longer behaved like a brain-damaged child, Jason's father changed his impression of his son, but Jason's mother revealed a fixed “negative portrait” of Jason in her mind that she could neither change nor erase. She could see only his hidden anger and selfishness and completely mistrusted his sincere expressions of affection, sadness, and fear. She visited less and less often, and was always angry when she did. Gradually, as treatment progressed, she relinquished her conscious conviction that Jason was possessed with evil; her overt anger diminished, and she complained of feeling that there was a “transparent wall” between herself and her son. Yet, the discomfort they experienced with each other remained intolerable.

Mrs. M. confided that when Jason was still an infant she had developed a completely negative view of him and had been desperately frightened that he would “destroy” all she had obtained in life. She was self-critical and deeply depressed at the time, a significant factor in the origin of her parenting disorder. She believed that her depression was caused by her infant son's “anger” and “disappointment” with her. In our conversations, she began to express her rage and to talk about fantasies in which she violently assaulted her son; she attributed supernatural powers to him and used terms appropriate for a demon or an animal. As it turned out, Mrs. M.'s portrait of her son was modeled on similar sketches from her childhood, in which she worked constantly but unsuccessfully for the approval and affection of her own depressed and bitter mother.

##### Comment

The outcomes of extremely serious cases, like this one, are variable. In some instances, it is possible to help parents as disturbed as Mrs. M. to alter significantly the character of the mental portrait of the child. In this case, however, Jason's mother was not able to relinquish her negative mental portrait of her son because it was required to stabilize her sense of self. Jason's mother and father decided, for reasons too complex to describe here, that Jason should live with supervised foster parents. The decision was experienced with great sadness by everyone, but it was accomplished in an atmosphere of honesty. Jason remained symptom free and well adjusted while living in a foster home where he came to be loved. Working in his own individual psychodynamic psychotherapy, Jason gradually began to understand that his mother's rejection was real and not imaginary, and that it was primarily the result of her own psychological problems and not because he was a bad or inadequate person.

---

## PSYCHOLOGICAL REACTIONS OF PARENT THERAPISTS

## **Pain Associated with Dual Empathy for Both the Hurt Child and the Hurtful Parent**

The painful psychological reactions of a therapist doing parent therapy stem from many sources. It is painful to identify with a parent who is suffering. It is even more painful to identify with a child who is suffering, a problem faced in all child psychotherapy. Identifications with the child are especially challenging, because they reactivate the therapist's early memories of being a hurt child, memories that are, in turn, associated with the superstitions, magical thinking, and unbearable global emotional states that are similar to fragmenting terror, homicidal rage, and hopeless despair. In addition, parents with character problems subject therapists to intense projective identifications that encourage empathic failures. All these factors are difficult for psychodynamic therapists, but not extraordinarily so in parent psychotherapy. However, other extraordinarily powerful and disruptive psychological reactions are inevitably elicited.

Such reactions stem primarily from three sources that force therapists to contemplate difficult, often unresolved, moral judgments about themselves, judgments that are central to the meaning of their lives. First, identifications with the hurtful parent force a therapist to contemplate memories of choices they have made that have hurt others in love relationships. Although there are important differences among individuals, every therapist has painful memories of hurting some loved one. No therapist, however mature, could ever become fully invulnerable to the painful guilt and shame associated with such memories. For therapists who are themselves parents, memories of hurting their own children are particularly difficult to revisit.

Second, identifications with the child force a therapist to contemplate the extraordinarily confusing experience of a child who is being mistreated, humiliated, and betrayed by a parent who also loves that child and who is basically committed to being a good parent. Such an experience for the child is complicated by a context in which the dominant parent and the entire social world of the child, sometimes including a misguided parent therapist, collude to "silence" the child by denying that the child's experience of the parent's betrayal is even in part valid and by insisting that the child accept a false interpretation of reality that depicts the parent as only doing as much as possible to be helpful. Thus, the child experiences as real both his or her own valid perceptions of the parent's decisions to hurt and also the incompatible misinterpretations that are imposed by that child's dominant social reality. Similarly, the child experiences his own rage and despair as both a valid response to the parental betrayal and a malignant response to trustworthy caregiving.

Third, dual empathy for both the hurtful parent and the hurt child forces a therapist to think about the everyday indulgence in human evil by us all. Most hurtful parents are ordinary, good enough people, not too different from therapists, who, without being subject to extreme pressure or coercion, do choose to betray their fidelity to the well-being of their own children, one of the most unusually important moral commitments in any society. Therapists who contemplate the immorality associated with good enough ordinary people hurting their own children are vulnerable to terror that is associated with attending to the high potential for unethical acts in our neighbors and ourselves. Such contemplation also stimulates the guilt that is associated with being reminded of the responsibility we all bear for the ways we choose to tolerate the degrading mistreatment of other human beings in our own extended families and communities, not to mention that of the millions of people in remote, underdeveloped areas of our world. Every therapist is vulnerable to such intense terror and guilt when reminded that his or her daily life is embedded in a society that routinely harms and degrades classes of people and fails to do all that could be done to help those who are being hurt by others.

## **Therapists' Denial and Defective Moral Reasoning as Defense**

When such extraordinary powerful psychological reactions are not managed well, problems arise that disrupt effective diagnosis and treatment. Therapists look away from the serious nature of the parenting problem either by using denial or by adopting an exclusively narrow, short-term focus that allows therapists to divert their attention from the parenting disorder, the inner life of the parent, and the moral dimensions of the clinical problems. In addition, therapists may ignore the complexity of the parents' ethical infidelity, by engaging in unsystematic, dichotomous moral reasoning that results in exaggerated moral blaming of the parent, blanket exoneration, or the self-deluding pretense of abstaining from any ethical judgment.

Therapists engaging in exaggerated blaming often think of the parent in a caricatured fashion, as a villain. Only a total villain deserves unqualified blame, because he or she does not try to love the child. For a villain, nurturing child-rearing practices are employed only to avoid social and legal censure. Characterizing a parent as a villain protects the therapist from painful identifications with a hurtful parent who is a good enough ordinary person, loves the child, but is in part ethically responsible for decisions that betray that parent's commitment to protect the well-being of their own child. Exaggerated blaming also protects the therapist from some of the most painful aspects of identifications with a child who is being hurt by a parent. It simplifies the child's experience to fit the character type common in children's folktales, by ignoring that the child is not just being mistreated but is being betrayed by a primary caregiver who is loved and feared, who determines the validity of child's own experiences, and who also loves that child and wants to treat the child well.

Blanket exoneration of the hurtful parent is usually achieved by the therapist who chooses to believe that the parent is trying as hard as possible to love and treat the child well but, compelled by forces beyond human control, is completely powerless to be less hurtful. In such instances, the therapist adopts a simplistic view of the parent as a martyr to the burdens of caring for a child that no parent could manage successfully or to a set of circumstances that would leave any parent too handicapped to care for a child that other more fortunate parents could enjoy. Blanket exoneration can also be achieved if a therapist relies exclusively on the concepts, methods, and findings of natural materialist science. Using such natural science concepts, parenting problems can be characterized only as patterns of thoughts, feelings, and behavior that are solely determined by natural forces interacting within a complex biopsychosocial system. Such false exoneration of the parent also protect the therapist from painful identification with the hurtful parent who is a good enough ordinary person, loves the child, but is in part ethically responsible for decisions that betray that parent's commitment to protect the child's well-being.

In the most extreme instances of blaming, therapists are not able reliably to suppress their contempt for the villain parent who persists in hurting the seemingly innocent child. In the most extreme instances of parental exoneration, therapists experience conscious contempt for the bad child or pity for the totally incompetent parent. However, such blaming and exoneration are sustained by experienced therapists most often because they are masked and therefore unexamined. They are masked by the false conviction that the therapist should abstain from ethical judgment of the patient to be "professional." Such a prohibition against moral judgment is associated with a misleading standard that is often mistakenly referred to as "scientific objectivity," "therapeutic neutrality," or a "nonjudgmental therapeutic stance." ([Langs, 1982](#); [Schafer, 1983](#))

All these common defensive strategies are almost impossible to sustain unless therapists allow themselves to accept an overly simplified psychological understanding of the clinical problem, the child, the parent, the parent-child relationship, and the therapeutic process. Such overly simplified psychological thinking cannot be sustained, in turn, without being buttressed by inappropriate clinical theory and clinical science. The inappropriate clinical theory that most therapists use to sustain these defensive strategies involves the rote application of established standardized methods of disease identification and management, methods that exclude the complex psychological meaning of the child to the parent and the moral dimensions of parental choice and responsibility. The inappropriate clinical science most therapists use to sustain their defensive strategies involves the exclusive misapplication of the language, concepts, and methods of natural science to formulate clinically defined defects in the mental lives of parents.

A clinical formulation that is based exclusively on the knowledge of determinist natural science automatically excludes the parent's agency on which the moral dimension of parental responsibility depends. The parent is likely to be characterized simply as ignorant, socially disadvantaged, incompetent, character disordered, or psychiatrically disordered. The child is characterized simply as genetically vulnerable, temperamentally difficult, or psychiatrically disturbed. The proper treatment is characterized simply as the reliable application of specific empirically validated standardized interventions to modify the specific symptoms or signs of identified disorders.

In addition, the defensive strategies, denial, and dichotomous thinking about the moral dimension of parenting problems are almost impossible to sustain if the therapist can maintain dual empathy for both parent and child or if the therapist can hold onto a focus on the long-term primary goal of parenting assessment and treatment, which is the long-term well-being and healthy mental life for the child. To engage in denial of the parenting problem, the therapist must suppress empathy for the child. Simplistic blaming of the parents requires that therapists suppress empathy for the parents. Such empathic failures are self-evident. However, empathic failure associated with unqualified exoneration of the parent who is not taking responsibility for the hurtful behavior is less easy to comprehend. A comprehensive consideration of the various types of empathy and of the components of the empathic process is needed. In contrast to instances of blaming, a therapist who simplistically exonerates a parent may retain empathy for many aspects of the parent's life experience outside the hurtful interactions with their child. In addition, an exonerating therapist may even maintain a capacity for some components of empathy for a parent's experience within the parent-child relationship, for example, intuitively sharing a parent's conscious experience of anger toward a child who refuses to be comforted or a child who chooses to destroy property and hurt other people.

However, the therapist who has completely exonerated a parent as a result of defensive moral reasoning will not be able to achieve empathy that encompasses the

complexities and paradoxes that make up the unique conscious and unconscious subjective experiences of a hurtful parent who both loves and hates and who is both victim of powerful forces and responsible perpetrator of mistreatment. For example, a therapist who simplistically exonerates parents can comprehend the frustration of parents who cannot comfort a child they love, but that therapist will not be able to share important aspects of the guilt, shame, and helplessness that accompany the rage and terror that parents unconsciously experience for a crying child who cannot be comforted.

### **Practical Consequences of Therapists' Denial and Defensive Moral Reasoning**

The practical problems that stem from therapists' denial of parenting problems and defective moral reasoning disrupt all critical phases of the work with parents. First, the clinical assessment may be inadequate. Although the most glaring abnormalities of parenting behavior may be noted, much more common problems in the emotional atmosphere of the parent-child relationship are usually overlooked. Similarly, clinicians may ignore most parenting problems altogether to focus exclusively on the child's psychiatric disorder and on genetically determined etiologic neurobiological factors.

Second, the formulation of the clinical problem may be inadequate. In a defensive frame of mind, when clinicians formulate ongoing problems in parenting behavior, they are prone to ignore the central role of unconscious parental thoughts and feelings about the child. They tend to understand the inappropriate parenting behavior simply as the result of the parents' ignorance about the child's development or ignorance about the child's psychiatric disorder or as a direct result of the child's difficult behavior and symptoms, parental psychiatric disorders, physical illnesses, marital problems, family problems, or environmental stressors. Based on overly simplified understandings of the problem that exclude the most critical aspects of the hurtful parent's mental life, clinicians most often recommend only individual treatment for the child with no treatment for the parent or only child guidance, psychoeducation, environmental manipulations, respite, or case management, when psychodynamic parent psychotherapy is required. Even when the parents' mental life is included in the formulation, the central defect in parenthood is often ignored, and as a result individual psychotherapy, marital therapy, or family therapy is recommended when psychodynamic parent psychotherapy would be much more effective.

Third, when clinicians engage in denial or defensive moral reasoning, the implementation of the psychodynamic psychotherapy is often ineffective. In the course of a parent treatment, the parent psychotherapist may lose empathy for the parent, lose empathy for the child, assume a rigid prescriptive treatment style, or allow the parent to avoid the thoughts and feelings associated with the parent-child relationship by inappropriately drifting toward other spheres of the parent's inner life.

### **Guidelines to Help Manage Therapists' Reactions**

The approach to the management of therapists' strong psychological reactions recommended here relies heavily on the use of practice guidelines. Effective personal psychotherapy is essential, but it cannot possibly completely insulate therapists from the strong psychological reactions discussed here. Reducing the therapist's activity, increasing vigilance about following the ground rules, and making conscious efforts to be morally neutral limit some of the detrimental consequences of these strong reactions, but they do not adequately protect the therapy. However, the six principal guidelines suggested in this chapter are required to sustain the therapeutic frame of mind required for psychodynamic parent psychotherapy. In addition, case consultations and peer supervision are often necessary. Consultation and supervision are most helpful if they involve psychodynamic therapists who are experienced in working with children and parents, have been striving already to work in a fashion that addresses the moral dimensions of the parenting problems and the treatment, and are familiar with the six primary guidelines presented here.

Current psychoanalytic theoreticians clarify the role of the therapist's conscious judgment and choice in the empathic process. Systematic professional approaches to conscious self-scrutiny are used primarily to detect and to rectify various countertransference distortions and impediments. In addition, disciplined self-scrutiny is used to prepare the way for a more complete kind of empathy, in which a therapist actively and consciously projects his or her consciousness into the inner world of the parent, as an experiment in thinking and feeling, to grasp intuitively a more complete sense of the experience of that parent ( [Buie, 1981](#); [Flax, 1994](#); [Margolis, 1989](#)).

The six guidelines recommended in this chapter are expressions of unspoken norms of psychodynamic psychotherapy. Although they are not explicitly articulated in the clinical theory that guides most psychodynamic psychotherapists, many of them have been deeply ingrained in the training of psychotherapists through clinical mentoring. These guidelines are meant to supplement, not supplant, the use of established guidelines of psychodynamic psychotherapy, standardized, "evidence-based" (e.g., DSM-IV) classification of psychiatric disorder and consensus parameters of intervention for identified psychiatric disorders. The approach advocated here is built on a moral foundation that includes a commitment to each child's inner life and autonomy, the particular meaning of the child to the parent, the unique meaning to each parent of specific aspects of his or her history and circumstances, and the parent's ethical responsibility to uphold fidelity to the child's autonomy and best interests. These aspects of the clinical situation can hardly be addressed at all if therapists rely solely on the language, concepts, and methods of evidentiary-based medicine. Similarly, such aspects cannot be adequately addressed, even when a therapist is able to make wise use of theory and technique from both the evidence-based approach and psychoanalysis. Hence, the guidelines suggested here are essential supplements to established practice.

#### ***GUIDELINE 1: THE PARENTAL MENTAL PORTRAIT OF THE CHILD***

A full evaluation of parenting should always be organized in accordance with a model with the parental mental portrait of the child at its center, because this model best helps the therapist to implement the primary goal of the treatment, that is, lasting improvements in the parent-child relationship that promote the long-term well-being, autonomy, and healthy mental life of the child. The parental mental portrait is a psychodynamically informed description of enduring patterns of thoughts and feelings, primarily unconscious thoughts and feelings, about a particular child. The parental mental portrait model for the formulation of parenting disorders has the parental mental portrait at its center. The model embeds the parental mental portrait in the context of a dynamic interactive systemic profile of that parent's particular psychological, biological, social, economic, and political circumstances and gives priority to the unique characteristics of the child and the parent-child relationship. In addition, the formulation of the portrait should reflect a developmental perspective informed by a thorough psychological history of the parent, the child, and their relationship in the family unit. Most important, the formulation of any parenting problems should always include an understanding of the parent's conscious decisions about how to think, feel, and act in relation to the problems experienced as a result of the disorder of the mental portrait. It should include the variety of competing and often incommensurate values that are relevant to those decisions and also the parent's effort and capacity to make wise judgments and to act with courage and discipline to implement them. Clinicians should reject as incomplete any formulation of the parenting problem that undervalues the importance of the parent's unconscious thoughts and feelings, ecological circumstances, developmental processes, or psychological history. Similarly, clinicians should reject any formulation of a parenting problem that does not explicitly address the parent's ethical responsibility adequately.

#### ***GUIDELINE 2: SUSTAINING DUAL EMPATHY FOR BOTH PARENT AND CHILD***

Parent psychotherapists should consciously discipline themselves to achieve, monitor, and sustain dual empathy for both the hurtful parent and the hurt child, throughout the diagnostic and treatment phase of the work, because dual empathy is an essential condition of successful parent psychotherapy. Empathy for the child is required to resist the tendency to deny the parenting problem, to achieve a full appreciation of the clinical problem, and to prevent defensive drift of the therapeutic focus to other pressing concerns. Empathy for the parent, which includes an appreciation of the parent's ethical responsibility for choices that are harmful to the child, is required to make accurate judgments about the parent and to sustain the professional healing relationship required to manage the suffering associated with the exploration of unconscious mental processes.

#### ***GUIDELINE 3: ASSESSMENT AND ATTRIBUTION OF ETHICAL RESPONSIBILITY***

The parent therapist should make a carefully reasoned assessment of the responsibility of a parent for making decisions to act in ways that perpetrate harmful behavior toward the child or fail to seek or accept help. Deliberate, sound assessments of the parent's ethical responsibility, which are essential to successful psychotherapy, are distinguished here from defensive moral judgments that disrupt diagnosis and treatment. Such a professional assessment of responsibility is needed for many reasons. It is required to help the therapist avoid inadvertent defensive moral reasoning. Therapists also need to assess parental responsibility to help parents both to forgive themselves for their own irresponsible behavior and to assume full responsibility for their choices.

The experience of forgiving oneself, taking responsibility, accepting appropriate guilt and shame, and making appropriate internal changes and reparations relieves excessive guilt, shame, and other kinds of psychological suffering that are associated with moral self-deception. The experience of forgiving oneself relieves suffering by liberating parents to experience the child more realistically, to analyze negative dystonic thoughts and feelings associated with the child, to mourn the psychological losses associated with parenting, to identify the hurtful behavior accurately, and to pursue their own value-based life goals in parenting and in other areas of their adult lives.

Parents also need to help their children, other family members, and friends to understand and forgive them for the hurtful behavior. However, children also hurt

parents in a disturbed parent–child relationship, and parents need to forgive their children and to help them to forgive themselves because children, like parents, are responsible for their own hurtful behavior. Although especially important in psychodynamic parent psychotherapy, an honest assessment of various immoral behaviors is needed to help almost all psychotherapy patients understand better the role of freedom and responsibility in their efforts to pursue their own life goals and values.

Therapists should use a nuanced, informed, and flexible assessment of parental responsibility. The assessment should be based primarily on values implicit in child psychiatry as it is practiced in our secular, pluralistic, free society, but also on the personal values of the therapist and those of the parents, their family, religion, and ethnic culture. The assessment of parental responsibility is very difficult to do constructively. Such an assessment requires systematic consideration of many different factors, but even with an extensive profile of data, it is still very difficult to judge accurately how courageous and hard working a parent has been at various times and in various contexts.

Parents are often more desperate than they know and than anyone around them can tell. In view of these complexities, a therapist's assessment always should be tentative and performed in a spirit of generosity, empathy, and respect. Responsibility for hurting the child should be estimated initially and reevaluated often during the course of treatment. In the course of ongoing psychotherapy, reassessments should be performed collaboratively with increasing leadership by the parents. However, helping parents to acknowledge ethical responsibility requires caution, respect, tact, and empathic support, because relinquishing their own caricatured self-image of victim, martyr, or incompetent person can be extremely dangerous for some parents at certain times in their lives.

#### *GUIDELINE 4: PRIMARY ADVOCACY FOR THE MENTAL LIFE OF THE CHILD*

Parent therapists should explicitly adopt and advocate for changes in the parent–child relationship that promote the optimal inner life and long-term well-being of the unique individual child as the primary goal of the parent treatment, although the parent is the patient engaged directly in the therapy. Explicit commitment to the long-term well-being of the child as primary is required by therapists to manage their own reactions to the moral failings of the parents who are their therapy patients and to resolve ethical conflicts about treatment goals, conflicts that arise when the needs of the children are in conflict with needs or preferences of their parents. Similarly, but not unique to parent psychotherapy, an explicit commitment to the child's long-term well-being, inner life, and autonomy is required to protect the children's needs when they are in conflict with the needs of insurance companies, hospitals, outpatient clinics, or the financial needs of the professional. In the presence of these very real conflicts, it is often difficult and painful for clinicians to keep the child's unique needs primary.

The commitment to the child's long-term well-being is expressed in an explicit advocacy for the development of healthy qualities in the child's mental life. A value-based view of an optimal “healthy” inner life for that child ( [O'Rourke et al., 1992](#) ) is defined by accepted norms of our liberal democratic society, Western medical traditions, and a legacy of centuries of experience in caregiving. Such norms are implicit in the aspects of child psychiatry, pediatrics, and child development that are focused on achieving enduring changes in the mental life of children. Similarly, an implicit understanding of a “healthy” parental mental portrait is one that supports best the development of a healthy inner life for a child.

In practice, the clinician should discuss the explicit value-based child advocacy position during the initial evaluation to build the initial treatment alliance with a parent and to guide the decision to recommend psychodynamic parent psychotherapy in the first place. Many very valuable clinical interventions for children or parents are not primarily committed to enduring improvements in the child's inner life. Although the goals of relieving symptoms, managing disorders, and improving social maladjustment are usually complimentary to the unique value-based personal goals for the individual patient, they are sometimes incompatible for a particular child, with a particular history, at a particular time, in a particular circumstance. In circumstances in which there is a parenting disorder, interventions that successfully help the child to achieve good social adjustment to a parent–child relationship that remains psychologically destructive to the child are inconsistent with a primary commitment to support the development of healthy personality, including self-determination, self-respect, and freedom from inner torment. Similarly, successful interventions to relieve symptoms and maladjustment most often are associated with improvements in the child's inner life, but sometimes the child's inner life remains unhealthy, although that child has become relatively asymptomatic. In such cases, giving priority solely to the child's social adjustment leaves the child's personality development unprotected.

Therefore, clinicians should accept treatments for a child that are directed solely toward symptom relief, disease management, and improved social adjustment only when they best serve the particular child's inner life and long-term well-being. Short-term relief of pain and improved adjustment in family, school, and other important life contexts are always subordinate goals to a healthy long-term quality of inner life for a child. Parent therapists should advocate for psychodynamic parent psychotherapy on behalf of the child whenever the potential benefits to the child outweigh the costs and risks for the child, even if parents prefer a less expensive or less painful approach.

The advocacy position provides a place to stand from which a parent therapist can consciously and systematically review the costs and benefits of a parent entering into parent psychotherapy. Such a value-based position is required to decide properly when to encourage parents to endure pain, to accept personal risk, or to assume expenses on behalf of their child. The explicit advocacy position also helps clinicians to decide when they must vigorously oppose strong financial and administrative incentives from insurance company managed-care or school systems to do only the most inexpensive, focused treatments. ( [Hoffnung and Ferholt, 1997](#) ) Similarly, during the course of a treatment in progress, a commitment to the inner life of the child and his or her long-term well-being helps therapists to sustain a focus on the parenting problem and especially on the parental mental portrait of the child and the emotional tone of the parent–child interactions. For example, the advocacy position helps parent therapists to resist parental pressures to support the parent's social adjustment, the parent's fulfillment in another love relationship, or other aspects of the parent's life goals in ways that conflict with the long-term well-being of that parent's child.

#### *GUIDELINE 5: PROTECTING CLINICAL JUDGMENT BASED ON APPROPRIATE VALUES*

Clinicians should diagnose each parent's clinical problems and determine all aspects of individual patient care by using expert clinical judgment. The primary goal of the treatment, which is the long-term well-being and autonomy of each unique child, serves as the primary guiding principle for all clinical judgments. However, many other values are taken into account, as are a wide range of data, formulated from various perspectives.

Good clinical judgment requires an appropriate assessment of the clinical situation, including reliable data about the personal characteristics of the parent, child, parent–child relationship, and family that is gathered in the context of a traditional, professional, caregiving relationship. Such good clinical judgment also requires an appropriate formulation of the clinical data, a model to guide the synthesis and organization of the data, that is informed by the best available knowledge and theories in the natural and various human sciences. Such a formulation should encompass various accounts of the clinical situation as viewed from diverse perspectives and levels of organizational complexity, including biological, psychological, behavioral, interpersonal, family, social, cultural, spiritual, and moral dimensions.

Good clinical judgment must be based on the consideration of many different alternative actions including those drawn from a diversity of professional orientations, including, descriptive, psychoanalytic, cognitive, learning, existential, interpersonal, and family systems perspectives, while taking into account the best current biobehavioral technology and the available resources. Algorithms for the management of psychiatric disorders cannot be used to determine treatment decisions, but they are useful as one important factor to consider when making individualized clinical judgments. Clinical judgment is informed by calculations of the likely therapeutic outcomes of such actions by taking into account the unique circumstances of the patient and the likely losses, risks, and economic costs of those same actions.

The cost-to-benefit and risk-to-benefit determination for any action or inaction that is being considered not only should be based on the primary goal of treatment, but also should take into account several other sources of competing and often incommensurate values ( [Sider, 1984](#) ). Such values include the unique life goals of the parent in treatment, values appropriate for the particular child, values of any other parent, those of other important members of the family, explicit medical ethics, appropriate professional medical mental health values goals and standards, and the psychiatrist's personal values ( [Hundert, 1987](#) ).

The expert clinical judgments that are used to determine all aspects of care should be made by professionals of the parent's choice in collaboration with the well-informed, relatively autonomous, uncoerced parent in treatment, often including consultation with both parents and sometimes the child and other family members. Such collaborative judgment requires an adequate professional caregiving relationship characterized by fidelity, privacy, empathy, respect, and compassion.

All clinical judgments about care must be held to the standards of professional practice, which are designed to serve the well-being of the individual patient and to do no harm. Professional standards that guide professional judgment are only valid when they are established, maintained, and implemented by a profession that is relatively independent of commercial pressures from large employers, government bureaucracies, the vicissitudes of politics, and the self-interest of the professionals. A full discussion of the training, supervision, support, and conditions of practice that are required to ensure and protect adequate standards of clinical judgment is not

feasible here.

#### **GUIDELINE 6: ADOPTING APPROPRIATE CLINICAL THEORY AND CLINICAL SCIENCE**

The misapplication of concepts and methods appropriate for the study of the material world to the way in which clinicians think about diagnosis and treatment undermines the primary practice guidelines that clinicians need to manage the moral dimension of work with hurtful parents. To sustain these guidelines, parent psychotherapists need explicitly to endorse an approach to science that can support a body of clinical theory that is appropriate to guide clinical judgment, to protect dual empathy, and to provide a credible basis on which to defend the values, goals, standards, guidelines, and conditions of practice required to protect psychodynamic psychotherapy from both the powerful internal psychological reactions to the moral dimension of parenting problems that undermine it and the powerful external commercial forces that threaten to eliminate it ([Ferholt et al., 1986](#); [Hunter et al., 1991](#)).

First, clinicians must retain a strong conviction that valid empirical science is not limited to the methods appropriate to study of the biological and other aspects of the natural world, but it also includes the concepts, methods, and data that are uniquely suited for the rational, systematic, reliable, and valid study of important human phenomena. Such phenomena include consciousness, autonomy, self-definition, identity, moral responsibility, love relationships, and rational judgment based on complex systems of human values ([Berlin, 1954](#); [Eddington, 1957](#); [Ferholt et al., 1986](#); [Harré, 1972](#); [Koch, 1959–1963](#); [Krutch, 1953](#); [Manicus and Secord, 1983](#); [Searle, 1993](#); [Spence, 1982](#); [von Bertalanffy, 1968](#)).

Second, while admitting the serious limitations of the extensive body of scientific research on professional caregiving, parent therapists must achieve the self-confidence and philosophical sophistication required to reject the misapplication of the language and methods of biology, economics, commerce, or industrial management to the study of clinical caregiving. They must also be able to resist efforts to eliminate the language, concepts, standards, guidelines, and practice conditions required to support professional caregiving and to refute the false view that dismisses clinical judgment based on individualized caregiving values as the unscientific art of medicine, an art that requires little professional expertise because it is based solely on folk wisdom, intuition, and basic human kindness. In addition, therapists must be able to resist the dismissal of individualized judgment-based professional caregiving based on the false claim that it is less essential than standardized evidentiary-based disease management.

Third, parent therapists must insist that clinical theory guiding individual patient care, although informed by behavioral and biological data generated in controlled clinical trials, must not be derived from the direct application of natural science knowledge. This is because many of the uniquely human experiences that are most important to clinical care include complex psychological variables that are not determined by the same types of predictable causal relationships that characterize the laws and theories of the biological and behavioral sciences. The foundation of good clinical theory must rest on human science that gives priority to the more thickly descriptive empirical methods required to study of the most important clinical phenomena that are not readily reducible to easily measured biological or behavioral variables without compromising their validity.

For example, complex mental data and reliable scientific empirical methods that are not experimental in design are essential to the rational systematic study of the complex, conscious and unconscious, dynamic, mental life of parents and children, freedom of choice, moral dilemmas, love relationships, family culture, mind–body interactions, and individualized patient care, including various relationship-based psychodynamic psychotherapies. In fact, they are the only scientific methods that offer valid knowledge suitable to help clinicians to determine treatment goals and to apply the knowledge and technology of natural science in a manner that properly reflects the unique values, needs, and situation of each individual patient.

Fourth, parent therapists should employ clinical theory that pluralistically, rather than eclectically or syncretically, combines many sources of knowledge from both the natural sciences and human sciences ([Havens, 1987](#)). A full discussion of the best way for clinicians actually to use explicit clinical theory, scientific knowledge, and technology in clinical practice is not feasible here. Briefly, good practice requires a professional healing relationship and value-based clinical judgment, both of which, in turn, depend on a good therapeutic clinical stance. The psychotherapeutic clinical stance is the frame of mind or, as Schafer puts it “a version of a therapist's personality or second self,” that is shaped especially for a particular psychotherapeutic role. The clinical stance depends on both the personal qualities and the training of the therapist, and it is focused by a small group of basic clinical concepts and guidelines. A parent therapist regularly brings such clinical concepts and guidelines to mind to generate and sustain the best therapeutic stance, even under pressure.

#### **PRACTICAL SUGGESTIONS FOR THE INITIAL PHASES OF TREATMENT**

The clinical evaluation of a child should take place over several sessions, spaced over several weeks, if possible. In addition to the history of the child and family, it should include direct observations of the child alone and the emotional tone of the parent–child relationship and other family interactions. Once a parenting disorder is identified, the psychiatrist should consider recommending psychodynamic parent psychotherapy even when a parenting disorder is not the reason the evaluation was initiated. For example, psychodynamic parent therapy may be the best recommendation for some adults who present to therapists with a chief complaint of marital problems, or even psychiatric symptoms or their own, especially during pregnancy, the postpartum period, or during their child's adolescence.

Usually, both parents should be involved in the treatment (conjointly or individually). Too often, fathers still are neglected in or excluded from treatment ([Ferholt and Gurwitt, 1982](#)). Occasional sessions including the children and their parents and sessions of the whole family are useful, but the children should most often be seen in concurrent individual therapies of their own, even if they are participating in family sessions, are not obviously disturbed, or are very young.

The same therapist may be able to perform a treatment for both the child and the parents; however, it is often best for two therapists to work in close collaboration. The collaborative arrangement is often required when the child needs very intensive and private treatment. Such an arrangement may also be essential to avoid intense unmanageable transference reactions in the parent, which are dangerous to the child and the therapist, if the child is an adolescent who is misbehaving or acting defiant in the family or when either an adolescent or a parent has a severe character disorder or a tendency to be dishonest and vengeful. Further, when it is clear that a parent has serious psychopathology, it is helpful for the parent therapist to insist at the outset on individual therapy for the vulnerable parent, in addition to and concurrently with the parent therapy. Serious clinical crises do occur regularly in these treatments, and some are serious enough to cause concern about murder, suicide, divorce, a major psychiatric episode in a family member, extrusion of the child (or one of the parents) from the family, or a lawsuit, grievance proceeding, or other form of attack on the therapist by a parent.

#### **PRACTICAL SUGGESTIONS FOR ONGOING TREATMENT**

A therapist's self-knowledge about his or her own psychological reactions to hurtful parents can be used to help parents to sustain self-esteem, to enhance empathy for their victimized children, and to learn better strategies to manage their parenting defects. By using an intersubjective formulation of the therapeutic relationship ([Bollas, 1987](#); [Little, 1981](#); [Searles, 1979](#); [Tansey and Burke, 1989](#)), carefully selected countertransference disclosures can be especially helpful. However, the intersubjective approach to psychodynamic formulation and transference analysis should not be allowed to become the primary technique in this work.

Therapists should deliberately strive to enhance every parent's self-respect by expressing appreciation for the parent's courage and discipline in the therapy and by helping the parent to identify the stressors impinging on him or her and the pain associated with them. In some cases, therapists should educate parents to help them develop a parenting stance guided by the same ethical and psychological tenets underlying the basic guidelines of parent psychotherapy. Such a parenting stance can be applied constructively to family decision-making and to a parent's conduct in interactions with a child.

For example, when a child feels hurt and acts sullen or angry in response to a parent's behavior, it is not useful for the parent to view the event simply as a matter of the parent's behaving inappropriately or the child's being overly sensitive. Rather, it is most useful to think of the interaction in terms of shared responsibility. Often in such instances, a parent should learn ways to acknowledge responsibility for behaving in a way that hurt his or her child, even if the parent's behavior is conventionally appropriate and would not have hurt most children, or even this child at other times. Acknowledging responsibility for hurting the child may even be part of the best course for a parent who has acted only in response to angry, rude, or destructive behavior from the child. Parents are advised to extend themselves to their children in this way to accommodate the vulnerability of children who feel insecure about themselves or unsafe with that parent and in the world. Many children are too guilt prone to think or talk about their responsibility for a hard interaction until after their parents first concede some regret for hurting them. Although these are simple truths, applying them over and over again in the context of the trials and tribulations of every day family life is extremely difficult.

In some cases, the therapist must also teach parents to avoid circumstances that elicit their own destructive states of mind, to recognize destructive mental states early when they inadvertently recur, and to manage them with discipline. Ironically, this often requires that the parent recruit the help of others, including, at times, the

child who may have provoked the very state of mind that the parent is trying to manage.

---

#### CASE ILLUSTRATION

Although the discussion in this chapter focuses on the more severe disorders of parenting that are most difficult to treat, many cases that require psychodynamic parent psychotherapy are less difficult. This case illustrates the course of parent treatment relatively free of countertransference disturbance. Dual empathy is sustained in good part because the therapist has adopted the clinical schemes purposed in this chapter. This case also demonstrates the characteristics of a more subtle disorder in the emotional tone of the parent-child relationship than that in Jason M.'s family.

#### Case History

Douglas, age 7 years, in the second grade, lived with a 3-year-old sister, an infant brother, and his parents, who were both college educated, professionally trained, and financially secure. Over the past year, he had gradually developed an oppositional defiant disorder with anxiety symptoms. Douglas had early indications of poor neurobehavioral self-regulation, and as he grew older, he was unusually intolerant of frustrations and transitions and prone to brief periods of exaggerated developmental anxieties, unusual fears, and withdrawal associated with sadness and self-criticism. Conversely, Douglas also showed evidence of intrinsic resilience and acquired competence.

Douglas's psychiatric disorder developed in association with parenting problems and marital discord at the time his parents were forced to cope with severe environmental stressors. Both parents were competent and well motivated; they wanted to address the family problems before they asked Douglas to be in treatment. Thus, the initial child psychiatry intervention selected in this case was parent psychotherapy, performed during weekly, 50-minute sessions, almost always attended by both parents.

#### Therapy

A trusting therapeutic relationship was built with both parents during the first months in the course of gathering data, discussing formulation and diagnosis, seeking solutions to pressing management problems, and providing a cognitive framework for sustaining empathy and understanding for Douglas. This was a kind of psychoanalytically informed psychoeducation offering a clinical theory of parenting to help create a better mental stance in the parents when they were interacting with their son. The parent counseling also focused on the organization of family life, the collaboration of the parents, and the practical management of difficult situations involving Douglas.

The parents came to feel less frightened, confused, and self-critical about their parenting, improved the schedule and behavioral rules within the household, criticized each other less, and arranged for the father to spend more time with his son and to take more leadership in discipline. They learned to anticipate difficult periods for their son, to avoid some, to prepare him better for others, and to respond more constructively when he did become very upset.

They also learned an unconventionally generous way to respond to their son's oppositional defiant behavior, based on an interactive formulation that interprets his defiant behavior as a result of his one-sided interpretation of their actions, not as a problem with the development of his conscience or his capacity for impulse control, sustained attention, social skills, or moral discipline. They used an unconventional way of sharing responsibility for their son's misbehavior while sustaining a clear-cut although attenuated set of limits and expectations associated with unnegotiable, enforceable, reasonable consequences for transgressions. Over time, Douglas began to seem more comfortable and to behave better.

The nature and procedure of psychodynamic psychotherapy were explained, and gradually the conversations in the therapeutic sessions shifted focus to feelings the parents had for each other, those they each had when Douglas behaved in ways that hurt them, and those associated with their early memories about Douglas. The father's negative feelings, once exposed, were easily modified. Douglas's mother, on the other hand, discovered intense feelings of frustration, deprivation, guilt, shame, and anxiety in association with a tendency to slip into a frame of mind dominated by an ego-alien prejudice that reflected a negative mental portrait of her son. In this primarily unconscious frame of mind, the mother viewed Douglas as a self-centered, ungrateful, manipulative, dishonest, immoral person who was dominating, exploiting, and abusing her because she was not good enough for him no matter how hard she tried to make him happy. He dominated her by provoking her guilt, threatening to hurt her, and threatening to abandon her.

A crisis in the mother developed as she experienced an onslaught of very uncomfortable thoughts and feelings about interactions with her parents, now and in her difficult childhood. With a great deal of support from her husband at home and in the sessions, a strong relationship with the therapist, the help of several dear old friends, and a brief course of antidepressant medication, she managed to sustain herself during a period of intense grieving associated with uncovering very painful repressed memories of early experiences and a reconsideration of her current experiences with her parents. As the conversations about her past were elaborated, the therapist guided them to retain a focus on Douglas, and the connections between the feelings and thoughts she had about her mother and her son emerged without interpretation.

Over the time this work was being done in therapy, dramatic improvements occurred in the tone of the interactions between Douglas and both parents, his oppositional defiant disorder was resolved, his dysphoria was reduced significantly, and he became more expansive in his life outside the family. After 18 months (approximately 70 sessions), the parents were ready to stop the conjoint parent psychotherapy, and Douglas's mother decided to seek her own individual psychotherapy. Douglas did not require medication or individual psychotherapy.

#### Comment

The psychiatric disorder in this child may well have been ameliorated by any one of a variety of interventions, or it may have even dissipated without professional intervention. Thus, the parent-child interactions would have improved as well; however, it is argued in this chapter that without psychodynamic parent psychotherapy the improvements in the parent-child relationships would have, almost certainly, been more narrow, superficial, and transient, and the child's personality development and long-term well-being would have been compromised.

---

## CONCLUSIONS

In conclusion, a disorder of a parent's mental portrait of a child is always painful and destructive. If it is severe and persistent, it can create a tormented inner life for the child, can destroy the qualities of personality we value in this culture, and can contribute to the creation of an adult prone to crush the inner lives of others. A serious parenting problem also adversely affects the course of a psychiatric disorder in the child, no matter how prominent the neurobiological substrate. Child psychiatrists and other mental health professionals responsible for children should (a) be proficient at discerning the presence of parenting disorders even in the absence of deviant child-rearing practices, (b) be competent at performing psychodynamic parent psychotherapy, (c) engage parents in this kind of treatment more often, and (d) advocate for changes in the health care system that will restore the powers, resources, and time that professional child psychiatrists need to restore, maintain, and implement standards of care that include the assessment of the inner lives of parents and appropriate diagnosis and treatment when defects in parenting are identified.

**Acknowledgments.** *I wish to acknowledge my appreciation to Robert J. Hoffnung, who has collaborated extensively on the revision of this chapter in connection with our joint study of the impact of insurance company managed care and the use of evidentiary-based disease management methods on professional caregiving in medicine; to David E.K. Hunter, who contributed to the preparation of the original version of the chapter and extensively to the development of the ideas contained in it; and to Melvin Lewis, who supervised my early work in psychodynamic child psychotherapy and commented as editor of the textbook in ways that forced me to clarify difficult ideas and to make the chapter more accessible to the reader.*

### About this Review

#### Some Fundamental Questions about Psychotherapy

##### 1. Can Psychotherapy be Validly Researched?

##### 2. Does Psychotherapy Work?

##### 3. If It Works, Just How Good Is It?

##### 4. Is Psychotherapy Better than Placebo?

##### 5. Is One Kind of Psychotherapy Better than Another?

##### 6. Can Psychotherapy be Taught?

##### 7. Is More Psychotherapy Better than Less?

##### 8. Is Psychotherapy Better for Some Children than for Others?

##### 9. Is Psychotherapy Safer than Biological Therapies?

##### 10. Is Psychotherapy Acceptable to Consumers?

##### 11. Is Psychotherapy Cost Effective?

#### Summary and Conclusion

#### Chapter References

The power of one person to comfort, to teach, or to influence others is a universal part of human experience or, in short, has incontrovertible face validity. Psychotherapy is merely an attempt to capture this power within a healing context, to systematize it so it becomes transmissible (and researchable), and to regulate it in a helping professional relationship for the protection of the consumer and therapist alike. In this section on treatment, some chapters address the various kinds of psychotherapy used with children and adolescents. In general, these chapters focus on the theory, practice, and clinical indications of particular methods. Beneficence of outcome and an established place in the therapeutic armamentarium and in teaching programs in child and adolescent psychiatry are largely assumed.

In this review, the field of psychotherapy is examined as a whole and is subjected to critical scrutiny using the assumptions and value systems accepted in medicine and other helping professions; that is, the best way to establish efficacy and safety and to advance theory is through the scientific method, based on the null hypothesis or, as Bertrand Russell put it, not doubt, but dogmatic doubt.

However, the scientific basis of medicine is rather recent and was made possible only by enormous growth first in the physical sciences and then in the biological sciences in the 19th and 20th centuries. Yet medicine is as old as the first civilizations, all of which defined certain individuals as healers and expected them to care for—and cure—the sick and the dying, whether they had the knowledge to do so or not. Given the lack of effectiveness and downright noxiousness of most medical remedies until the 20th century, the wonder is that medicine survived at all as a profession. Cynics could say that this is mostly the result of the patient's fear of death and need to believe in a savior and the result of the skill of the medical profession in disguising its impotence and chicanery, as portrayed by Racine, George Eliot, and Mark Twain, among others. However, also important in the continued survival of the medical profession is what is portrayed in the famous, if sentimental, 19th-century painting *The Doctor* (in the Tate Gallery in London), in which late at night, a doctor sits, thoughtful and troubled, at the bedside of a sick child. It is said that the painter, Sir Luke Fildes, executed this work in gratitude for the most attentive care given to his child. (The fact that the child died does not seem to have diminished this gratitude!) The physician was perceived as trying all remedies, but more important, as being there when needed and showing care and concern.

Medicine is thus equally a humanistic and a scientific profession, and the spectacular growth in technologic knowledge has been matched, it seems, by increasing public concern about the diminution in personalized, humanistic care. In addition to its own value system, medicine is influenced by the political, economic, and cultural ecosystem that shapes its form and dictates its execution. It is thus necessary to temper any critique of what doctors do with due consideration for all these factors besides the scientific.

Psychotherapy has some distinctive features that differentiate it from many other medical treatments. First, its practice is not limited by statute to licensed physicians, and there are those who will argue that the rules of medicine thus do not apply. However, it can be said equally that physicians who practice psychotherapy are still so obligated, and that should be one of the discernible differences between psychiatrists and nonmedical professionals. Second, although medicine did originally depend on charisma and caste to establish validity of treatment, this has gradually faded considerably in favor of hard data from well-designed clinical trials (evidence-based medicine). For a variety of reasons, some of which reflect the sheer complexity of the subject although others are less worthy, traditional child psychotherapy was and is still largely dependent on charismatic leaders and innovators rather than on data ( [Werry, 1989](#)).

## ABOUT THIS REVIEW

Since the previous edition of this textbook was published in 1996, there has been increased interest in the issue of psychotherapy research with children. In 1998, two important journals devoted issues to descriptions of current status, problems, and outcomes in psychotherapy research: the *Journal of Abnormal Child Psychology* and the *Journal of Clinical Child Psychology*. One aspect of this interest has been definitions of psychotherapy, which are increasingly attempting to include issues of patients' collaboration with the therapist and the context of therapy. An example is [Brent and Kolko's \(1998\)](#) definition that psychotherapy is a modality of treatment in which the therapist and patient work together to ameliorate psychopathologic conditions and functional impairment through focus on the therapeutic relationship, patient attitudes, thoughts, affect and behavior, and social context and development. This definition remains independent of the technique or underpinning theory, whether psychodynamic, client-centered, behavioral, individual, play, group, family, brief and long term, and so on.

What is striking is the generic nature of this definition, which may appear simplistic to practitioners of particular modalities of psychotherapy. However, there is both a utility and a good reason for keeping the definitions broad. First, with a few exceptions, research has demonstrated that much of the therapeutic power stems from a set of variables common to all kinds of psychotherapy, however different they may seem. Second, many kinds of child psychotherapy are insufficiently explicated to examine their putative differences from each other. Third, there are insufficient data to examine all kinds of child psychotherapy individually, and aggregation of studies, despite all the problems therein, is necessary to obtain sufficient statistical power. Finally, those who think that their kind of psychotherapy is superior, despite insufficient data to support their contention, may be motivated to do the studies necessary to prove the point.

Unless otherwise stated, in this chapter psychotherapy is described as applied to children, with *child* taken to include infants, children, and adolescents. This is not an exhaustive review of psychotherapy. Detailed analysis of individual studies is not undertaken because these already exist ( [Barnett et al., 1991](#); [Casey and Berman, 1985](#); [Faubert and Long, 1991](#); [Hazelrigg et al., 1987](#); [Henggeler et al., 1993](#); [Kazdin, 1991, 1993](#); [Kovacs and Paulauskas, 1986](#); [Ollendick, 1986](#); [Shirk and Russell, 1992](#); [Target and Fonagy 1996](#); [Tramontana, 1980](#); [Weiss et al., 1999](#); [Weisz and Weiss, 1993](#); [Weisz et al., 1987](#); [Weisz et al., 1992](#); [Weisz et al., 1995](#) ). Rather, some basic questions are posed, and some of these reviews are used in response. The answers are cast in terms of their implications for research training and practice in child psychiatry.

## SOME FUNDAMENTAL QUESTIONS ABOUT PSYCHOTHERAPY

Our overview of 1996 in the earlier edition of this text posed a list of 12 questions that are, in our opinion, fundamental to improving treatments in this area. Since this first overview, some further issues have arisen. However, it is striking that many of these questions remain of relevance and regrettably still unanswered several years.

1. Can psychotherapy be validly researched?
2. Does psychotherapy work?
3. If it works, just how good is it?
4. Is psychotherapy better than placebo?
5. Is one kind of psychotherapy better than another?
6. Can psychotherapy be taught?
7. Is more psychotherapy better than less? Or what is the dose effect for psychotherapy?

8. Is psychotherapy better for some children than for others? How does the child's context (e.g., family, social, ethnic) influence the effectiveness of psychotherapy?
9. Is psychotherapy safer than biological therapies?
10. Is psychotherapy acceptable to consumers?
11. Is psychotherapy cost effective?

## 1. CAN PSYCHOTHERAPY BE VALIDLY RESEARCHED?

As all the cited reviews show, one of the more persistent problems in evaluating psychotherapy is the lack of sufficient good research to answer the questions under discussion. There are those who believe that psychotherapy is not measurable because it concerns the elemental nature of human beings not only within the individual, but also as interacting with others such as parents or therapists. Indeed, this argument was used to dismiss the findings of some of the first attempts to evaluate psychotherapy such as the American Institute of Psychoanalysis study of the 1960s. Much of the good research on traditional individual psychotherapy with children (excluding behavior therapy) was done in a flurry of optimism between 1963 and 1973 ([Barnett et al., 1991](#)), although since the mid-1990s there has been a resurgence of interest in the area, perhaps driven by the funding issues that force clinicians to produce data to support their approaches ([Kazdin, 2000](#), [Salzer et al., 1999](#), [Weisz et al., 1995](#)).

None doubts that the task of researching psychotherapy is extremely complex and, as with applied research in humans, very difficult to pursue, but that should be a challenge, not a deterrent. Science operates by removing only one skin of the infinitely layered onion of Nature at a time, and although the task will never be complete, the success of science in our everyday lives is there for all to see. Is any research about psychotherapy better than nothing? Clearly, if the result is meaningless nonsense, or worse, misleading sense, the answer must be no. However, the rules for good psychotherapy research were set out many years ago ([Heinecke and Strassman, 1975](#)), and methods by which to enact these rules, especially those derived from adult psychotherapy, have advanced considerably since then ([Barnett et al., 1991](#); [Kazdin, 1991](#); [Kazdin, 2000](#); [Shirk and Russell, 1992](#)). Add to this advances in the technology of measurement in psychiatry as a whole and in adult psychotherapy ([Bergin and Garfield, 1994](#); [Kazdin, 1991](#)) and in other areas of child psychiatry (e.g., psychopharmacology), and there is now a formidable body of knowledge to facilitate this process. In particular, Kazdin's book is full of practical suggestions for research that must surely end the argument that psychotherapy cannot be properly researched once and for all ([Kazdin, 2000](#)).

In any case, a reviewer does not get the sense from serious writers on psychotherapy (apart from gurus) that the dearth of good research in most forms of psychotherapy except behavior therapy results from a lack of tools to do the job ([Barnett et al., 1991](#); [Shirk and Russell, 1992](#); [Shirk and Russell, 1995](#)). What appears to be lacking is the will. There are those who would defend child psychotherapy, especially its traditional forms, on the grounds that it has not been adequately studied ([Shirk and Russell, 1992](#)), however, such research as there is with children suggests that the findings do not differ qualitatively from the much vaster, more robust, and more active field of psychotherapy research in adults ([Kazdin, 1991](#); [Kazdin, 1993](#); [Kazdin, 2000](#)). Thus, it is possible to draw on this fund of knowledge ([Andrews, 1993](#)) to make tentative statements for child psychotherapy when child data are inadequate. Further, the issues of methodologic complexity and shortcomings in studies have been overstated. It has been shown ([Weiss and Weisz, 1990](#); [Weisz et al., 1995](#)) that even when the effects of methodologic flaws are allowed for in metaanalyses, substantial effects of psychotherapy are still discernible.

There is one serious criticism that clinicians may legitimately level at research in psychotherapy—to meet the requirements of rigor (and publication within the time span imperative to success in promotion, reputation, and grantsmanship!), there is little resemblance between what researchers study (i.e., efficacy of treatment) and what practitioners do (i.e., treatment effectiveness) ([Kazdin, 1991](#); [Ritvo and Papiłsky, 1999](#); [Weisz et al., 1992](#)). For example, Kazdin lists several major differences such as subject recruitment, locus, duration and theoretical orientation of treatment, and involvement of parents ([Kazdin, 1991](#)). There is also the issue of adequate follow-up because delayed (sleeping) effects have been demonstrated ([Kazdin, 1993](#)). The answer to this problem seems to be clear—there is a need for practitioners to research themselves or actively to promote and assist in the process, rather than have unfriendly and uncomprehending researchers speaking for what they do. If psychotherapists fail to do this, then they have no right to complain that research rarely reflects the real world of clinical practice. How to bridge this gap is discussed in detail by [Weisz et al. \(1995\)](#).

## 2. DOES PSYCHOTHERAPY WORK?

There are now more than a thousand controlled studies that look at different treatments for children and adolescents ([Kazdin 2000](#)). With the exception of one reviewer ([Levitt, 1957](#); [Levitt, 1963](#)), all others, especially the metaanalyses ([Barnett et al., 1991](#); [Lonigan et al., 1998](#); [Weisz et al., 1987](#); [Weisz et al., 1992](#); [Weisz et al., 1995](#)) involving hundreds of studies, conclude that, *independent of the kind of psychotherapy, treatment is better than no treatment*. Some have been concerned that this comforting convergence of results conceals serious problems of method, which either inflate the efficacy ([Shirk and Russell, 1992](#); [Shirk and Russell, 1995](#)) or raise doubts about the validity of conclusions ([Barnett et al., 1991](#); [Heinecke and Strassman, 1975](#); [Klein, 2000](#)). Although these concerns do have some legitimacy, as already noted they have been overstated, especially when there are sufficient studies for a metaanalysis ([Weiss and Weisz, 1990](#); [Weisz et al., 1995](#)). Thus, it seems quite in order to say that the evidence does favor efficacy and thus that the practitioner can claim that psychotherapy is a *legitimate treatment*, although, as discussed later, this statement is subject to caveats regarding for whom, for how long, and for which kinds of psychotherapy.

## 3. IF IT WORKS, JUST HOW GOOD IS IT?

If, as just concluded, psychotherapy is better than no psychotherapy, just how often is it so and to what degree? In their metaanalysis of more than 100 studies, [Weisz et al. \(1987\)](#) found the effect size was 0.79; that is, 79% of children were better off treated than not—a very substantial proportion. Only 6% of children were made worse. In clinical practice, then, this means that the odds that psychotherapy will help are very high, provided, of course, that approximately the same criteria for selecting patients used in most studies are applied, which they are not ([Kazdin, 1991](#)), although the algebraic summation of these differences is probably zero, because some would favor and others disadvantage practice. This may explain why [Weisz et al. \(1987\)](#) did not find much difference between genuine clinic and “analog” studies (e.g., recruited subjects).

However, the actual *amount* of benefit produced is less impressive, accounting for less than 20% of the outcome variance ([Weiss and Weisz, 1990](#)). This finding suggests that the *average effect* of psychotherapy is rather small, although most practitioners would probably consider a 20% improvement as realistic and valuable. In addition, as discussed in more detail later under cost:benefit ratio, the measures used may not do justice to the flow on effects of psychotherapy beyond mere clinical improvement.

As the question of efficacy continues to be debated, interest grows in the role of theory. Kazdin (1999) argues that theory has been almost entirely neglected, the consequence being that there is little to guide us about how treatment works and how to refine it. This theme has been expressed by others as well ([Ritvo and Papiłsky, 1999](#); [Weisz and Hawley, 1998](#).) A further issue has been the lack of developmental focus of much research to guide such areas as timing of outcome measures or even planning and executing of research ([Eyberg et al., 1998](#)).

## 4. IS PSYCHOTHERAPY BETTER THAN PLACEBO?

In his review of adult psychotherapy, [Andrews \(1993\)](#) points out that, although psychotherapy has been demonstrated to be better than no treatment, few studies try to find out whether psychotherapy is better than “placebo” or, in short, has effects not solely dependent on expectancy, ordinary human caring, status of the therapist, and what Andrews calls “good clinical care.” Even in adult psychotherapy, this question appears still to remain unanswerable ([Andrews, 1993](#)). Of all the psychotherapies, behavior therapy has by far the greatest amount of evidence to suggest that its effect extends beyond mere placebo ([Andrews, 1993](#)), although there are those who would query the clinical relevance of some of its effects.

Nearly all the studies of child psychotherapy compare its effects against no treatment or alternative forms of psychotherapy, thus making estimate of the placebo effect impossible. Kazdin ([1991, 2000](#)) and [Fonagy \(1997\)](#) point out that it is often practically difficult to design effective placebo-type procedures. For example, how does the researcher ensure that therapists have the same commitment and enthusiasm to the placebo as practicing therapists have to their treatment? What are the ethical and legal implications of common placebo conditions such as random assignment to treatment or no treatment? These issues may be complex but cannot be avoided: as differences between placebo and psychotherapy emerge, then second-stage research to identify the variables responsible for the superiority becomes economically and ethically justifiable. However, as Kazdin writes, “random assignment is preferred but it ought not to be worshipped” ([Kazdin, 2000](#)). The state of evidence in the area is such that almost all questions remain open or doubtful, and findings from even well-formulated naturalistic studies could be of considerable use.

## 5. IS ONE KIND OF PSYCHOTHERAPY BETTER THAN ANOTHER?

In their review, [Casey and Berman \(1985\)](#) conclude that there is no difference among therapies, although protagonists for traditional psychotherapy seem to be unaware that data were sufficient to compare only behavioral and client-centered therapy. [Weisz et al. \(1987\)](#) criticize the way that Casey and Berman's evaluative methods disadvantage behavioral studies, add more studies, and conclude in their metaanalysis that behavior therapy is clearly superior to other therapy in children. Similar conclusions are reached by [Andrews \(1993\)](#) for adult psychotherapy, for which he estimates the size of the superiority to average at least half a standard deviation. In rebuttal, Shirk and Russell ([1992, 1995](#)) conclude that it is not possible to say that behavior therapy is superior to psychodynamic psychotherapy in children because the studies of the latter have been so flawed as to make them invalid. [Kazdin \(1991\)](#) also believes that the issue is undecided because of lack of data in most methods other than behavioral. However, [Weiss and Weisz \(1995\)](#) find little support for this hypothesis using metaanalysis. Furthermore, Weisz et al. (1999) have examined nine studies of traditional child therapy and have found an average effect size of only 0.01. None of these studies included randomized design: when such a study of 160 children was completed, the effect size shrank to  $-0.08$ .

Thus, whereas the answer is still not clear, there is some indication that behavior therapy may be superior to other forms of psychotherapy (although only by half a standard deviation, which may not be a great deal in terms of clinical effect). This is particularly true if the symptom focus of behavior therapy is accepted as a legitimate focus of all psychotherapy. Other forms of psychotherapy do themselves a disservice in their persistent reluctance to conduct research because most of the apparent superiority of behavior therapy resides not only in more data but also in the rather narrower and therefore more measurable targets ([Kazdin, 1991; Weisz et al., 1995](#)).

Since the last edition of this book was published in 1996, there have been both an expanding study of some modes of psychotherapy and an increased likelihood that specific problem-domains rather than general symptoms will be selected for study. It is now possible to state that a few treatments are empirically supported, for example, systematic desensitization for anxiety, fears, and phobias, cognitive-behavioral therapy for depression, classroom contingency management for attention deficit disorder with hyperactivity, and parent management training for conduct disorder ([Kazdin, 2000](#)). Kazdin notes the extreme brevity of the list (12 treatments in all, a marked contrast to the 551 psychotherapies listed in an appendix in his book) and points out the ongoing dominance of behavioral and cognitive-behavioral methods.

## 6. CAN PSYCHOTHERAPY BE TAUGHT?

Training is taken as essential for the practice of any kind of psychotherapy, and some modes, notably psychoanalysis, go to extraordinary lengths in training. However, is there any evidence that these training programs improve efficacy and efficiency of therapy? Research on training in child psychotherapy has suggested that it has little discernible effect on therapist efficacy ([Shirk and Phillips, 1991](#)), and in fact, the evidence suggests that training may have negative effects ([Weisz et al., 1987](#)). Again, in the carefully controlled Newcastle study ([Kolvin et al., 1988](#)), it was found that untrained teacher aides were more effective than psychologists. A similar result was found by [Weisz et al. \(1995\)](#). However, most of the studies examining this issue are seriously flawed in that training was often confounded with other critical variables, such as method of psychotherapy. Also against the value of training, graduates of training programs often view their training as seriously defective, although this may be not so much a problem with training itself but with the way in which it is done. Finally, there is lack of apparent difference in efficacy of therapists from differently oriented training programs ([Shirk and Phillips, 1991](#)). There are, however, persistent indications that some persons make better therapists than others ([Bergin and Garfield, 1994; Shirk and Phillips, 1991](#)). Moreover, the type of problem treated may interact with training in a complex way ([Weisz et al., 1995](#)).

Collectively, these uncomfortable facts suggest that whatever is needed to do psychotherapy may well be acquired by the trainee before or after training is undertaken—because the critical ingredient in psychotherapy may not be so much theoretical framework or technique, but some nonspecific personal capacity to relate to other human beings, melded into the combination of other humane or common sense things that go to make up Andrews' "good clinical care." If this be so, it is hardly surprising that a training program has little impact on a trainee who has been learning human relationships for most of the life span and will continue to do so. [Shirk and Phillips \(1991\)](#) point out that because of the lack of any real effort to relate research findings to the practice of psychotherapy, training lacks the kind of explicit goals that could improve its efficacy. Even cognitive-behavioral therapy, the one type that seems to have clearly explicated training methods (often in manuals), does not seem to have looked at the efficacy of training.

## 7. IS MORE PSYCHOTHERAPY BETTER THAN LESS?

The average duration of treatment varies greatly across psychotherapies, practitioners, and researchers. It is therefore reasonable to ask whether more is better than less. Although analogies are hazardous, pharmacotherapy accepts the concept of an optimum dose—too low and it is ineffective, too high and it becomes poisonous. Research on dose effects of psychotherapy in adults ([Andrews, 1993; Koss and Butcher, 1986; Orlinsky and Howard, 1986](#)) is limited, most of it is flawed to some degree, and there are almost no comparative data on really long-term treatment (2 years or more). However, the general conclusion is that the dose-response relationship is logarithmic. Most of the gain occurs within the first 10 to 20 sessions, the size of the effect is enhanced by therapist's and patient's knowing that therapy is time limited, and the effect may even diminish in some patients with longer periods of therapy ([Koss and Butcher, 1986](#)).

There are few data in child psychotherapy on dose effects ([Andrade et al., 2000; Kazdin, 1993; Salzer et al., 1999](#)), but what data there are do not support the idea that more is better ([Casey and Berman, 1985](#)). There is also the disconcerting fact that dosage is dictated largely by patients rather than by therapists and by what underwriters will pay rather than by clinical considerations ([Andrews, 1993](#)). If psychotherapists want to convince underwriters that more is better, they will have to do some urgent research in these days when the push is to reduce health care costs ([Krupnick and Pincus, 1992](#)). The adult literature ([Orlinsky and Howard, 1986](#)) and that pertaining to children ([Fonagy and Target, 1994](#)) suggest that such research is worth pursuing.

## 8. IS PSYCHOTHERAPY BETTER FOR SOME CHILDREN THAN FOR OTHERS?

One of the more dramatic changes in child psychiatry since 1980 has been the rise of disorder-based classification. Pharmacotherapy has disorder-specific indications, and it seems plausible that diagnosis would affect psychotherapy, too; indeed, this seems to be the case in adults ([Andrews, 1993](#)). Child psychotherapy seems to have been slow to catch up with these advances, but it is now doing so to some extent. The list of empirically supported treatments for particular disorders is small, as already noted ([Kazdin, 2000](#)). This is clearly work that needs pursuing.

Other variables that ought to affect the efficiency and the type of psychotherapy needed (and are common clinical issues), but that are only just beginning to be addressed, are comorbidity, concurrent pharmacotherapy, age, socioeconomic class, family variables, and culture ([Armbruster and Kazdin, 1994; Fauber and Long, 1991; Fonagy and Target, 1994; Kazdin, 1991; Kazdin, 1993; Kazdin, 2000; Tharp, 1991; Trainontana, 1980; Weisz et al., 1987](#)). For example, [Weisz et al. \(1995\)](#) found that adolescent girls may do better, a finding suggesting that more attention to such variables is required. Practitioners often complain that these are the factors that influence treatment to the greatest degree, yet very little work examines such issues.

## 9. IS PSYCHOTHERAPY SAFER THAN BIOLOGICAL THERAPIES?

It is also often assumed that psychotherapies are preferable to pharmacotherapy because they are less "invasive" and can therefore present no risk to life or limb. This may be true at a physiologic level, but psychotherapy is clearly not free of side effects of stress and emotional upheaval during treatment and may make an unknown percentage of patients worse ([Andrews, 1993](#)), although this number appears quite small in children ([Weisz et al., 1987](#)). In addition, up to 50% of child patients never complete treatment to the satisfaction of the therapist ([Armbruster and Kazdin, 1994](#)). The causes of this are complex and could include rapid response but may help to conceal adverse outcomes. Practitioners of pharmacotherapy recognize the need to monitor closely side and adverse effects. The lack of data on side and adverse effects of child psychotherapy clearly needs addressing, because it reflects practice based on unproved assumptions of safety and efficacy.

## 10. IS PSYCHOTHERAPY ACCEPTABLE TO CONSUMERS?

The findings that many children are considered unsuitable for psychotherapy, that up to 50% of those selected may drop out of treatment ([Armbruster and Kazdin, 1994](#)), and that some patients and families report negative experiences ([Andrews, 1993; Weisz et al., 1987](#)) suggest a gap of unknown size between consumers and therapists. The causes are complex but deserve careful study because acceptability to young people and families is likely to be an important variable in efficacy. Conversely, [Weiss et al. \(1999\)](#) found that even though little support was shown for the effectiveness of traditional child psychotherapy, parents of children receiving it

reported higher levels of satisfaction compared with parents of control children who received academic tutoring.

Finally, almost no data exist about the views of children and adolescents regarding their treatment. This lack raises the issue of outcome measures. How are decisions made about the kinds of outcomes that will be examined? As [Fonagy \(1997\)](#) says, “whose outcome is it anyway?” Outcome measures have often lacked practical utility, seldom moving far beyond whether children continue to be symptomatic. Clearly, there is a much bigger world out there.

## 11. IS PSYCHOTHERAPY COST EFFECTIVE?

This issue is reviewed in detail for adult psychotherapy by [Krupnick and Pincus \(1992\)](#). They conclude that, despite an impressive body of research attesting to the power of psychotherapy to alleviate destructive and painful illness, data needed to assess cost effectiveness are lacking. Although underwriters and administrators seem to think otherwise, this is a most complex issue, too much so to discuss here. (Interested readers are referred to the cited article and its reference list.) However, by way of example, one of the bigger problems is the failure of a substantial body of outcome research to use measures critical to the cost:benefit equation of the impact of treatment on functions such as education, creativity, work, social obligations, health, and social costs, rather than the usual estimates of improvements in illness-related variables, such as depressive or anxiety symptoms. Again, because of even greater paucity of data, the view with children is even more opaque. Although it seems agreed that psychotherapy is effective with children to some, if rather modest, degree ([Weiss and Weisz, 1990](#)), no answer can be given on whether it is cost effective. Conversely, the long-term costs of *not* treating children are equally unknown but are probably enormous ([Kazdin, 1993](#)). This suggests that good studies using the principles outlined by [Krupnick and Pincus \(1992\)](#) are likely to show the worth of psychotherapy in terms acceptable to the businesses that increasingly control both public and private resources for health care. It is worth noting, too, that it is not just a question of psychotherapy showing its worth—it will need to be shown that other methods such as social reforms or government policies will not do much better for considerably more children.

Although the cost:benefit ratio of child psychotherapy is unknown, some indicators suggest that cost efficiency could be improved a great deal. First, it does not make economic sense to use highly trained expensive staff such as psychiatrists to do what the research suggests can be done as well by less trained staff ([Kolvin et al., 1988](#); [Weisz et al., 1995](#)). However, there are a few signs that, in some areas, better trained staff may do better. Moreover, supposedly “untrained” staff in most studies have very experienced supervisors ([Weisz et al., 1987](#)). It may be more a matter of moving to the executive role in a team than discontinuing involvement with psychotherapy altogether. It is likely that [Andrews' \(1993\)](#) concept of good clinical care can be delegated, but management plans, treatment manuals, and some kinds of specific or complex treatments will, rather like complex surgery, still have to be done by experienced therapists.

Second, it seems likely that most of the benefit from psychotherapy occurs in less than 10 to 20 sessions and is facilitated by knowledge in both parties that treatment will be time limited ([Koss and Butcher, 1986](#)). Therefore, any longer-term therapy should be reserved for exceptional cases. For example, the finding of a crude logarithmic relationship between duration of therapy and effect ([Orlinsky and Howard, 1986](#)) means that the law of initial values applies; that is, when the disability or suffering is very large, longer treatment, though ever diminishing in effect, may still produce sizable changes simply because there is so far to go. However, the decision to extend treatment should be based on demonstration that psychotherapy is effective and, if so, for which particular disorders.

Third, behavior therapy seems more efficient than other psychotherapies, and it seems reasonable to make this the treatment of first choice (after good clinical caring). In addition, behavior therapy is remarkable for its emphasis on delegation of therapy by explication of targets, process, and outcome, thus reducing costs further. Until research can show the advantages of pursuing other forms of treatment and for which patients (as indeed seems most likely it could), it is hard to justify them, in the first instance.

Fourth, it is customary in some forms of therapy (e.g., family therapy, group therapy) to use cotherapists, and there may be further discussions among cotherapists and supervisors after each session. Although this is laudable in terms of peer quality assurance, it doubles or triples the cost of the treatment. Of course, this is offset if the alternative would be multiple, individual treatments. Research to see whether cotherapists and supervisors improve efficiency to the degree that they increase costs is sorely needed.

Fifth, in some disorders, other treatments such as biological therapies are likely to be far more cost effective. For example, methylphenidate produces much larger effects in the core symptoms of attention deficit hyperactivity disorder than do psychotherapies of any kind ([Barkley et al., 1993](#)), although there remain many problems that medication does not touch.

## SUMMARY AND CONCLUSION

The most significant finding is the lack of good data by which to make critical decisions about the teaching and practice of psychotherapies, especially those that dominate in child psychiatry. Paradoxically, in view of their continued popularity, the traditional psychotherapies have been little studied since the early 1980s ([Barnett et al., 1991](#)). Family therapy fares a little better ([Henggeler et al., 1993](#)) in that there seems to be more research activity, although not nearly enough has been addressed to outcome. No other method comes close to behavior therapy in amount and quality of research ([Kazdin, 1993](#); [Kazdin, 2000](#); [Weisz et al., 1987](#); [Weisz et al., 1995](#)).

Such data as there are reveal some disquieting findings that are at odds with the certainty with which psychotherapy is taught, practiced, and marketed, and this makes it seem, at times, more like a religion than a professional activity ([Weiss et al., 1989](#)). For example, serious doubts exist about the specificity of different treatments (except behavior therapy), the value of training, the high cost of psychotherapy, and socioeconomic and cultural limitations in application. Inexplicably, despite these doubts, traditional and family therapies continue to flourish and form a centerpiece of most training programs in child psychiatry.

In child psychiatry as a whole, there is currently a sense of excitement, an intellectual renaissance. Although fueled largely by biological psychiatry including taxonomy, epidemiology, molecular biology, and psychopharmacology, behavioral scientists are increasingly lending their specialized research and theoretical knowledge to round out this medical subspecialty, as any issue of the *Journal of the American Academy of Child and Adolescent Psychiatry* makes clear. Amid this intellectual ferment, psychotherapy still depends too much on tradition, charisma, extended preceptorship, assertion, and presumption of beneficence. In this respect, it resembles medicine of a bygone era, out of step with the 21st century. We hope that the sleeping giant is beginning to awake, as the generally impressive articles and reviews cited here show, although these are almost exclusively written by nonmedical behavioral scientists. As [Kazdin \(2000\)](#) notes, it is now possible to compile a list of empirically supported treatment of children. However, the list is short and does not include any traditional methods of child therapy, which still lags behind the intellectual activity in adult psychotherapy.

There is good reason to teach and practice behavior therapy, including cognitive-behavioral therapy, because it has a clear advantage in efficacy and in volume of supporting data, and its approach is generally more transmissible and heuristic. However, child psychiatrists need to overcome their idea that this is something that only psychologists do and move on to master, teach, practice, and supervise it.

Teaching and practice of forms of psychotherapy other than behavioral are less defensible unless they are perceived for the moment as simply part of good clinical caring, in which case, it is unlikely that prolonged training, high fees, or long-term or intensive treatment can be justified. The finding that many practitioners currently earn their living from long-term or traditional psychotherapies does not mean that child psychiatry training and practice can be exempt from the painful radical restructuring that is a feature of the economic world. As long as child psychiatry belongs to and wishes to avail itself of the privileges of being part of medicine, it must adhere to the fundamental ethical values that no treatment can be assumed to be effective and safe—it must be demonstrated to be so. The 21st century will be that of evidence-based medicine, and child psychiatry cannot afford to be left behind averring instead of proving.

The strongest justification for continuation of nonbehavioral psychotherapies is in research and in care of the severely ill, in whom proven treatments have failed. Even then, these treatments should ordinarily be delegated to less highly paid personnel to reduce cost—until such time, if ever, it is clearly demonstrated that child psychiatrists can do it better.

As discussed in the introduction, psychotherapy may be justified as an essential part of medicine's other arm—humanistic concern and care for the sick and their relatives ([Pardes, 1990](#)). Psychiatry must maintain its current prerogative among medical specialties of being able to take time to listen to children and their families and thus to exercise the traditional medical activity of humane clinical caring ([Pardes, 1990](#)). In view of the lack of distinctive effects in different kinds of psychotherapy, it seems likely that many practitioners of psychotherapy, when faced with a distressed patient, abandon most of the theoretical orthodoxy they were taught in favor of what seems sensible, caring, and ethical. Those practitioners who conceptualize children's suffering, handicaps, and maladaptations within traditional frameworks have no need to change if it enables them to deliver this most important element of medical care. However, there is a substantial difference between such a position and promulgating, teaching, or practicing most psychotherapies as proven treatments for child psychopathology, especially within child

psychiatry, which is supposed to show medicine's skepticism toward treatment and proper regard for the cost of health care.

Looking at the dramatic remedicalization of psychiatry since the early 1980s (Wilson, 1993) and the main thrust of current research, it seems clear that the role of the child psychiatrist in the 21st century increasingly will resemble that of other physicians (i.e., performing diagnostic assessments encompassing medical, psychological, social, and cultural issues; participating in multidisciplinary case conferences; delegating administration of all except especially skilled treatments) and thus will differ substantially from that of many teachers in the past, who spent much of their time on psychotherapy. Unless it can be shown that psychotherapy greatly enhances effectiveness in diagnosis and delivery of good clinical caring, there seems little justification for the predominance of nonbehavioral psychotherapy in child psychiatry training. Because skill in psychotherapy and clinical caring seems more related to personal qualities than to training, it may make more sense to concentrate on better selection of medical students and psychiatric trainees.

The time has come for psychotherapy to undergo a painful personal analysis and confront the nagging perennial questions about psychotherapy, by using the tools of science: What do we know about psychotherapy that is derived from research, not assertion or tradition? How can this knowledge be used to determine what sort of psychotherapy should be given, to which patients, for how long, at what cost, and by whom? How should psychotherapy be taught, if at all? What is needed is more research, more intellectual curiosity, and more excitement and less complacency, less dogma, less training, and less unexamined clinical practice.

## DEFINITION

*Partial hospitalization* has been used historically as an umbrella term describing many varieties of alternative care. With the advent of managed care and health care reform, less costly and less restrictive treatment modalities are in increasing demand. To provide definition for these alternatives, which stretch along the continuum of psychiatric care between inpatient and outpatient office visits, three levels of ambulatory behavioral health care have been outlined ( [Kiser et al., 1993](#)). In this new environment, partial hospital programs (PHPs) are providing short-term, crisis stabilization services as an alternative to or as a step down from acute inpatient care. Day treatment programs (DTPs) are serving the needs of children and adolescents with moderate to severe disorders who require interventions focused on improved level of functioning, skill building, and disease management. Intensive outpatient programs (IOPs) or partial day programs function as intermediate or step-up programs from outpatient psychotherapy. These programs offer treatment for up to 3 hours per day and often accommodate children and adolescents after a half-day or full day at school ( [Robinson, et al., 1999](#)).

In the behavioral health delivery system, these services represent a specific segment along the continuum of care and offer more intensity than outpatient services without the iatrogenic effects of hospitalization. Ambulatory behavioral health care services strive to provide intense, highly structured treatment. They do so by using a variety of therapeutic modalities: individual, group, and family therapy, as well as medical and nursing services. This multimodal treatment requires an interdisciplinary staff typically drawn from psychiatry, psychology, social work, educational or vocational therapy, occupational or recreational therapy, and nursing. A working definition of ambulatory behavioral health care follows:

Ambulatory behavioral health care is a time-limited, active treatment offering therapeutically intensive, coordinated, and structured clinical services that incorporate the benefits of a therapeutic milieu within a program or within the home and community ( [Kiser et al., 1993b](#)).

## HISTORY

The history of ambulatory behavioral health care for children and adolescents is brief. The first PHPs were for adults in Russia (late 1930s), Canada (late 1940s), and England (early 1950s). The Menninger Clinic (Topeka, KS) introduced the concept to the United States when it opened its unit in the mid-1950s. (The closure of Menninger's partial hospitalization services in 2000 marked the end of an era.) In 1963, the Community Mental Health Center Act mandated comprehensive services including partial hospital care for children and adolescents. This movement had three main origins: deinstitutionalization, interest in the role of family and community, and movement to cost-effective treatment alternatives.

Throughout the late 1990s and into the present, the modality has been severely underused ( [Novello, 1979](#); [Prevost, 1981](#)). With only 2% of those in need of treatment receiving services in PHPs ( [Krizay, 1989](#)) and with more than 46% of programs operating at less than 75% capacity [ [Association for Ambulatory Behavioral Healthcare \(AABH\), Overview of the Partial Hospitalization and Ambulatory Care Industry, 2001](#) ], underuse is a major problem for the survival of many programs. Three clinical issues contribute to underuse of partial hospitalization. First, for providers, it is difficult to serve moderately to severely disturbed children and adolescents in an open system with less restrictiveness and a less structured environment. Second, for families, it requires major commitments to family therapy, to transportation, and to keeping a difficult child at home. Third, for referral sources more accustomed to and better trained to treat severely dysfunctional patients in inpatient programs, it necessitates a shift in the style and conceptualization of clinical practice. Fourth, reimbursement policies serve as a major impediment to wider use of PHPs. Traditionally, most policies with mental health care benefits had better coverage for inpatient than outpatient services and no coverage for PHPs ( [Leibenluft and Leibenluft, 1988](#); [Novello, 1979](#); [Weithorn, 1988](#)).

Now, with an emphasis on cost containment, managed care focuses on eliminating unnecessary inpatient services with efforts directed toward development of systems favoring outpatient practices ( [Hoge et al., 1992](#)). Although early indications from managed care pointed to a desire to ensure both quality and efficiency, fiscal management frequently translates to either rationing care or providing the cheapest services for the shortest length of time possible regardless of clinical decision-making and effectiveness data ( [VandenBos, 1990](#)). Cost-containment pressures are driving the development and use of less intensive options, such as IOPs or multimodal outpatient treatments. Approvals for care at the ambulatory level are sometimes based on cost without adequate consideration of the child's or adolescent's treatment needs.

## THEORETICAL ISSUES

The continuum of ambulatory mental health services is founded on six essential principles:

1. Services are designed for [children and adolescents] who present with a psychiatric and/or chemical dependency diagnosis and the need for treatment more intensive than outpatient office visits and less restrictive than 24-hour care.
2. Services provide a coordinated array of active therapies determined by an individualized treatment plan and based upon a comprehensive evaluation of patient needs.
3. Patients are treated in a manner that simulates real-life experience with the least amount of disruption to normal daily functioning [allowing for optimal transfer of therapeutic benefits to the natural environment].
4. Services require active involvement of the [child/adolescent and the family].
5. Services are available on a consistent basis, augmented with 24-hour crisis backup.
6. Services are cost efficient ( [Kiser et al., 1993b](#)).

From these six essential principles, two basic philosophies of care provide the core for child and adolescent ambulatory behavioral health services. First, these services provide treatment to patients requiring intensive therapeutic intervention with the least amount of disruption to their normal daily functioning. This requires ambulatory services to define the limits between when patients can be treated safely in an outpatient setting and when they require the restrictiveness of hospitalization. Thus, ambulatory behavioral health services are designed to maintain a balance between treatment in the least restrictive environment and risk management.

Second, ambulatory behavioral health care encourages providers to take advantage of the "open system" inherent in the modality. This philosophy emphasizes the use of family supports and strengths, as well as community agencies and programs. Two major sequelae result from this philosophy of care. Ambulatory services invite the patient and the patient family to maintain a higher level of functioning than treatment settings that remove the patient from the home. Philosophically, this

translates into a program of therapeutic interventions designed to maintain power within the parental and familial subsystem and to view that subsystem as competent in providing care for the child. Interventions are structured to alter dysfunctional interactional patterns rather than remove the child from these interactions. Translated into program policy, ambulatory behavioral health programs only use techniques and treatment strategies that a family can also implement at home.

Additionally, ambulatory programs promote reliance on community support systems and programs whenever possible. Benefits of this approach include limiting the development of dependence on the treatment team, expansion of and appropriate use of resources, decreased lengths of stay, and improved adjustment after discharge (Herz, 1982). This unique combination of providing “security and structure while simultaneously promoting patient responsibility and autonomy” (Hoge et al., 1988) may be the particular advantage of this modality.

The philosophies underlying ambulatory behavioral health care can be accomplished in programs with a variety of theoretical orientations. Behaviorally oriented programs use principles of learning theory. The goals of a behavioral program are, consequently, to teach desirable behaviors and to extinguish undesirable ones. For example, most PHPs, although not operating from a behavioral orientation, use some form of level system for determining the consequences of patients' behavior (Kiser et al., 1986). Another approach uses a psychoeducational orientation with the classroom as the basic structure for program design. “Students,” rather than “patients,” usually receive psychotherapy in conjunction with classroom instruction. Programs using systems theory emphasize the theoretical proposition that many different areas of a child's life influence functioning: biological, intrapsychic, family, peers, school, work, neighbors, religious affiliation, and others. Within a systems orientation, programs are challenged to assess problems and to intervene on multilevel basis (Kiser and Pruitt, 1991). Many of the programs operated in conjunction with inpatient services within general hospitals are based on a medical model in which all patients receive psychiatric diagnoses and treatment is prescribed by a child and adolescent psychiatrist (Novello, 1979).

These orientations differ in the manner in which they view the child, his or her problems, and the treatment program. Although many theoretical orientations are possible, within an organization, the model used should be consistent across the continuum of care. Conflicting models established among components of care may cause confusion for the staff as well as the patient and family.

## GOALS OF TREATMENT

The clinical functions of ambulatory behavioral health care differ according to the level of care offered (Glasscote et al., 1977; Kiser et al., 1993b). Partial hospitalization and other intensive nonresidential treatment options function to provide short-term crisis intervention and stabilization of symptoms as an alternative treatment to hospitalization or an intensive transition setting to shorten a hospital stay. Less intensive ambulatory modalities provide support, maintenance, symptom reduction, and skill-building to prevent relapse, longer-term hospitalization, or residential care. Finally, multimodal outpatient services provide a step up for patients for whom one or two office visits per week may be insufficient. Another goal or function of ambulatory behavioral health services can be extensive evaluation involving observation, identification of problem areas, diagnosis, and formulation of treatment plans (Casarino et al., 1982).

## CLINICAL ISSUES

### Indications

The continuum of ambulatory behavioral health care represents three levels of care, each of which targets populations with differing needs. The important tenet is that admission decisions are based on matching interventions and services with the needs of the patient in terms of intensity, structure, and accessibility, for example.

Treatment organizations define their target population by establishing admission criteria. From this programmatic standpoint, evaluation to determine appropriateness for ambulatory behavioral levels of care involves the following six factors: (a) psychiatric signs and symptoms, (b) level of impulse control, (c) level of functional impairment, (d) parental support, (e) physical health, and (f) ability to pay. Specific criteria for the three levels of ambulatory behavioral health care are presented in Table 88.1.

Class	Level 1	Level 2	Level 3
Psychiatric signs and symptoms	Current DSM diagnosis, acute to distressing symptoms related to acute or chronic condition	Current DSM diagnosis, moderate to severe symptoms related to acute or chronic condition	Current DSM diagnosis, moderate symptoms related to acute or chronic condition
Level of impulse control	Unstable control of impulses	Unstable control of impulses	Good control of impulses
Level of functional impairment	Severe difficulty functioning in multiple areas including school, activities, community, and home	Severe difficulty functioning in one or more areas including school, activities, community, and home	Moderate difficulty functioning in at least one area including school, activities, community, and home
Parental support	None to provide adequate control and support of program during meetings and weekends with close monitoring and frequent contact with staff	None to provide adequate control and support of program during meetings and weekends with monitoring and assistance from staff	None to provide adequate control and support of home during meetings and weekends with monitoring and assistance from staff
Physical health	No requirement for 24-hour medical care	No requirement for 24-hour medical care	No requirement for 24-hour medical care
Ability to pay	Economic resources available to support care of this level	Economic resources available to support care of this level	Economic resources available to support care of this level

Table 88.1. Admission Criteria for Child and Adolescent Ambulatory Behavioral Health Care

As pressures increase to manage children and adolescents with unstable, crisis presentations in less restrictive settings, it is critical for providers to develop decision-making tools for patient placement that take into account risk management. For child and adolescent providers, family and community support and structure become major factors in this decision-making process. A decision matrix, assessing both level of impulse control and parental support and structure, is a valuable tool for assessing appropriateness for admission (Fig. 88.1) (Kiser et al., 1991). Level of impulse control can be viewed along a continuum, with some patients demonstrating no problems and other patients requiring a structured, locked treatment environment because of severe problems with behavior control.

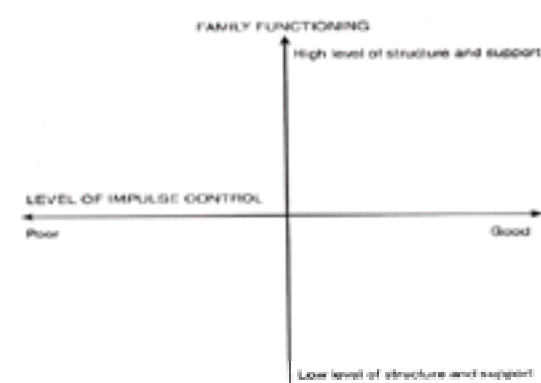

Figure 88.1. Decision matrix: risk management assessment. (From Kiser LJ, Heston JD, Millsap PA, et al.: Testing the limits: Special treatment procedures for child and adolescent partial hospitalization. *Int J Partial Hosp* 7:39,1991, with permission.)

On the other axis, the continuum of family functioning (support and commitment to treatment) is evaluated. It is expected that families will work with the treatment team to encourage their child to comply with program limits. Families who are unable or unwilling to participate in this manner are less likely to provide the daily support and structure needed by the patient, who is therefore unlikely to derive significant benefit from treatment in an ambulatory behavioral health care setting.

## PROGRAM OF THERAPEUTIC ACTIVITIES

The clinical components, that is, each patient's daily activities, are based on an individual treatment plan developed by the treatment team ( [Block et al., 1991](#); [Kiser et al., 1986](#)). Continuous monitoring of the patient's response to treatment dictates alterations in this plan. Therapeutic progress is monitored frequently by the multidisciplinary staff, and periodically, a treatment update is prepared and the patient's case is reviewed by the entire treatment team. Progress to date on problems is reviewed, new problems are discussed, and progress toward transition to a less intensive level of care or discharge is monitored.

A distinguishing characteristic of ambulatory behavioral health care is the intensity of diverse clinical components that most often include individual, group, family, and medical management. As with all treatment with children and adolescents, it is important that the structure and content of the therapy be appropriate for the patients' developmental levels.

### INDIVIDUAL THERAPY

Individual therapy is offered by most ambulatory behavioral health providers in the United States (AABH, Overview of the Partial Hospitalization and Ambulatory Care Industry, 1998; [Kiser et al., 1986](#)), usually on a weekly or twice-weekly basis, with a mean greater than 2 hours per week (AABH, 2001). Like individual therapy in other settings, it provides the patient with an opportunity to develop a close, interpersonal relationship with an adult other than a parent and an opportunity to work on intrapsychic problems.

Individual therapy in ambulatory behavioral settings differs from outpatient individual psychotherapy because of the wealth of information available to the therapist through contacts with or observations of the patient in other parts of treatment. An example of this occurs in a partial hospital setting when a depressed child denies withdrawal from peers but is frequently observed sitting alone during milieu periods. Differences between individual psychotherapy in ambulatory and inpatient settings are also significant and are mainly the result of the openness of the ambulatory system. Individual therapy in ambulatory behavioral health care can use material from daily encounters with parents, siblings, and peers to address dysfunction in these areas.

### GROUP THERAPY

Most ambulatory behavioral health services rely on group psychotherapies as a mainstay of their clinical programming. Group psychotherapy plays an important role in ambulatory behavioral health settings by allowing peers to develop the ability to deal with problems through the expression of feelings and experiences in a safe environment. This therapy also provides an opportunity for work on group dynamics, including cohesion, roles, and norms. Skill building is another important function of group psychotherapy. As with individual therapy, therapists in ambulatory behavioral health care have direct knowledge about patient functioning in multiple areas, thus allowing immediate and specific feedback to the group members.

### FAMILY THERAPY

The use of family therapies by many programs is consistent with the research demonstrating that family structure is predictive of successful completion of treatment and follow-up ([Prentice-Dunn et al., 1981](#)). Family involvement in treatment may take a variety of forms including traditional family therapy, multifamily groups, parent education classes, parent support groups, marital therapy, and in-home services.

Family therapy provides an opportunity to focus on family dynamics to facilitate change in the home environment. Within ambulatory behavioral health care, this therapy allows intensive work on family conflict and family structure on a day-to-day basis. Because patients remain part of the family while participating in treatment, new skills can be practiced and evaluated in a continuous manner. Another important benefit of family therapy in ambulatory behavioral health care is the ability to establish consistent rules and limits for the child both at home and in treatment. Work with the family and community helps to extend the therapeutic benefits of treatment into the patient's overall familial and social milieu. Finally, one powerful difference between family treatment in this modality and that of an inpatient unit is the emphasis on maintaining parental authority. For example, in partial hospitalization, parents are involved in every level of decision making and problem solving. Parents are, in effect, viewed as cotherapists.

### THERAPEUTIC ACTIVITIES

The extent of therapeutic activities such as expressive activities, daily living skills, diversional activities and the availability of a programmatic therapeutic milieu depend on the structure and intensity of the services offered. However, at all levels of ambulatory behavioral health care, providers emphasize development of an active, therapeutic milieu. In ambulatory behavioral health services that do not incorporate a programmatic milieu, the treatment plan prescribes active interventions to extend milieu-based therapeutic benefits to the home, workplace or school, and community, as needed. Recreation, movement, art, occupational, and milieu therapies, as well as community-based activities, provide staff and peer support for appropriate behavior in social settings. Patients learn constructive ways to use leisure time in activities that foster teamwork, cooperation, and task commitment. Frequent involvement in community events is consistent with the ambulatory behavioral health care belief that children and adolescents should remain active members of the community ( [Kiser and Pruitt, 1997](#)).

### EDUCATION

Because much of a child's life and often many of a child's problems revolve around school and related activities, intensive treatment programs for children and adolescents must grapple with ways to meet academic needs and difficulties. Ambulatory services meet the needs for educational services in very different ways. Intensive, full day programs may offer a school component daily ( [Block et al., 1991](#)). Acute programs with lengths of stay of less than 2 weeks may provide educational experiences based on a "homebound" model. Finally, less intensive ambulatory services, such as after-school programs or IOPs, may simply focus on enhancing school performance by offering tutoring or study skills and consultation with classroom teachers. Regardless of the level of care offered, ambulatory behavioral health care providers use the treatment environment to aid children in dealing appropriately with the frustrations encountered in the school setting, including dealing with authority and assuming responsibility for work. They also understand the importance of schooling in the lives of children and adolescents and thus view active school liaison as a major component of treatment. Obtaining fiscal support for the educational portion of treatment is an area of concern; cooperative arrangements with local education authorities are often necessary, thus requiring programs to meet several sets of standards and answer to several local and state agencies.

Provision of intensive mental health services integrated within the school setting is a growing trend in the provision of delivery of ambulatory behavioral health care to children. Programs of this nature are often joint projects of community mental health and the school system. Often these services are classroom based with lengths of stay that more closely resemble school grading periods. Individualized, multimodal treatment is offered on site delivered by an integrated, multidisciplinary team of educational and mental health professionals ( [Matzner, 1998](#); [Milin et al., 2000](#)).

### MEDICAL MANAGEMENT

The extent of medical involvement in the management of patients in ambulatory behavioral health care varies depending on the intensity and theoretical background of the program. Medical involvement within ambulatory behavioral health care ranges from medical supervision for patients with unstable, crisis needs to medical consultation for patients with low levels of risk and only moderate symptom presentations.

Trends are toward emphasizing aspects of the medical model in the most intensive ambulatory services such as PHPs. As various forces work toward decreasing rates of hospitalization for children and adolescents, more severely disturbed patients and those with combined medical and psychiatric disorders will be referred to PHPs. In such programs, psychiatrists function as attending physicians and members of the treatment team. Under this model, the physician can be seen as the team leader, orchestrating the treatment provided. The use of [Engel's \(1980\)](#) biopsychosocial model of medical practice is particularly congruent with the philosophy of ambulatory behavioral health care. Physician involvement is not limited to the specifics of medical management, but it includes substantial input into program administration and direction. The cost disadvantage may be counteracted by the preference of insurance companies and Medicaid to reimburse for medically directed services.

Thus, within programs offering acute symptom reduction and crisis stabilization, medical management includes an assessment of the patient's general medical and behavioral health status. Both medical and psychiatric diagnoses are assigned. This approach may involve direct physical examination done by a physician

associated with the program or, in those programs that are more community based, consultation and liaison with the patient's primary care physician or pediatrician. It is the responsibility of nurses and physicians to identify specific health problems that may be important factors in the overall functioning of the patient. These problems may be treated directly or referred to a community physician. Referrals often serve to educate and guide families in accessing needed health care services and to use these resources effectively.

Pharmacotherapy, another aspect of medical management, may be practiced within the structure of ambulatory behavioral health care with advantages over other therapeutic settings. As on an inpatient unit, observations from multiple viewpoints are available to determine specific indications for medications. The ability to monitor new medications or changes in regimens is augmented by daily contact with the patient and information about the patient's status in many different activities. This use of medication within a structured environment is frequently seen as an advantage over medication management developed on an outpatient basis. Moreover, in distinction to an inpatient hospitalization, the family is able to provide and to learn to provide ongoing feedback about medication response, side effects, compliance, or other concerns about medication.

In those programs that are designed as IOPs, psychiatrists may be contracted to function as consultants to provide specific, limited services. These services typically include initial psychiatric evaluation and diagnosis as well as monitoring pharmacotherapy. The psychiatrist may not be a part of the treatment team and is usually not involved in the day-to-day care of the patients or administration of the program. Although the advantages of this model are financial and logistical, and although they save the program the cost of a full-time specialist in a profession that is relatively undersupplied, the main disadvantage is the lack of physician input into the overall treatment of patients.

Finally, as managed care grows and continues to influence psychiatric care, physicians may be expected to help programs, patients, and their families to negotiate appropriate financial coverage for treatment. This assistance may come in clarifying diagnoses and in outlining treatment options. Frequently physicians in ambulatory behavioral health care are called on to participate in physician-to-physician reviews of cases that have been tagged as questionable by the managed-care company. The effective psychiatrist will be called on to document rationale for treatment in ambulatory behavioral health care and should be familiar with medical necessity criteria and effective arguments for obtaining treatment appropriate to the specific needs of each patient.

### Special Populations

Proponents of ambulatory behavioral health care suggest that it is a viable treatment mode for many special populations (e.g., juvenile offenders, patients with eating disorders, alcohol and drug abusers), as well as for nonpsychiatric populations (e.g., those with head trauma or epilepsy). Several reports of PHPs designed for adolescent offenders or those with adolescent antisocial behavior have appeared in the literature ( [Byrnes et al., 1999](#); [Comer, 1985](#); [Gaylor, 1979](#); [Kolko, 1995](#); [Matzner et al., 1998](#); [Myers et al., 2000](#); [Rey et al., 1998](#)). Treatment emphasis for offenders appears to be intensive group therapy and social, recreational, and special educational services, with generally positive outcomes noted for these teens, who are very difficult to treat.

Another special population described in the literature is preschoolers. Special emphasis in preschool PHPs and therapeutic nurseries for young children is placed on play, communication and language, socialization, skill development, and parent-child interaction. Young children benefiting from treatment in a therapeutic preschool include those with developmental delays, victims of physical and sexual abuse, and children with other severe emotional or behavioral disturbances ( [Rogers and Lewis, 1989](#)).

Health care reform and the interest in development of cost-effective treatments have resulted in programs that address the psychosocial as well as physical needs of chronically ill pediatric patients ( [Gavin et al., 1996](#)). Certain patients with eating disorders, sickle cell disease, asthma, diabetes, and other disorders may benefit from specialized treatment in ambulatory settings that incorporates health care professionals from appropriate pediatric specialties.

### Limitations and Complications

As various theoretical, ethical, economic, and other factors discussed earlier continue to discourage the use of hospitalization, ambulatory providers will be challenged to manage patients whose behavioral symptoms and impulsivity have escalated to the point that special treatment procedures are indicated. Policies and procedures for dealing with patients displaying aggressive, acting-out behaviors, noncompliance with program rules, and suicidal or runaway ideation are a necessary part of programming ( [Kiser et al., 1991](#)). Special treatment procedures designed for use in child and adolescent ambulatory settings must adequately address the issue of safety and must involve the family and the community, while maintaining the patient in the least restrictive environment.

Management of acutely and severely disturbed patients necessitates policies that address seclusion, physical holding, and restraints. Often PHPs simply do not offer these services because staff members believe that these procedures are appropriately used only in inpatient units. Other child and adolescent PHPs use quiet rooms and physical holding policies that do not violate the mandate of the program, in other words, procedures that can also be used by parents or guardians in the home environment. The quiet room and physical holding are used sparingly with adolescents; immediate transfer to a secure facility may be indicated for an aggressive or acutely psychotic, disruptive adolescent. Manual and chemical restraints are typically not used in PHPs or other ambulatory settings.

Just as programs must develop policies to help patients to control their behavior that are compatible with the program's theoretical basis and intensity of treatment, they must address similar issues with other problems both within the treatment setting and at home. For example, PHPs may be able to treat patients with significant suicidal ideation if these programs are able to maintain appropriate levels of observation and to plan for continued supervision after program hours using family therapy, telephone contact, beeper services, or other interventions. Runaway patients may similarly be placed in ambulatory treatment given policies for structure after hours and ability for liaison with community resources such as runaway homes or other community emergency shelters. Thus, intensive programs that are designed to serve as alternatives to inpatient treatment are able to treat severely disturbed patients using policies that address program structure, family resources, and community involvement.

Because of the intensity of programming, the developmental level and the severity of illness of patients treated, and the lack of restrictiveness, most ambulatory behavioral health care services operate with very small staff:patient ratios. Obviously, the level of staffing required depends on the intensity of care offered and the degree of disturbance within the target population. Within PHPs, a typical ratio is one staff person to fewer than four patients ( [Kiser et al., 1993a](#)), with a recommended range from 1:3 through 1:6 ( [Block et al., 1991](#)). For after-school programs or IOPs, staff:patient ratios of 1:8 to 1:10 are probably sufficient.

Even with small staff:patient ratios, the high intensity of the programs results in staff stress and burnout ( [Kiser et al., 1986](#); [Novello, 1979](#)). A fuller explanation no doubt lies in the philosophy of the approach: maintaining severely affected patients in the least restrictive environment.

### CRISIS MANAGEMENT AND HOSPITAL LIAISON

Ambulatory behavioral health care services that attempt to shorten or eliminate hospitalization must have adequate policies and procedures to handle emergencies that prompt immediate admission to treatment and the inevitable crises that develop during treatment. Although general principles are described earlier in the discussion of limitations and challenges, specific details of crisis management should be identified by each ambulatory behavioral health service, depending on the level of care offered.

At the most intensive level, providers of ambulatory care should have an integrated emergency system that allows immediate access to current clinical and treatment information. The following recommendations meet these crisis management needs ( [Kiser et al., 1986](#)): (a) an on-call child and adolescent psychiatrist available 24 hours per day, 365 days per year; (b) additional on-call services, to help families to resolve conflicts that do not require hospitalization or major changes in treatment plans, that are staffed primarily by partial hospital professionals; and (c) an established affiliation with both pediatric and psychiatric inpatient units. In the case of hospital-based programs, this should be addressed in policies regarding transfer between PHPs and inpatient units. In free-standing PHPs, formal affiliations with hospitals must be made so admissions can occur quickly and safely for patients with acute emergencies.

Less intense ambulatory programs must also develop emergency plans. These may include policies to admit patients to the PHP within a number of days and consultation with a psychiatrist to assist with decisions regarding emergency management and possible hospitalization. Coverage of crisis situations while a child or adolescent is in care can be handled by a 24-hour crisis call service. To provide a summary of ambulatory behavioral health care's indications and limitations, the advantages and disadvantages of the modality are presented in [Table 88.2](#).

Advantages	Disadvantages
1. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	1. Partial hospitalization programs are often expensive.
2. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	2. Partial hospitalization programs are often expensive.
3. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	3. Partial hospitalization programs are often expensive.
4. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	4. Partial hospitalization programs are often expensive.
5. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	5. Partial hospitalization programs are often expensive.
6. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	6. Partial hospitalization programs are often expensive.
7. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	7. Partial hospitalization programs are often expensive.
8. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	8. Partial hospitalization programs are often expensive.
9. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	9. Partial hospitalization programs are often expensive.
10. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	10. Partial hospitalization programs are often expensive.
11. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	11. Partial hospitalization programs are often expensive.
12. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	12. Partial hospitalization programs are often expensive.
13. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	13. Partial hospitalization programs are often expensive.
14. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	14. Partial hospitalization programs are often expensive.
15. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	15. Partial hospitalization programs are often expensive.
16. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	16. Partial hospitalization programs are often expensive.
17. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	17. Partial hospitalization programs are often expensive.
18. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	18. Partial hospitalization programs are often expensive.
19. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	19. Partial hospitalization programs are often expensive.
20. Partial hospitalization programs provide a continuum of care for children and adolescents with serious mental illness who do not require 24-hour care.	20. Partial hospitalization programs are often expensive.

**Table 88.2. Advantages and Disadvantages of Ambulatory Behavioral Health Care for Children and Adolescents**

**Discharge and Aftercare Services**

As integrated systems of care for child and adolescent become more prevalent, planning transitions between levels of care often replaces discharge planning for ambulatory services. Regardless, transition or discharge planning remains an integral part of treatment planning, beginning during the initial intake and continuing throughout the treatment process as transition or discharge goals are formulated and clarified. During the course of treatment, progress toward transition or discharge is continually monitored by the treatment team with input from the patient's family.

The following principles govern the planning process: (a) patients receive treatment in the least restrictive environment that provides the structure and intensity necessary; (b) patients receive treatment for the shortest time possible, to reach maximum treatment benefit; and (c) planning is done in a fashion that maximizes a successful transition to the patient's new setting (either more or less structured). Thus, transition or discharge planning involves attention to issues of termination, liaison with community resources (e.g., inpatient settings, school settings), and follow-up to encourage compliance with transition recommendations.

CASE ILLUSTRATION

The case of Tammy, a 16-year-old, African-American girl admitted to a PHP after a suicide attempt, is presented to illustrate the use of partial hospitalization in emergency care. Tammy was first seen in a pediatric emergency room on a Saturday morning by a psychiatry resident who determined that, although she had continued suicide ideation, she did not have a specific plan and could be treated without hospitalization. Over the weekend, the resident contacted Tammy and her family twice by phone and arranged for her to be admitted to a PHP on Monday morning. During her first few days in the program, she was monitored closely by the staff, and her suicide potential was evaluated at the end of each day by the medical director. During the first week, her suicide ideation resolved in response to the support and structure of the program. At the end of her second week in the PHP, she was stabilized, she started taking antidepressant medication, and she made the transition to outpatient family and group therapy after she and her parents stated their commitment to follow-up. The use of partial hospitalization prevented a psychiatric inpatient admission for this acutely symptomatic adolescent patient.

CASE ILLUSTRATION

Other aspects of ambulatory behavioral health care are highlighted in the case of Jamie, a 15-year-old boy who made the transition to a medium-intensity DTP. During a hospitalization for a life-threatening suicide attempt, Jamie's family's managed-care company decertified his admission and stated that he was no longer at acute risk of suicide. Because of continued serious depressive symptoms and chronic family dysfunction, he was determined to be inappropriate for routine outpatient management. He was admitted to a DTP with a strong family systems orientation. Over the course of his 8-week treatment, he was able to develop a therapeutic alliance with his individual therapist, and significant family restructuring was accomplished. The consulting child and adolescent psychiatrist was able to manage Jamie's medication and regularly monitor his suicide potential. At the end of 8 weeks, his depressive symptoms were decreased to the extent that he could make the transition to outpatient therapy and return to school successfully. This use of the ambulatory behavioral continuum allowed for prompt discharge from the hospital with continued consolidation of progress in a highly structured system.

CASE ILLUSTRATION

Finally, Eric provides an illustration of the ambulatory services offered within an integrated mental health and school setting. Eric, a 7-year-old African-American boy, was referred to a rural community mental health center for services. Eric presented with a family history of schizophrenia, extreme irritability, labile mood, noncompliance, tantrums, and physical violence toward his peers and adults. He had received multiple school suspensions and was at risk of expulsion. On intake to services, the clinician recommended participation in a newly established DTP housed at Eric's elementary school. The clinician also recommended individual therapy, family therapy, case management, psychiatric evaluation, and nursing services.

During Eric's 6-month participation in the DTP, Eric's academic program was infused with daily mental health services in the classroom setting. His daily goals included increasing compliance, decreasing anger outbursts, and decreasing physical aggression. He was able to improve peer relations while receiving immediate feedback and direct instruction on social skills by a master's level clinician, teacher, and teacher's assistant. Each staff member was able to apply behavior management principles consistently in his or her domain areas. Eric's parents actively participated in parent conferences as well as in family therapy sessions. After initial reluctance, they agreed to schedule a psychiatric evaluation, after which Eric was further stabilized on medication. Eric gradually made the transition to a regular classroom setting, where he is being maintained successfully. He continues with outpatient services.

**RESEARCH AND EVALUATION**

**Quality of Care**

Partial hospital and other nonresidential hospital alternatives share many common treatment goals and techniques and differ in important ways from both inpatient treatment and outpatient office visits. Accordingly, the measurement of quality in this modality presents some unique challenges. Using the underlying philosophies, the unique therapeutic aspects, the distinctive treatment procedures, and the historical problems and promises of the field, specific quality indicators can be formulated.

Several specific quality indicators of effectiveness for partial hospital and intensive outpatient services include valid and accurate admission criteria, standards of care, and low negative, critical treatment incidents. As an alternative treatment modality, it is incumbent on partial hospital and other ambulatory behavioral health services to establish admission criteria that reliably and validly identify patients who need intervention at a more intensive level than outpatient visits yet at a less restrictive level than 24-hour care. Having targeted an appropriate patient population, the standardization of services rendered and special treatment procedures need to ensure that the care offered provides the safety and security necessary to provide intensive treatment in a nonresidential setting.

Additional unique quality indicators include specific aspects of cost efficiency and patient satisfaction. Providing intensive treatment within a nonresidential environment mandates the use of outside resources and the reliance on strengths within the family and community for augmenting treatment, both of which translate into cost-efficient care. For ambulatory behavioral services, two specific areas of patient satisfaction become applicable: the patient's feelings regarding receiving treatment as an outpatient and the family's sense of contentment with their role in the treatment process.

Finally, for all ambulatory providers, viability is a critical factor, both at the level of the individual program and industry wide. Increased use, cost containment, internalization of quality, and establishment of an evidence base are integral to survival of the modality. It is incumbent on leaders in the field as well as managed care to improve patterns of use if alternative, intermediate forms of behavioral health care are to fulfill a role in the overall continuum of mental health services.

**Treatment Outcome**

Research on treatment effectiveness and outcome in psychiatry involves a complex constellation of factors, and major problems are encountered, including providing an objective, standardized definition of effectiveness and solving methodologic constraints such as difficulties of selection procedures and randomization ( Moskowitz, 1980). The scope of the research literature on the effectiveness of child and adolescent partial hospitalization is not yet broad enough to provide definitive information. Limited research has been done on treatment effectiveness or outcome with child and adolescent samples with only one or two controlled studies ( Burns et al., 1999). A summary of the studies conducted to date on adolescents in PHPs indicates generally positive outcomes, with gains in relationships and school performance (Corky and Zimet, 1987; Kettlewell et al., 1985). Decreased symptoms have been found after treatment in PHPs, and the effects are evident for up to 1 year after discharge (Grizenko et al., 1994; Kiser et al., 1996; Milin et al., 2000). Review of studies on treatment outcome with children suggests that 66% to 90% of patients demonstrate improvement and successful return to community-based schools. Studies suggest that family functioning (structure and stability) are major factors in improvement (Prentice-Dunn et al., 1981; Sack et al., 1987) whereas others conclude that younger children show greater benefits from treatment in partial hospital settings than do older patients (Blom et al., 1973; Prentice-Dunn et al., 1981). Baenen et al. (1986), after a review of outcome studies, report improvements in

behavioral, academic, and family role functioning after partial hospitalization with a variety of aftercare services needed. In a 5-year follow-up of severely disturbed children treated in a multimodal day program, improvements in global functioning, behavior, self-esteem, peer relations, and academic performance were maintained with parental cooperation of primary importance to positive outcomes (Grizenko, 1997). Poorer outcomes are associated with diagnoses and symptoms of disruptive behavior, family and patient history of mental health treatment, and family separations such as out-of-home placements (Kiser et al., 1996; Milin et al., 2000; Rey et al., 1998).

Movement to partial hospitalization away from traditional treatment modes would be alarming and irresponsible without treatment comparisons. It is essential to look at treatment effectiveness of partial hospital settings in comparison with effectiveness of other modalities. Again, published research has not been as extensive as desirable (Weir and Bidwell, 2000). The literature on child and adolescent populations contains four studies that compare treatment outcomes in partial hospitalization and residential settings (Byrnes et al., 1999; Goldfarb et al., 1966; Leone et al., 1986; Valesquez and Lyle, 1985). Overall, the findings suggest that partial hospitalization is equally effective with some patients on some variables, is more effective with some patients on some variables, and is less effective with some patients on some variables. Clearly, advocates of partial hospitalization must continue to compare outcomes from different treatment modalities and from various partial program models, as well as compare treatment outcomes of specific populations.

One of the major difficulties encountered in the area of outcome measurement is the lack of standardization of outcome variables and instruments. Six areas of outcome measurement are recommended for ambulatory behavioral health care, including cost of services, use of services after discharge, severity of symptoms, level of functioning, patient ecology (family and community support network), and satisfaction (American Association for Partial Hospitalization, 1994). Standardized assessment of these variables is a goal with the objective of providing industry-wide information regarding expected outcomes.

## CONCLUSION

Ambulatory behavioral health care represents an important segment of the continuum of psychiatric care available to children and adolescents with a wide array of disorders and allows these patients treatment in less restrictive settings than hospitals. In the current era of health care reform, this and other ambulatory mental health services will likely face increased demand. As policies encourage such options, it is necessary to be aware of differences among PHPs, DTPs, and IOPs, so patient needs can be matched with service variables such as theoretical orientation, targeted populations, types of treatments offered within the program, staffing patterns, and the degree of structure provided (Masters, 1997). Issues related to quality of care, therapeutic outcome, and cost effectiveness must also be considered. With careful review, it is possible to identify intensive PHPs that serve as alternatives to inpatient hospitalization, DTPs or IOPs that function as transitions between highly restrictive treatments and outpatient services, and programs that serve as outpatient alternatives.

Although partial hospitalization is an established concept and has a significant history, the field of ambulatory behavioral health care is in transition, as is health care in general. In the years to come, several questions will require answers as ambulatory behavioral health care providers face the broad challenges brought by health care reform. How will PHPs integrate with other children's services such as special education systems, juvenile courts, and state departments of child protection and human services? How will they fit into large health care organizations to provide prevention and related services? We are beginning to discover some solutions to these larger issues of integration and look to the future and the further development of these exciting modes of treatment.

### HISTORY

Just as child psychiatry as a specialty is only 50 years old, inpatient child psychiatry is virtually a fledgling treatment modality. Although the first few inpatient units were started in the 1920s and 1930s ([American Psychiatric Association, 1957](#); [Barker, 1974](#)), their treatment remained narrowly focused on children with postencephalic brain disorders, and their numbers remained small for nearly 4 decades. In the 1970s, a confluence of scientific, political, and fiscal factors produced a rapid rise in child psychiatric inpatient services.

This reached its apogee in the mid-1980s with a proliferation of child and adolescent units in both general and specialty psychiatric hospitals. The best of these services provided comprehensive, multimodal evaluation and treatment for several months' duration ([Harper and Geraty, 1985](#)). However, by the early 1990s, enormous fiscal and political pressures ([Woolston, 1993](#)) resulted in a halt to the expansion in the total number of inpatient beds as well as a dramatic reduction in the average length of stay ([National Association of Private Psychiatric Hospitals, 1992](#)). Despite the apparent dramatic reduction in length of stay, the rate of admission has not been similarly diminished ([Patrick et al., 1993](#); [Tsai et al., 1988](#)).

Current child psychiatric inpatient units are deeply embedded in the milieu of the hospital environment and therefore are quite distinct from other institutionally based treatments of emotionally and behaviorally disturbed children and adolescents. However, children and adolescents have been, and continue to be, treated in a variety of other nonpsychiatric, institutional settings, including juvenile detention, social welfare, and educational systems. To date, the choice of treatment settings has been determined more by politics and custom than by diagnostic need. Until the middle of the 20th century, serious mental illness in children was thought to be rare, and therefore psychiatric hospitalization was rare. Conversely, at the beginning of the 20th century, child welfare facilities such as orphanages and shelters for the homeless housed the largest group of institutionalized children. In 1935, the U.S. Congress authorized Aid to Families with Dependent Children, which provided federal welfare funds for home care. Concurrently, professionals and politicians came to believe that "normal" children did not require the expensive course of institutional programs, so many children in welfare facilities were deinstitutionalized.

Unfortunately, the juvenile detention system experienced a concurrent increase in children that completely offset the trend of deinstitutionalization in the child welfare system. Specifically, admissions to all types of juvenile correctional facilities increased ninefold from 1923 until 1979. This burgeoning use of the juvenile detention system was reversed by the passage of the Juvenile Justice and Delinquency Prevention Act in 1976 by the U.S. Congress. Between 1975 and 1979, the rate of detention for juvenile offenders decreased by 68% ([Weithorn, 1988](#)).

Two sets of legal decisions by the U.S. Supreme Court, one that supported the requirement for mental health coverage in insurance plans (*Massachusetts vs. Metropolitan*) and another that broadened the rights of parents to hospitalize their children voluntarily (*Parham vs. J.R.*), served to accelerate this trend. As a result of these various influences, in the mid-1970s, the rate of admission to psychiatric hospitals began to increase as the rate of institutionalization in the juvenile detention system began to decline. The more recent trend in the mid-1990s toward greatly reduced lengths of stay in psychiatric hospitals has apparently been offset by a corresponding increase in placements in residential treatment programs, juvenile detention, and group homes. This phenomenon of shifting children and adolescents from one institutional setting to another as a result of nontherapeutic or nonclinical forces has been described as *transinstitutionalization*. ([Weithorn, 1988](#)).

In the 1970s, the transinstitutional shifts not only resulted in a higher rate of psychiatric admissions for minors but also changed the specific type of psychiatric facility to which they were admitted. In 1970, the rate of children's admissions to private for-profit psychiatric hospitals was 9.3 per 100,000 children or one-fourth of the rate of admissions to federal, state, and county public hospitals (37.8 per 100,000). During the 1970s, admissions of minors to public hospitals declined by 30%, and admissions to private for-profit hospitals increased almost 100%, so in 1980, the rate of admissions of minors was about the same for both types of institutions. The rate of admissions of minors to private nonprofit general hospitals with inpatient services increased slightly from 63.3 per 100,000 in 1970 to 68.5 per 100,000 in 1980 ([U.S. Department of Health and Human Services, 1986](#)). In addition to reduced admission rates to public hospitals, the average length of stay dropped from 74 days in 1970 to 54 days in 1980. Lengths of stay remained constant in private for-profit psychiatric hospitals at 36 days and increased slightly in general hospitals from 9 to 14 days ([U.S. Department of Health and Human Services, 1986](#)).

In the late 1980s and early 1990s, three separate forces combined to reverse this trend of increased inpatient use, especially in the private psychiatric hospitals. First, the proportion of money spent on mental health services had become unacceptably distorted toward inpatient services. For example, in 1986, residential and inpatient mental treatment for minors used up 78% of the \$3.5 billion spent on all mental health services in the United States. Partial hospitalization and various outpatient services accounted for 22% or \$0.77 billion. For one specific insurance program, the Civilian Health and Medical Plan for the Uniformed Services (CHAMPUS), in 1989, the total mental health costs were \$613 billion, of which \$500 million went for inpatient psychiatric care in general and \$305 million for child and adolescent inpatient care in particular. Thus, nearly one-half (49.75%) of the entire CHAMPUS mental health costs for 1989 were accounted for by the hospital and residential treatment of children and adolescents ([U.S. House of Representatives Select Committee on Children, Youth and Families, 1992](#)). This rapid escalation of hospital costs combined with the national recession of the late 1980s to stimulate the development of cost-saving strategies such as managed care review and institutionally negotiated contracts with capitated reimbursements.

A second major brake on the rapid growth of hospitalization for minors was a nationally publicized series of criminal and unethical scandals that rocked private psychiatric hospitals ([U.S. House of Representatives Select Committee on Children, Youth and Families, 1992](#)). A third, and apparently much more positive, force has been the trend toward intensive, noninstitutional psychiatric treatments. Examples of this trend include the following: federal legislation such as the Children and Adolescent System Services Program ([Stroul and Friedman, 1986](#)); innovative state programs in Alaska, Vermont, and California; parent advocacy groups such as National Alliance of the Mentally Ill; and support from foundations from organizations such as the Robert Wood Johnson Foundation. All these various programs emphasize the need for multiple services (e.g., mental health, welfare, education, recreation, and housing) to be available in a seamless fashion to children and families. Rather than requiring the child and family to accommodate to the demands of various institutions, the programs seek to develop individualized integrated services customized to the needs of the child. These various reform-oriented groups have attempted to reconceptualize inpatient units as the most restrictive and rarely used component of an integrated system of care, rather than as the most accessible but disconnected fragment in a mental health nonsystem ([Foster, 1998](#)).

### DIMENSIONS OF PSYCHIATRIC SERVICES FOR CHILDREN

These extraordinarily rapid and constant changes in inpatient psychiatric treatment have been accompanied by numerous growing pains. The model (and perhaps modal) child and adolescent inpatient service of the mid-1980s was a 10- to 20-bed unit dedicated to comprehensive evaluation and treatment with a length of stay of several months ([Harper and Geraty, 1985](#); [Woolston, 1989](#)). More recently, beginning in the early 1990s, the average length of stay has dropped to several weeks. This change has resulted in a focus on crisis intervention and evaluation rather than on longer-term treatment. Such facilities are specialty units in general or larger psychiatric hospitals and are staffed with a multidisciplinary treatment team including child psychiatrists, pediatricians, psychologists, social workers, nurses, and teachers. High-technology diagnostic testing, including brain imaging, electroencephalography, and chromosomal analysis, is frequently employed ([Woolston and](#)

[Riddle, 1990](#)). Treatment is characterized by an orchestrated blend of milieu, family, pharmacologic, and individual therapies. For these and other reasons, children and adolescents may receive intensive evaluation and short-term treatment in hospital programs but then may be unable to progress to less restrictive and less expensive but longer-term treatments. This increasing intensity of treatment provided in inpatient units has tended to cut off such services from their historically related programs provided by educational, juvenile detention, and social welfare agencies. The very same medical, financial, and political forces that have promoted the growth of these inpatient units have created artificially rigid boundaries with these other related treatments. Typically, children may receive public or private insurance funding for a relatively short hospital treatment but are without benefits to cover intensive outpatient or residential treatment. Ironically, the shortening of hospital lengths of stay to several weeks frequently results in a more disruptive hospital experience because welfare agencies, schools, and outpatient treatment programs cannot respond to the newly identified needs of the child before discharge.

Although the psychiatric treatment of children and adolescents is sometimes conceived of as a relatively homogeneous treatment modality, considerable heterogeneity actually exists in inpatient facilities. Although inpatient units can be characterized by many different factors, the following six dimensions account for most of the variance: level of restrictiveness of treatment, length of stay, type of psychiatric disorder, developmental level of patient, hospital organization or affiliation, and philosophy of treatment. Although each of these dimensions is distinct, they are obviously interdependent. For example, children with severe, chronic disorders, such as mental retardation and autism, frequently need very long-term treatment. Their families usually do not have the financial resources to pay for such treatment, so the treatment facilities must rely on some form of public funding. A completely different constellation of factors is represented by adolescents with adjustment disorders. They are frequently treated in emergency or acute services funded by private insurance. Despite such clustering, these six dimensions provide a useful guide to understanding the current heterogeneity of services.

### **Level of Restrictiveness of Treatment**

Perhaps the fundamental dimension of inpatient child psychiatry is level of restrictiveness of treatment. By definition, inpatient treatment is the most restrictive modality, by virtue of its being an out-of-home, institutional setting. However, level of restrictiveness can vary considerably among psychiatric hospitals by such variables as whether admissions are voluntary or involuntary, the unit is locked or unlocked, participation by parents is encouraged or discouraged, and visits to the home community are facilitated or prevented.

This dimension of restrictiveness indicates part of the explanation for the rapid shifts among the population of mental hospital, welfare institutions, and juvenile detention facilities. All three sets of institutions, although supposedly treating children with quite different diagnostic descriptions, have in common the most restrictive treatment setting. Thus, from the point of view of funding or licensing agencies, hospitals, juvenile detention centers, and state institution shelters have virtually nothing in common. From the point of view of level of restrictiveness, all three facilities are nearly identical: They are highly restrictive, out-of-home, institutional placements.

### **Length of Stay**

Length of hospital stay is both reflective of other dimensions of a hospital program and a determinant of constraints on these very same dimensions. Attempts to apply rational prospective payment systems (e.g., diagnostic related group system) to inpatient child psychiatry have shown that the major determinant of length of stay is finding availability or explicit program limitations, rather than patient diagnosis ([Christ et al., 1989](#)). Traditional groupings of lengths of stay include emergency (3 days), acute (<4 weeks), short-term (1 to 3 months), intermediate (3 to 5 months), and long-term (>9 months). Although these divisions are somewhat arbitrary, they both reflect and organize treatment philosophy, psychiatric diagnosis, type of patient served, and institutional organization. For example, very short-term lengths of stay preclude comprehensive interventions because the necessary relationships cannot be formed and evaluations cannot be completed. In addition, therapies that require a definite time period, such as some medication trials or educational programming, are not feasible. However, such short-term lengths of stay may be minimally disruptive to the child's important social relationships. In contrast, hospital programs with very long lengths of stay can reasonably attempt such goals as character change and academic disability remediation, but they run the risk of deleterious institutionalization effects.

### **Psychiatric Disorder**

The typical psychiatric disorders of a specific inpatient population are determined by such factors as length of stay and institutional organization and, in turn, determine other variables, such as philosophy of treatment. The broad groupings of psychiatric disorders include adjustment disorders, mixed behavior or affective disorders, eating disorders, adolescent- or adult-onset psychosis, substance abuse, pervasive developmental disorders, childhood-onset psychosis, and mental retardation. Although the basic rudiments of diagnostic grouping exist, surprisingly little is known about the most basic aspects of the phenomenology of serious childhood-onset psychiatric disorders, including such aspects as natural history, epidemiology, etiology, and associated comorbidity ([Woolston et al., 1989](#)). The current state of ignorance about these fundamental issues places major constraints on specificity of treatment design as well as on intervention outcome evaluation.

### **Developmental Stage**

Hospital programs designed for the treatment of children and adolescents usually stratify their units according to the developmental age of their patients. Not surprisingly, hospital facilities follow the same developmental groups as do education programs. These include programs for children up to 3 years old (infant, toddler, and preschool), from 4 to 14 years old (elementary and middle school), and from 15 to 19 years old (high school and college). A program that is relatively homogeneous in developmental age automatically defines some of the constraints of psychiatric diagnosis, philosophy of treatment, and level of restrictiveness. For example, programs for adolescents typically treat patients with eating disorders, affective behavior disorders, substance abuse, and adolescent-onset psychotic disorders, whereas programs for young children focus on pervasive developmental disorders, disruptive behavior disorders, and, less frequently, childhood-onset eating disorders. Organization of elements of the treatment programming, such as the type of milieu and family therapy employed, is greatly influenced by the developmental stage of the patient.

### **Institutional Organization and Affiliation**

Another dimension defining hospital treatment is related to institutional organization or affiliation. One fundamental dichotomy is between publicly funded or affiliated hospitals and private hospitals. The publicly funded hospitals may be local, state, or federal, or some mixture of all three. Until recently, publicly funded hospitals have tended to be large psychiatric hospitals for severely and chronically disturbed children who frequently came from socially disadvantaged families. Because of the chronic nature of the psychiatric disturbance and relatively poor funding, these public hospitals tend to focus on benign environmental amelioration as a treatment philosophy. In these ways, some programs may more closely resemble residential treatment centers than inpatient services. The recent trends of deinstitutionalization and diminishing publicly funded hospitals have combined to result in shortened lengths of stay and decreased admission rates. Unfortunately, because few alternative mental health services for poor, chronically disturbed children have been implemented, the juvenile detention, social service, and education systems may well be forced to resume their previous roles in providing services. The other fundamental type of institutional organization group, nonpublicly funded hospitals, occurs as either nonprofit or for-profit hospitals. Typically, inpatient units in nonprofit private institutions are part of a general medical hospital that provides a full array of medical, surgical, and psychiatric services. These hospitals may be primary (local), secondary (state based), or tertiary (regional) facilities; each level has an attendant structure of resources and typical patient population. Psychiatric inpatient treatment in general hospitals is quite heterogeneous. Some general hospitals do not have discrete children's psychiatric units. Instead, patients are admitted to general medical or pediatric units in so-called "scattered beds."

Typically, children treated in these settings receive crisis intervention and then are discharged within 1 to 7 days. Conversely, discrete, dedicated child psychiatric inpatient units in general hospitals offer comprehensive evaluation and treatment services by a multidisciplinary treatment team. Average lengths of stay in these units range between 7 and 60 days. Although the median length of stay reported for psychiatric inpatients in general hospitals is 14 days, this number is probably a meaningless average between these two disparate groups in a bimodal distribution. Even within this special group of dedicated child inpatient units in general hospitals, there is considerable variation in philosophy of treatment, length of stay, and developmental or diagnostic characteristics of the patients.

For-profit private proprietary psychiatric hospitals have experienced tremendous growth since the early 1990s. In 1971, about 6,500 children and adolescents were admitted to proprietary psychiatric hospitals, whereas by 1980, about 17,000 children less than 18 years of age were admitted. By 1984, 23,000 adolescents (ages 13 to 17 years) alone were admitted to these hospitals, and by 1986, 38,000 teenagers were hospitalized ([Weithorn, 1988](#)). The explanation for this explosive growth of proprietary psychiatric hospital admissions is multifaceted, but it probably devolves on four main factors: diminished availability of juvenile detention and child welfare systems; increased funding provided by private insurance and Medicaid; increased social instability because of divorce, moves, and social disruption; and the relaxation of the statutory rights of minors by the Parham decision of the U.S. Supreme Court in 1979 ([Weithorn, 1988](#)). This rapid growth of proprietary psychiatric hospital admissions was accompanied by a storm of controversy and criticism that focused on excessive and inappropriate hospitalization of adolescents as a result

of unprofessional and unethical admission policies ([U.S. House of Representatives Select Committee on Children, Youth and Families, 1992](#); [Weithorn, 1988](#); [Woolston, 1993](#)). This rapid proprietary hospital growth and its attendant abuses have had certain consequences. Closer scrutiny by third-party payers and licensing agencies has occurred. This has resulted in numerous hospital closures and consolidations. In the 1990s, lengths of stay dropped dramatically in response to reduced insurance benefits and aggressive utilization review oversight by managed-care companies ([Patrick et al., 1993](#)).

## Philosophy and Goals of Treatment

The philosophy and goals of treatment espoused by various psychiatric inpatient services occur in a continuum ranging from custodial care to comprehensive evaluation and treatment of the child, family, and the important social environment. Although less ambitious treatment philosophies may reflect a callous or unethical approach to disturbed children, they may equally likely emerge from a realistic appraisal of fiscal, social, and clinical realities. Frequently, the level of intensity of the philosophy of treatment is highly correlated with the severity or chronicity of the psychiatric disturbance and the adequacy of funding. As the severity or chronicity of a disturbance increases and the level of funding decreases, the intensity of treatment diminishes.

### CUSTODIAL CARE

Custodial care is geared toward preventing harm from befalling the patient, whether from an inability to provide self-care or from injury. Custodial care is usually the dominant treatment philosophy only for the most severely disturbed psychotic and retarded children. Ironically, the only other setting in which custodial care is the prominent treatment philosophy is for acute, "social" admissions of relatively high-functioning children who need protection from their parents.

### ENVIRONMENTAL AMELIORATION

The next level of treatment philosophy is nonspecific, benign, environmental amelioration. Specifically, the institution provides good nutrition, safe and pleasant surroundings, medical care, appropriate recreational activities, and an adequate education. For example, this level of treatment is rarely the officially stated philosophy of a hospital program; it may be the *de facto* treatment goal because of inadequate staffing and treatment planning. For institutions such as child welfare agencies that provide services for children who are considered "normal," environmental amelioration may actually be an appropriate and desirable level of treatment.

### SELECTED EVALUATION AND TREATMENT

The next level of treatment is selected evaluation and treatment of some aspect of the child and his or her important social environment. For example, many traditional psychiatric hospitals and residential treatment centers focus on evaluating and treating the child's psychiatric and behavioral problems. These programs emphasize milieu and individual as well as special education programs and parental counseling therapies ([Harper and Geraty, 1985](#)).

Of all the specific treatment modalities currently employed, milieu therapy encompasses the broadest range and is most specific to this form of treatment philosophy. Milieu therapy has its roots in the writings of [Aichorn \(1935\)](#), [Bettelheim \(1950\)](#), [Redl and Wineman \(1952\)](#), and [Trieschman et al. \(1969\)](#). These authors emphasize the use of the child's "Life-Space Model," the notion that every aspect of the child's physical and social environment is important in therapeutic understanding and treatment. Although milieu therapy at first focused on an individual psychoanalytic understanding of the child, it has successively incorporated concepts of group, occupational, recreational, and behavioral therapies to create a multimodal therapeutic life experience. Although the specifics of each milieu program are different, depending on the psychiatric diagnoses and the developmental levels of the patient, the overall principles are similar ([Cotton, 1993](#)).

Individual therapies are considered to be all those interventions directed specifically toward the individual patient. They include individual psychodynamic psychotherapy, cognitive psychotherapy, individual behavior therapy, and pharmacotherapy. Although these therapies are employed in a similar manner and for the same indications as they are for nonhospitalized patients, modifications are necessary to account for greater frequency and intensity of treatment and greater severity of psychiatric disturbance in the patient.

Regardless of the specific treatment, inpatient psychiatry requires active coordination in implementing the program. This issue of creating a coherent, well-synthesized treatment program fashioned out of many different treatment elements and employing many different clinicians is a major challenge for hospital treatment. [Stanton and Schwartz \(1954\)](#) highlighted the frequently described phenomenon of significant clinical deterioration of patients when the coherence and consistency of the hospital program are destroyed by poor communication, divergent clinical opinions, and strongly held, emotionally charged differences among staff members.

Special education programs are an important, albeit much neglected, component of hospital programs. Perhaps most children hospitalized in psychiatric inpatient units have a significant cognitive (e.g., mental retardation or borderline intellectual functioning) or academic (e.g., specific developmental learning disability) disorder ([Woolston et al., 1989](#)). The identification of these disorders and the subsequent development of remedial teaching strategies can play an important part in a child's treatment. Unfortunately, wide regional variation occurs in the level of funding available for these educational services. Services may vary from 2 hours of tutoring in the child's bedroom to 8 hours of special education in a comprehensive school setting. As lengths of stay diminish below 4 weeks, linkages with the child's original school become more difficult, and providing a *bona fide* school curriculum becomes increasingly difficult.

In the service of maximizing the impact of these therapies on the child, those programs that use this level of treatment philosophy tend to disconnect the child from the important social environment, the family, and local school. Although family therapy or parent counseling may be offered, it occurs in parallel and quite separate from the active hospital treatment of the child. This level of treatment philosophy is heavily influenced by the traditional medical model of hospitalization: The child is sick; the hospital treatment is to cure the child's illness; when cured, the child can return home. Although this model works well for some acute illnesses, it is not appropriate for many chronic conditions, whether medical or psychiatric. Because such definite "fixing" of the child is not possible, changing the child's important social environment to be more suitable to the child's developmental needs may be as important as changing the child.

### COMPREHENSIVE EVALUATION AND TREATMENT

The highest level of treatment philosophy aims at comprehensive evaluation and treatment of the child, the child's important environment, and the interaction of the two. An appreciation of the complex and powerful effect of the evolving interaction between the child and his or her important social environment follows from understanding the concept of a transactional risk model ([Woolston, 1989](#)). The transactional risk model rests on the concept of "goodness of fit" proposed by [Chess and Thomas \(1984\)](#), as well as concepts of resilience proposed by such authors as [Gannezy \(1983\)](#), [Rutter \(1979\)](#), and [Werner and Smith \(1982\)](#).

Articulation of this transactional model is a relatively recent development in the inpatient treatment of children and awaits testing and development to determine its applications and problems. This model may provide a guide for both the orchestration of specific treatment modalities in an inpatient unit and the development of a network of services linking inpatient and outpatient programs to provide the most comprehensive and least restrictive treatment. Perhaps of greatest importance, this treatment philosophy attempts to address a major problem for hospital treatment: How can the gains achieved during the hospitalization be generalized and continued in less restrictive, more normative settings? In addition to "fixing" the child or, less frequently, "fixing" the family, this treatment philosophy attempts to ameliorate the interaction between the child and his or her environment so the child's developmental potential will be maximized.

In the current climate of several-week hospitalizations, a major focus is on developing a more comprehensive, more appropriate outpatient system of care. This development entails bringing the new information learned about the child and family to the professionals who provide social services, education, and mental health services. To accomplish this development of a new system of individualized care, the inpatient facility must have preestablished linkages with an array of services such as school systems, day treatment, in-home services, therapeutic foster care, protective services, medical providers, traditional outpatient services, housing resources, and recreational programs ([Bickman et al., 1996](#); [Foster, 1998](#); [Stroul and Friedman, 1986](#)).

One innovative approach has been intensive, home-based psychiatric services that begin as the child is discharged and continue until the child and family have an adequate system of outpatient care established ([Woolston et al., 1998](#)).

## FUTURE DIRECTIONS OF INPATIENT SERVICES FOR CHILDREN

The current status of inpatient child psychiatry is characterized by an exciting ferment of rapid development with a huge perceived need for treatment, but with a

nearly total absence of data about the mechanisms to meet this need (Manderscheid et al., 1993; Weller et al., 1995). In addition, the paucity of research on effectiveness and efficacy of inpatient treatment is remarkable given the large proportion of mental health resources devoted to this modality (Burns et al., 1999). As delineated in this chapter, psychiatric hospitalization is an enormously heterogeneous treatment modality. Before any assessment of the efficacy of hospital treatment, either absolute or in comparison with other treatments, can occur, the specifics of the hospitalization must be stated and spelled out in a manual, so fidelity can be ensured. Research has reported home-based, multisystemic therapy as an effective alternative to hospitalization. Although this research carefully described the experimental treatment, the hospital treatment had no such standardization (Henggeler et al., 1999). The further development of inpatient psychiatry will occur in response to the acquisition of more refined knowledge. Specifically, research is needed to increase understanding in several areas, including the following: basic phenomenology about childhood-onset psychiatric disorders and their association with psychosocial stressors (Gutterman, 1998); the development and refinement of specific treatment strategies; the use of biomedical diagnostic and treatment techniques; and the implementation of an integrated network of mental health services with an appropriate, nondiscriminating funding basis (Bickman et al., 1996; Foster, 1998; Stroul and Friedman, 1986).

### DEFINITION

*Residential treatment centers* (RTCs) are defined by the National Institute of Mental Health ( [Stroup et al., 1988](#)) as psychiatric organizations serving children and meeting the following criteria:

1. It is an organization, not licensed as a psychiatric hospital, whose primary purpose is the provision of individually planned programs of mental health treatment services in conjunction with residential care for its residents.
2. It has a clinical program within the organization that is directed by a psychiatrist, psychologist, social worker, or psychiatric nurse who has a master's or a doctoral degree.
3. It serves children and youth primarily less than 18 years of age.
4. The primary reason for the admission of 50% or more of the children and youth is mental illness, which can be classified by the codes set forth in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the tenth edition of the *International Classification of Diseases* (ICD-10), other than those codes for mental retardation, substance (drug)-related disorders, and alcoholism. )

### HISTORY AND ORIGINS

In 1729, the first U.S. orphanage was founded by Ursuline nuns in New Orleans to provide care for a group of children whose parents had died in a smallpox epidemic. This is the origin of the custodial, or residential, component of residential treatment in the United States. Religious institutions remained prominent in offering custodial care for many years. Recognition of the developmental differences characteristic of children gradually led to the formation of the specialties of pediatrics and child psychiatry and, in the 1880s, to the emergence of numerous special agencies for children. In the 1900s, mental health professionals, particularly psychoanalysts, child psychiatrists, psychologists, and social workers, began discovering and applying psychodynamic theories in the care and treatment of children. The main needs of the developing child were increasingly recognized, and comprehensive programs designed to meet those needs were planned. This program development constituted the first treatment component of residential treatment. Group living experiences, educational, physical health, and creative opportunities, and psychotherapy for children and their families, both individually and in groups, began to replace rigid custodial care, with its strong moral and discipline-oriented attitudes.

The field of residential treatment for children subsequently developed on an empirical basis to provide multiple models of treatment to suit different needs. The different models also reflected different theories of child development. Thus, psychoanalysis and learning theory initially provided significant foundations for two polar treatment approaches, between which various admixtures of the two could be found. Subsequently, other theoretical models were introduced, including a "goodness-of-fit" model and various cognitive and behavioral approaches.

A view that has gained ground conceptualizes the residential experience as a whole—group living, on-grounds schools, and psychotherapy—as constituting each child's therapy. Working under this view, all staff members are in full communication as they deal therapeutically with the children, their parents, and, in some cases, the whole family. Combined treatment modalities are used, including milieu therapy, family therapy, parent work, psychodynamic psychotherapy (individual, group), behavior therapy, pharmacotherapy, recreational therapy, art therapy, music therapy, and special education.

### STATISTICS, TRENDS, AND FUNDING

In 1990, approximately 68,729 emotionally disturbed children in the United States received residential treatment in 501 facilities representing a total bed capacity of 29,756, with a year-end census of 27,785. In 1998, approximately 78,520 emotionally disturbed children in the United States received residential treatment, with no significant increase in the number of facilities. Previous figures showed a general increase in growth in the 1970s and 1980s in the number of treatment beds available. There was a period of temporary decline in the early 1980s and a period of slight growth between 1986 and 1988 ( [Table 90.1](#)). During the 1990s, there was a renewed emphasis on reducing length of stay and placing children in the least restrictive treatment settings.

	1972	1976	1984	1986	1988	1990
Number of children	19,384	20,384	16,745	24,547	25,547	27,785
Number of facilities	340	375	322	457	440	501

Statistics from unpublished data National Institute of Mental Health, 1994.

**Table 90.1. Trends in Residential Treatment Bed Occupancy**

Statistics published by the National Institute of Mental Health in 1991 note the following trends in residential treatment. In 1988, California and Massachusetts had the highest number of RTCs, 48 and 38, respectively. Other states with 15 or more RTCs were Colorado, Illinois, Minnesota, Ohio, Pennsylvania, and Wisconsin.

Approximately 70% of RTCs had 50 or fewer beds. Twenty percent had 50 to 75 beds. Ten percent had more than 100 beds. More than 33% of children were in residential treatment facilities having more than 100 beds ( [Table 90.2](#)).

Staff Discipline	Number of Full-Time Equivalent Staff (1978-1984/1988)			Percent Distribution (%)		
	1978	1984	1988	1978	1984	1988
Psychiatrists	36	30 (+7%)	48 (+37%)	0.8	1.1	1.1
Psychologists	47	62 (+32%)	124 (+125%)	1.1	1.7	3.3
Social workers	176	233 (+32%)	477 (+169%)	4.0	5.8	12.7
Nurses	33	45 (+36%)	87 (+161%)	0.7	0.8	2.1
Other (A.A.)	147	173 (+18%)	374 (+155%)	3.3	2.5	8.6
Other (A.S.)	540	476 (-12%)	945 (+71%)	12.4	6.8	21.5
Administration and maintenance	579	574 (-1%)	1086 (+87%)	13.1	8.2	24.1

Full-time equivalent (FTE) staff in residential treatment centers. Reservations taken from the National Health and Medical Research Council, 1988 and 1990. All data are based on data from the National Health and Medical Research Council, 1988 and 1990. All data are based on data from the National Health and Medical Research Council, 1988 and 1990.

**Table 90.2. Number, Percent Change in Number, and Percent Distribution of Full-Time Equivalent Staff in Residential Treatment Centers, by Staff Discipline, United States, January 1978 and 1984 and December 1988**

In 1988, 28% of RTC patients were black and 10% were Hispanic. Mental illness was considered the major disability of 94% of RTC admissions. Only 1% to 2% were diagnosed as alcohol or drug abusers. Occupancy rates increased from 87% in 1977 to more than 95% in 1983 and remained at more than 95% throughout the 1980s and 1990s.

Indicators of higher turnover rates and shorter lengths of stay began to appear, and from 1986 to 1988 there was a dramatic increase in the number of RTCs that offered partial care and outpatient treatment services. In the 1990s, this trend continued. Directors of RTCs offering partial care and outpatient services reported that the severity of emotional and behavioral disturbances of children being referred to them increased markedly during the 1990s. Directors of RTCs also reported an increased need for psychiatric consultation because of increased use of psychotropic medications for children in all modes of treatment. Multiservice RTCs have also increased partial and outpatient services to children and families with substance abuse problems.

An estimated \$359.1 million was spent to maintain RTCs in 1977. By 1983, the figure had risen to \$573 million, an increase of 60%. In 1988, the figure rose to \$1.3 billion. However, in constant dollars, this represents an increase of less than 5%. In 1988, of funds available for RTCs, 70% came from state and local government sources, 5% came from federal funds, 10% from client fees, and 12% from all other sources. In 1999, the U.S. Surgeon General's report on mental health stated that RTCs were used by 8% of treated children while using nearly 25% of the national outlay on child mental health.

## CONTINUUM OF RESIDENTIAL GROUP CARE OF CHILDREN

Historically, children are placed in the continuum of group care through the channels of the social welfare, juvenile justice, and mental health service delivery systems. According to the National Survey of Residential Group Care in 1981, conducted by the University of Chicago, 3,914 facilities in the United States operated with a total daily census of 125,323 (Young et al., 1989). Children classified as being in facilities for emotionally disturbed children accounted for 16% of the total in 1981 ( [Table 90.2](#)). RTCs account for only a portion of the reporting facilities. Placement of children in different categories of facilities does not represent an accurate differentiation of children by diagnosis. The type of placement a child receives is also influenced by factors such as economic status, race, and geographic location.

## STAFF AND SETTING

The professional staff of an RTC includes child care workers, teachers, social workers, psychiatrists, pediatricians, nurses, and psychologists.

There were dramatic increases in the number of staff working in RTCs between 1984 and 1988. This increase followed a time of decline from 1978 to 1984. In 1978 RTCs employed 22,443 full-time equivalent staff. The number dropped 5% in 1984 to 21,211. Between 1984 and 1988, the number of full-time equivalent staff members working in RTCs nearly doubled, reaching 39,186. In 1988, there were only 103 full-time psychiatrists working in RTCs, with an additional 808 psychiatrists working part-time in RTCs. There were 370 full-time doctoral level psychologists and 472 part-time psychologists. Social workers with master's degrees (M.S.W.) comprise the largest number of professionally degreed staff, reaching 2,753 full-time and 328 part-time staff in 1988. Registered nurses with master's degrees numbered 163 full-time staff and 36 part-time staff in 1988. The percentage of distribution of full-time equivalent staff remained relatively stable from 1978 to 1988 ( [Table 90.2](#)).

The Joint Commission on Mental Health of Children made the following structural or setting recommendations in 1970:

In addition to space for therapy programs, there should be facilities for a first-rate school and a rich evening and weekend activity program and there should be ample space for play, both indoors and out. Facilities should be small, seldom exceeding 60 in capacity with 100 a maximum limit, and should make provision for children to live in small groups. The centers should be located near the families they serve and be readily accessible by public transportation. They should be located for ready access to special medical and educational services and to various community resources, including consultants. They should be open institutions wherever possible; locked buildings, wards, or rooms should only rarely be required. In designing residential programs, the guiding principle should be this: Children should be removed the least possible distance—in space, in time, and in the psychological texture of the experience—from their normal life setting ( [Joint Commission on Mental Health of Children, 1970](#)).

The actual design of the building should take into account the physical, cognitive, and emotional needs of children between 6 and 15 years of age. Private or shared bedrooms, separate showers and bath facilities for boys and girls, communal living rooms and dining rooms, safe and easy access to recreational facilities and classrooms, and therapists' offices close to the group living area are some of the requirements. Units serving specific age groups are preferred.

Most RTCs gradually increase in size; as they do so, the number of children in each residential unit tends to increase. At the same time, Marsden et al. (1970) find that the duration of treatment seems to shorten as this growth occurs. Older children tend to remain in residence for shorter periods of time than do younger children.

## INDICATIONS

The child's lack of age-appropriate internal controls and need for more consistent external controls, as well as the child's need for intensive specialized treatment, constitute basic indications for residential treatment. Such children may present with moderately severe symptoms of antisocial and aggressive behaviors; they may have psychotic symptoms, including loose associations and hallucinations; or they may exhibit precipitous, severe regressions. Bedwetting is a common symptom. Most, if not all, children referred for residential treatment have severe learning problems.

Genetic factors, organic brain damage, neurochemical dysfunctions, and adverse psychological experiences in the child, together with psychosis and other psychiatric disorders in the parents and an impoverished socioeconomic climate, are major causative factors. A history of parental deprivation, loss, seduction, incest, sexual and physical abuse, and physical injury is common, as is a history of multiple foster home placements.

Children and adolescents in residential treatment often have been exposed directly or indirectly to traumatizing physical and sexual abuse and have subsequently become aggressive, disorganized, and out of control. Milieu therapy using containment, structure, support, involvement, and validation is often helpful ( [Lawson, 1998](#)).

An unusually high prevalence of encopresis, especially in boys, has also been reported in children in residential treatment. In one study of 23 boys in residential treatment, nine were encopretic. Among these nine boys, seven had histories of sexual abuse, particularly sodomy, usually perpetrated by the father or father

surrogate ([Morrow et al., 1997](#)).

Using the classification system of the fourth edition of the DSM (DSM-IV) ([American Psychiatric Association, 1994](#)), the clinical diagnoses most often attached to the child include pervasive developmental disorders (not otherwise specified), attention deficit hyperactivity disorder, specific developmental disorders, conduct disorder, dysthymia, major depressive disorder, and anxiety disorders.

## REFERRAL, INTAKE, AND ADMISSION

Most children who are referred for residential treatment have been seen previously by one or more professional persons, such as a school psychologist, pediatrician, or members of a child guidance clinic, juvenile court, or state welfare agency. Unsuccessful previous attempts at outpatient treatment and foster home or other custodial placement often precede residential treatment. Consequently, considerable data are usually available to and are usually required by the intake staff of the RTC; however, residential centers differ in the evaluation and decision-making process used for selecting children for admission. Satisfactory studies comparing admission criteria and outcome correlations have not been done. The type of child referred to a particular institution is often idiosyncratic to that institution. The age range of the children varies from institution to institution, but most children are between 5 and 15 years of age. Boys are referred more frequently than girls.

An initial review of the data enables the intake staff to determine whether a particular child is likely to benefit from their particular treatment program. The next step usually involves interviews with the children and their parents by various staff members, such as a therapist, a group living worker, and a teacher. Psychological testing and neurologic examinations are performed when indicated, if these have not already been done. Children and their parents should be prepared for these interviews. A useful practice is to have the child spend a day at the center, both in class and in a residential unit.

During this admission and diagnostic process, a comprehensive profile of each child is established. There is at present no standard profile in use. Structured interview schedules are useful. A mental status examination of the child is essential.

The needs of each child, the skills of the staff, the balance of the patient population, and estimates of the prognosis are some of the variables weighed when children are accepted for admission. The parents may or may not be available for treatment. This entire evaluation and assessment process forms the basis on which the staff reaches a decision and makes a tentative treatment plan. A preplacement visit by the children and their families is usually arranged to help to prepare each child for admission.

## TOTAL STAFF COLLABORATION

Group cohesiveness among the staff improves performance. [Johnson \(1982\)](#) describes the measures that promote such cohesiveness: meetings to discuss team process issues; acquisition of leadership skills; clear lines of authority and role expectations; training programs; total team participation in decisions; and prompt expressions of support, concern, and empathy by the leadership. The cooperative attitude of administrative leaders sets the tone for residential treatment staff. [Haley \(1980\)](#) suggests that success in therapy may be determined in part by what happens among the professional staff members. Resolving communication problems, sharing perceptions and experiences, clarifying transference and countertransference issues, and providing a means by which staff can receive feedback on how well they are doing are matters that are as important for the staff as they are for the children.

## ADMINISTRATION

Administration of an RTC requires sound business practices in regard to defining the organization's purpose and mission, securing adequate financial and personal resources, clarifying lines of authority and accountability, and developing responsive programming. RTC administrators must be involved in statewide and national professional and political organizations, because changes in health care and social service policies require rapid adaptive changes in RTC programming and funding. Since the early 1990s, strong state and national consortiums of residential treatment facilities have been developed to play a vital role in assessing the changing needs of children, advocating for children's services, and sharing resources.

In addition to employing sound business practices, administrators of RTCs must understand the impact of severely disturbed children on the individual and group functioning of the staff. This has become more important in recent years as psychiatric hospital stays and other factors have led RTCs to admit even more seriously disturbed children, many of whom take psychotropic medication, than they had in years past. Administrative commitment to a supervisory process that acknowledges the impact of severely emotionally and behaviorally disturbed children on all agency staff members is essential. R. Howenstine (unpublished manuscript, 1984) suggests that a key administrative role in achieving staff collaboration is to conceptualize interdepartmental collaboration and conflict management as a vehicle for identifying, containing, and dealing with the aspects of the children's disorders that are internalized by the staff. [Brown \(1983\)](#) provides a theoretical and systematic approach to managing conflict at departmental interfaces from a management perspective and focuses on six major opportunities for change: (a) to alter perception, (b) to alter communication, (c) to alter behavior, (d) to alter the interface, (e) to alter one or both departments, and (f) to alter organizational context.

## CHILD CARE WORK

By far the largest amount of time in the child's life in a residential treatment setting is spent in group living. [Northrup \(1982\)](#) maintains that the child care worker in group living is usually responsible for the improvement in deeply disturbed children in residential treatment. These workers' use of "good enough parenting" allows them to serve as role models for the children. Child care workers also offer a structured environment that constitutes a therapeutic milieu. Tasks are defined within the limits of the child's abilities; incentives, such as increased privileges, encourage the child to progress rather than to regress. Every member of the staff is important; for example, the dietary staff may have a special role and meaning for some children for whom food and its associations have special significance, including feelings of security, deprivation, love, and aggression.

Children often select one or more staff members with whom to form a relationship through which they express, consciously and unconsciously, many of their feelings toward their parents. The child care staff should be able to recognize such transference reactions and to respond to them in a way that is different from the children's expectations based on previous or even current relationships with their parents. Sometimes, the child care workers know enough about a child to make an interpretation to the child when it seems appropriate—the so-called life-space interview ([Redl, 1959](#)). The literature on milieu therapy extends back to [Aichorn \(1935\)](#). The child care worker must also be aware of the countertransference problems stimulated by the child's behavior and, indeed, by other staff members in what is essentially a large, close, familylike community.

To maintain consistency and balance, the group living staff must communicate freely and regularly with one another and with the other professional and administrative staff members of the residential setting, particularly the child's teacher and therapist. The group living worker has perhaps the most potential among the staff members to produce therapeutic gains.

The child care staff members must recognize any tendency toward being the good, or bad, parent in response to the child's splitting behavior. This tendency in a staff member may become manifest as a pattern of blaming other staff members for the child's disruptive behavior. Similarly, the child care staff must recognize and avoid such individual and group countertransference reactions as sadomasochistic and punitive behavior toward a child.

A common milieu dilemma occurs when the child care worker has to differentiate the approaches needed for, say, the conduct-disordered or psychotically disturbed children in their care from an understandable tendency to want to apply a consistent approach to all children. Therapists and consultants need to be called on to educate child care staff regarding the developmental and psychodynamic needs of each child and how different techniques may be applied while maintaining unit cohesiveness and avoiding countertransference problems.

The structured setting should offer growth-promoting experiences and opportunities for facilitating and improving the adaptive behavior of the children. Particular deficiencies such as speech and language deficits, intellectual retardation, inadequate peer relationships, bedwetting, poor feeding habits, or attention deficits may be at the base of the children's poor academic performance in school and their unsocialized behavior, including temper tantrums, fighting, and withdrawal, and require particular attention.

Behavior therapy principles are also applied, particularly in group work with children. In the course of group therapy, behavior that is socially adaptive and appropriate may be awarded points. At the end of the session, all the children receive a prize of, say, candy, but the child who has the most points gets first choice. Behavior

therapy is a component of the total therapeutic effort of the residential center.

Unfortunately, many child care workers feel frustrated and confused, and they experience job dissatisfaction. [Rick and Charlesworth \(1982\)](#) suggest that this is partly because they do not have sanction to cross certain professional boundaries. Child care workers and other professionals—psychiatrists, psychologists, social workers, teachers—need to recognize the problem as a systems issue and should participate in education and accommodation aimed at realignment of professional roles. There is a corresponding need for a career development ladder for child care workers.

## PHYSICAL HEALTH

Many children referred to RTCs have physical health problems, including poor nutrition, dental problems, and frequent infections. Attention must therefore be paid to health care. Particular attention must be given to adequate hygiene, and standard universal safety precaution procedures should be followed. On-staff registered nurses are indispensable, along with a panel of physician consultants.

## SCHOOL PROBLEMS

Children in residential treatment frequently have severe learning disabilities, as well as disruptive behavior, and usually they cannot function in a regular community school. A thorough diagnostic assessment of a child's specific learning difficulties is required as a basis for a rational approach to the application of specific remedial measures ([Table 90.3](#)).

- 
1. Pediatric history: birth, development, personal, social, family, school, previous illnesses, life events
  2. Specific strengths: sports, creative arts
  3. Specific symptoms or skill delays or both: reading, writing, arithmetic, directionality, visual and auditory sequencing, memory, coordination, attention
  4. Associated behavior, personality trait or difficulties: adaptations, defenses, self-esteem, anxiety, depression
  5. Comprehensive pediatric physical examination and diagnostic consultations: visual, auditory, speech, and language evaluations
  6. Neurodevelopmental examination
  7. Psychiatric and psychological assessment
  8. Educational assessment
- 

**Table 90.3. Evaluation Process for Assessment of School Difficulties in the Child**

A special on-grounds school setting is usually required. Some of the characteristics of this on-grounds school include staff members who are skilled in special educational assessments, a low teacher:student ratio, specialized learning equipment including computers and word processors, and a curriculum designed to captivate the children's interest and motivate them to begin learning again.

The teacher is also often in the same relationship with the children as the group living worker and can offer them a structured environment, a model for identification, and a clarifying interpretation of their behavior, when appropriate. The teacher must be in free and regular communication with the other professional staff members, including the group living staff and the children's therapists. [Figure 90.1](#) shows some of the components of the educational process.

**Figure 90.1.** Components of the educational process. (From Lewis M: Residential treatment. In: Kaplan HI, Sadock BJ (eds.): *Comprehensive Textbook of Psychiatry*, vol 4. Baltimore, Williams & Wilkins, 1985, p. 1800, with permission.)

A major goal of the on-grounds school is to motivate the children to learn. This is done, in part, by providing multiple success experiences at whatever level the child is capable. While the children are in school, the school should have full responsibility for dealing with them. School staff should take advantage of what is known about the children as they attempt to improve the children's self-esteem, to motivate them to learn, and to provide opportunities for them to acquire adaptive skills. [Comer \(1980\)](#) notes that the child and adolescent psychiatrist can offer useful consultations to school staff members in this regard, and the child care workers and therapists can offer support to the teachers in understanding and managing a particular child. If the location of the RTC permits, the occasional child may attend a nearby public school, if indicated, while he or she remains in the residential program.

## THERAPY

Traditional modes of psychotherapy have a definite place in residential treatment. These modes include intensive individual psychotherapy with the child, group therapy with selected children, individual or group therapy or both for parents, and in some cases family therapy. However, several modifications need to be kept in mind.

The child also relates to the total staff of the setting and therefore needs to know that what transpires in the therapist's office is shared with all professional staff members. The therapist informs the child that what they discuss and do in individual therapy will not be revealed to other family members or to other children in the residential center but will in most instances be shared with professional staff members within the setting itself. Indeed, psychotherapeutic encounters often continue outside the setting of the therapist's office. Psychotherapy within a residential setting can hardly proceed without a full knowledge of the daily life of the child with peers and staff members in the group living situation and in the school. In addition, group living and school experiences can be made more meaningful if the therapist communicates freely and frequently with the child care worker and the teacher.

## PARENTS

Concomitant work with the parents is essential. The child usually has a strong tie with the parent, no matter how disturbed that parent may be. Sometimes the parent is idealized by the child but repeatedly fails the child. Sometimes the parent has an ambivalent or unrealistic expectation that the child will return home. In some instances, the parent must be helped to enable the child to live in another setting when that is in the best interest of the child. Most RTCs offer individual or group therapy with the parents, couples therapy, and, in some cases, conjoint family therapy.

The therapist who works with the child should also be the person who works closely with the family to help them deal with their feelings of guilt regarding placing the

child and with their tendencies to overcompensate for this placement by trying to indulge the child. Wild swings of ambivalence and reaction formation toward children before admission are sometimes replaced by hostility after they enter residential treatment.

Similarly, the parents need help when the children go home for a visit. The children's behavior often represents a demand for reparations in the form of constant demands for attention, sometimes virtually compelling their families to rearrange their schedules around the children's wishes. Children almost become tyrants during these visits and lead the parents to resent them because the parents are unable, without instructional help from the staff, to set limits. Children may also present a distorted picture of their parents to the staff as part of an unconscious attempt to ward off anxiety through splitting and projection.

### **Case Management**

All components of residential treatment must be effectively coordinated with regard to each specific child. The program should be carefully tailored to meet the needs of each specific child. Individualized treatment goals and objectives should be written with input from the therapist, teacher, child care worker, psychiatrist, psychologist, child, parent, referral source, and accountable funding source. Clinical social workers are specifically trained in the coordination of child and family services, as well as in individual psychodynamics and group dynamics. Clinical social workers increasingly play a case management role in residential treatment facilities, in addition to providing specific modes of therapy. In most RTCs, the clinician assigned to the child is also designated the case manager and is responsible for coordinating and integrating the work of the school, child care department, and clinical department, as well as that of the parent or guardian and accountable funding source. The case manager must have the responsibility and authority to ensure coordination and consistency of programming for designated children. In most RTCs, the clinician must also, of necessity, play a broader role in overall program management and the coordination of treatment teams. A particularly challenging problem must be faced by the clinician who serves as the case manager and therapist for the same child at the same time. The child and adolescent psychiatrist can serve a useful role as consultant to the case manager.

### **ROLE OF THE CHILD AND ADOLESCENT PSYCHIATRIST**

The presence of a fully qualified child and adolescent psychiatrist is essential for the staff of any RTC serving children and adolescents and their families. The exact administrative position may vary from that of chief administrator to medical director to psychiatric consultant and must be clearly understood by administrator and psychiatrist. Whatever the position and title, the psychiatrist should be asked to provide certain clinical, consultative, and educational services.

The need for the psychiatrist in RTCs has continued to increase in recent years because of changes that have occurred in the mental health delivery system and the resultant changes in the needs of the children and adolescents who are being admitted and treated. For example, relatively long-term inpatient psychiatric hospitalization has nearly disappeared in the United States. Many of the young patients who must be discharged under current criteria are not ready or able to be returned to their families even with the provision of the most extensive and sophisticated types of "wrap-around" services.

Thus, RTCs are receiving young patients with more serious, and less well-stabilized, psychiatric illnesses than in the past. To meet the challenge of this situation, the psychiatrist must be available to have significant input and responsibility in the intake process, in the communication with the referral source, in the initial evaluation and treatment planning, and, in particular, in the increasingly complex psychopharmacologic regimens the referring hospital may have initiated for many of the incoming young people.

As a corollary to the foregoing changes, there is an increasing need to be able to use referral to the short-term inpatient psychiatric hospital for emergency situations affecting the patient's safety or for severe regressive episodes that the RTC is not able to handle. Here again, the psychiatrist's role is crucial in helping the staff of the RTC make decisions in a given case, and in communication with the receiving hospital during the referral stage, after the patient has been admitted and during the planning for the return to the RTC.

The well-functioning RTC calls for a carefully orchestrated and multifaceted effort by all staff members, who come from many disciplines and from all departments (including "nonclinical" areas such as housekeeping, dietary, maintenance, and business office) whose goal is to help the individual child and his or her family. The psychiatrist must become integrated into the organization so to be able to help provide the unique understanding of the complexities of the individual child and to help in the ongoing and often changing need for balance in the many approaches concurrently being used to help that child.

The specific duties and functions of the psychiatrist should be carefully spelled out, understood, and clarified when necessary. Among these, it is recommended that the following should be included:

1. *Direct case consultation with the clinicians:* The psychiatrist consults once a week for 30 to 45 minutes individually with each clinician, to discuss the issues of that person's caseload as indicated. Both client-centered and consultee-centered case consultation should be offered ( [Caplan, 1970](#)). Especially important is a discussion of any psychopharmacologic treatment of a given child for whom the psychiatrist and the nonpsychiatric clinician may be collaborating.
2. *Participation in case conferences with team members:* At least 1 to 2 hours per week of the psychiatrist's time should be available as needed for participation in conferences dealing with any and all issues regarding a given child, ranging from crises to milieu dilemmas to longer-range treatment problems.
3. *Direct psychiatric evaluation of children:* Whenever needed, the psychiatrist will be available to evaluate a given child for various purposes, including intake evaluations, evaluations on admission, evaluations for psychopharmacologic treatment, evaluations for psychiatric emergencies, and direct consultative evaluations to explore clinical issues as requested by staff clinicians.
4. *Continuous case conference with clinicians:* A weekly 1-hour conference is suggested, led by the psychiatrist, at which one of the clinicians presents, for a series of weeks, an informative treatment process. Should there be clinical trainees in the agency, their supervisors may want them to be present at such a conference.
5. *In-service educational conferences:* The psychiatrist provides talks and seminars and participates in panel presentations on topics of interest to all staff of the agency.
6. *Informal visits to classrooms, living units, and other residential activities.* As the consultant becomes more familiar to staff and clients, communication is enhanced, and the consultant's contributions in more formal meetings are enhanced.
7. *Participation in agency committees and working groups:* On an as-needed basis, the psychiatrist should be available to make contributions to agency groups.
8. *Administrative consultation.* In many agencies, the administrators and the psychiatrist have developed a relationship such that the psychiatrist may be asked to provide consultation on the development of new programs, revision of existing programs, or other related problems ( [Caplan, 1970](#)).
9. *Direct monitoring of patients on psychotropic medications:* The psychiatrist not only must take responsibility for prescribing the medications, but also must follow-up the patients directly on a regular basis. A useful way to do this may be to conduct a weekly "medication clinic" wherein the psychiatrist spends approximately half an hour evaluating each child, reviewing the chart, and writing a progress note. In an agency of 40 residents, 20 of whom are taking medication, for example, the "medication clinic" would last for about 2½ hours each week in order that each patient be seen once a month.
10. *Medication rounds with agency nursing staff:* Once a week, a systematic review of charts should be done with appropriate documentation of findings and recommendations. The psychiatrist and nurse conduct the review, but input by other staff members is welcome.

In most RTCs, the psychiatrist does not have complete responsibility for the treatment of a given child or adolescent, but must in some aspects act as a consultant, in some as collaborator, and in the matter of medication, as the responsible physician. It is important that the psychiatrist and agency staff members understand and remain aware of these interrelationships at all times.

### **ADMINISTRATION OF MEDICATION**

Medication is most helpful when there is a clear indication or target symptom for a particular drug; it may help the child to engage in a therapeutic relationship and may facilitate attention and learning. Sometimes a drug is a useful additional measure during the stress of the initial period of residential treatment or later at times of crisis. Many children with thought disorders or hallucinatory experiences can be maintained in the RTC only with appropriate antipsychotic medications. As noted earlier, many children admitted are already receiving medications.

Inasmuch as the total staff, the child, and the family are all involved, it is important to develop a well-understood medication procedure. The initial request for medication may arise from the child, a parent, or any staff member and is then processed by the child's therapist. A full discussion by the entire staff is necessary to clarify the goals for medication use and its anticipated effects on the child. Impulsive proposals for the use of medication are sometimes made by staff members who feel frustrated and desperate in their efforts to manage especially difficult behavior. Countertransference problems are sometimes an unrecognized motivation.

The child should have as thorough an understanding as possible of the medication's effect and the reasons for taking it. Children may have special fears about taking

psychotropic medication. Often, these fears and unrealistic expectations are elaborations of statements or attitudes of peers, staff members, parents, or other family members.

It is important to talk with the child's parents or guardians about the proposal for medication. In addition to obtaining informed consent, the staff members can correct misunderstandings and can encourage the parents to develop a reasonable, supportive attitude toward the child's use of medication. To achieve this end, the following procedure is useful:

1. The therapist, in consultation with the staff, the child, and the parents, defines the target symptoms, the expected goals, and the anticipated effects of the medication. The therapist explains the procedures to the parents.
2. A careful history is taken of significant previous illnesses or allergies in the child or family members and of any history of previous drug experience.
3. The child's physical state is reviewed.
4. A baseline mental status examination is performed, and various behavior ratings may be made.
5. Informed consent is obtained in writing from the parents or legal guardians.
6. All this information is made available to the entire staff for discussion. For this purpose, a brief synopsis of the drugs commonly used should be available to the staff, and the therapist should prepare a summary that follows a standard outline for all to read. A key decision-making conference should then be held.
7. After the decision is made, appropriate laboratory tests are performed, and the medication is prescribed and administered.

Since the early 1990s, the numbers of children admitted to RTCs with severe psychiatric disorders and those taking psychotropic medications have increased steadily. It is not uncommon now that 90% of such children in residential treatment are on such medications, and in some settings two thirds of such children will have received two or more psychotropic medications simultaneously ([Connor et al, 1997](#)).

Appropriate medical records and written procedures and protocols for psychopharmacologic therapy must be in place for these children. The procedures and protocols include the following:

1. *Medical records:* The child's medical records relevant to psychotropic medications should include doctor's orders, prescriptions, laboratory reports, reports from other hospitals or facilities, progress notes, documentation of medication reviews with the nursing staff, copies of informed consent, and authorizations by parents or guardians.
2. *Written protocols for psychopharmacotherapy:* These should include procedures for initiating therapy (including the issues as described earlier) and for maintaining and discontinuing therapy. Staff are sometimes reluctant to discontinue medication because they fear a return of difficult behavior in the child. The reluctance may take the form of rationalizations such as upcoming vacations, schedule changes, room changes, staff changes, parental visits, or other possible stresses. The clinical reasons for discontinuing medication should therefore be carefully documented.
3. *Protocols for laboratory and other studies:* For a given medication, or for a given category of medications, the specific schedules of studies including vital signs, laboratory studies, abnormal involuntary movement scale testing, rating scales, checklists of side effects, electrocardiograms, and other tests should be documented for the premedication phase, for the times of changes of dosage, and for the ongoing maintenance phase. Behavior changes in relation to itemized target symptoms and initial behavior ratings should be regularly documented.
4. *Procedures for discharging clients on medications:* Before discharge, it is important to have established which outside practitioner will take responsibility for continuing the treatment and to document that the parent or guardian accepts the responsibility to implement it.

## COMMUNICATION

To maintain the necessary communication in the residential staff, the staff members must meet as a total group, without an agenda, at least once a week. These meetings allow feelings to come to light that may otherwise remain hidden and silently ferment. Role conflicts, countertransference problems, treatment blind spots, and residential center policies with regard to such issues as limit setting, outside visits, treatment approaches, and work with such agencies as an outside school and a welfare agency are some of the subjects that are discussed. Greater staff cohesion, collaboration, and commitment occur when all staff members are involved in every aspect of the child's treatment. Contributions from social system theory have enabled RTC staff members to view their interaction as part of a complex social system, constituting a further aid to communication.

To monitor the course of treatment, staff members must also attend regular comprehensive case review conferences, at which reports from group living, school, and therapy staff members are presented and discussed, along with additional data derived from neurologic examinations and psychological tests. Diagnoses and treatment goals often need to be revised as the child becomes better known to the staff. The revision may go in either direction; that is, a psychotic process may gradually be revealed, or a child may show strong restitutive capacities once he or she is in a stable environment. [Colligan et al. \(1981\)](#) developed an organizational grid to provide a visual representation of the factors involved in residential treatment. The grid evaluates diagnostic information from four developmental dimensions: physiological, emotional, sociobehavioral, and cognitive—academic. The effects of these dimensions on family, school, and group living can then be monitored.

## COURSE OF TREATMENT

Children who enter a residential center may experience anxiety and feelings of loss, as well as some relief. They may temporarily deal with this anxiety or relief by exhibiting good behavior and a strong apparent wish to please. This so-called honeymoon period, which may last from a few days to a few months, soon gives way to the reemergence of the children's characteristic behavior patterns, albeit in modified form. The children seem to attempt to reestablish many of the characteristics of their relationships with adults and peers. The slow and difficult task of working through unconscious attitudes and fantasies that perpetuate their now maladaptive behavior constitutes a major part of the total therapeutic effort, which may last for 2 or more years. There is no single course of treatment because the variables are many, including the strengths and weaknesses of the particular child, the strengths and weaknesses of the parents, the skills of the staff, and the degree to which a suitable discharge plan can be put into effect.

## TERMINATION

As termination and discharge approach, earlier feelings of loss are often evoked again, and temporary regression may occur, with heightened acting-out behavior, sometimes of an aggressive kind. Intense anxiety about abandonment may also reappear. The child with a diagnosis of borderline personality disorder especially needs a great deal of support at this time. It is necessary to arrange preplacement visits to avoid precipitous changes in the child's life.

## DISCHARGE PLANS AND FOLLOW-UP CARE

Children, parents, and staff members all anticipate with ambivalence the time of leaving. Expectations—some realistic, others unrealistic—tinged with apprehension and anxiety about real or imagined problems abound. In a sense, preparation for departure begins at admission. Actual preparation for leaving should be a planned process, with the child's best interests being of paramount importance. It is important that the children at all times participate in planning their future lives.

Cure, whatever that may mean, is rarely an attainable goal for children in residential treatment. Improved object relations and social adaptation, ability to function in an outside school and later at work, and the working through of certain kinds of trauma are more realistic goals for the child. Similar goals obtain for the parents. The degree to which these goals are achieved is sometimes difficult to determine. The outcomes that may occur range from no change at all to improvement in the whole family.

The range of disposition plans varies according to the outcome. Return to the family with or without further outpatient treatment, day treatment, placement in a group or foster home, boarding school, further residential treatment, and custodial care are some common options. Many RTCs have developed some of these options as part of their own programs, so a child may be admitted, say, into a day treatment program or into a day treatment and on-grounds school program, with full residential treatment reserved as a possible option, or vice versa.

Intensive residential treatment should be seen as a phase of treatment, rather than as the one definitive treatment. Both the children and their families are usually vulnerable. Some may always show a tendency to paranoid behavior when under stress. The residential treatment home may well need to continue to represent the core of stability for these children as they progress through adolescence and young adulthood.

## RESULTS

Many attempts at follow-up studies have been made, but unfortunately, numerous serious methodologic problems plague research in this area. Most studies of outcome are subjective and are difficult to evaluate. Criteria for diagnosis, treatment, and outcome are not sufficiently well defined for research purposes, and the intervening variables make controlled studies virtually impossible. Clinical impressions suggest that good residential treatment programs do provide a beneficial experience for the child during the period of residential treatment and may lead to more satisfactory development and functioning in the child than would otherwise have occurred had the child not been admitted.

[Taylor and Alpert \(1973\)](#) find, however, that the degree of change that children achieved in residential treatment is not significantly related to postdischarge adaptation. [Lewis et al. \(1980\)](#) similarly find that most children who receive about 2 years of residential treatment in one particular setting fare poorly at follow-up according to the objective measures they use to assess outcome. Thus, improvement made in residential treatment does not determine the degree of adjustment experienced on return to the home and community. Instead, Lewis et al. find that ecologic factors and postdischarge factors are important in determining outcome. Successfully adjusted children show a greater increase in family and community support during enrollment and also receive more help from community agencies and special school programs.

Lewis et al. also note that, during the course of residential treatment, crucial attachments are formed between the children and the staff members, and these investigators recommend that these attachments be protected. Thus, the same residential facility staff should be prepared in many instances to continue their commitment and attachment to the children and their families through and beyond adolescence. In effect, the RTC in many instances should serve as a secure base until adulthood. Without that security, the hard-won gains achieved during residential treatment for the vulnerable child and adolescent are essentially undone.

[Wenning \(1988\)](#) reports a high recidivism rate and a high rate of affective conditions in a follow-up study of children diagnosed as borderline while in residential treatment. An outcome study using Child Behavior Checklists of 36 children and adolescents at admission, specific time points, and at discharge found that children who demonstrated oppositional defiant behavior and symptoms of a conduct disorder appeared to do most poorly in the residential treatment setting ( [Joshi and Rosenberg, 1997](#)).

Another study ([Leon et al., 2000](#)) notes that many RTCs are currently struggling to meet the intensive treatment needs of those children and adolescents in residence who have serious psychiatric disorders. One consequence of this struggle to provide the needed treatment is the increased rate at which these RTCs are now inappropriately referring for hospitalization children and adolescents who do not meet usual criteria for hospitalization. Further, RTCs that are struggling in this way are "failing to provide the same levels of supervision as programs whose referrals were largely high risk" ( [Leon et al., 2000](#)). This raises the question of the level of training staff receive in intensive crisis management and the need for state departments of children and families to provide more resources to these struggling RTCs.

## FUTURE TRENDS

The place of residential treatment in the continuum of childrens' services and the vitality of residential treatment programs face serious social, political, and economic challenges in the years ahead. The dearth of follow-up studies demonstrating the efficacy of residential treatment continues to plague its advocates in the presence of increased demands for results and cost effectiveness. Many state and federal policymakers emphasize family preservation or alternative family placement for children currently using residential treatment. Unfortunately, residential treatment is sometimes only viewed as a treatment of last resort, especially when child and family psychopathology has increased to a dangerous level just short of requiring hospitalization of the child. A preferred concept is to view residential treatment within the context of a connected broad range of mental health services.

Staff recruitment and staff retention are serious problems for many residential treatment organizations because budgetary constraints limit resources in many areas for childrens' services. The statistical trend toward an aging society not only increases the demand for resources for the elderly but also potentially pits the elderly against the very young in the increasing competition for mental health, medical, and social services. The resources needed to combat the epidemic of acquired immunodeficiency syndrome and the rapid rise of drug abuse and drug-related violence increase the strain on all social service resources. Emotionally disturbed children are not a voting constituency, and historically their families have not been an effective political force in advocating for their specific needs. Residential treatment organizations often act as advocates for disenfranchised children but are often discredited as being biased or self-serving in their advocacy.

[Davis et al. \(1989\)](#) report that traditional long-term residential treatment facilities are adapting their programs and treatment foci in an attempt to meet the changing needs of children and adolescents. Children are presenting with more intensive treatment needs, whereas family and community resources have diminished for a large population of children. Consumer demands for results and accountability have increased, and agencies must offer a larger range of specialized clinical services to children who are in residential treatment. Residential treatment facilities have responded by developing subacute intensive treatment services within existing facilities. These include 90-day intensive assessment units, 30- to 90-day alcohol and drug treatment units, physical and sexual abuse and trauma response teams, specialized foster care and adoption services, aftercare and independent living programs, outreach family support services, and family preservation services such as Home Builders.

In response to consumer demand for results and accountability, many residential treatment facilities have also modified their programs to be in compliance with the standards of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). The JCAHO provides comprehensive standards for residential treatment in the areas of administrative and clinical management, patient management, special treatment services, patient services, and environmental management. JCAHO standards emphasize professional staff organization and development, program evaluation, patient safety, patient rights, and all aspects of quality assurance ( [Joint Commission on Accreditation of Healthcare Organizations, 1989](#)).

The Civilian Health and Medical Plan for the Uniformed Services (CHAMPUS) and the American Psychiatric Association have also played a major role in developing comprehensive quality assurance standards and in implementing a peer review system for residential treatment. As of July 1989, 108 JCAHO-approved residential facilities also met CHAMPUS quality assurance requirements and were being monitored through a peer review process.

## NATURE AND SCOPE

The emergency nature of a child or adolescent psychiatric problem is defined both by the severity and urgency of the potential threat to the child's and family's safety and well-being and by the community and clinical resources the family is able to access and use to address it. Thus, some situations, such as intense aggressive or homicidal threats or outbursts, acute psychotic or anxiety states, serious suicide attempts, ingestions or intoxications, or acute toxic metabolic states, usually require immediate psychiatric attention in a setting that can muster the full range of acute medical and psychiatric diagnostic and therapeutic interventions. Conversely, the presentation of many other more chronic or less urgent cases to the pediatric psychiatry emergency service reflects the absence of adequate mental health resources in the community or the family's relative inability to access or use clinical and social resources that could have prevented the crisis or permitted its management in a less acute outpatient setting.

Although it is usually clear that these latter cases require prompt intervention, the perception that the case is an emergency and should be seen in a tertiary emergency service is more relative. For example, under what circumstances does an unhappy, neglected child's suicidal ruminations or threats indicate an imminent risk and need for crisis intervention? When does normative adolescent oppositionality or risk taking evolve to illicit substance use, unprotected sexual activity, and other antisocial and high-risk behaviors, and at what point do these become so severe that emergency psychiatric intervention becomes urgently imperative?

The judgment that a given child's thoughts, feelings, or actions constitute a psychiatric emergency reflects some adult's perception that the child's condition is serious, urgent, or unmanageable in the current environment. As a corollary, a multiplicity of adults or agencies may potentially initiate the referral to a child psychiatric emergency service. These include parents, extended family members, teachers, police, mental health clinicians in the community, and child welfare workers (Halamandaris and Anderson, 1999). In addition, many facilities such as youth shelters, residential treatment centers, and juvenile detention use the hospital-based child psychiatric emergency service in the absence of adequate on-site emergency psychiatric capacities.

Psychiatric emergencies were once considered uncommon in childhood. In recent years, however, the number of child and adolescent emergency patients has been on the rise. For example, between October 1, 1963 and July 31, 1964, the number of psychiatric consultations in the Yale–New Haven Hospital emergency department (ED) in New Haven, Connecticut, for children less than 15 years of age, represented only 0.61% of the pediatric ED population ( [Schowalter and Solnit, 1966](#)). In contrast, the annual number of child psychiatry-related visits to the Yale–New Haven Hospital pediatric ED was 2.49% of all pediatric visits in 1995 and 3.94% of those in 1999. Thus, by 1999, as a percentage of all ED cases, the proportion of child psychiatric emergency cases increased almost 60% over 1995 and over 500% compared with 1963. The increase in absolute numbers was even greater, given the increased number of pediatric ED visits for all complaints. The higher number of cases in 1999 versus 1995 resulted, in part, from an increase in referrals for depression and an upward trend in aggression-related complaints ( [Santucci et al., 2000](#)). The magnitude of this clinical burden is apparent if this referral rate is extrapolated to the more than 31 million annual child and adolescent ED visits occurring nationally ( [American Academy of Pediatrics, 2001](#)).

The extent and causes of these dramatic changes are unclear, given the paucity of national data on child psychiatric ED use. However, it may be speculated that increases in the number of children living in poverty and single-parent families may be taking their toll in what many perceive as rising rates and severity of childhood psychopathology ( [Achenbach and Howell, 1993](#)).

Dwindling funds and efforts at cost containment in mental health and community-based social service systems in many states have transformed hospital-based emergency services into a major provider of mental health services. Managed-care–driven strictures have further eroded the availability of mental health resources in the community and have dramatically shortened lengths of hospital stay, thus denying many children and families adequate outpatient treatment in the community and effective inpatient treatment when that becomes necessary. This is apparent in the rising number of repeat visits to child psychiatry emergency services and the number of children receiving repeated “revolving door” short-term hospitalizations. Indeed, in many communities, the psychiatric ED has become the *de facto* mental health system of care.

Availability of community services aside, epidemiologic data help to illuminate the high rates of ED use. For example, although the incidence of completed adolescent suicides has leveled off for the United States as a whole over the past few years after a multidecade rise, the rates of serious suicidal ideation and clinically significant suicide attempts remain strikingly high in the general adolescent population (Centers for Disease Control and Prevention, 2000). In addition, rates of completed, and presumably attempted, suicide continue to rise in certain segments of the youth population, such as children younger than 10 years of age and African–American adolescent boys ( [Centers for Disease Control and Prevention, 1995](#); [Centers for Disease Control and Prevention, 1998](#)).

The increasing rates of child psychiatric ED use and the shifting ecology of these cases raise largely understudied and important practical and research questions regarding how child psychiatric services are actually used, how well they address the emotional and behavioral problems of patients and their families, and how they may be more efficiently organized in the context of comprehensive systems of care.

With this background in mind, this chapter discusses the complexities of child and adolescent psychiatric emergencies and hospital-based assessment and examines the problems confronting ED-based child and adolescent psychiatrists. We also discuss approaches to assessment, treatment, and disposition planning that are unique to this population, with a special focus on the uncooperative patient. For the broader topics of the psychiatric evaluation of the child and the assessment of the suicidal child, see [Chapter 41 \(American Academy of Child and Adolescent Psychiatry, 1995; American Academy of Child and Adolescent Psychiatry, 2001; King et al., 2000\)](#). For emergency psychiatric evaluation in the inpatient pediatric setting see [King and Lewis, 1994](#).

# HOSPITAL-BASED CHILD PSYCHIATRIC EMERGENCY EVALUATION

## Adaptive Context of Child Psychiatric Emergencies

Child psychiatric emergencies presenting in the hospital setting are most often characterized by intense symptoms, perceived danger, and a sense of urgency complicated by the perception of imminent catastrophic outcome and frequent conflict among the parties involved. Despite this acuity, child psychiatric emergencies are usually the outcome of complex ongoing processes rather than sudden, discrete events. Occasionally, a previously well-functioning child with some underlying vulnerabilities may abruptly decompensate and may display psychiatric symptoms in the presence of some critical or traumatic event or organic process. More often, however, the acute emotional or behavioral symptoms that bring the youngster to the attention of the emergency service have been preceded by a longer history of emotional or behavioral difficulties. Thus, a key element of the emergency child psychiatric assessment is to answer the questions: "Who is concerned about the child?" and "Why now?"

A child's functioning and psychological well-being are highly dependent on the family, school, and community setting in which he or she lives and studies. Anything that adversely affects this system has the potential to precipitate a crisis. A child psychiatric emergency usually represents some perturbation or pathology in one or several of the elements in this delicately balanced ecosystem. Either an efflorescence of the child's psychopathology has overwhelmed the caretaking system or the caretaking system has, in some fashion, become less sufficient or less adequate. From this perspective, many child psychiatric emergencies can be conceptualized as a mismatch between needs and resources (Allen, 1999). The corresponding goal of child psychiatric emergency services evaluation is then to clarify the nature and the cause of the imbalance that has arisen and to identify the resources needed (e.g., safe environment, psychoeducation, psychopharmacotherapy, outpatient therapist, family support services) to restore a stable equilibrium. Systematically clarifying the details of the precipitants to the crisis is thus paramount in determining the needed interventions and disposition.

## Goals and Aims of the Hospital-Based Child Psychiatric Emergency Assessment

The primary goals of the child psychiatric emergency evaluation are, as expeditiously as possible

1. To obtain each informant's account of the reason for referral.
2. To develop a working alliance, if possible, with the patient and other involved parties around the assessment and disposition planning.
3. To obtain a focused developmental history of the child's current difficulties and prior functioning against the backdrop of the child's family, current living situation, and any involved clinicians or agencies with particular attention to the possible precipitants of the current crisis.
4. To perform a mental status examination, with particular attention to evidence of suicidal or homicidal ideation, hallucinations, delusions, or thought disorder, evidence of confusion, disorientation, or other signs of delirium, and intense anxiety.
5. To develop a differential diagnosis, including a formulation of what changing factors have precipitated the need for emergency evaluation at the present time.
6. To arrive at a judgment regarding the degree of probable risk to the patient's safety or that of others.
7. To identify interventions that will help to contain and ameliorate the patient's difficulties.
8. To plan and implement a disposition.
9. To collaborate effectively with other clinicians and care providers involved in the case, both within and beyond the hospital setting.

## General Considerations

The hospital ED is designed to contain and resolve urgent or life-threatening situations. The "triage model"—rapid determination of imminent dangerousness, containment, and referral—typifies the process of most hospital-based psychiatric emergency consultation and care. Some beleaguered psychiatric emergency services confine themselves to addressing only two questions: (a) is the child a danger to himself or others? (b) does the child need to be hospitalized or can he or she be discharged back home? Although these dispositional questions must remain at the forefront of the busy emergency clinician's mind, circumscribing the evaluation too narrowly to these areas both precludes an accurate understanding of the clinical situation and renders the ED visit of little ongoing value to the child, family, or treatment effort. Given that most crises referrals arise out of multiple factors in the child's life, it is important that, no matter how expeditiously the evaluation is conducted, it provides the child, family, and clinicians with some useful perspective on how the crisis came about and how it fits into the overall trajectory of the child's life and clinical care.

The assessment and management of child psychiatric emergencies differ from the routine office evaluation in several important ways. The severity, dangerousness, or urgency of the symptoms usually requires rapid clinical decision-making and treatment implementation. Furthermore, the emergency assessment must often proceed under unpropitious circumstances constrained by time pressures, in the relative absence of trained support personnel or optimal physical arrangements, with an unfamiliarity with the patient and family, with the unavailability of key informants, and with the lack of timely, appropriate alternatives for disposition.

Yet another constraint on emergency evaluations is the inconvenient hours at which they often occur—late at night or on weekends, when important informants, such as primary clinicians, teachers, or social welfare agency workers, may be unavailable. The already difficult task of arranging an appropriate disposition at such hours is further complicated by the frequent unavailability of insurance reviewers needed for precertification, psychiatric hospital admissions staff members who can provide prompt information regarding bed availability, or outpatient clinicians who can undertake the responsibility of seeing the patient promptly for follow-up. The availability of sufficient social work, psychiatric nursing, or other professional staff members to assist in these information-gathering and coordinating tasks is essential to prevent burnout of clinicians faced with large volumes of child emergency evaluations.

Time constraints and the urgency of the situation do, of course, require that the clinician be active in eliciting the most relevant data in a time-efficient manner. Right from the onset of the interview process, the experienced emergency clinician begins to prioritize symptoms and to formulate and test tentative etiologic and diagnostic hypotheses that guide further questions. At the same time, the clinician also begins to ponder what interventions and dispositions these diagnostic hypotheses imply. Unlike less urgent settings, the emphasis is on clarifying the child's current symptoms and functioning, the factors in the child's living situation that have served to stabilize or exacerbate difficulties, and the resources and competencies available to the patient and the family.

## Physical Setting

It is important to find a quiet evaluation area, where the clinician, adults, and child will not be frequently distracted by the sights and sounds of physically ill and upset children and their families. The area needs to be free enough of dangerous or delicate medical equipment or furnishings so the clinician need not be preoccupied with keeping the room and the patient safe. The spot needs to be secluded enough that the belligerent or uncooperative psychiatric patient will not disturb other families in the ED, yet near enough to other staff that reinforcements can be called on if needed for safety or calming or to prevent elopement.

## Informants

The clinician's first task is to identify why this particular child has been brought to the ED at this particular time. The impetus for child psychiatric emergency referrals, with few exceptions, comes from adults in the child's life, rather than from the child. Obtaining a full and accurate diagnostic picture for any child psychiatric assessment requires gathering information from diverse sources, including the family, school staff, clinicians, and the child himself. In the emergency situation, however, the initial or primary informant may be an adult other than the primary caretaker, for example, police or corrections officers, school personnel, or representatives of various social service agencies. The wide array of potential referents and perspectives complicates the task of the evaluator, who must efficiently interview multiple informants and, like a detective, rapidly consolidate and reconcile sparse, often conflicting data.

From a practical standpoint, data are collected as they become available. At a minimum, the emergency assessment entails direct interviews with the child and all adults who accompany the child to the hospital setting, as well as any caretakers, clinicians, or caseworkers who are accessible by telephone. On a practical level, if the child is brought in by nonparental parties (e.g., friends, police, correctional officers, or child welfare workers) who may not want to remain in the ED for the evaluation, it is essential to speak with them directly and to obtain immediate contact information for those persons with direct knowledge of the precipitating crises and the child's recent circumstances and responsibility for the child's care and disposition. Even when the child is not accompanied by a custodial parent or legal guardian, most states give the emergency clinicians the latitude to initiate emergency treatment of a child, including contacting of collateral informants, without parental consent. In such cases, it is always clinically desirable to contact and to involve the parents as soon as possible. Many states also permit adolescents to

seek mental health without a parent's involvement. These patients should also be encouraged to involve parents and other adult supports.

The presenting complaint and reasons for the referral are often described very differently, depending on the informant. These discrepancies, referred to in the research literature as *informant variance*, arise for a variety of reasons ([American Academy of Child and Adolescent Psychiatry, 1995](#)). Although these discrepancies complicate the diagnostician's task, when markedly differing accounts or divergences of perspective do occur, they provide potentially important clues to the nature of the child's crisis. At the very least, they point to troublesome lacks of continuity in the child's holding environment and a lack of shared consensus between the child and important adults.

Differences may stem from the different contexts in which the child is observed, the standard of judgment employed, and variations in the demands or stressors impinging on the child in each setting. This is particularly the case when children's symptoms are situation specific (e.g., occurring only at school, only at home, or only at one parent's house, but not the other's).

Informants may differ in their access to information concerning the child's feelings and behavior. Parents may be quick to report a behavior of the child that they find disturbing or annoying, but they may fail to recognize how discord within the family system (e.g., domestic violence, separation, divorce) may directly precipitate crisis symptoms within the child. The child, in contrast, even if aware of and able to describe the problematic behavior verbally, may refrain from doing so out of defensiveness, shame, or fear of reproach. The interviewer must also be aware that vagueness and minimization of problems can sometimes indicate an attempt to maintain some secret within the family system, such as a parental mental illness, illegal activity, child or parental substance abuse, domestic violence, or physical or sexual abuse. In these cases, the evaluation can be extremely difficult, because the events surrounding the crisis may never be completely clarified.

### **Child Interview**

In traditional office-based child psychiatric assessment, several hours and more than one interview with the child are usually desirable to place the child at ease with the interviewer and to obtain a full picture of the child. In contrast, the emergency assessment must be completed within the confines of a single interview. The emergency child interview and mental status examination must also reckon with the characteristic lability of children and their propensity to fall back to more immature or oppositional ways of coping, especially when they are confronted with the anxiety and distress associated with a hospital ED setting. Although it may not accurately reveal the child's optimal or characteristic level of functioning, this "snapshot" of the child in the ED often provides a valid picture of the child's vulnerability to regress under stress and how such regression may have led to the emergency referral.

Although every effort must be made to place the child at ease and to obtain his or her cooperation in understanding what has brought about the crisis, this is often difficult. The high levels of expressed emotion in the events leading up to ED referrals and the coercive processes required to bring the child to the ED often stimulate the child's oppositionality. As a result, the child in the ED is often sullen, mute, withdrawn, or antagonistic.

To the child who is aggrieved or sullenly refusing to talk, the clinician can validly invoke what has been termed the "constructive use of ignorance" by observing that, because they have never met before, the clinician really does not know what has led up to the ED visit and would genuinely like to hear the child's view of what has been happening.

### **Child Mental Status Examination**

The mental status examination is of particular importance in the emergency evaluation ([American Academy of Child and Adolescent Psychiatry, 1995](#)). In trying to understand the nature of the crisis and the interventions needed, the clinician will be especially attentive to evidence of psychosis, delirium, or other organic process, intoxication, dissociation, or extreme anxiety, depression, or elation. The presence of any of these factors is likely to render the patient more labile and vulnerable and points to the need for more intensive interventions and diagnostic studies. Hence, the clinician must be alert to and explicitly note the presence of the following:

- Disorientation, confusion, and fluctuating levels of consciousness
- Incoherence of thought or speech
- Evidence of hallucinations or delusions
- Impaired memory
- Slurred speech, ataxia, or apraxia

Assessment of safety additionally requires explicit attention to the following:

- The presence of suicidal or homicidal ideation
- Aggressive threats or ideation
- Impulsivity
- Proneness to regression or agitation during the interview
- Poor judgment and insight and limited intelligence
- Mood lability

### **Family Mental Status**

The child and parents' attitudes toward the examiner and toward each other during the interview provide valuable clues to whether the child and family can be effectively and safely worked with in an outpatient setting if the child is discharged from the ED. Hence the examiner will note carefully how the child and family interact, how the child relates to the examiner, and to what extent the child can own and reflect on the behaviors that have led to the ED visit.

To what extent can the child and parents, with the examiner's help, at least partially agree about the problems that must be addressed and achieve a working consensus about possible realistic (nonmagical) ways of working on them? In the absence of such a consensus, outpatient follow-up is not likely to be feasible or successful, as for example, when the child persists in denying any problem, the child and parent remain locked in mutual recrimination. If the referral for emergency assessment comes from adults or agencies other than the parents (e.g., neighbors, police responding to a family disturbance, or school personnel concerned about a student's behavior), both child and family may portray the "problem" as the result of the school or neighbors' unreasonable expectations or the derelictions of others. This posture of defensive externalization also bodes ill for enlisting the child and family's cooperation with any treatment recommendations. Conversely, families and children who, with admitted concern, recognize that certain problematic behavior patterns recur in their family may be more likely to have the commitment to make the transition from crisis intervention to ongoing outpatient treatment.

## **UNCOOPERATIVE OR AGGRESSIVE PATIENT**

### **Special Considerations**

We now consider special challenges posed by the uncooperative or aggressive patient. Oppositional and aggressive outbursts at school or at home are frequent precipitants of ED visits. Many such youngsters are brought to the ED by either police or emergency medical services, sometimes in physical restraints. In the ED, such children and adolescents often continue to be agitated, belligerent, and impulsive. Profanity, yelling, and verbal threats are unnerving and upsetting to the clinician, ED staff, and other families and children in the ED.

Aggressive or violently oppositional behavior is perhaps the most difficult management challenge facing the child psychiatry emergency clinician. The clinician must approach the potentially violent patient calmly but cautiously, with the twin goals of performing an assessment and simultaneously bolstering the child or adolescent's capacity to remain in behavioral control.

### **Establishing the Differential Diagnosis**

The assessment of the aggressive, agitated patient begins with an evaluation of the possible causes. Aggressive behavior can occur in the context of a wide spectrum of psychiatric conditions. Thus, establishing a differential diagnosis is important in choosing short-term interventions and developing a disposition and longer-term

treatment plans.

The cause of oppositional, aggressive, and ultimately violent behavior in children and adolescents is usually multidetermined. It evolves from a transaction between the child's temperament and immediate environment, and both social and psychological factors and neurobiological processes influence it.

Poor impulse control is an important risk factor for aggressive outbursts. Impulsivity is a symptom common to several mental disorders of childhood and adolescence, most notably attention deficit disorders, hypomania, and conduct disorder. Children with cognitive deficits and developmental delays, such as mental retardation, autism, or other pervasive developmental disabilities, may have a limited repertoire of social coping skills and hence may react to stress and frustrations with aggressive behaviors.

Children reared in poorly structured, chaotic, or violence-prone families and children who have been chronically or acutely traumatized may exhibit maladaptive, aggressive behaviors in response to stress or confrontation. Especially in adolescents, substance use is a common precipitant of disruptive, aggressive behavior by virtue of impairing judgment, increasing irritability, disinhibiting behavior, and exposing the youngster to potentially threatening situations. Underlying psychotic states, especially those characterized by mania, paranoia, or command auditory hallucinations, are also associated with agitated, aggressive behaviors.

It is also important to be alert for various organic conditions that can result in irritable, aggressive, or disorganized behavior. Toxic metabolic states, whether from ingestions, medication side effects, encephalopathies, or other medical illness, can produce delirium with disorganized and aggressive behavior. Neurologic conditions associated with irritability and aggressive behavioral outbursts include postconcussive states, frontal lobe lesions, and temporal lobe epilepsy. Hence, a careful medical history, including medications and substance use, is important ( [King and Lewis, 1994](#)). Finally, the overstimulating, chaotic, and confining nature of the ED itself can exacerbate anxiety, irritability, and aggressive impulses for many patients and families.

### Specific Aspects of the Assessment

Data crucial for rendering an accurate portrayal of the context include a history of recent and past aggressive behavior, as well as psychiatric, family, and social information. A detailed history of the presenting violent episode is mandatory. This includes preceding and precipitating events, the details of the episode itself, and its aftermath. It is important to elicit the patient's own perspectives regarding the episode and to compare these with the perspectives of the other involved or witnessing parties. The social setting and behavior of the victim and the response of others in the environment should be clarified. The precipitant of such challenges is often a clash between the child and an adult authority figure over limit setting. The role of narcissistic injury, humiliation, intense anxiety, or challenges to the child's autonomy, self-concept, or inability of the youngster to escape from such challenges should be sought in the interview. It is important to assess and document the following in the child or adolescent (Reid, 1988):

1. The degree of premeditation and planning versus impulsiveness.
2. Egosyntonicity or dystonicity.
3. Consistency with the patient's past behaviors or style (including chronic bullying).
4. Extraordinary or uncontrolled rage and use of weapons.
5. The validity of perceived self-defense.
6. Evidence of grossly impaired judgment or consciousness.
7. Bizarre or delusional behavior of thought content.
8. Risk of self-injury during the violent episode.
9. The extent to which the child can remember the details of the episode (including his actions and their consequence), accept responsibility, or express remorse.

Each of these variables has implications for the diagnosis and disposition.

### Management

#### *BASIC TENETS*

In approaching the emergency assessment of the potentially violent patient, the first and overriding consideration should be that of safety: the safety of the patient, the safety of others, and the clinician's own safety. A patient must be under behavioral control before a thorough medical and psychiatric evaluation can be conducted. Safety can be maintained and harm averted in the following ways.

The clinician should always be polite and respectful to the patient and concerned parties. Maintaining a calm atmosphere and avoiding irritable and counteraggressive responses go a long way toward diffusing hostile interactions. The clinician should never be isolated with an aggressive patient without the ability to summon assistance. Placing oneself between the patient and the door permits exiting without obstruction, should the need arise. It is important to be attentive to one's own feelings of discomfort, anger, or threat, because these feelings provide important cues alerting the clinician to the potential for violence and the need to seek help.

#### *SETTING*

The interview and waiting area should also be free of sharps, cords, or other potentially hazardous furnishings or medical equipment that are unfortunately ubiquitous to most emergency examination rooms. Interviews should be conducted in a space that will allow some degree of privacy and decreased stimulation. The interview area should, however, also allow some level of visual surveillance from the outside and ease of physical access should summoning staff assistance or security personnel become necessary. An easily identifiable alarm code should be used to alert other staff members to potential or actual violence. The space must also be adaptable to facilitate seclusion and restraint, if needed; restraints should be available nearby in areas where violence could occur.

#### *BEHAVIORAL INTERVENTIONS*

Protocols for managing disruptive or aggressive pediatric patients should include algorithms for the progression of interventions, from least restrictive and invasive to more restrictive and invasive. Clarity of communication and firm limit setting are essential and may be effective at deescalating a potentially violent situation. Staff should supportively and firmly communicate to the patient and family what will and will not be tolerated in the ED while at the same time offering a small range of acceptable alternatives.

When agitation is the result of organic causes and is accompanied by confusion and disorganization, particular attention is necessary to try to keep the patient carefully monitored and oriented. This can be accomplished by diminishing stimulation while maintaining adequate levels of lighting to avoid sensory ambiguity. It is often helpful to provide a staff companion or family member to remind the patient of where they are and to inform him or her of what is happening. Caution with sedation is needed, so as not to obscure fluctuations in level of consciousness.

#### *"Chemical Restraint"*

If these measures do not succeed, it is at this stage that the need for immediate medication should be assessed. There is no specific acute pharmacologic treatment for violent behavior *per se*. However, "nonspecific sedation" is frequently used in the management of acutely agitated patients, whatever the cause. The choice of agent is usually between a neuroleptic and a benzodiazepine. Haloperidol and lorazepam are perhaps the most commonly used agents and are available in most pediatric EDs.

Lorazepam is a nonspecific, sedative-hypnotic benzodiazepine that is readily absorbed after oral or intramuscular administration. It has a relatively short half-life (10 to 20 hours) and produces no active metabolites. In addition to its sedation and anxiolytic properties, benzodiazepines also have the advantage of reversibility with the benzodiazepine antagonist, flumazenil. Dosing in children ranges from 1 to 2 mg orally or intramuscularly every hour until sedation is achieved.

Haloperidol (Haldol) is a high-potency butyrophenone neuroleptic that has been shown to be more efficacious than lorazepam in controlling violent behavior in adult psychiatric patients ( [Citrome and Volavka, 1999](#)). Haloperidol may be given in doses of 2 to 5 mg intramuscularly or orally. The dose may be repeated in 1

hour if necessary to achieve sedation. When compared with the lower-potency neuroleptics (such as chlorpromazine), haloperidol causes less hypotension and less decrease of the seizure threshold, and it has fewer anticholinergic side effects. Despite these advantages, many clinicians prefer the more sedating low-potency agents, such as chlorpromazine (Thorazine), which is given at 0.25 to 0.50 mg/kg per dose orally or intramuscularly. This dose may be repeated in 1 hour if necessary to achieve sedation.

Droperidol, another neuroleptic in the butyrophenone class, is often used in ED (especially adult) settings to sedate acutely agitated patients. It has an antidopaminergic potency and side effect profile similar to haloperidol, but its sedative properties are similar to those of chlorpromazine. It is usually given in doses of 1 to 2 mg intravenously or intramuscularly and may be repeated in 1 hour if necessary to achieve sedation.

Some pediatric settings use the soporific antihistamine diphenhydramine (Benadryl) for sedating agitated, nonpsychotic pediatric psychiatric patients. It is readily available and is safely administered orally as well as intramuscularly. Caution is required, however, because both diphenhydramine and the benzodiazepines can idiosyncratically cause behavioral disinhibition or agitation in some children (particularly those with brain injury or mental retardation), thereby increasing behavioral dyscontrol.

When choosing a pharmacologic approach to rapid tranquilization of children and adolescents, any concurrent medications and medical conditions must be taken into consideration to identify possible adverse drug interactions or contraindications. If there appears to be an underlying psychotic process, delirium, or agitation caused by substance abuse, a neuroleptic may be indicated. If a neuroleptic is used, the physician should also consider the prophylactic administration of diphenhydramine (Benadryl), 25 to 50 mg per dose, or benztropine (Cogentin) 1 to 2 mg, to prevent dystonia, while taking into account any other anticholinergic drugs the patient is receiving. As with any other medication, ED staff should monitor the patient's vital signs and level of consciousness and should be alert to the possibility of side effects such as acute dystonic reactions (e.g., oculogyric crisis, torticollis).

If the indication for a neuroleptic is less clear (as is often the case in pediatric populations), the choice of sedating agent will depend more on the balance of the risk-to-benefit profiles of neuroleptic versus benzodiazepines, on the patient's history of previous treatment with similar agent, and on physician and institutional experience, preferences, and practices.

The choice of route of administration also depends on available formulations of sedative agents. In general, intramuscular injection of a sedative has a faster onset of action than oral medication. Liquid oral preparations are preferable to tablets, because they cannot be as easily "cheeked" or sequestered. Some children and adolescents may calm down readily after accepting an oral medication. Perhaps this is the result of some anticipatory sedation and the sense of relief that the adults have taken action to control the situation. Offering the child the option of taking the medication orally, rather than by injection, is preferable if the situation permits. Not only is it less invasive, but also it enlists the child in the task of exerting control over his upset. Often, however, the threat of violence quickly escalates beyond the point at which a child or adolescent can ally and cooperate with these less restrictive and invasive measures. Such patients must often be physically restrained before they can be approached to offer or give sedative medication.

### *PHYSICAL RESTRAINT*

The Health Care Financing Administration and the Joint Commission on Accreditation of Healthcare Organizations mandate the standards and guidelines for hospital-based use of behavioral restraint and seclusion and subsequent monitoring. Health Care Financing Administration standards specify that "restraint or seclusion should only be reserved for those situations when a patient's behavior becomes aggressive or violent, presenting an immediate danger to his/her safety or that of others" ([Health Care Financing Administration, 2000](#)). Patients must be released from restraints when the goals of the treatment have been achieved, that is, when the patient, and the patient's behavior are under control and no longer pose a threat to self or others or a further disruption to the therapeutic milieu.

Every accredited facility must have explicitly formulated restraint and seclusion policies and procedures particular to its institution. Staff members of all disciplines should be knowledgeable and trained in protocols for managing dangerous behavior. Elements of such a protocol should include the following:

1. The indications for ordering and application of restraint. Example: Restraints must be used only when less restrictive measure have been found to be ineffective in preventing risk of harm to self or others.
2. Clarification of personnel and roles. Example: The selected leader of the restraint determines the number of staff members required for a restraint and the need for hospital security staff and assigns each staff member to a specific task (e.g., restraining a particular limb, clearing a room).
3. Guidelines for monitoring the restrained child. Example: A staff person must be assigned to monitor the child continuously and to assess for restriction of airway, change in breathing pattern, decreased circulation, or increased body temperature.
4. Guidelines for evaluation, reassessment, and removal of restraints. Example: A physician or other licensed, independent practitioner must see the patient and evaluate the need for restraint within 1 hour after the initiation of this intervention. Reassessment and contemporaneous documentation of the need for continuation of restraint must be done by a designated staff person every 2 hours for a child aged 9 to 17 years and every hour for a child less than 9 years old. Orders for continuation of restraint must be written by a physician or other licensed, independent practitioner. When a child shows behavioral control and can verbally contract for safety, he or she must be removed from restraints.

### **Risk Assessment and Disposition Planning**

The assessment of risk is a difficult and often anxiety-provoking task for the clinician. The history, interview of child and adult informants, and the mental status examination usually provide the emergency clinician with the data for a tentative formulation of diagnostic possibilities and the factors that have led to the current crisis and emergency referral. The crucial dispositive question facing the emergency clinician, however, is whether the child can now return to the current living situation with additional interventions and supports or whether some other more intensive, secure, or restrictive disposition must be found, such as admission to an inpatient psychiatric or pediatric ward or other therapeutic residential setting. This crucial decision hinges, in turn, largely on an estimation of the child's probable risk to self or others.

Some cases are clear-cut. The child with a medically serious ingestion or other suicide attempt, active delirium or acute intoxication, or florid psychosis requires medical or psychiatric hospitalization. Similarly, a child who remains acutely aggressive or agitated despite crisis assessment and interventions in the ED also requires a secure placement.

In other cases, however, the assessment of risk and its implications are more complex. For example, a child's immediate suicidality or assaultiveness may subside during the course of the ED evaluation, but some youngsters remain prone to precipitous decompensations because of psychotic regression, ongoing substance abuse, or extreme reactivity to a chaotic or hostile living situation. When, as is often the case, it appears that these conditions are very likely to recur, hospitalization may be desirable, especially if outpatient treatment or intensive in-home services have already proved unfeasible or insufficient. Among the relative factors suggesting the need for more intensive intervention are a deteriorating course with recurrent crises, poor impulse control, judgment, and insight, escalating risky behaviors (dangerous driving, promiscuous or unsafe sexual activity, physical fights, substance use), or increasing self-mutilative behavior, such as self-cutting, even if not in suicidal intent.

### **Assessing the Context-Specific Aspects of the Crisis**

Assessing the context-specific aspects of the crisis is particularly important in weighing risk in these more relative cases. For example, many children and adolescents can become violent or destructive in one setting, such as home or school, and yet show little or no dangerous propensities in other settings, such as in the hospital or outpatient clinic. Making a prediction based solely on the child's behavior in the ED, then, may have little predictive value as to subsequent behavior after discharge. By the same token, a child who initially presents as aggressive or threatening may not always require inpatient hospitalization if appropriate interventions can be made in the setting in which the crisis occurred (Reid, 1988). For example, most child and adolescent emergency visits for aggressive or suicidal threats or behaviors occur in the context of conflict with immediate caretakers. Effective crisis family intervention, psychoeducation, and short-term problem solving in the ED may result in temporary amelioration and resolution of the family crisis.

Although managed care has disingenuously perpetrated the myth that "medical necessity" is an unambiguously determined criteria and synonymous with imminent risk to self or others, the judgment of risk and clinical indications for hospitalization are not easily decided in many cases. Disposition is often "the art of the possible." Locating an inpatient bed and obtaining insurance authorization when needed are often difficult and time consuming. It is important, however, for the clinician not to

confuse these pragmatic considerations with his or her own clinical judgment of what is optimal for a given child.

## LEGAL CONSIDERATIONS

Mental health clinicians should be familiar with the state laws and institutional regulations that apply to the emergency psychiatric evaluation and treatment of minors, as well as those mandating reporting of physical or sexual abuse. The clinician should also know whom to contact in the hospital administration to obtain legal guidance when necessary.

In terms of the clinician's own legal vulnerability, one of the most important elements in decreasing legal exposure is scrupulous documentation of a thorough clinical assessment and good faith judgment in weighing the risks and benefits of one's actions for the patient. The duty to warn a clearly identified potential victim of a serious threat of imminent harm by a patient (e.g., divulging relevant findings about an adolescent's expressed intent to harm another person) takes precedent over confidentiality ([Simon and Goetz, 1999](#)). Needs for communication should be documented and handled openly, in adherence to state laws and institutional rules.

State statutes vary in their provisions and due process rights governing the certification, psychiatric hospital admission, and discharge of mentally disabled minors. In the state of Connecticut, for example, the statute regarding involuntary psychiatric hospitalization states that "if a physician determines that a child is in need of immediate hospitalization for evaluation or treatment of a mental disorder, the child may be hospitalized under an emergency or diagnostic certificate" ([State of Connecticut Social and Human Services, Department of Children and Families, 1991](#)). In many states, these statutes provide greater latitude in compelling the involuntary psychiatric inpatient treatment of minors than of adults. States vary as to the age under which parents may psychiatrically hospitalize a minor under a "voluntary" admission status, even without the minor's assent, as well as the age at which a minor may contest such a hospitalization or may be entitled to a court hearing.

## SYSTEMS ISSUES

### Optimizing the Emergency Department Setting for Emergency Child Psychiatric Services

Even in specialized pediatric hospitals, ED personnel often have little training or comfort in handling child behavioral health emergencies. Preoccupied with large numbers of seriously ill children, ED staff members may look on psychiatric patients as a nuisance, tangential to the ED's perceived real mission and diverting vital space, time, and personnel resources away from the "truly medically patients." This skeptical atmosphere often pervades the setting and results in implicit and explicit pressures for the mental health clinicians to be quick in their assessment and to discharge psychiatric emergency patients who may appear to the medical and nursing staff as disruptive, uncooperative, or unpleasant.

To counteract these potentially divisive staff tensions and resolve obstacles, ongoing collaborative efforts are needed at both the individual and system levels to communicate with ED staff and for the different services involved to communicate effectively regarding their goals and activities. Periodically scheduled meetings that bring together ED psychiatric and pediatric physicians, nursing, and social work leadership are important, because the large numbers of rotating staff involved (reflecting the nature of emergency work as occurring 24 hours a day, 7 days a week) make collaboration difficult.

The use of child psychiatric nurses to provide in-service training and consultation to ED nursing staff helps to bridge some of the interdisciplinary issues that arise in the ED. In addition, the availability of trained child care workers with inpatient psychiatric experience who can assist with the management of child psychiatric patients in the ED decreases some of the demands on busy ED nursing staff.

Unless designed with mental health service needs in mind, the physical setting of many EDs is also suboptimal for conducting child psychiatric evaluations. One important focus of collaborative planning with ED staff is the identification or development of designated areas suitable for these purposes.

### Coordination of Emergency Department Services with Outside Systems of Care

All too often, child psychiatric emergency visits contribute to a pattern of fragmented care by taking place in isolation from the child's ongoing treatment (if any) and with little or no assurance of adequate follow-up. To some extent, the lack of adequate communication is often the result of the late hour and the unavailability (even by telephone) of key informants and care providers (outpatient therapists, school personnel), as well as the constraints of busy ED clinicians who may have to deal with large numbers of patients with little time, sleep, or support staff.

Both in individual cases and on an institutional basis, however, it is essential to foster better communication. An attempt to contact referring or treating outpatient clinicians should always be made, and, even if not available, they should be notified (with the requisite consents) that their patient has been seen in the ED. Community clinicians and institutions (e.g., residential treatment centers, detention centers, shelters) should be encouraged to call before or at the time of sending a child to the ED, to provide necessary history, information, and disposition collaboration. To as great an extent as possible, it is also important to develop good institutional relationships with referring institutions and receiving acute psychiatric hospitals, including regular channels for communication about children sent from the ED for hospitalization.

When children are discharged home from the ED with recommendations for outpatient follow-up, definite arrangements (specifying time and therapist) should be made if possible before the child leaves the ED. Obviously, this is easiest if the child and family will be returning to the ongoing care of a familiar clinician. Some child outpatient clinics reserve one or two appointment slots each day for urgent visits to which patients seen in the ED the previous evening can be referred. If the child is not already in treatment, it is important for the ED clinician to follow-up regarding whether the family has succeeded in making and keeping the initial outpatient appointment. Empirical studies of young suicide attempters seen in the ED and referred for outpatient therapy find that only about one-third ever keep even a single outpatient follow-up appointment ([Piacentini et al., 1995](#); [Trautman et al., 1993](#)). Although ED staffing patterns conspire against adequate follow-up provisions, with tired on-call mental health clinicians and social workers rotating off service the next morning, explicit institutional policies and staff support to optimize outpatient compliance are desirable.

## FUTURE DIRECTIONS

Given the growing demand for emergency child and adolescent psychiatric services described earlier and the burden of providing around-the-clock staffing, many services find it hard to step back and consider the broader issues and needs these challenges pose. Developing a data base for tracking ED psychiatric services, including chief complaints, discharge diagnoses, length of ED stay, sources of referrals, dispositions, and repeat users, permits identifying changing patterns of use and obstacles to efficient service ([Peterson et al., 1996](#); [Santucci et al., 2000](#)).

In many cases, emergency clinicians struggle with the quandary that it appears unsafe to permit a given child to return home with only traditional clinic-based outpatient services in place. Yet hospitalization, even if available, seems unlikely to provide more than a brief respite, especially if only very short-term and at a great geographic remove from home (hence precluding effective family work). Many cities and states are moving toward the development of regionally consolidated systems of care. These new structures will, we hope, allow for the integration and alliance of existing service providers, as well as facilitate the development of a fuller spectrum of outpatient services. These integrated care models would include intensive in-home, child and family psychiatric services, respite care services, partial hospitalization and day treatment programs, and mobile crisis teams. Moreover, they would ultimately contain behavioral health care costs and provide ED clinicians (and inpatient units) with a greater and much needed choice of viable dispositions. It also seems likely that the wider availability of such services would obviate the need for many ED child psychiatry visits.

Studies have demonstrated the clear association between physical disorders and psychiatric disturbances in children and adolescents ( [Shugart, 1991](#); [Steiner et al., 1993](#)). A higher rate of behavioral and emotional disorders occurs in children with chronic disorders (Faird–Rontman, 1992), especially if the child has physical disabilities (see [Chapter 116](#)). Other factors that increase the chances of psychological problems include age (younger children are more vulnerable), male sex, family stresses, single parenthood, and low family income. Psychiatric assessments of randomly selected hospitalized pediatric patients suggest that as many as two-thirds of children admitted to pediatric wards would benefit from a child or adolescent psychiatry consultation ( [Shugart, 1991](#)). Coexistent medical and psychiatric problems in pediatric patients appear to contribute to more complex diagnostic assessments, increased health care costs, and less satisfactory outcomes compared with those in patients without comorbidity ( [Steiner et al., 1993](#)). The child psychiatric consultation, then, is an important intervention to help improve the care of hospitalized pediatric patients and their families. This chapter summarizes common psychological responses in hospitalized children and adolescents and outlines the child and adolescent psychiatric consultation process.

### PSYCHIATRIC CONSULTATION IN PEDIATRICS

The process of child and adolescent psychiatry consultation–liaison in hospital pediatrics rests on a broad foundation that includes a knowledge of normal development ( [Knobloch et al., 1980](#); [Lewis and Volkmar, 1990](#)), psychopathology, diagnosis, and treatment ( [Lewis, 1996](#)), as well as a familiarity with pediatrics and pediatric hospital practices. The purpose of the consultation, the characteristics of the patient and the patient's family and their reactions to the hospitalization, the nature of the patient's illness or injury, and the nature of the relationship between pediatrics and child and adolescent psychiatry all influence the consultation–liaison process. An understanding of the child's concept of his or her body, of how these concepts change with development, and of children's (and family) reactions to illness is particularly useful ( [Lewis and Schonfeld, 1994](#)) as well.

### CHILDREN'S CONCEPT OF THE BODY AND ILLNESS

The child's developing concept of the body is reflected in the child's behavior, verbalizations, and drawings of the body ( [DeLeo, 1977](#)). Initially, the infant seems to experience the body as an external object that either gratifies or causes discomfort. Thus, the infant appears to be either content and oblivious of the body or appears enraged and cries vigorously when the threshold for bodily discomfort is exceeded. There appears to be very little ability in the infant to comprehend or tolerate discomfort or to delay gratification.

By the time children enter preschool, there is clear evidence they possess some knowledge about the body, as well as an increasing capacity to take care of the body. For example, 3-year-old children are curious about the body, can name body parts, including eyes, nose, and mouth, and are concerned about cuts and “booboos.” Very young children seem to view the body as a kind of fluid-filled sac that, if punctured, will ooze precious fluids. Maintaining body integrity is paramount at this developmental stage, and even minor injuries may seem catastrophic to the child. Adhesive bandages (Band-Aids) are very reassuring at this time. At this age also, a simple knowledge of internal organs is beginning, usually with those organs related to direct experience, such as stomach and stomachache.

In kindergarten, children 4 or 5 years of age can draw a simple representation of the body. Frequently, they draw a single circle within which simple features are drawn, such as dots for eyes and nose, a single line for the mouth, and a scribble for hair (the child frequently identifies the sex of the person “by the hair”). Limbs are represented by simple “stick” lines with an indeterminate number of digits emanating from the end of the stick limbs. Simple knowledge of internal organs (e.g., a heart in the shape of a valentine) begins to develop.

As children develop, more details appear in their pictures of the body. By 5 or 6 years, children can identify the jaw, temples, forearms, and shins. From ages 5 or 6, children draw a circle for the head and an ellipse for the torso and add more detail, such as eyebrows and ears. Articles of clothing also become more detailed between 7 and 10 years.

When the child approaches the cognitive stage of formal operations (usually age 12 years and older), the proportions of the body are more realistically represented, and such advances as profile views and representation of movement appear. Knowledge of physiologic functions of certain bodily organs begins to develop; however, adolescents, who may be expected to have a good working knowledge of major anatomic organs and functions, may still be surprisingly ignorant of certain body parts and functions.

Children's concepts of illness follow a similar developmental sequence ( [Lewis, 1994a](#)). In infants, there appears to be no concept of illness other than an external agent (the body) that is attacking the infant and causing discomfort. Very young children who are in the early stages of concrete operations seem to conceive of illness as a result of “immanent justice,” that is, the illness is a punishment for misdeeds committed or imagined and for which the child feels guilty.

The preschool child develops a “contagion” theory of illness, that is, illness is caused by a germ, or “bug.” Usually, the germ or bug is large and imaginary and “infects” in ways imagined by the child. By school age, the child develops a more sophisticated knowledge of the causes of illnesses and the relationship between

symptoms and medical treatments. At this developmental age, children may ask many more questions as they attempt to sort out their understanding of the symptoms, illnesses, and treatments that affect their bodies.

Again, although adolescents are cognitively more capable of understanding illness, they are often psychologically immature and sometimes behave as though they believe they are invincible and immortal. In any event, earlier concepts may persist or may reappear as part of the regression that often occurs with illness. Thus, feelings of guilt may accompany the onset of certain illness, and children and adolescents may have an inaccurate or incomplete understanding of how they became ill.

## TYPES OF REQUESTS FOR CONSULTATION

Requests from pediatricians for child psychiatry consultation in the hospital may fall into the categories described in the following subsections.

### Emergencies

The most common emergency that stimulates a psychiatric consultation is attempted suicide, usually by overdose or physical self-injury, in an adolescent ( [Chapter 91](#)). Other emergencies, also usually seen in the emergency room, include physical abuse (sometimes presenting as Munchausen syndrome by proxy), sexual abuse, drug abuse, acute agitation, acute psychotic reactions, and family crises. In addition, such conditions as anorexia nervosa with critical weight loss may require urgent hospital care.

Emergency consultation in the pediatric ward may be requested for the diagnosis and management of major disruptive behaviors in a child or parent. The consultation may merge into concomitant psychiatric treatment during the hospitalization or may entail making arrangements for psychiatric care after the pediatric hospitalization. Other emergency consultations in pediatric wards may be requested for the diagnosis and management of delirium caused by a wide range of medical conditions (e.g., brain infections and trauma, drug intoxications or interactions, adrenal, hepatic, pancreatic, or renal failure, burns and electrolyte imbalance, and space-occupying lesions) that severely affect the metabolism and function of the brain.

### Differential Diagnosis of Somatoform Symptoms

Anxiety and depression may be the underlying cause of such pediatric symptoms as recurrent abdominal pain, headache, and failure to thrive. Somatoform disorders, including somatization disorder, body dysmorphic disorder, conversion disorder, hypochondriasis, and pain disorder, as well as other related conditions, such as complex regional pain syndrome (formerly reflex sympathetic dystrophy), vocal cord dysfunction, and functional recurrent abdominal pain, characteristically present with symptoms that at first glance suggest a physical disorder but for which psychological factors are of major etiologic importance. The request for consultation and diagnosis may come late in the hospitalization, often after an exhaustive, and often expensive, somatic workup has taken place.

### Collaborative Care of Children with Stress-Sensitive Illnesses

Acute episodes of certain illnesses, including asthma, diabetic acidosis, and ulcerative colitis, are often precipitated by psychological stress in children who are particularly vulnerable and in whom the psychological component of the illness is especially prominent. Psychological assessment and care may be essential for the comprehensive treatment of such a child.

### Diagnosis and Care of Children with Psychiatric Symptoms after a Somatic Illness

Some illnesses seem to linger long after the acute phase in the form of a prolonged depression that may last for a long time. For example, acute infectious mononucleosis and other viral infections are often followed by symptoms of depression that may last for weeks or months.

### Chronic Illness

Chronic pediatric illness of almost any kind, with recurrent hospitalization, is a psychological risk factor for children ( [Lewis, 1994a](#)). The rate of psychiatric illness in children with both chronic medical conditions and disability is three times greater than in noncompromised children for conditions such as attention deficit hyperactivity disorder, overanxious disorder, depression, and conduct disorder ( [Cadman et al., 1987](#)). Many illnesses previously regarded as lethal are now categorized as chronic or curable. For example, children with acute lymphocytic leukemia now have a 90% cure rate.

### Reactions to Major Pediatric Treatment Techniques

Certain kinds of pediatric treatment evoke serious psychological symptoms. Bone marrow transplantation, in particular, gives rise to considerable anxiety and depression ( [Chapter 97](#)). Extensive surgical repair for injury and burns ( [Chapter 99](#)), especially in young children, may give rise to acute behavioral problems. Psychiatric assessment and care may be essential to the child's successful participation in the medical treatment. Some treatments may also give rise to psychological difficulties; for example, cranial irradiation treatment may give rise to cognitive deficits ( [Chapter 96](#)).

### Reactions to Pediatric Illness or Trauma

Finally, every child with a pediatric illness or trauma requiring hospitalization experiences a psychological reaction ( [Lewandowski and Baranoski, 1994](#)). The degree of the reaction varies with the developmental level and premorbid state of the child, the state and reaction of the family, and the seriousness of the illness. The more serious the illness (e.g., leukemia) or injury (especially head injury), the more likely it is that behavioral reactions will arise.

## PSYCHOLOGICAL RISK FACTORS

In general, psychological disturbances are more likely to occur when any of the specific risk factors listed in [Table 92.1](#) are present. Other psychological risk factors include impaired function, immobilization, disfigurement, and loss of autonomy in the child. Additional parental reactions that may increase the risk of psychological disturbance in the child include parental feelings of loss and grief, guilt, depression and anxiety, exhaustion, and isolation, as well as the effects of marital strain, financial drain, and disruption of routine family functioning.

---

1. Premorbid psychopathology in the patient
2. Poor parent-child relationships
3. Psychiatric disturbance in either parent
4. Infancy age group
5. More severe or ambiguous medical diagnoses
6. Chronic illness and multiple hospitalizations
7. Inadequate psychological preparation for hospital and invasive procedures
8. Parents' inadequate understanding of the illness, including unrealistic expectations and debilitating parental reactions, including feelings of extreme helplessness and pessimism
9. Involvement of other nonmedical agencies (department of child services, police, law) interested in the patient's welfare

---

**Table 92.1. Risk Factors for Psychological Disturbances in Hospitalized Pediatric Patients**

Some characteristics of the treatment team or the treatment process may also increase the risk of psychological disturbances in pediatric inpatients. In general,

psychological distress is more likely to occur in the presence of any of the following risk factors:

1. Use of multiple medical consultants (sometimes with conflicting opinions) without adequate, available, or clearly designated leadership
2. The hospital staff's inadequate response to or understanding of the psychological meaning of the illness, injury, or hospitalization to the child and other family members
3. The hospital staff's inadequate awareness of their transference and countertransference feelings about the child, the family, and the illness or injury

## SIGNS OF PSYCHOLOGICAL DISTRESS

Some of the common signs of psychological distress associated with pediatric illness are shown in [Table 92.2](#).

---

1. Biopsychological symptoms: malaise, pain, irritability, disturbances in appetite and sleep
2. Increased attachment behavior: clinging, demanding, heightened separation anxiety
3. Regression: thumbsucking, regression in developmental milestones (i.e., speech, bladder and bowel control, self-care)
4. Passivity and withdrawal: feelings of helplessness and powerlessness
5. Aggressiveness and acting out: tantrums, combativeness, oppositional behavior
6. Frightening fantasies about illness and procedures: ideas of punishment, fear of mutilation and bodily harm
7. Anxiety and mobilization of defenses: denial, projection, phobic symptoms, conversion symptoms
8. Precipitation or aggravation of premonitory psychiatric symptoms

---

**Table 92.2. Signs of Psychological Distress in Pediatric Patients**

## MODELS OF CONSULTATION

Several models of consultation–liaison have been developed in response to the kinds of consultations requested by pediatricians and to the kinds of psychological reactions prominent in hospitalized pediatric patients and their families ( [Lewis, 1994b](#)).

### Anticipatory Model

This model derives in part from an earlier concept of *anticipatory pediatrics* ([Senn, 1947](#)), and it is especially useful when serious psychological reactions to an anticipated procedure are to be expected. For example, children undergoing bone marrow transplantation, and their families, can benefit from a pretreatment psychiatric consultation to assess the strengths and vulnerabilities of the family and to prepare the child and family accordingly ( [Atkins and Patenaude, 1987](#)). When the expected psychological reaction does occur, the psychiatric consultation team is then already in place and informed and is in a much better position to offer further help. Sometimes the prior assessment process may be used to help avert serious psychological reactions.

### Case Finding Model

A modified form of the anticipatory model derives from the liaison work that can be offered to the pediatric staff in the ward. Thus, through the use of regular weekly ward meetings with pediatric and nursing staff members ([Lewis, 1962](#)), early detection or anticipation of psychological problems can help to alleviate stress and may possibly prevent severe psychological reactions. Unfortunately, the preventive and therapeutic uses of such liaison meetings are not directly reimbursable by most third-party payers, and the cost has to be absorbed into the general cost of the hospital care ( [Fritz, 1990](#); [Lewis, 1994b](#)). This liaison function is invaluable, but it rarely receives adequate financial support. In some instances, the liaison work may lead to a request for a formal consultation, which is usually then reimbursable.

### Education and Training Model

The consultant can make a useful contribution to the pediatric hospital care of infants, children, and adolescents through regular case conferences and discussions. Often this is most appreciated in the context of acute care units, such as a pediatric intensive care unit. Training for pediatricians can also be enhanced by the use of a study group ([Lewis and Colletti, 1973](#)). Training of child psychiatrists and child psychologists in consultation and liaison in pediatrics can be facilitated by direct, on-the-case supervision as well as by indirect supervision, case conferences, and regular seminars.

### Emergency Response Model

This model, as noted earlier, uses a 24-hour emergency on-call roster and is mostly used for emergency room calls, but it may also apply in the case of urgent consultation requests in the wards. Attempted suicide in an adolescent is a frequent reason for an emergency child psychiatry consultation in an emergency room, whereas the need for containment, restraint, or structure for a behaviorally out-of-control child in the wards ( [King and Lewis, 1994](#)) is a common reason for an urgent response by the consultant ([Chapter 91](#)).

### Continuing and Collaborative Care Model

In many pediatric illnesses, there is a need for consistent, collaborative, and concurrent pediatric and psychiatric treatment. Typical illnesses that require such care include anorexia nervosa, bulimia, and obesity. Children with recurring or chronic pain may also benefit from ongoing collaborative approaches for pain management, including behavioral approaches ([Cardona, 1994](#)) and psychopharmacologic approaches ([Chapter 76](#) and [Chapter 77](#)).

None of these models is mutually exclusive. Indeed, a good child and adolescent psychiatric consultation–liaison service in pediatrics should incorporate all the foregoing models for comprehensive consultative care.

## BASIC CONSULTATION PROCESS

The psychiatric consultation is generally facilitated when the consultant is part of a team consisting of a child psychiatrist, child psychologist, social worker, developmental pediatrician, and child psychiatry clinical nurse specialist. The team approach allows for comprehensive understanding of the medical, psychiatric, and social issues that may be involved in a referral, as well as for greater coordination of services within the hospital and at the time of outpatient referral. Attention to the factors described in the following subsections enhances every form or model of consultation.

### Availability

Prompt, practical, and understandable recommendations ([Leslie, 1992](#)) from an easily available psychiatric consultant are the foundation of effective consultation and liaison work. The presence in the ward of the child psychiatrist at ward rounds, conferences, or other meetings is useful. Liaison work in particular facilitates accessibility, provides opportunities for informal suggestions, and may prepare the way for more formal consultation requests.

### Relationships

Collaboration is much more likely to occur when there are good relationships based on mutual respect and friendship between pediatrician and child psychiatrist. Because pediatricians and child psychiatrists work in different ways ( [Burket and Hodgkin, 1993](#); [Fritz, 1990](#)), misunderstandings may occur regarding the urgency of a referral or the speed of response needed ( [Black et al., 1990](#)). Understanding how the other functions in practice can encourage smoother collaboration between

pediatricians and child psychiatrists ([Lewis, 1994b](#)). Good relationships between pediatric and psychiatric colleagues make communication easier and more straightforward, reduce the tendency for acting out of ambivalent feelings, and ultimately improve the care of patients and families.

### Levels of Consultation

Five levels of consultation should always be kept in mind:

1. The inner life of the child
2. The dynamics of the relationship between the child and his or her family
3. The relationship between the child and family and the various ward staff
4. Interdisciplinary dynamics operating among attending pediatricians, housestaff, nurses, social worker, child psychiatrist, child psychologist, and other consulting specialists
5. In some instances, the relationship of the hospital staff to an outside agency, including state departments of children's services, police, or law

### Preparation for the Consultation

In preparing to respond to a request for psychiatric consultation, the following questions provide a useful checklist to review before going ahead with the clinical interviews:

1. *Who* is requesting the consultation? A consultation request must come ultimately from the physician responsible for the care of the hospitalized child and should include a brief written request by the responsible physician.
2. *What* is (are) the consultation question(s)? The question or questions must be clear and should be of a kind that can reasonably be answered in the often brief period that the child is in the ward and in the context of the particular ward environment.
3. *When* was the request made, and what is the time frame? In some instances, there simply may not be sufficient time before discharge in which to perform a reasonable consultation.
4. *Why* is the request being made at this time? Sometimes the ostensible reason for the request covers a hidden agenda, such as a pending court appearance, a possible custody conflict, or, in some instances, a conflict among hospital staff.
5. *How* much workup has been done or should be done (and by whom) before proceeding with the consultation? Because the available time is often brief, prior information about the child and family may enable the child psychiatrist to focus on specific areas.
6. Have the child and parents been informed and suitably prepared? Occasionally, parents may refuse to have a psychiatrist see their child. The cooperation of the parents is needed for a satisfactory consultation. When a child is a ward of the state, permission for child psychiatry consultation must be obtained in writing from the state agency.
7. Has the child's hospital record been read before one proceeds with the interview?

### Procedure

A flexible interview approach is often required for completing consultations in a pediatric ward. One may have to improvise through the use of a few portable materials (e.g., paper, pencil, crayons, deck of cards, and small rubber doll figures) and by adapting to frequent interruptions and lack of privacy in a pediatric ward.

The psychiatric evaluation is of necessity detailed and complex and should not be rushed, if possible ([Leslie, 1992](#)). If the time available for the consultation is not adequate to complete the necessary evaluation, the focus of the consultation should be adjusted, or the evaluation should be deferred to a time or setting (i.e., the inpatient psychiatric unit or the outpatient psychiatric clinic) when a more appropriate assessment can be made.

Ideally, one would first interview the patient's parents, but this may not be feasible. Suitable preparation of the child and parents by the requesting pediatrician usually reduces the child's and parents' reluctance, if any, to speak with a psychiatric consultant; however, the complete assessment of the child may still require multiple interviews with the child and parents. The basic items of a mental status examination ([Lewis, 1991](#)) ([Chapter 41](#)) need to be performed and additional inquiries or tests ordered as needed. A thorough knowledge of the patient's treatment and medication regimen is particularly necessary when one evaluates a patient for delirium or other possible medication-induced conditions (e.g., depression, anxiety, psychosis, and agitation).

Very useful information about the child and family can often be gathered from the observations of such ward staff as nurses, child life specialists, and social workers. Moreover, conversations with some of the patient's health care providers (inpatient and outpatient) may be necessary to sort out treatment issues that may be in conflict and contributing to the psychological stress of the patient or the patient's family. Clarification of any pending legal or social service issues may also be necessary to comprehend the patient's current stressors and may also determine in part the nature of the consultation and the child psychiatrist's report.

### Report

The findings of the consultation should first be reported to and discussed with the requesting pediatrician. Subsequently, and with the agreement of the pediatrician, one communicates as necessary and as appropriate with the parents (or, in some cases, a state agency), the child, and key ward staff members. The written consultation note should be relatively brief and should be organized in such a manner as to be easily read and understood. Useful headings may include the following: (a) a brief statement of the question and the purpose of the consultation; (b) a concise summary of pertinent historical data; (c) the important findings, both positive and negative, from the mental status examination and comprehensive psychiatric evaluation; (d) diagnosis, using a standard multiaxial classification (e.g., the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* or the 10th edition of the *International Classification of Diseases*); (e) a brief diagnostic formulation and summary; and (f) a recommended treatment or management plan or suggestions for further workup.

### Confidentiality

A hospital chart is not a particularly private or confidential record; it may be seen by the parents or child as well as other people. For this reason, the words used must be carefully chosen to avoid offense, slander, or potential dissemination of possibly damaging information. The written record is at the same time a legal document carrying the consultant's signature and should be written with that in mind.

### Follow-Up

Follow-up after a consultation by inquiring of the requesting pediatrician about the subsequent course of the child is helpful. The consultant obtains general information about the accuracy of the psychiatric assessment and the effectiveness of the intervention, and the pediatrician often appreciates the psychiatrist's continuing interest. Follow-up studies of matched pediatric patients who received psychiatric consultations and those who did not can help assess the efficacy of psychiatric interventions in hospitalized pediatric patients ([Shugart, 1991](#)).

## IMPEDIMENTS TO CONSULTATION—LIAISON IN PEDIATRICS

Difficulties that may interfere with a well-functioning consultation—liaison service ([Anders, 1977](#); [Anders, 1982](#); [Burket and Hodgkin, 1993](#); [Eisenberg, 1967](#); [Fritz, 1985, 1990](#); [Jellinek, 1982](#); [Kanner, 1937](#); [Lawrence and Adler, 1992](#); [Leslie, 1992](#); [Lewis, 1973](#); [Lewis, 1994a,b](#); [Lewis and Vitulano, 1988](#); [Lourie, 1962](#); [Oke and Mayer, 1991](#); [Rothenberg, 1979](#); [Senn, 1946](#); [Shugart, 1991](#); [Wright et al., 1987](#)) include the following:

1. The failure of some child psychiatrists to understand how pediatricians function in practice, and vice versa
2. A perceived, or real, lack of availability of child psychiatrists
3. Professional identity problems in both disciplines
4. Different perceptions of patients (health versus disorder)
5. Different interviewing techniques ("anamnesis" versus "listening")
6. Anxiety among pediatricians in dealing with the emotional problems of children and their families
7. Transference and countertransference issues

8. Time constraints in both pediatric rotation training schedules and inpatient load
9. Financial considerations, including inadequate funding for child psychiatry consultation–liaison services in pediatrics (When payment is determined by the type of insurance plan held by the parents, special rules may apply.)
10. Ambivalent support for the concept of coordinated multidisciplinary care for the whole child and his or her family
11. Limited opportunities for continuity of care in pediatric training
12. Compartmentalized, disease-oriented research, rather than collaborative biopsychosocial research
13. Inadequate outcome studies

None of these impediments is irremediable. With positive motivation and cooperation among all the disciplines involved, one should expect to have a thriving child and adolescent psychiatric consultation–liaison service in pediatrics ( [Lewis and Vitulano, 1988](#)).

## RESEARCH DIRECTIONS

Current national health policies and health plans have affected the role for child psychiatry consultation in pediatrics. At the same time, advances in pediatric medical knowledge and technology sometimes give rise to an increase in requests for child psychiatric consultation and liaison. For example, advances in bone marrow and solid organ transplantation, neonatal and pediatric intensive care, and prolonged survival from cancer, cystic fibrosis, chronic renal disease, and other once fatal pediatric conditions not only illustrate the effects of technology on pediatrics but also identify new regions of pediatrics in which the expertise of the consultation–liaison child psychiatrist is relevant.

Increased awareness about the coexistence of psychiatric and medical problems in pediatric patients has contributed to the development of pediatric medical–psychiatric units ( [Fritz, 1990](#); [Sexson and Kahan, 1991](#); [Steiner et al., 1993](#)) and triple-board programs, which prepare physicians to be board eligible in pediatrics, general psychiatry, and child and adolescent psychiatry. The role of the consultation–liaison child psychiatrist in such settings, as well as in the general pediatric setting, continues to undergo changes ( [Fritz, 1990](#)).

Problems of training, funding, and organization continuously need to be addressed, particularly in the changing health care environment. New ethical and legal issues continue to arise and need to be considered as well. Perhaps most important, research projects designed with clear short-term and long-term outcome measures (e.g., hospital length of stay, improved compliance with medical care, decreased use of medical services, improved functioning, or improved quality of life) are needed to assess the efficacy and cost-effectiveness of particular psychiatric consultation–liaison interventions ( [Shugart, 1991](#)).

[Ongoing Consultation with Pediatricians](#)

[Summary](#)

[Chapter References](#)

Since the 1950s, the introduction of and increased use of preventive vaccines and more effective antibiotics (as well as improvements in nutrition and sanitation in general) have greatly decreased the number of children presenting with acute or chronic contagious and infectious diseases in pediatric practice. Similarly, new technology and better science have expanded the number of children with chronic diseases and infirmities of many kinds and have prolonged their survival enormously. At the same time, the swelling pressure on families and environments has helped to bring to attention a growing number of children with developmental and psychological problems. Whether this is real or seems so only because of more attention to these issues and the availability of better diagnostic procedures and criteria, it is now widely acknowledged that 12% to 15% of children in the general population are in need of direct, intensive mental health services, and 20% to 40% could benefit from less intensive mental health services ([Garralda and Bailey, 1989](#); [Starfield et al., 1980](#); [Starfield et al., 1984](#); [Sturner et al., 1980](#)). It is probable that in populations where poverty, violence, drug use, broken families, inadequate housing, and run-down schools are present, the morbidity is closer to 100%.

These facts present a clear case for the need for close collaboration between pediatricians and child psychiatrists in the health care of children. Children with serious psychopathology need to be referred to and managed by mental health professionals, preferably child psychiatrists. Failure to receive, or even delay in receiving, such services leads to greater psychological dysfunction, school failure, substance abuse, and other sociopathies. Children with more ambiguous mental health needs and those with chronic organic disease need to be managed in consultation between practitioners in the two fields. It has been well demonstrated that intervention informed by mental health principles can reduce pain, suffering, and time of recovery from injury and illness in patients with chronic organic problems ([Granger, 1990](#)).

Despite all this evidence, the relationship between the two fields has been less collegial than it needs to be to serve the best interests of children and their families. Both sides have much to answer for in this regard. Myriad reasons have been suggested for the mutual discomfort ranging from time constraints and financial considerations to differences in personality and temperament, in training, in theoretical framework, and in therapeutic approach between those who choose the two fields ([Greene, 1984](#); [Lewis and Vitulano, 1988](#); [Work, 1989](#)). As usual, these reasons hold up better when group averages are discussed than when individuals are the subject of comparison. Be that as it may, strong forces are now at work that make a rapprochement between the fields more imperative than ever.

## FACTORS IN COLLABORATION

The nature and needs of children have not changed, but four factors introduced into the ecology of medicine in general and into child psychiatry and pediatrics in particular are helping to blur the borders between them. These factors are (a) managed care, (b) the increasing use of psychotropic medications in treatment, (c) the creation of a subspecialty board in developmental/behavioral pediatrics, and (d) the decrease in number of child psychiatry training programs and applicants for them.

### Managed Care

The mushrooming growth of managed-care programs has had more effect on mental health care than on any other area of medicine. It has become the policy of almost all these programs to minimize both the availability and length of treatment—other than drug treatment—for even the most serious psychopathology. Psychiatrists are discouraged or prevented from participating with many managed-care organizations because of closed panels and inadequate reimbursement levels. Patients and referring physicians find it difficult to identify participating psychiatrists because many plans do not make these lists readily available. Instead, clerks in distant cities maintain lists of participating mental health professionals of all types in various regions and often provide only a few names from that list. These lists do not include information on the training of these professionals. The source seeking referral (often the family itself) has no way to distinguish child psychiatrists from general psychiatrists, and many of the latter have taken to listing themselves as capable of dealing with the mental health problems of children. This makes it more important than ever that the child psychiatrists in any community help the pediatricians in that community to know who they are and how they may be reached.

### Psychotropic Medications

In recent years, child psychiatry as a field has learned much about basic brain science—physiology, biochemistry, pharmacology—and this has led to the development of a rapidly increasing pharmacopeia aimed at the treatment of various psychopathologic conditions. At the same time, the use of drug treatment has been encouraged by managed care, which, in the interest of the bottom line, looks for the least time-consuming and labor-intensive treatment available. One of the byproducts of this trend has been that child psychiatrists have prescribed medications for patients and then left it to the pediatricians to write continuing prescriptions and do follow-up care. This can be a good source of collaborative effort when the psychiatrist communicates with the pediatrician at the time of prescription, informs him or her of the rationale for the treatment, and maintains periodic contact with the pediatrician to monitor the course. It is *not* a collaboration at all when the child psychiatrist merely tells the family to get in touch with the pediatrician and leaves the latter with an unsought and poorly understood responsibility. Pediatricians are under increasing pressure from families and nonphysician mental health clinicians to prescribe psychotropic medication without psychiatric evaluation. Most pediatricians are not as knowledgeable as psychiatrists about these medications and would welcome a child psychiatrist's collaboration in the care of their patients.

### Pediatric Subspecialty Board

For more than 50 years, some pediatric centers have provided some of their trainees with knowledge and skills derived from some of the mental health fields. The number of such trainees has slowly increased over the years aided by support, both financial and organizational, from the National Institute of Child Health and Development, and most centers currently have some representation in the field. After long discussions with other specialty groups, the American Board of Pediatrics established a subspecialty board in developmental/behavioral pediatrics that is currently generating a curriculum for a fellowship program in this area and will soon begin certifying graduates of such programs as well as some others who will be allowed under a "grandfather clause." The institutionalization of this program means that every pediatric training center in the country will now have to have such a program and faculty with expertise in the subject. The new subspecialists will not be trained to be junior child psychiatrists. Much of their training will be in early child development, in the development and management of community outreach programs, in the management of common psychosomatic problems such as enuresis and encopresis, in some family counseling and in the detection and appropriate referral of serious psychopathologic entities. They will have been trained, in many cases, in conjunction with child psychiatrists or psychologists and will be natural collaborators with mental health professionals in a plethora of activities.

### Decreasing Number of Child Psychiatrists

This has been an alarming trend in recent years. Driven by economics as well as other issues, there has been a considerable decline in the number of child psychiatry training programs in the United States and an overall lessening of the numbers of candidates applying for and completing such training. Many of those completing training are entering academic research programs rather than going on with clinical work. This trend will certainly help extend the breadth of the field, but it does indicate a continuing diminution of the number of clinical resources available to deal with the many children and their families who need psychiatric treatment. This will put more and more pressure on those child psychiatrists doing clinical work in the community, and most of them are already overloaded. It may be

that some of their time spent in consultation or collaboration with pediatricians, as well as others, may serve as an extender of services.

Nothing in this chapter is meant to suggest that collaboration is automatic or even easy—or even desired by either participant in a case. At the present time, many pediatricians in practice are still relatively uninformed about most aspects of mental health work and may not be particularly interested in ongoing contact with the psychiatrist. However, there are more pediatricians who are interested in such a collaboration today than there have ever been, and the increased emphasis this work will now assume in pediatric training programs will ensure more in the future. Those pediatricians who are interested can be a valuable source of information for the psychiatrist. Most often, they have known the family for a long time and may have watched the problems develop while working with the family to find and accept help.

## NATURE OF COLLABORATION

In community practice, collaboration will consist primarily of the interactions between a pediatrician and a child psychiatrist around the clinical care of a child and family. The source and the nature of this interaction may vary considerably. The child may be referred directly to the psychiatrist by the pediatrician for evaluation or treatment. The child may be referred to the psychiatrist by a school or other agency with or without the knowledge of the pediatrician. The pediatrician and the psychiatrist may have an ongoing relationship that allows them to consult with one another—in either direction—around a case they have already worked on together or on one unknown to one or the other but about which advice is sought. There may also be times when information is sought about a subject (an article, a community activity, a disease) without a specific case at reference. Each of these modalities requires give and take, but of a different nature.

## REFERRAL BY PEDIATRICIANS

In the first mode, the pediatrician essentially indicates confidence in the child psychiatrist by asking him or her to take the case on for evaluation and treatment. Sometimes the family is well prepared for the referral, and at other times they are not. Sometimes the referral is both thoughtful and appropriate, and at other times it seems more like an impulsive rejection of the child and family by the pediatrician. This depends both on the sophistication of the pediatrician and on the anxiety level of the parents. The pediatrician may have made more effort to prepare the family than is evident on the first visit, and the psychiatrist should withhold judgment of this issue. The child psychiatrist should remember that the pediatrician is usually asking him or her to share the burden of managing what has become, for the pediatrician, a difficult and problematic family or child. At the very least, collegiality suggests that the psychiatrist try to sort these factors out on behalf of both the patients and the pediatrician, rather than abandoning them in turn.

For many pediatricians, the process of assessing the mental health needs of a child and family is difficult, and the act of suggesting and making a referral often puts a strain on the pediatrician–family relationship. Although some parents initiate this process themselves, most parents are still strongly ensconced in some level of denial and are resentful of the pediatrician's intervention. The child psychiatrist can help to strengthen the pediatrician–family relationship by the way in which he or she supports the actions of the pediatrician and encourages and facilitates the family's maintenance of close ties with the pediatrician. Child guidance agencies often do this quite poorly. The agency's refusal to communicate with the pediatrician gives the family a message about the pediatrician that is, at the very least, ambiguous and ambivalent. Sometimes this results in the family's leaving the pediatrician, but at other times the ongoing tie to the pediatrician is stronger than the developing tie to the mental health agency, and the result is the shortening or interruption of treatment. The private child psychiatrist should be aware of all the possibilities and dangers in these dynamics and should act accordingly. The child will certainly continue to need access to ongoing health supervision and illness treatment, and it is not likely to be desirable that such access be blocked or changed in the middle of psychiatric treatment. One way the psychiatrist can help in this process is by providing regular and periodic feedback to the pediatrician about the status and progress of treatment. The child psychiatrist is likely to obtain useful feedback from the pediatrician, in turn, about new or ongoing illnesses or complaints. Especially if the family has more than one child, the pediatrician is likely to have continuing contact with the family in a way that can provide important information for the therapist. Successful collaboration also enables the pediatrician to encourage the family to remain in treatment with the child psychiatrist when resistance emerges, rather than inadvertently colluding with the resistance.

There is no suggestion in this that confidentiality should be breached. However, over the years, a dangerous mystique has arisen about this issue. It certainly is no longer true that most patients wish to hide all evidence of their being in treatment or that they want no communication to occur between the therapist and other important caretakers in the child's life. In our experience, most families, if asked, encourage ongoing contact between the child psychiatrist and the pediatrician. There is no need for the therapist to provide the pediatrician with details of dynamics or treatment processes. He or she should merely make a brief phone call or provide a short note about the continuing nature of the treatment.

In regard to this mode of referral, many pediatricians choose to refer many kinds of cases to mental health professionals other than psychiatrists—social workers, psychologists, even other psychologically oriented pediatricians. A major reason for this is the pediatricians' belief that child psychiatrists are less available, less responsive, and less communicative than these other professionals. However, there is also evidence that pediatricians often do not understand what types of problems child psychiatrists are trained to treat ([Fritz and Bergman, 1985](#)). Finally, the problems and issues superimposed by mental health managed-care organizations have resulted in decreased access for patients to child psychiatrists in many communities, a further challenge for child psychiatrists.

## REFERRAL BY OTHER SOURCES

When the referral comes to the child psychiatrist from a source other than the pediatrician, the child psychiatrist may assume that the pediatrician does not know about the problem or is not interested in it. This may sometimes be true, but it is not a safe or useful conclusion. In these cases, just as in those mentioned earlier, the therapist should ask for permission to communicate directly with the pediatrician. If the family really does not want such communication, they will not hesitate to say so. However, even in these cases, it is likely that the pediatrician may have information that will be both useful and germane to the evaluation and treatment process. Occasionally, the family may want to exclude the pediatrician specifically because he or she does know a great deal about the family, and the family wants an unbiased, "blind" opinion about the problem from the psychiatrist. This dynamic is seldom useful to the child, and the psychiatrist may want to examine his or her options in these cases. Finally, inasmuch as the pediatrician has ongoing supervision of the health of the child, he or she may be able to provide some insights into other areas in the child's life about which neither the child nor the parents may be forthcoming.

## ONGOING CONSULTATION WITH PEDIATRICIANS

In the course of busy, ambulatory practice, pediatricians assume the management of many children with difficult and complicated illnesses and difficult and complicated families and psychosocial situations. Studies of pediatric primary care practices ([Goldberg et al., 1984](#); [Starfield et al., 1980](#); [Starfield et al., 1984](#); [Sturner et al., 1980](#)) reveal that between one-fourth and one-half of all well-child visits to pediatricians revolve primarily around psychosocial issues. The pediatrician may choose to ignore all the signs and symptoms involved in this, but he or she will almost certainly need and want to manage some of them more directly. In doing this, pediatricians often want consultation from a mental health colleague, and many of them have developed some ongoing pattern of presenting such issues to a child psychiatrist in their area—if they are lucky enough to have one. This consultation may take the form of telephone calls or of more formalized meetings. It may be seen as an intrusion by the psychiatrist, but this type of contact is useful in helping the pediatrician to assess the kind of help available from the mental health field and from individual colleagues in particular. It is an important and valuable service that the child psychiatrist would do well to foster in the community. Such initial calls often lead to referrals for more extensive evaluation and treatment, but even if they do not, they create a goodwill that cannot be overestimated. The need for such consultation is especially clear and acute around emergency situations such as suicide attempts, but it is equally important for less dangerous and acute problems as well.

In some communities, a specialized form of this type of collaboration has been in place for varying periods ([Granger, 1985](#); [Solnit, 1968a](#); [Solnit, 1968b](#)). In this model, a group of pediatricians meets regularly with one or two child psychiatrists to discuss difficult cases from the pediatricians' practices. The pediatricians present the cases to the group, and the group discusses them under the leadership of the psychiatrist and perhaps a senior pediatric colleague as well. The ongoing nature of the group provides more benefit for its members than just the case discussions themselves. The members, pediatricians and psychiatrists alike, come to see the group as a support in the continuing struggle against the vicissitudes of practice. This has become even more important as access to direct mental health services has been limited by managed care. Pediatric members of the group unquestionably develop both knowledge and skills in the management of psychological and developmental problems in their practices. They become more sophisticated in their understanding of psychotropic medications. Psychiatrists often use the process to keep up with the changing biological factors in pediatric practice, many of which impinge on the etiology and treatment of psychological disease. In fact, studies in the educational field suggest that the only mode of continuing education that actually results in changed behavior among practitioners is the one in which they interact around cases from their own practices in a continuing manner.

One common ground for collaborative work between pediatricians and child psychiatrists is the use of the concept of temperament in pediatric practice ([Carey, 1986](#); [Carey, 1994](#); [Chess and Thomas, 1986](#)). Temperament measurements can be useful, for example, in educational discussions with parents as well as in formulating

first-time intervention measures when an interference with the “goodness of fit” has given rise to behavioral problems in the child ( [Cameron et al., 1994](#)) (Chapter 15). The concept of temperament has also proven useful in the collaborative care of certain children with chronic illnesses ( [Lewis, 1994](#)) and with uninfected children in families affected by human immunodeficiency virus ( [Lewis, 1985](#)).

The collaborative relationship also opens the door for the possibilities of joint research between child psychiatrists and pediatricians. Some of the most interesting aspects of clinical case management come out of such collaborations. There is ample room in the process, especially in the group process outlined earlier, for more definitive intervention research in pediatric practice settings. Such research can be set up to conform with good psychological practice and can be carried out in multiple practice settings to offer truly useful information on the possibilities of what may be called preventive mental health.

#### CASE ILLUSTRATION

Jim Smith is an 18-year-old adolescent, the only child of a Midwestern couple in their midforties. Jim was born in Milwaukee and appeared to be developing normally until around 18 months, when he suffered from a severe, persistent bout of otitis. During this time, his language development was believed to regress, and he was referred to numerous specialists. He eventually was seen by a child psychiatrist, who reported that although Jim had some developmental delays, he was not autistic. Mr. Smith had just received an attractive job offer on the east coast, and the psychiatrist recommended that the family seek the services of a child development resource when they relocated. After the family's move, Jim was evaluated at 22 months of age by a child psychiatrist at a child development center and was referred by the center to a developmentally knowledgeable general pediatrician. This child psychiatrist's assessment contrasted markedly with the first evaluation, and she informed the family that Jim was autistic. The family was ill-prepared for this diagnosis; the psychiatrist had not involved the pediatrician in helping to prepare the family for it, and the family rejected the diagnosis and fled from the child development resource.

Dr. Marks, the pediatrician, consulted with another child psychiatrist, Dr. Cooper, with whom he had an ongoing collaborative relationship, about the management of this child and family. They agreed that the child and family would need mental health help as the child grew, but that Dr. Marks should proceed slowly to pave the way for them to accept this. In the meantime, Dr. Marks was able to arrange speech and language resources for this child in his hometown. He arranged for an educational specialist to consult with the preschool to modify the regular program to meet Jim's needs. Jim responded well to the speech and language intervention, and gradually language ceased to be a problem, whereas Jim's social awkwardness and lack of relatedness became more central.

By the time Jim was 4 years old, his parents were ready to talk with a child psychiatrist, and they were referred to Dr. Cooper. He worked with the parents and evaluated the child. In the first few years, most of Dr. Cooper's work was with the parents. It became apparent that Mr. Smith shared some of Jim's relatedness issues. Mrs. Smith, in contrast, was extremely nurturing and supportive and was the crucial family resource facilitating the work of both the psychiatrist and the pediatrician. When Jim was 6 years old, Dr. Cooper began to see him on a more regular basis. During Jim's "latency" period, some of the content of the sessions suggested a thought disorder, although Jim appeared to have no trouble distinguishing between fantasy and reality. In adolescence, Jim's verbalizations and imagery appeared more psychotic. The guidance counselor at school was frightened by some of his statements and needed help from the physicians to understand him. Drs. Cooper and Marks both believed that Jim would benefit from medication. Risperidone was helpful with his thoughts, but it exacerbated his exercise-induced asthma, thereby interfering with his swimming, which was very important for him. Again, the pediatrician and the psychiatrist were able to work together to balance Jim's myriad needs.

Jim currently carries the diagnosis of Asperger's disorder. He is taking medication and is functioning well, with reasonable self-esteem and self-awareness, in a vocational training program.

#### Comment

The favorable outcome that was achieved in this case was far from certain, given its beginnings. The complexity of developmental problems in children with spectrum disorders requires the utmost collaboration between child psychiatrist and pediatrician. Pediatricians have ready access to these families and are generally perceived as nonthreatening. They can help families to cope with and confront the problems of their children, and they are often first to become aware of new issues. Child psychiatrists can help families and children to understand and work through their difficulties for an optimal outcome. Close communication between the two professionals significantly improves the result.

---

---

## SUMMARY

Given the differences between their disciplines, pediatricians and child psychiatrists have not found it easy to collaborate. However, more and more of them are managing to do it and, as they become more experienced with the process, are finding it a rewarding way to manage their professional lives. The process results in an improvement in the management of health care for children that neither discipline can achieve alone. It can only be hoped that more and more pediatricians and child psychiatrists will discover the satisfactions and rewards of true collaboration.

[Chapter References](#)

Physicians realize how difficult it is to provide adequate and effective explanations of illness and proposed treatment to their adult patients. Medical education has left the physician with a qualitatively different way of understanding illness, both physical and mental, that is beyond the grasp of the lay public. Explanations must be translated by the physician so the patient can understand. This is not a simple process of merely replacing unfamiliar medical terminology with words from the patient's own vocabulary, but it often involves the much more difficult task of restructuring the explanation to comply with a conceptual framework that is comprehensible to the patient. When the patient is a child, the clinician is confronted with a broad range of conceptual frameworks, some of which may initially seem idiosyncratic. The challenge of ensuring effective communication therefore becomes far greater, but it is of no less importance.

The prospect of determining each child's unique conceptual framework for understanding illness may at first seem difficult. Fortunately, systematic research has been conducted that provides important insights into the developmental process by which children obtain an understanding of the fundamental concepts of physical illness, such as causality, prevention, and treatment. These cognitive–developmental studies ( [Burbach and Peterson, 1986](#)) demonstrate a systematic and predictable sequence by which children acquire these concepts to explain both general physical illness, as well as specific conditions such as acquired immunodeficiency syndrome ( [Schonfeld et al., 1993](#)). This developmental process is comparable to that of the acquisition of causal understanding as described by Piaget ( [Piaget, 1929](#)). According to Piaget's model ( [Brewster, 1982](#); [Ginsburg and Opper, 1969](#); [Perrin and Gerrity, 1981](#); [Piaget and Inhelder, 1969](#)), as the result of biological maturation and the accumulation of experience, the child progresses through four sequential stages of cognitive development: the sensorimotor period (infancy), the preoperational period (early childhood, roughly 2 to 7 years), the concrete operational period (middle to late childhood, roughly 7 to 11 years), and the formal operational period (adolescence to adulthood). Although experience has shown that children often progress through these stages at a faster rate than was initially predicted by Piaget, the nature and sequence of these stages, described by Piaget as invariable, have been confirmed by extensive research. Children in the preoperational period rely on direct personal experiences and have little ability to generalize to related situations or to appreciate multiple aspects of one situation; their thought processes tend to be empirical rather than logical. Later stages involve an increasing ability to use logical thought processes, with abstract thought attained only during the formal operational period. Later stages also are characterized by the child's increasing ability to differentiate self from others and to distinguish internal wishes, needs, and thoughts from the realities of the external world.

Efforts to promote the child's adjustment to physical illness and its treatment require an appreciation of this developmental process. Effective support and assistance are predicated on an understanding of not only the child's feelings but also the child's beliefs about being ill ( [Bibace and Walsh, 1980](#)). For example, it is often assumed that children fear blood drawing because of the pain associated with the procedure, and reassurances thereby take the form of "It will only hurt a little." In reality, the child's feeling of fear may be related to a belief that the phlebotomist will remove too much blood and the child will die ( [Licamele and Goldberg, 1987](#)). In this situation, the reassurances offered are ineffective, and the child is left to deal, alone, with a terrifying misconception about the treatment process. Efforts to facilitate the child's adjustment to physical illness and its treatment must therefore be based on an appreciation of the child's knowledge of the relevant concepts of illness. Otherwise, the ill child will be left, as depicted by Anna Freud, "to submit uncomprehendingly, helplessly and passively" to both the illness and the treatment process ( [Freud, 1977](#)).

The child's knowledge and understanding of the concepts of illness can thereby be viewed as vital determinants of the child's adjustment to illness. The focus of this chapter is to review what is known of the developmental process by which children acquire an understanding of the concepts related to illness and the implications of this knowledge for clinicians.

### PRIOR RESEARCH

On the basis of a review of the cognitive–developmental literature on children's concepts of physical illness, Burbach and Peterson (1986) conclude that a positive relationship exists between the level of understanding of the concepts of illness and the child's chronologic age and cognitive maturity that is consistent with Piaget's theories of cognitive development. Wide variability in children's understanding as a function of age is noted across studies; a similar but somewhat smaller variation persists when analysis is conducted as a function of cognitive–developmental level (frequently measured in terms of piagetian tasks). Global estimates of a child's cognitive abilities are thereby often inaccurate predictors of the level of understanding of concepts about illness; on average, the understanding of the causality of illness typically lags behind that of general causality ( [Perrin and Gerrity, 1981](#)). Children bring their own personal experiences to bear on their understanding of illness; some of these experiences may promote understanding of the concepts for a particular child, whereas others may have been negative experiences that only serve to heighten anxiety and interfere with the acquisition of knowledge. It is not surprising, then, that it is still unclear what role personal experience with illness plays in the process by which children develop an understanding of the concepts of illness ( [Burbach and Peterson, 1986](#); [Perrin et al., 1991](#)). For this reason, in the sections to follow, the focus is not on what "a typical child" knows or thinks at a particular age. When possible, generalizations about representative age ranges are provided, but the emphasis is on an overview of the process and not a time line. Clinicians are advised not to rely on age-based normative data but to develop instead an appreciation of the process of cognitive development in this area. Simple inquiry into the child's views and understanding will then identify the child's level of comprehension and can lead to an appreciation of the child's unique misconceptions and concerns.

### Immanent Justice, Guilt, and Shame

With increasing cognitive maturity (and age), children's understanding of the causality of illness increases in a predictable manner. Younger children, lacking an adequate explanation for the cause of illness, are apt to resort to explanations that attribute the cause of illness to immanent justice, "the belief that a form of natural justice can emanate from inanimate objects," wherein misdeeds will be automatically punished. Such a belief leads to the acceptance of personal guilt and shame for the origin of illness. It is hypothesized that magical thinking and immanent justice concepts are employed by the young child in preference to the concept of chance, thereby allowing the child to retain the illusion of order and personal control in what would otherwise appear to be a random and often unfair world ( [Wilkinson, 1988](#)). Freud also appreciates the child's tendency to assume guilt for personal illness: "[Illness] appears to the child as a confirmation of the belief that wrongdoing, however secretly performed, is open to punishment, and that other, still undetected misdeeds, whether actually carried out or merely contemplated in fantasy, will likewise be followed by retribution of some kind" ( [Bergmann and Freud, 1965](#)). As one 11-year-old boy related about his diagnosis of polio 2 years earlier: "I was charged with having polio. I had to plead guilty, and my sentence was life imprisonment in a wheel chair" ( [Bergmann and Freud, 1965](#)).

Research has shown that explanations based on immanent justice are more persistently used for ailments for which the child has limited personal experience and for which another explanation is not readily available ( [Siegal, 1988](#)). With increasing cognitive maturity and with the accumulation of experience with illness, the child is more likely to reject the notion that illness and misbehavior are linked and instead acquires more accurate perceptions of personal control over illness and recovery ( [Burbach and Peterson, 1986](#)). It is hoped that, by providing the child with more appropriate explanations for the cause of illness, the child will be able to abandon immanent justice explanations at an earlier age ( [Kister and Patterson, 1980](#)). Such immanent justice explanations can be expected to result in guilt or shame, to impede competent understanding of the cause of disease and thereby hinder attempts to promote compliance with preventive health measures and treatment regimens, and to impair adjustment and coping to illness of self and significant others. It has been demonstrated that even preschoolers dismiss immanent justice as an explanation for familiar ailments with which they have had personal experience (e.g., colds) while they retain this concept in their explanations of causality for ailments with which they are less familiar (e.g., toothaches) ( [Siegal, 1988](#)). Such findings lend support for the role of personal experience, and indirectly education, in

advancing the child's understanding of the causality of illness.

### Further Understanding of Illness Causality

As children begin to develop an understanding of the true causes of physical illness, the concept of contagion appears in their explanations for the causality of disease. Younger children (preoperational stage) initially tend to overextend the concept of contagion to include noncontagious illness; the concept is applied most appropriately by children reaching the later stages of cognitive development (concrete and formal operational stages) ( [Kister and Patterson, 1980](#); [Potter and Roberts, 1984](#)). Yet in appropriate circumstances, proper discriminant application of the concept of contagion is within the grasp of children as young as the preschool level. Siegal (1988) demonstrates that most preschool children in his study (the mean age for study participants was 4 <sup>11</sup>/<sub>12</sub> years) could accurately attribute contagion to the common cold and differentiated this from certain noncontagious ailments (e.g., a scraped knee). As such, it is concluded that knowledge of the causes of illness is within the cognitive grasp of very young children, a finding offering support for the incorporation of causal knowledge into health education efforts for children even at the preschool level.

Subsequent to the acquisition of the knowledge that illness can be contagious, an understanding of the physical process by which this can occur must be developed by the child. Such an understanding typically takes the form of a germ theory. In a study of Scottish nursery children (3 to 5 years old), Wilkinson (1987) describes the early stages of children's understanding of the role of germs in the spread of disease. Initially, the child is unfamiliar with the word and often confuses *germ* with *bug*, and thereby *insect*, in addition to other terms ("I don't know what a germ is but I have heard of a German person."). Children view germs within their own magical and egocentric context ("Germs are not there all the time. They come when mummies go away."). They also attempt to draw on concrete experiences to explain what germs look like. Many children in Wilkinson's study stated that germs are blue and 1 to 9 inches in diameter, and although they had not seen one, they claimed "I think I will see one one day." Discussion with parents disclosed that the children were drawing these images from a television commercial for a cleaner wherein hidden imaginary blue germs were destroyed by the application of the product. Little understanding is seen at this age regarding how germs are transmitted or cause illness. One mother, attempting to have her son describe the nature of germs, inquired, "Why are you made to wash your hands before eating?" His reply illustrated his lack of comprehension: "So my plate doesn't get dirty."

Perrin and Gerrity (1981) found that by about 9 or 10 years of age, children generally believe that illness is caused by germs but still have little understanding of how this is accomplished once the germ is internalized. By about 12 or 13 years of age, illness is seen as the result of multiple causes; with this comes an appreciation of the role of host factors and the beginning of an understanding of the subtle interactions between host and agent in the causality of disease and the recovery from illness. It is therefore not until at least adolescence that the child can associate apparently unrelated symptoms (e.g., headache and rash) and view them as belonging to one illness and can identify and relate the various phases of an illness into a coherent progression of one disease process. During the formal operational period, children also develop an increased understanding of their bodies, which allows an appreciation of internal physiologic structures and functions that is demonstrated in the emergence of physiologic explanations for the causality of illness in early adolescence ( [Bibace and Walsh, 1980](#)). Only at this stage, with this improved understanding of internal physiology and the causality of illness, can the child be expected to comprehend many of the simplest treatment regimens that adults take for granted, such as the use of oral antibiotics to treat an ear infection or the use of injections of insulin in diabetes.

### IMPLICATIONS

Knowledge of what children understand about illness and its treatment at various stages of cognitive development has practical implications for child psychiatry consultations to clinicians. It provides a framework for offering guidance on how to approach discussions about illness and its treatment with children, both to advance their understanding and coping skills and to promote their attainment of an active role in the decision-making process for their health care. As children acquire increasing knowledge about the concepts related to illness and the cognitive skills to process this information, they become more able to report symptoms of illness accurately, to comply with the treatment regimens prescribed, to adjust to the illness and its treatment, and to make informed decisions regarding preventive health measures.

#### Child's Ability to Report Symptoms

Young children, with their immature understanding of disease processes, may fail to report important symptoms of serious illness. The reason may be, in part, a lack of sensitivity to the relevant internal cues and objective signs of even serious illness ( [Pidgeon, 1985](#)). However, even when children are aware of their symptoms, egocentrism and magical thinking may lead them to withhold this information from caregivers, and they may prefer instead to rely on internal mechanisms of dealing with the illness. They may assume that if they do not wish to be ill, then they will not be ill; they may worry that the mere vocalization of their concerns may be sufficient to bring their fears to reality. Children who persist with immanent justice explanations for the causality of illness may also be disinclined to voice their symptoms out of shame or fear of retribution. These issues are particularly relevant for children with chronic illnesses that require prompt recognition and management of often subtle internal symptoms, such as hypoglycemia in the child with diabetes.

#### Child's Compliance with Treatment

Attempts to communicate effectively with children about illness and its treatment also maximize efforts to enlist the child's cooperation in the treatment process. Such efforts should maintain as a long-term goal the child's attainment of an active role in the decision-making process in the child's own health care. In times of frustration, it is easy to lose sight of this goal, such as when a child with asthma is noncompliant with treatment and is warned, "If you don't take your medicine, you'll have to go to the emergency room and get a needle," but is not provided with a developmentally appropriate explanation of the treatment process. Parents need help in appreciating that such threats may yield temporary compliance, but at the expense of reinforcing maladaptive concepts of illness, that may, in the long run, lead to decreased compliance. This approach could be justifiable if it were shown that the concepts of illness were beyond the grasp of children and that illness in the child could be effectively prevented through compliance with recommendations. Both assumptions are incorrect. First, the preceding discussions illustrate that an understanding of the concepts of illness is possible even in very young children, if they are given appropriate explanations and are provided with constructive learning experiences. Second, even if children are able to comply fully with all the numerous restrictions and requirements placed on them by their parents in the hopes of preventing illness (e.g., to get enough sleep, to eat the right food, to dress correctly), many will still become ill. If the only explanations provided about the causality of illness reinforce immanent justice, then the child is left with no other recourse but to accept self-blame for personal illness. Hospitalization and increasingly invasive medical management, when required, are then not perceived as a result of the natural process of the disease but instead as a personal failure on the part of the child. The child believes that he or she has failed and is being punished; in addition to feeling ill and frightened, the child is now apt to feel angry and rejected. As one child remarked about his failure to be discharged from the hospital: "I did everything the doctors told me to do, and now they won't let me go home." He had been told in simple terms what he needed to do to get better, but he had not been given explanations that he could understand of how these procedures would influence his illness. After complying fully with the requirements placed on him and failing to become well and be discharged, he was understandably hurt and angry.

#### Child's Adjustment to Illness and the Treatment Process

Explanations for children about their illness and treatment should seek not only to achieve compliance but also to promote the child's understanding. The explanations should be presented in a manner that is consistent with the current level of understanding of the child or perhaps is slightly advanced ( [Bibace and Walsh, 1980](#); [Brewster, 1982](#)). These explanations should aim to replace frightening misconceptions and to supply constructive information in a manner that will promote coping and adjustment. This is, of course, an ongoing process. Children need to be questioned about their understanding of the explanations provided, thereby allowing the discussion to become a true dialogue. Vocabulary used should be simple and direct. Indeed, even adult patients misinterpret terminology at a rate that exceeds the expectations of most physicians. In one study of women attending a public health clinic, 80% of patients confused "anemia" with "enema," and more than 50% defined "well-nourished" as "nervous body" ( [Collins, 1955](#)).

When under stress, such as during an acute illness, children often regress in their developmental abilities and are least amenable to techniques to advance their developmental progress. Even in this setting, recognition of children's current level of functioning still has practical implications for efforts to restructure their thinking and provide support during the illness. For example, when one is constructing a plan to help control pain for a child in the preoperational period, the connection between the medication taken orally and the relief of the pain can be emphasized, but more concrete measures that will be reassuring to the child (e.g., application of a heating pad for abdominal pain) should also be employed. As much as possible, the use of intramuscular pain medication should be avoided, in view of the child's tendency to associate treatment with punishment and to fail to comprehend the logic of giving a painful intramuscular injection to treat abdominal pain. Moreover, when one is selecting the oral medication to be given, knowledge of the child's cognitive abilities regarding comprehension of quantity and number may have further practical implications; it may be preferable when the dose of pain medication is to be adjusted to give two 15-mg pills instead of one 30-mg pill, or to use an elixir instead, because of the even clearer concrete representation of increasing dose with increasing amount ( [Clark, 1985](#)). Appreciation of children's understanding of

their illness and its treatment and knowledge of their cognitive abilities can thereby provide guidance not only in the selection of explanations but also in the selection of the most appropriate techniques for the delivery of health care.

Research also has shown that, parallel to the process of conceptual development wherein children acquire an understanding of the causes of illness, children also develop increasing appreciation for the intent of medical procedures. Brewster (1982) describes three stages in this process: The child initially views the procedures as punishment, is subsequently able to understand the intent of the procedures but feels that the staff will be empathetic only if the child outwardly expresses pain, and, finally, is able to infer both empathy and intention. To enlist cooperation and to decrease anxiety and fear surrounding the procedures, children should be prepared for procedures with information and explanations that are consistent with their level of understanding of the relevant concepts. Preoperative teaching for the child in the preoperational period, for example, could focus on acquainting the child with what the concrete experiences will be (e.g., what the room will look like, who will be there), whereas preparation for the child in the formal operational period could also include a more detailed discussion of the procedure, including mention of anatomic and physiologic principles within the cognitive grasp of the more mature child ( [Perrin and Gerrity, 1981](#)).

Programs to prepare children psychologically for procedures have been shown to be effective in helping them to cope with the associated anxiety. Edwinston (1988) demonstrates that such programs are effective in reducing anxiety, even in the setting of emergency surgical procedures (e.g., acute appendectomy), when compared with standard, unstructured preoperative preparation. Research is also just beginning to demonstrate empirically that preparation programs for hospitalization and medical procedures that are consonant with the child's cognitive–developmental level are more effective in decreasing distress and anxiety in response to procedures when compared with preparations that are not designed with these concepts in mind ( [Rasnake and Linscheid, 1989](#)).

### Preventive Health Education for Children

Health education only at the time of illness or hospitalization may not be the most effective means of advancing the child's understanding of illness. During times of illness, as in other stressful periods, children often regress in their developmental abilities. At these times, they are least prepared to understand the situation confronting them and least able to benefit from educational efforts to promote this understanding, but most in need of this information to facilitate adjustment and successful coping. This observation provides a strong argument for the need to promote the acquisition of these concepts before they are needed to deal with acute crisis in the form of illness. Health education efforts, then, should begin when the child is well, with the aim of promoting increased understanding, knowledge, and skills in this area. Research has demonstrated that developmentally appropriate health education in elementary school can advance young children's conceptual understanding and factual knowledge of illness ( [Schonfeld et al., 1995](#)). Children should be taught to do more than “just say no” to bad health decisions; they should be helped to understand the rationale behind these choices and to acquire the skills to make informed and responsible health decisions that affect them in the future. For health education to be effective, it must be developmentally based, so discussions coincide with the child's level of understanding ( [Schonfeld, 2000](#)).

Physicians should use preventive health visits during the pediatric years to educate not only the parents but also the child. Unfortunately, research has shown that, during pediatric visits, the pediatrician spends little time talking directly to the child. In one study of children 4 to 7 years of age who were attending private pediatric practices for routine health maintenance visits or visits for minor illness, only about 5% of the discussion during these visits was directed by the physician toward the child. Interviews of the children after the visits illustrated that most of them desired more information about their medical problems; their concerns were well formed and relevant to the reason for the current visit, yet these concerns were not addressed by either the parent or physician. In fact, explanations about treatment and symptoms were not provided to the children in this setting, and the children were treated instead as passive recipients of health care ( [Perlman and Abramovitch, 1987](#)).

Other studies have shown similarly low rates of communication between physicians and pediatric patients. This is unfortunate, because children are interested in clinical information even at a young age and are capable of comprehending the information if it is presented in an appropriate manner. Pediatricians should take advantage of this opportunity to advance the child's understanding of the concepts of physical illness in a salient and relevant context—that of the child's own medical visit. One reason for this oversight may relate to the observation that pediatricians, and other health care professionals who work with children, are unfamiliar with the developmental stages of children's understanding of illness: “Professionals do not operate with an intuitive sense about cognitive development. . . . They lack an understanding of the important qualitative differences in the very basic ways in which children at different stages of development see, interpret, and understand the world around them” ( [Perrin and Perrin, 1983](#)). One study ( [Lewis et al., 1991](#)) demonstrated that a brief educational intervention targeted to 5- to 15-year-old children, parents, and physicians enhanced physician–child communication and rapport during pediatric office visits and allowed children to take a more active and effective role in their health care.

### CONCLUDING REMARKS

The focus of this chapter has been on the cognitive process by which children develop an understanding of their illness and treatment and on the implications of this for health care professionals. Such a cognitive–developmental approach to viewing the child's understanding of illness is not in conflict with other theories that aim to explain the child's psychological reaction and behavioral response to the illness experience. Conscious understanding (cognitive factors) is only one component of the child's response to illness. Unconscious developmental fantasies, too, may alter the child's perceptions of the illness and treatment process, despite the presence of mature cognitive abilities. For example, a fear of surgery may be heightened by underlying castration anxiety ( [Lewis, 1982](#)). Even adolescents who have reached the formal operational stage of cognitive development may still be overwhelmed by anxiety from unconscious developmental conflicts. These conflicts may distort their perceptions and may result in misconceptions and fears out of proportion to what would be predicted by a purely cognitive–developmental approach. An integrated approach to viewing the ill child that incorporates both the child's cognitive abilities and an appreciation of the psychological factors pertinent to his or her personality development is therefore likely to yield the most insight into the complex process by which the child comes to understand, accept, and respond to both the illness and treatment process.

Subsequent chapters highlight the child's unique response to specific illnesses and components of the treatment process, such as hospitalization and surgery. An increased appreciation of the stages of children's understanding of illness will allow the physician to communicate more effectively with children, to improve their medical care, to minimize their anxiety and fear, and to promote their adjustment to illness and its treatment. Health care professionals will thus be able to assist the children to acquire the requisite skills to become increasingly active and effective partners in their health care management.

As child psychiatrists have become more involved with infants, toddlers, and their families, they are often asked to consult when a child is medically compromised. These consultations involve assessment of the child, the family, and often the medical care system responding to the child's illness. Conditions such as prematurity, birth defects, and/or serious genetic malformations are accompanied by profound psychological disturbances in the child, family, or both; these psychological disruptions contribute to the family's and child's recovery or continued psychological debilitation. In the instance of early childhood death, the impact on the family and subsequent children may be pervasive and long lasting. In this chapter, we review the role of child psychiatrists in three situations—preterm birth, birth defects, and sudden infant death. We discuss the instance of preterm birth in greatest detail, with the understanding that many of the clinical issues a child psychiatrist encounters in that situation are also applicable to birth defects and infant death.

## HISTORICAL NOTE

Although the topics discussed in this chapter represent forms of family crises experienced since the dawn of humanity, the child and adolescent psychiatric literature was relatively sparse in these areas until approximately 30 years ago. Prior relevant literature appeared in the early 20th century, when the topic of loss and its psychological implications was discussed by [Freud \(1957a\)](#) in the classic paper, "Mourning and Melancholia." Although Freud used normative mourning in order to understand the more pathologic state of melancholia, his interest appears to have legitimized the normative experience as an area for further study. It was not until the 1940s, however, that a formal descriptive study appeared in the literature. In 1944 Erich Lindemann and colleagues reported on studies of acute traumatic loss in families who had lost a close relative in the catastrophic "Coconut Grove" fire in Boston. In one case vignette unrelated to the fire, they alluded to mothers of infants who had died being especially vulnerable to severe grief reactions. Many of the victims in this study were very young servicemen and their escorts and might therefore be considered to be late adolescents.

In the 1950s child and adolescent psychiatrists began more specific inquiries into the stresses of prematurity as a family crisis. Dane Prugh, one of the first consultation-liaison child psychiatrists, published in 1953 an anecdotal and theoretical article on parents and premature infants. Slightly later, Gerald Caplan, the founder of community psychiatry, and associates studied families with premature infants as a paradigm for acute stress in normative families ([Caplan et al., 1965](#)). Prematurity was one reason for early infant loss; crib death was another. The term sudden infant death syndrome (SIDS) was not present in the medical nomenclature until the 1970s. Furthermore, although the term crib death had been used in the pediatric literature, no family studies were conducted, most likely because these families were inaccessible at the time. Instead, efforts were directed toward parents with children dying in the hospital ([Solnit and Green, 1959](#)). In 1961, Solnit and Stark directed their attention to parents of children with birth defects, particularly retarded children. All of these early papers were primarily descriptive and anecdotal in nature, with theoretical postulates and management approaches being suggested. It was not until the mid-1960s that formal studies of significant numbers of parents began to appear in the literature.

In 1963, Friedman and associates studied prospectively the parents of 27 children admitted to the National Cancer Institute and followed the parents' adaptation to their child's illness irrespective of the course of illness ([Friedman et al., 1963a](#)). Special emphasis was placed on families whose children died; measurement of corticosteroids in the parents' urine was used during the study for the first time to document the biological effects of chronic stress ([Friedman et al., 1963b](#)). These studies can be said to have ushered in the modern era of family studies of a more specific nature, which have produced management techniques in dealing with parents in the premature intensive care unit, general hospital unit, and at home. Also, as the care of preterm and/or very sick infants and young children has advanced technologically, child psychiatrists are called on to act therapeutically at the interface between complex medical systems and parents' psychological reactions and adjustments to such systems.

## THE FAMILY AND PREMATURE BIRTH

### Early Studies and Crisis Theory

The premature birth of a baby has been viewed historically in psychiatry as a crisis for the family as a whole. The crisis has been described as a period of normative emotional disequilibrium, during which individuals demonstrate symptoms resembling psychopathology ([Caplan, 1960](#); [Caplan et al., 1965](#); [Friedman et al., 1963b](#); [Kaplan and Mason, 1960](#)). Early authors, such as [Prugh \(1953\)](#), highlighted the mother's emotional responses to the baby, staff caregivers, and family members. He pointed out that the complex psychological reactions on the part of the mother included anxiety (particularly related to lack of confidence as a caretaker), guilt about the prematurity, resentment and disgust toward the baby, and competition and jealousy toward the nursing staff. Furthermore, Prugh described an "emotional lag" or period of alienation on the part of the mother during the first few days, as well as an occasional tendency to overprotect. Suggested interventions included early contact with the baby, provision of information, encouragement of emotional expression, involvement of the father and other family members, and discussion groups of mothers on the ward.

Caplan, in another early description in the literature, studied 30 cases of prematurity ([Caplan, 1960](#)). He depicted "healthy" and "unhealthy" outcomes based on the mother's sensitivity to the infant's needs, her respect for and satisfaction of these needs, and the maintenance of other family relationships. Caplan related the patterns of parental response to their cognitive grasp of the situation, handling of associated feelings, and seeking of help.

[Kaplan and Mason \(1960\)](#) presented the hypothesis that maternal reactions to the stress of the premature birth, although expected and normative, are usefully described as acute emotional disorders. Unique psychological tasks related to the prematurity were enumerated sequentially. The first task included preparation for the possible loss of the child ("anticipatory grief"). The second task related to the mother's failure to deliver a normal full-term baby. (They noted that the first two tasks were often associated with grief and depression.) The third task was the resumption of the process of relating to the baby, which had been interrupted by the

premature birth. The fourth task related to the mother's understanding and attention to the baby's special needs and growth patterns. These authors further described pathologic deviations from the normative accomplishment of the tasks. These included maladaptive denial and failure to respond positively to the progress of the baby.

In a pivotal integrative paper, [Caplan and colleagues \(1965\)](#) described patterns of parental response to the crisis of prematurity. They defined the crisis state as analogous to [Lindemann's \(1944\)](#) classical description of bereavement. Caplan and coworkers more fully elaborated "healthy" and "unhealthy" adaptations to the premature birth. For instance, they questioned whether the parents continuously attempted to gather information about the baby. Did they acknowledge ambivalent feelings about the premature baby, with accompanying verbal and nonverbal expression? Was there an active seeking of help for the family, related to the child's special needs and the need of the parents for emotional expression?

### Development and Bonding

Somewhat later, there appeared many articles in the literature relating to the associations among premature birth, neonatal complications, developmental difficulties, and subsequent problems with bonding between the mother and baby. Several authors postulated a link between dysfunction in bonding and later potential for abuse and/or neglect ([Elmer and Gregg, 1967](#); [Hunter et al., 1978](#); [Klein and Stern, 1971](#)). This association has remained controversial and was not confirmed by other investigators ([Minde, 1980](#); [Steele and Pollock, 1974](#)). Several researchers describe the behavioral and interactional difficulties that preterm babies have during the first years of life ([Als, 1981](#); [Als and Brazelton, 1981](#)). They and others also presented the difficulties parents have in engaging the attention of their babies ([Als, 1981](#); [Als and Brazelton, 1981](#); [Brown and Bakeman, 1980](#); [Field, 1979](#)).

[Minde and colleagues \(1983\)](#), in a well-controlled study of 184 low birth weight infants in a neonatal intensive care unit, demonstrated that parents of "sick infants" interacted far less with them than parents of well babies. Furthermore, they found that this pattern continued at home after discharge from the hospital. [Bidder and associates \(1974\)](#), comparing mothers' attitudes to their preterm and term babies, found that the mothers perceived the preterm baby to be "weaker" than the term babies. They highlighted two specific periods of particular anxiety for the mother: immediately after the birth and when the baby goes home.

[Jeffcoate and colleagues \(1979\)](#) compared attitudes of parents of preterm infants to those of parents of full-term infants. They found that there was evidence of some disturbance in parent-child relationships in the preterm group. This consisted of delays in maternal attachment, negative maternal perception, and continuing parental anxiety about caretakers. Two of their sample of preterm infants had been abused or neglected. Jeffcoate and colleagues emphasized the need for ongoing psychological support for these parents.

[Silcock \(1984\)](#) utilized the previously mentioned four-task framework of Caplan and coworkers to investigate the intensity of maternal experience of these tasks, mothers' success in dealing with them, and the relationship between successful task completion and later mother-infant interaction. The author studied 24 mothers of preterm infants and found that the ability to cope with the crisis was correlated with better mother-infant relationship at 1 month and 4 months of age. She also ascertained that the degree of intensity of emotion accompanying each task varied widely among the mothers and related to individual prior life experience. [Macey and colleagues \(1987\)](#) reported that mothers of preterm infants felt overprotection toward them, were apprehensive about surrogate caretakers, and believed the baby's birth had had an initially negative effect on the family. These authors also noted that preterm infants demonstrated less exploratory play and stayed close to their mothers while at play.

### Demographic Characteristics of Prematurity and Acute Hospital Care

Approximately 10% of all newborn infants are born at a gestational age less than 37 weeks and between 1% and 2% of infants are born at a birthweight of less than 1,500 grams ([Goldberg and DiVitto, 1995](#)). Between 80% and 85% of infants weighing 1,000 to 1,500 grams at birth, but only 50% to 60% of infants less than 1,000 grams, survive the perinatal period ([Pharoah and Alberman, 1990](#)). Preterm births are also now more common among families with limited resources and much increased among single, young mothers with little to no prenatal care. These factors define not only a postnatal (or postnursery) environment of risk but also describe families who have few psychological as well as physical resources to deal with the crisis of a preterm infant's birth and subsequent care needs.

The severely preterm infant may be hospitalized for several weeks to months. Longer hospitalizations exact greater psychological tolls from parents and siblings as their daily lives are rearranged for several months to encompass the infant's hospital stay. Also, although it is rarely written about ([Mayes, 1995](#)), longer lengths of stay for preterm infants exact a cost from nursery staff as well and the impact on nursery staff affects how much they are available to parents. Both nurses and physicians become more deeply involved with an individual infant and family and must repeatedly work through the infant's multiple medical crises, debilitating complications that are sometimes fatal, and the infant's eventual discharge to someone else's care. As the infant improves, nurses begin to play, talk, and hold the baby beyond the requirements of routine medical care ([Corter et al., 1978](#)). These greater demands on forming, remodeling, and mourning personal attachments also occur in the context of multiple acute, life and death crises that are the daily substance of an intensive care nursery. Thus, psychological processes that require time and reflection are evolving in an atmosphere of urgency and a compressed sense of time. These disjunctions between psychological time and the urgent, crisis-colored time frame of the infant's acute illnesses are equally powerful for parents and shape certain aspects of their later relationship with their infant ([Mayes, 1995](#)). At the very least, for many parents, they find themselves always feeling vigilant and crisis-ready, even years later as their infant boy becomes an active, athletic, bright teenager. In addition to long hospitalizations with the attendant stresses on family functioning, very low birthweight preterm infants are at greater risk for acute medical complications that often carry severe risks for neurologic and physical sequelae. These include intraventricular hemorrhage, necrotizing enterocolitis, and cardiopulmonary complications. Not only do these prolong an infant's hospitalization and increase the risk for later neurodevelopmental compromise, but they also define acutely life-threatening conditions that further lead to the sense of fragility and uncertainty surrounding the preterm infant. Recurrent threats to survival pose recurrent threats to the ability of parents to make a place for their very sick infant in their lives and to construct within their inner object world even a nascent sense of the child as a part of them and their family. Mourning and "letting go" conflict with forming attachments and "taking in," as occurs in the birth of a full-term, healthy infant.

The neonatal intensive care unit is also like no other place parents or their other children might encounter. The primary goal of the unit is to ensure the physical well being of the infant by whatever means necessary, and this often involves highly sophisticated mechanical technology. Many studies document the relatively high noise and lighting levels, the large number of adults, frequent painful, stressful procedures for the infant, and the lack of relation between the infant's behavior and environmental structure or events ([Goldberg and DiVitto, 1995](#)). For example, the need to monitor the infant's physiologic status continuously precludes altering levels of light or sound to approximate a day-night cycle, as would occur for a term infant. Additionally, preterm infants may be more sensitive to levels of environmental stimulation and thus more easily overwhelmed by standard nursery environments than term infants ([Thoman, 1993](#)). Indeed, the extent to which nursery conditions affect long-term development is not at all clear, and it is very difficult to separate potential effects of the environment or interventions from the medical condition that necessitates them. In any case, the neonatal intensive care environment is surely stressful and often overwhelming for parents and is continuously functioning at a level of intensity and vigilance found in few other environments caring for infants and young children.

### Parenting and the Preterm Nursery Experience

The nursery experience and interventions required to medically support a preterm infant often stress and in some instances severely compromise the development of expected parent-infant relations. Traditionally, as medical expertise in intervening with and caring for the very preterm infant improves and technology becomes more advanced, families are more often separated from their infants during the most acute phases of their hospitalization. In the early 1960s, neonatal intensive care units stressed maintenance of a sterile environment to prevent infection and parents were often excluded. Furthermore, parents often felt overwhelmed and frightened by the sophisticated technology designed to support the infant and were sometimes more likely to stay at a distance. Their reluctance to approach the baby was given functional credence also by the prevailing wisdom of that era that touching and handling the preterm infant was stressful and only medical procedures should be allowed, with touching or caressing kept to a minimum.

Policies such as these began to change in the 1970s when careful studies revealed no increase in infection rates after parents were allowed in the nursery ([Barnett et al., 1970](#)). Parents were encouraged to visit their infants, and these shifts in nursery policies have generated a number of studies on the effects of holding, massage, and skin-to-skin contact on the immediate status of the infant ([Field, 1990](#); [Goldberg and DiVitto, 1983](#); [Goldson, 1992](#)). As these physical barriers were removed, more psychological interventions for parents also were instituted, including direct involvement in the infant's care, areas within the nursery for parents to be alone with their infant, and therapeutic groups for families with infants in the intensive care unit. Liberalized contact between family members and the baby has become routine in the vast majority of special care nurseries. As a result of such increased access, several authors have maintained that the emphasis of concern on the part of the mother has shifted from her own feeling of psychological loss to the outcome for the baby ([Pederson et al., 1987](#)). How these types of liberalized interventions impact on later parenting after the infant is discharged from the nursery has not been systematically studied, but at least acutely in the nursery, more direct parent involvement potentially increases parental self-confidence and self-esteem and likely impacts on the early formation of internal working models and attachment

patterns between parents and infants.

Many writers have alluded to the significance of networks of social and emotional support to aid parents who are dealing with a preterm birth crisis ( [Bidder et al., 1974](#); [Blackburn and Lowen, 1986](#); [Fox and Feiring, 1985](#); [Pasco and Earp, 1984](#); [Prugh, 1953](#)). [Pederson and associates \(1987\)](#), utilizing an interview format, confirmed the continuing need for such a supportive network to aid the mother in particular with the ongoing stress of caring for the infant. They reported that husbands, parents, and members of church were viewed as the major sources of ongoing support. Several authors ( [Leifer et al., 1972](#); [Trause and Kramer, 1983](#)) have also investigated the stresses a premature infant places on the marital unit. [Leifer and associates \(1972\)](#) showed that parents of such an infant are at increased risk for divorce; however, this finding was not confirmed by another clinical investigation ( [Boyle et al., 1977](#)). [Trause and Kramer \(1983\)](#) evaluated a middle-income group of parents of premature infants in comparison with a group of parents of healthy full-term infants. They found that the premature birth caused a crisis in the immediate postpartum period, but the stress decreased significantly after discharge home. With time, parents of preterm infants reported themselves to be "more attuned to each other" than parents of full-term infants. They also found that mothers in both groups consistently rated themselves as more distressed than fathers.

Blackburn and Lowen examined the impact of premature birth on grandparents (1986). Referring to the grandparents as the "forgotten grievers." In a retrospective exploratory study, they ascertained that grandparents experienced intense stress as well as parents. The stress was exacerbated by the fact that the grandparents, lacking direct access to physicians, were forced to rely on the distressed parents as their sources of information about the infant. In a study of mothers of preterm versus full-term infants, [Crnic and associates \(1983\)](#) confirmed the positive effects of social network support on lowering overall stress and increasing positive parenting interactive behaviors. [Beckman and Pokorni \(1988\)](#) recently reported that stresses related to preterm birth are specific but also change over time. They found that lowered levels of stress were associated with the continuity of informal, intimate environmental support. Although of significant clinical interest, the majority of these studies of network support suffer from small sample size and lack of adequate control groups.

In addition to the stressors of the nursery experience itself, there are the psychological effects of delivering an infant before term. During pregnancy, parents undergo a complex psychological reorganization as they form expectations and fantasies about their growing infant ( [Leckman et al., 1999](#)). They prepare themselves, and late in the pregnancy their physical surroundings, to meet their new infant. For mothers, these processes take vivid shape as fetal movement becomes more regular and active. Preterm births interrupt these normal developmental processes and for the very preterm infant, the birth may occur just a few weeks after the mother begins to appreciate movement. Parents' expectations and fantasies about when their baby will arrive and about a normal delivery with a healthy, full-term infant are shattered by a preterm delivery. As they adjust to the disappointment, they must also face their fears for the infant's life and reorient their views of their future and the infant's future ( [Pedersson et al., 1987](#); [Zeanah et al., 1984](#)). There is also the added stress and disappointment that they cannot care for their new baby on their own, and they are often, at least acutely, separated from their infant as he or she is moved to another hospital with the appropriate level of technical support needed to care for the infant. Instead of imagining joyfully bringing their infant home to friends and families, they are confronted with the uncertainty of a prolonged hospitalization, potentially fatal complications, or at least compromising sequelae and are often left isolated from their usual social supports ( [Jeffcoate et al., 1979](#)).

When the time comes for the preterm baby to go home, parents who for weeks or months have watched professionals care for their infant may be frightened and intimidated by the responsibility of caring for an infant who still seems fragile and vulnerable ( [Mayes, 1995](#)). Families are abruptly isolated from the psychological support of hospital staff and other families. Although many nurseries now make ongoing parent groups available after discharge, more systematic study of the effectiveness of these types of interventions and involvement of child psychiatrists are needed. [Minde and colleagues \(1983\)](#) demonstrated that mothers of preterm infants who participated in a self-help group were more comfortable encouraging autonomy and sociability in their infants and overall more confident in their caregiving roles.

It has often been observed that mothers of preterm infants express continued anxiety and low confidence in their caregiving competence during at least the first year of their infant's life ( [Corter and Minde, 1987](#); [Crnic et al., 1983](#)). Preterm infants are often difficult to care for and many of the apparent alterations in parenting behaviors seen among parents of preterm infants may reflect the preterm infant's altered state regulatory patterns and potentially slower information processing times ( [Mayes, 1995](#)). Limits in the perceptual and cognitive skills of preterm infants may also modify the impact of parent behaviors on the preterm infant. [Field \(1982\)](#) conceptualized the preterm infant as having a relatively high threshold to adult social stimulation coupled with a low tolerance for stimulation. In response to the differences in stimulation tolerance and perceptual and cognitive skills, mothers of preterm infants appear to take a more active role than mothers of term infants, indeed almost to appear overstimulating ( [Minde, 1993](#)). They direct attention more, hold and touch more, and provide more tactile and kinesthetic stimulation ( [Barnard et al., 1984](#); [Crnic et al., 1983](#); [Field, 1979](#)). These strategies in parental activity increase the amount of mutual gaze between mother and infant and, in effect, structure the infant's attention ( [Goldberg and DiVitto, 1995](#)). In turn, differences in parental activity also influence preterm infants' performances on novelty preference and exploration tasks ( [Landry, 1986](#); [Landry et al., 1986](#); [Rose, 1980](#); [Ruff, 1986](#)).

### **Child Psychiatric Consultation in the Intensive Care Unit**

In the literature there is overwhelming agreement among authors about the type and frequency of psychosocial intervention that are most constructive for the families of premature infants. Liberal access to the babies by family members is desirable, particularly in light of technological advances in neonatal intensive care units that otherwise tend to isolate babies for extended periods of time. [Harper and colleagues \(1976\)](#), in a retrospective questionnaire format study of 58 families, determined that perceived parental anxiety correlated with the degree of the infant's illness. However, despite the associated anxiety the parents felt at the time, parents did maintain much contact with the infants and would have been opposed to more restricted contact. They noted that even parents of babies who died expressed no regrets about the time spent with the infant in the intensive care unit.

Child psychiatric involvement in the intensive care nursery (or, for that matter, on a pediatric inpatient service for infants and toddlers) may occur on at least three levels ( [Mayes, 1995](#)). The most traditional is direct involvement with the infant and his or her parents. The second involves consultation to the staff of a nursery or medical unit who are involved in the care of that infant and family. The third level consists of more general and long-term consultation to the nursery to effect changes in nursery policy and standards of care that directly and indirectly impact on parents and families. These changes may consist of interventions for families (e.g., assigning a mental health professional to each family on admission to the nursery), alterations in nursery routines in ways potentially more appropriate for the infant's developmental needs (e.g., alterations in the amount of sensory stimulation), and organizing parent groups for families during their nursery stay. The work in each of these areas may be done by a child psychiatrist who is a regular part of the nursery team (a model available in only a few nurseries) or a clinician who has special training in issues of infancy and preschool-aged children and regularly does consultation-liaison work with pediatric wards and nurseries. The more the clinician is familiar with nursery routines, knows the staff, and is a familiar presence in the nursery environment, the more likely it is not only that he or she will be consulted but also that the consultative work will be effective. Each intensive care nursery has its own individual ecology and structure that markedly influences how families and staff interact. Understanding these individual system differences is critical for understanding how best to help families and medical personnel. Participating in nursery activities may include joining in regular medical rounds, staff rounds, or psychosocial rounds, or offering regular in-service conferences. Also, the more mental health clinicians are present on a day-to-day basis in the nursery, the more likely they will be to see families coming at unusual or irregular hours and the more comfortable families will feel in approaching the clinician.

Direct work with infants and their families in the intensive care nursery is usually requested because of concerns about the parent's reaction or adjustment to the infant's condition. Rarely do parents themselves request such consultation. More often, staff or concerned family physicians request additional support for the family. Child psychiatrists are able to evaluate the severity of parental depression and limitation owing to anxiety that may be both acute and chronic and develop a therapeutic plan before the infant is discharged to the parent's care. For parents with preexisting affective disorders, this is particularly critical given the increased stress created when preterm infants are discharged from the hospital.

Child psychiatric consultation in the nursery may involve several different approaches. Most often in the acute phases of the preterm infant's nursery course, neurodevelopmental assessments are neither indicated nor warranted. But the child psychiatrist's appreciation of the level of neurodevelopmental competency of a preterm infant at a given gestational age may be used as an intervention with the parents. For example, knowing that infants as young as 32 weeks respond differentially to voices or touch may be used to help parents feel like they can contribute something to their infant's care, and that their presence is important. Interventions such as these grounded in understanding of early neurologic integrity may also be the beginning of helping parents start to build an internal view of their infant as a person with awareness and an individual identity. Additionally, as already outlined, parents with a preterm infant have had an essential developmental process for their role as a parent abruptly interrupted. Child psychiatrists working with families bring an appreciation of the psychobiologic importance for parents of the third trimester of pregnancy, which they will not experience with a preterm birth. Because many parents who give birth to premature babies have had previous miscarriages or other serious obstetric complications, they may be especially sensitized to the threat of loss of their infant. They may experience acute depression and withdrawal that requires intensive individual intervention for one parent or both. The child psychiatrist also is able to help parents understand their feelings and actions and help them feel less out of control.

Child psychiatrists also may be asked to consult about the older siblings in the family whose lives are acutely affected by the loss of their parents, when one or both

are in the nursery, and by the disruption in daily routines. Siblings have recently been permitted as visitors in a number of nurseries ( [Ballard et al., 1984](#)), but their reactions to the disruption in the family have been less systematically studied. Younger siblings may experience acute changes in eating or sleeping patterns, withdraw, or become more irritable and difficult. Older children may have more trouble in school, resist leaving their parents, and also withdraw from peer groups or usual activities.

Child psychiatric consultations to the nursery staff may also be about and for the parents. Nursery staff may be helped to understand an individual parent's response that they have found anxiety provoking or excessively frustrating. For example, the parent who requests to know the exact respirator settings, values of the last blood oxygen level, and the amount of fluid intake is likely attempting to maintain a form of control over a debilitating sense of uncertainty and the unknown. But such strategies often run counter to the routines of any medical unit and an implicit philosophy of protecting parents from the weight of technical details. Similarly, the parent who anxiously refuses to touch or hold the baby may also make nursery personnel uncomfortable and worried about the parent's capacity to care for the baby. The staff's insistent efforts to bring the parent and baby closer may be met with increasing resistance and perhaps avoidance of the nursery altogether. In these instances, the child psychiatrist's initial task is not to help the parent be in contact with the baby but rather to understand what the baby means to the parent and what he or she imagines it will be like to care for the infant. The essential challenge of this type of individual work with parents of infants in an intensive care nursery is that it has to be done in an atmosphere that conveys time for reflection against the backdrop of the urgency and life-and-death nature of the nursery. The child psychiatrist may begin his or her interview with a parent of an infant while standing by the infant's bed. New admissions and emergencies may be going on around the family and clinician and become also the context of the interview. It is important that the consulting clinicians be familiar enough with the nursery environment that they are not initially overwhelmed, but also so that they can stay in touch with the experience from the perspective of the parent struggling to accept his or her infant.

Consulting to the staff of the nursery involves not only case management around the work with a particular family but also consultation to the staff around their own reaction to a particular infant. Nursery staffs often develop deep attachments to an infant and family and need support when it is time for the infant to go home. These issues become even more critical when the infant is going home to a high-risk environment such as a single parent or a family affected by substance abuse. In these instances, nursery personnel may feel extraordinarily protective and unable to let the infant go. Careful group work and consultation in the days before discharge may be effective in both allowing the staff to move on and also helping them to facilitate the family's taking over the care of the infant. Also, in high-risk situations, the child psychiatrist can be influential in helping with discharge planning that includes family support services, immediate referrals to early intervention services for the infant, and detailed plans for follow-up developmental assessments.

## **BIRTH DEFECTS AND THE FAMILY**

### **History and Special Considerations**

The birth of a child with congenital abnormalities presents the family with a severe crisis that shares some features of a premature birth but has specific characteristics of its own. Although there is usually less uncertainty about the survival of the child compared to the situation of premature birth, the defective baby's birth is generally associated with mourning over the loss of the expected child ( [Solnit and Stark, 1961](#)). In addition, continuing conflicts surrounding the appearance of the baby, and the difficulties of physical care of the deformed child complicate the family crisis as well. The societal stigma often associated with physically defective children is a continuing issue for the parents and siblings and must be considered in planning psychosocial intervention strategies.

Descriptions of family adaptation to the birth of an infant with congenital abnormalities began appearing in the literature in the 1950s and 1960s. [Schonell and Watts \(1957\)](#) wrote about the effects of a "subnormal child" on the family unit. This early report from Australia, focusing on a heterogeneous group of retarded children, documented the frustration experienced by, and lack of information and psychosocial supports provided to, parents who were attempting to rear their children at home.

In their paper on the crisis of the birth of a child with congenital abnormalities, [Solnit and Stark \(1961\)](#) referred to the acute grief reaction originally described by [Lindemann \(1944\)](#). They referred to the initial shock, denial, and sense of disequilibrium observed in these families. In addition, they utilized a "theoretical approach founded on the psychoanalytic explanation of the process of mourning as applied to the mother's reactions to the birth of a defective child" ( [Solnit and Stark, 1961](#)). Referring to the original descriptions by Freud ( [1957a,b, 1961](#)), and later by [Engel \(1961\)](#), Solnit and Stark explained the mother's psychological reaction as relating to the loss of the image of the expected baby. During the pregnancy, the mother's normative anticipatory process of expecting a healthy baby is acutely interrupted by the birth of a child with congenital abnormalities and possibly disabilities. Furthermore, her reaction is influenced by her own past experiences with family members and significant life events. Solnit and Stark suggested that because of the acute crisis, there is no time for the mother to work through the loss of the expected child before there is a demand to bond to the ambivalently viewed new baby. Although the emphasis of these authors was focused on the mother's emotional reactions, their advice was to clarify continuously to both parents the situation and needs of the new infant. They also strongly suggested that the mother view the new child as soon as possible, a step that had often been omitted based on a well-intentioned attempt to spare the mother pain.

### **Family Stress in Relation to Specific Birth Defects**

An early description of the psychosocial sequelae of the birth of a child with birth defects was by [Tisza and Gumpertz \(1962\)](#), writing about infants with cleft palate. They described parents who, after experiencing the initial shock and disbelief components of acute grief, became obsessed with etiology (e.g., genetic linkages, which are associated with guilt). They emphasized the need for early imparting of information about the baby to the parents, preferably by the physicians, who should be available to answer the variety of questions posed. They described occasional pathologic attachment between mother and child, based on the mother's viewing the child as an extension of herself.

Recent studies have studied the adaptation of parents to a disabled infant in relation to the type of disability presented. [Pelchat and associates \(1999a\)](#), utilizing a self-report questionnaire, indicated that parents of infants with Down's syndrome and congenital heart disease reported greater levels of parenting stress and psychological distress than parents of children with cleft lip and palate. They also found mothers to report greater levels of distress overall, but differences across diagnostic groups were similar for mothers and fathers.

In Wales, [Hare and associates \(1966\)](#) studied family stress in relation to an infant born with spina bifida via the use of a prospective interview format. Many of the parents reported that the medical staff did not seem to appreciate their initial worries and concerns. The study pointed to the fact that many mothers were unable to comprehend much of what was explained to them soon after the delivery. The parents also expressed a keen interest in meeting with other parents of children with spina bifida.

[Walker and associates \(1971\)](#), in a prospective questionnaire study of 107 British families of infants with spina bifida, reported the parents' dissatisfaction with the manner in which they were informed about the abnormality. The parents complained of chronic tension in the home, difficulties with siblings, and a sense of isolation because of the arrival of the baby. Walker and associates suggested to physicians that a psychosocial team closely monitor these at-risk families.

Very few investigators have applied a psychoanalytic point of view to the issue of birth defects and parental reaction. [Lax \(1972\)](#), in an anecdotal report of only a few patients, described the mother's "narcissistic trauma" in relation to the arrival of the impaired child. Interestingly, she noted that the severity of the mother's depressive reaction often was unrelated to the magnitude of the birth defect ( [Lax, 1972](#)). Lax emphasized preexisting personality features in the mother as clinical clues to her adaptation and acceptance of an impaired child. She presented a dramatic illustration of the rejection by the mother of a newborn with a large nevus of the cheek: "On seeing the child for the first time, the mother turned away and said: 'She's ugly—it can't be a two-faced monster' (referring to the normal side of the child's face and the deformed one)" ( [Lax, 1972](#), p. 341).

### **Studies of Heterogeneous Defects**

[Johns \(1971\)](#), in an Australian study, performed a prospective 6-month investigation of 12 consecutive infants born with a congenital abnormality. Initially and subsequent reactions of the mothers and family were observed. Johns found that parents of children with more visible or more severe defects were the most anxious and accessible to offers of psychological help. Facially disfiguring lesions were of particular concern to the parents. The author suggested an early but brief announcement to the parents of the abnormal finding, an early statement of the plan to correct the deformity, ready access to genetic counseling, and continuing emotional monitoring and support.

[Drotar and associates \(1975\)](#) reported a large sample of parents of 20 children with a wide range of malformations. The malformations included Down's syndrome, cleft palate, and congenital heart disease. They arranged structured interviews after the birth of the child (elapsed time ranged from 7 days to 5 years). They

emphasized the more adaptive elements in the coping of these parents, which had previously been largely overlooked. Successive stages of parental reactions were outlined by this group as components of a normative pattern; shock; denial (feelings of unreality); a mixture of sadness, anger, and anxiety; eventual adaptation; and reorganization. According to Drotar and colleagues, mixtures of sadness, rejection, hatred, and fears of becoming attached to babies who might die were often seen in the middle phases of coping. The last stage, reorganization, included positive long-term acceptance of the child with mutual support between parents. These investigators emphasized the importance of early physical contact (bonding) with the child, referring to earlier work by [Klaus and Kennell \(1970\)](#). They maintained that the early initiation of a relationship, specifically through physical care, served as a major means of anxiety reduction in the parents.

Recently, in a study of predictors of parental distress after the birth of a child with congenital disabilities (including cerebral palsy, spina bifida, and limb deformities), it was found that families with adaptive distribution of responsibilities, including domestic tasks and unrelated life stressors, were at less risk for dysfunctional distress ([Wiegner and Donders, 2000](#)).

Many of the descriptive studies noted in the preceding, although clinically rich in detail, generally lack relevant control groups and large sample size of subjects.

### Effect on the Marital Relationship and Siblings

Several clinical investigators have studied the significant effects of the arrival of a child with a birth defect on the marital relationship. [Tew and associates \(1974\)](#), utilizing a prospective interview format, were the first researchers to note significant deterioration in the couple bond after the birth of an atypical child. The divorce rate of the index parents (of offspring with spina bifida) was twice that of the control group and the national average (in Wales). Only one-fourth of the index families appeared to be free of marital difficulties; mothers pregnant at the time of the marriage appeared to be at the greatest risk for divorce or separation subsequent to the birth. [Martin \(1975\)](#), in a slightly later study, also documented a high rate of marital breakdown in families of babies with spina bifida.

[Drotar and associates \(1975\)](#) underlined the importance of synchrony between the parents and their reactions. Parents who were viewed to be “out of synch” with each other were more prone to emotional separation coinciding with the stresses on the family of such a child.

[Gath \(1977\)](#) reported on a prospective controlled study of 30 families of infants with Down's syndrome. This author found few differences in the mental or physical health of the two groups of parents, but marital rupture or severe disharmony was found in nine of the families with a child with Down's syndrome and in none of the controls.

Little work has been presented in the literature regarding the specific reactions of siblings to the arrival and presence of a child with birth defects and/or physical handicaps. In a clinically descriptive case study, [Poznanski \(1969\)](#) pointed to the resolution of stress and conflict in the family through displacement onto a “well” sibling. The author pointed to the frequent overinvolvement on the part of the mother with the handicapped child, and her lack of sensitivity to the more subtle needs of the other siblings. According to Poznanski, this constellation of dynamics often led to “behavioral reactions as a consequence of emotional neglect.”

In a more recent longitudinal study, [Fisman and associates \(2000\)](#) reported that of 137 normal siblings of children with Down syndrome, Pervasive Developmental Disorder, and a normal control group, significantly more adjustment problems were found in the sibs of children with Pervasive Developmental Disorder when compared with the others.

Several investigators have examined the respective responses of mothers and fathers in relation to the birth of a disabled child. [Hobdell and Deatrick \(1996\)](#) surveyed mothers and fathers of 69 children with a neural tube defect. Mothers reported a mood state change in the very intense category, from more pessimistic at the time of diagnosis to more optimistic later on. Fathers, although also indicating severe mood change, had somewhat more pessimistic ultimate responses.

[Hunfeld and colleagues \(1999\)](#) assessed the burden on the parents and grief 1 year after having a child with a congenital anomaly. The parents of 27 children with defects who had been admitted for surgical treatment as newborns participated in the study. Results showed that the mothers and fathers showed no significant differences in overall burden and grief; however, mothers reported more personal strain. The authors suggested that foreknowledge from prenatal diagnosis, a low perceived functional health status of the child, and multiple anomalies increased the sense of burden and grief. A perinatal counseling team providing clear and consistent information about the defects, treatment, and prognosis would help to reduce stress and uncertainty, particularly for parents who received prenatal information.

### Intervention and Counseling Techniques

Intervention strategies for counseling families of infants with defects have been discussed in the literature since the 1960s. Focusing on 140 families of infants with Down's syndrome, [Giannini and Goodman \(1963\)](#) emphasized the point that, through immediate crisis intervention counseling, families were better able to participate in decision-making relating to institutional placement outside the home. [Goodman \(1964\)](#), in reference to the same population with Down's syndrome, recommended group counseling for the parents to provide peer support, as well as counseling in the home if possible.

The [British Working Party \(1971\)](#) suggested to clinicians guidelines of communication with the parents of an abnormal child. They recommended that a familiar staff person tell the parents as soon as possible to prevent unfortunate discovery of the problem by the parents. They warned of psychological reactions to be expected, such as anger, projection of blame and guilt onto staff, and, at times, temporary rejection of the infant. A multidisciplinary team approach, including the pediatrician and medical social worker, was suggested for communications with the family during the crisis.

In a description of work with families of children with Down's syndrome, [Golden and Davis \(1974\)](#) emphasized that clinicians should carefully evaluate their own feelings about the child in order to better counsel the family. They found that a surprising number of parents are able to accept raising these children at home if their questions are answered and psychosocial needs met.

[Drotar and associates \(1975\)](#) suggested pediatric management guidelines as a result of their study of parents of children with congenital malformations. Familiarity on the part of the physician with the predictable psychological stages of adaptation to the birth crisis is critical. Furthermore, they stated:

Since the parents' initial shock and disbelief limit the amount of information that they can absorb in regarding their child's condition, information regarding the child's handicap may have to be communicated very clearly and repeated many times ( [Drotar et al., 1975](#), p. 716).

Again, early physical contact with the baby was highly urged in order to minimize the parents' feelings of estrangement.

Drotar and associates recommended that more senior staff physicians assist young house staff officers in intervening with these parents. Family counseling by the physician during the infant's first year of life was strongly urged to maximize the development of the child within the family. Van Riper and associates, in a study of 90 parents of children with Down's syndrome, found that pediatric house officers often avoided interacting with parents of the affected child. They suggested that all involved clinicians need to adopt a more interactional and positive approach to the family ( [Van Riper et al., 1992](#)).

Various clinicians recently have described the positive and preventive effects of early counseling intervention. A British group lately described a questionnaire study to determine anxiety among mothers who had undergone a neonatal screening for occult spinal defects. They concluded that a program of investigation for neonatal abnormalities need not cause excessive parental anxiety; they suggested ongoing psychological monitoring and intervention for the parents of affected infants. An interesting finding was that some of the mothers remained anxious even after receiving normal results ( [Gibson et al., 1997](#)). [Pelchat and associates \(1999b\)](#) described better adaptation among parents of children with congenital disabilities (Down's syndrome, cleft lip and palate) who participated in a psychosocial intervention program compared with those without such intervention ( [Pelchat et al., 1999b](#)).

The child psychiatrist's role in management is critical and requires both an understanding of the psychological reactions of the parents and a willingness to deal with personal responses to these infants.

---

#### CASE ILLUSTRATION

Mrs. C., a 32-year-old mother, gave birth to a baby boy with Down's syndrome. This was the first child for the mother, a college professor, and her husband, a 36-year-old attorney. The mother had carefully arranged her work schedule around the planned birth

and expected to resume teaching soon afterward. The father was present for the delivery, which was by natural childbirth. Amniocentesis had not been performed during the pregnancy.

When the baby was born, Mrs. C. noticed the concerned expressions of doctors, nurses, and her husband. Mr. C.'s first instinct was to protect his wife, but he was encouraged by the medical staff to show her the infant. There was medical evidence of an endocardial cushion defect for which surgery would most likely be indicated by age 5.

Mrs. C.'s response was to reject the baby because of his physical appearance, future retardation, and cardiac status. She refused to breast-feed the infant and directed much of her anger toward the nursing staff, whom she felt were forcing her to deal with the child. Although the father expressed concern about the future, he was certain that he preferred to keep the baby at home. Mrs. C. continued to be obsessed with the stigma of having such a child and expressed the desire to place him in an institution because he'd "never be perfect."

A pediatric social worker was enlisted to discuss disposition options with the parents. The child psychiatrist was regularly consulted by the social worker regarding the counseling.

This case underlines several important features and implications of psychosocial support in relation to modern pediatric practice. Because there are too many children born with congenital defects for all to be seen by child psychiatrists, the management of these families is best undertaken by social workers or child life specialists, with psychiatric consultation and intervention as needed.

The families generally experience such psychological reactions as shock, a sense of unreality, denial, sadness, anger, rejection of the baby, and eventually adaptation. It is crucial that the family members work through the mourning process of the loss of the "expected" intact child and be encouraged to involve themselves rapidly in the physical care of the infant. In our society, the family more readily accepts nonvisible remediable physical defects and nonmentally handicapping conditions. On the other hand, facial deformities and retardation syndrome elicit more severe emotional reactions in family members.

Although some families eventually do place defective, particularly retarded, infants in institutional settings, it is generally agreed that the outcome for children with special handicapping conditions is better if they are raised in the home environment.

---

## THE FAMILY AND EARLY INFANT DEATH

### History and Medical Considerations

The sudden death of infants has been familiar to clinicians for centuries, indeed since biblical times. Sudden infant death syndrome (SIDS), previously referred to as cot death or crib death, is defined as the sudden death of an infant that is unexpected by history and unexplained by a thorough post mortem examination that includes a complete autopsy, investigation of the scene of death, and review of the medical history ( [Hunt, 2000](#)). An autopsy is essential in all unexpected infant deaths because all known causes need to be investigated, even in the context of a detailed history and scene investigation. Sudden infant death syndrome is the most common cause of postneonatal infant mortality in the United States after congenital anomalies and disorders relating to short gestation and low birth weight. In developed countries, it is the most common cause of postneonatal infant mortality, and accounts for 35% to 55% of infant deaths between 1 month and 1 year of age and about 20% of all deaths in infants discharged from a neonatal intensive care unit. In 1996, about 3,000 infants in the United States died of SIDS, a rate of 0.74/1,000 live births. Among full-term infants, SIDS is rare before 1 month of age, with the peak incidence at 2 to 4 months, and 95% of all cases occurring by 6 months of age ([Hunt, 2000](#)).

Over the past three decades, SIDS has been described more specifically, and its etiology has been aggressively studied. The most common hypothesis to explain SIDS seems to be a brain stem abnormality in cardiorespiratory control, including arousal responsiveness, and perhaps other autonomic controls such as blood pressure and sleep-wake regulation. The post mortem data are consistent with this hypothesis ( [Hunt, 2000](#)). An increased incidence of SIDS has been associated with premature and low birth weight infants, lower socioeconomic status, nonwhite ethnicity, young age of mother, smoking during pregnancy, and male sex of baby ([Hoffman, 1987](#); [Valdes-Dapena, 1980](#)).

Over the years, the hypothesized causes of sudden infant death have been numerous. In the remote past, it was thought to be associated with "overlying" or smothering by the parents (Templeman, 1892). In the 1930s, spasm of the glottis and cardiac failure were suggested ( [Goldbloom and Wigglesworth, 1938](#)). Other theories of causation have included enlarged thymus gland, allergy to cow's milk, suffocation from bedding, infection, and cardiac immaturities ( [Weinstein, 1978](#)). Other research has focused on sleep apnea, enzyme irregularities, and chronic oxygen deficiency ( [Naeye, 1974](#); [Steinschneider, 1975](#)). Newer theories have pertained to brain stem function and metabolism, cardiac predisposition, and possible genetic linkages ( [Giulian et al., 1987](#); [Kinney, 1987](#); [Sadeh et al., 1987](#)). [Beal \(1992\)](#) found a slightly increased incidence of SIDS in siblings, which may be attributable to biological or environmental factors. The definitive etiology remains obscure at present, and researchers ultimately may conclude that the syndrome is related to multiple factors.

The sleeping position of the infant has been implicated most recently in the etiology of SIDS, and in 1994, the American Academy of Pediatrics initiated a program that warned of the dangers of SIDS when infants were placed in prone position (on their stomachs) to sleep as opposed to their backs (supine) ( [Willinger et al., 1994](#)). In the past several years, the decrease in the incidence of SIDS in the United States has been attributed to the change in infant sleep positions and a reduction in bed sharing with parents ( [Thogmartin et al., 2001](#)).

### Psychological Reactions

It has often been noted in the literature that the acute psychological reaction of the family to SIDS death is extremely intense and severe in quality. Most authors refer to Lindemann's (1944) description of normative acute grief reactions as a reference point. These descriptions included various somatic symptoms, guilt secondary to perceived negligence, and anger and hostility directed toward health professionals. Pathologic or "morbid" grief reactions presented by Lindemann and observed among SIDS parents include delayed mourning, overactivity without a sense of loss, alteration in relationship to friends and relatives, furious hostility directed against specific persons, schizophrenia-like symptoms, and agitated depression.

According to [Friedman \(1974\)](#), the intensity of reaction to the loss of the infant is related to the absence of "anticipatory mourning." The parents lack the time to prepare themselves psychologically for the overwhelming event. In addition, the death occurs in otherwise healthy infants, the etiology is unclear, and parents often feel blamed or responsible for the child's death ( [Friedman, 1974](#)).

### Descriptive Studies

[Bluglass \(1981\)](#), in a review of psychosocial aspects of SIDS, stated that few well-controlled prospective studies have been done relating to bereavement, and none at all in relation to SIDS. However, some descriptive studies of family reaction to SIDS have been reported. [Bergman and associates \(1969\)](#) delineated the acute phase of family reactions to the sudden death of the baby. They mentioned feelings of disbelief, anger, helplessness, severe guilt, and loss of meaning of life. Parents felt they were "losing their minds," and there was associated disruption of usual routines. Following the death, they described some of the parents demonstrating denial of the event and experiencing persistent dreams of the child. Hostility to friends and relatives was common as well.

[DeFraun and Ernst \(1978\)](#), in a clinical study of 32 parents of infants who died of SIDS, found through mailed questionnaire responses that SIDS was the most severe crisis the parents had ever encountered. In addition, they found that the majority of parents suffered feelings of personal guilt and other psychological difficulties and that relatives were also affected. An interesting finding of their study was that 60% of the parents who had experienced SIDS had moved from their hometowns within 2½ years of the death. They also reported that behavioral difficulties were found in siblings and that better psychological recovery of the family was associated with higher income.

[Cornwell and associates \(1977\)](#) reported on a small Australian prospective questionnaire study. They stated that three families sought formal psychiatric attention for severe difficulties (e.g., delusional hypochondriasis, severe depression, and extreme anxiety). In addition, marital difficulties were common (one-third of the group), siblings were noted to be overanxious, and "anniversary reactions" were usual. Physical health was reported to have deteriorated, with the emergence of psychosomatic symptoms. They also noted parents' overprotective tendencies toward surviving siblings. There was a preoccupation with subsequent fertility, and thoughts of a "replacement child" were common. The questionnaire studies may be critiqued on the basis of sample bias; specifically, it is possible that the families who replied to the questionnaire were more disturbed and dysfunctional than were the nonrespondents. [Salk \(1971\)](#) discussed the prominent role of guilt in the reaction of SIDS parents, which is exacerbated by the mysterious etiology. In an anecdotal summary, he argued that parents who are prone to self-blame are more likely to do so after SIDS death because of the ambiguity of cause. He underemphasized the role of the physician in helping families to cope with the crisis of SIDS.

[Smialek \(1978\)](#) conducted a 2-year follow-up study involving 351 families, most of which (75%) had lost a baby to SIDS. (The remaining 25% lost infants suddenly owing to other causes.) In addition to the common psychological reactions noted by other clinicians, the author found that certain parents expressed (relief) at the death because of extreme ambivalence about the child. She noted that the stages originally described by [Kübler-Ross \(1969\)](#) in relation to dying patients were useful in understanding the adaptation of parents to sudden infant death.

[Zebal and Woolsey \(1984\)](#) reviewed parent's reactions to sudden infant death and emphasized the relative youth of the parents, for whom this may have been the first death experience. Consequently, the parent may misinterpret normative grief reactions and fear he or she is becoming mentally ill. The authors noted that individuals in the surrounding social network tend to underestimate the intensity and duration of the grief reaction and therefore are less supportive than they might be. Furthermore, police investigations and legal proceedings are usually involved, which heightens the initial stress. Parents are not infrequently accused of child abuse and/or neglect pertaining to the death of the infant. A recent study showed no correlation between death from SIDS and prior reports of the family to child protection agencies ([O'Halloran et al., 1998](#)).

### Family Adaptation

A "long-term adaptation" model with key transitional points was presented by [Zebal and Woolsey \(1984\)](#) in their review. After several days or weeks, the initial shock or denial reactions give way to the acute grief reactions described previously. Six or 8 weeks later, the reality of death is more clear, coinciding with the gradual withdrawal of external supports. Four to 6 months after the death, there is a shift to future-oriented concerns. Significant dates (birthdays, holidays) are associated with anniversary reactions. After 1 to 2 years, consideration of a new pregnancy usually occurs; if a pregnancy occurs, there is heightened anxiety about the vulnerability of the baby to SIDS and other dangers.

A recent Scandinavian study surveying 251 parents after infant death demonstrated that the women received more and continuing emotional support for their loss than the men in the group. The study also found that social support in connection with the death was related to long-term psychological adaptation to some extent ([Thuen, 1997](#)).

Several authors have noted that there are sex differences among the parents regarding their psychological adaptation to SIDS ([Benfield et al., 1978](#); [Cornwell et al., 1977](#)). [Benfield and coworkers \(1978\)](#) reported on 50 parent pairs whose children had died suddenly. They noted that fathers appeared to experience less intense and more accelerated "grief work" because of involvement in practical matters (funeral arrangements, etc.). They postulated differences in societal expectations for men and women regarding expression of grief and mourning. Mandell, in a clinical study of paternal response, described fathers of SIDS infants as driven to "keep busy" through increasing involvement with work; they also demonstrated stoicism and a limited ability to verbalize feelings or ask for support ([Mandell et al., 1980](#)). A recent European study demonstrated that a high proportion of the mothers who had lost infants to SIDS 5 years previously still had higher levels of symptoms compared to a normal control group. In general, the male respondents displayed fewer symptoms and a higher level of subjective adaptation than the females ([Thuen and Schlytter, 1996](#)). A contrasting study of sex differences in mourning in 13 couples rated 6 months after the infant's death showed no significant difference between the mothers and fathers. The study found, moreover, that the correlations between mothers' and fathers' subscales and total scores on a grief scale were low, indicating that parents do not grieve in the same ways or over the same time ([Hunfeld et al., 1996](#)).

### Marital Issues

Regarding the effect on the marital bond, Benfield and associates noted that, in couples where communication was poor, it appeared that critical emotional issues were avoided for extended periods of time ([Benfield et al., 1978](#)). [Zebal and Woolsey \(1984\)](#) noted that the differing styles of adaptation of men and women could lead to difficult interactional cycles in the marriage. There is often misunderstanding of the respective styles of grieving, which often leads to conflict. [Mandell \(1980\)](#) observed that, of his study sample of 28 parent pairs who had lost babies, six marriages had dissolved after the death.

Several authors have referred to the desire of some parents to replace the dead infant with another child. [Cornwell and associates \(1977\)](#) found that most parents they studied seemed to be aware of the psychological risks of replacing a lost child. [Rowe and coworkers \(1978\)](#), in a follow-up study of 26 families who had experienced perinatal death, found that a prolonged grief reaction in the parents was associated with early subsequent pregnancy. The implication of this work is that the necessary grief work had been interrupted by the new pregnancy and birth.

### Effect on Siblings

The effects of SIDS on surviving siblings have been presented often in the literature, although there have been no published long-term longitudinal studies. Most authors highlight the particular difficulties older siblings have in dealing with the infant's death, owing to preexisting rivalrous feelings. [Cain and associates \(1964\)](#) described the sense of responsibility and guilt reactions the older children suffer. They noted distorted views about the concept of death, death phobias, and a subsequent feeling of deprivation experienced by the surviving sibling. [Halpern \(1972\)](#) mentioned the tendency of some mothers to project blame and guilt onto the older sibling, which may lead to behavioral problems. He also described painful anniversary reactions experienced by the family, which affect surviving siblings.

Several authors have presented the frequent occurrence of behavioral difficulties in siblings of SIDS infants, as well as the tendency on the part of the parents to overprotection of the remaining siblings ([Cornwell et al., 1977](#); [Mandell et al., 1988](#)). [Williams \(1981\)](#) studied a group of surviving siblings and noted developmental age-specific differences in response. He found that the children between 6 and 9 years of age showed the least direct expression of their distress. The younger children (preschool age) were confused and angry, and the older children (over 10 years) demonstrated an adult-like pattern of grief. [Gaffney \(1992\)](#) has recently described that well-intentioned attempts to spare the feelings of the siblings often result in increasing isolation and tendencies to fantasize in a maladaptive manner.

[Swoiskin \(1986\)](#) also noted age-specific developmental reactions and cautioned that misleading euphemisms about the baby's death often exacerbated the emotional reactions of the surviving siblings. She also described occasional parental distancing from a sibling, related to idealization of the lost child.

[Burns and colleagues \(1986\)](#), in a questionnaire study of 50 siblings of 43 families, noted that 54% of them experienced extended grief reactions lasting over 1 year. In a recent prospective interview study of 45 surviving sibs of 36 families, [Mandell and colleagues \(1988\)](#) described changes in sleep patterns, social interaction, and parent-child interaction. They noted that these behavioral changes reflected both patterns of adjustment by the child and persistence of parental concerns.

### Effect on Grandparents

In a questionnaire study, [DeFrain and Jakub \(1992\)](#) examined the psychological and social impact of SIDS on surviving grandparents. The loss of the baby was found to be devastating for them as well, with mixed emotional reactions of disbelief, anger, guilt, anxiety, and depression identified. They described difficulties inherent in grieving for the baby, at the same time attempting to console and comfort their own grown children. Bereavement support groups were found to be quite helpful for the grandparents involved.

### Interventions and Counseling Techniques

In the two decades of active recognition of SIDS, much has been written about intervention and management techniques. Most authors have pointed to the tendency of medical staff to avoid dealing actively with the psychosocial issues confronting these families. Referring to the work by [Kennell and colleagues \(1970\)](#), correlating more adaptive mourning with prior physical contact with the infant, the majority of clinical investigators have urged increased visual and physical contact between the parents and the dead infant. Many authors suggest that autopsies be routinely performed, in order to decrease the atmosphere of confusion, ambiguity, and mystery surrounding the death of the infant (Bergman, [1974, 1979](#); [Weinstein, 1978](#)). Any available information should be rapidly transmitted to the family by the medical and nursing staff to minimize tendencies of self-blame or blame of others. [Powell \(1991\)](#) has suggested that providing medical information to the family within the first 3 months after the death leads to more normative grief reactions and acceptance. The vast majority of investigators suggest that the medical team, including active involvement by the physician, participate in ongoing psychosocial follow-up of the affected families.

More specific counseling interventions have been suggested in the literature. To foster mutual support, [Salk \(1971\)](#) recommended regular group meetings of parents of infants who have died of SIDS. [Goldberg \(1992\)](#) has suggested that group parental sessions comprised of recently affected parents and "veterans" are quite effective and should contain a significant educational component regarding recent medical research findings in SIDS. [Smialek \(1978\)](#) outlined a multiple-step counseling model based on a large prospective study of 351 families of infants who died of SIDS. These steps include accepting parents' grief reactions, encouraging ventilation of feelings, clarifying misconceptions about the death, allowing private access to the dead infant, and assisting with autopsy and funeral arrangements. Smialek advised that siblings be permitted to attend the funeral of the infant to encourage their grieving process.

[Zebal and Woolsey \(1984\)](#) and later [Woolsey \(1988\)](#), writing independently, made the point that many families experience a withdrawal of social support several months after the death of the infant. [Buschbacher and Delcampo \(1987\)](#) recently reported that relatives in the extended family network often are unable to provide

necessary support because of their own grieving. Most authors agree that a network of aid should be arranged to be available to the family over an extended period of time, considering that the grieving process for the lost child often takes place over years. The network might include other parents whose infants have died of SIDS, family members, friends, and members of the psychosocial or medical team. Many states provide services through SIDS Information and Counseling Projects and the National SIDS Foundation.

In a critical review of adaptation following perinatal loss, [Zeanah \(1989\)](#) emphasized several important points. He maintained that hospital management of these families, including encouragement to view the deceased baby, has not been based on adequately tested assumptions. He also stated that other specific areas need to be more systematically tested as well, including differing mourning patterns of mothers and fathers, differentiation of grief and mourning during the course of bereavement, and advice-giving about subsequent pregnancies.

[Maclean \(1999\)](#) has described the experiences of a group of parents who lost infants to SIDS and who monitored their subsequent infants at home for signs of apnea. The caregiving experiences were explored in comparison to children with other life-threatening chronic illnesses; in both groups, the condition of "sustained uncertainty" was the continuing psychological challenge to the family.

[Davis and associates \(1989\)](#), in an investigation about subsequent pregnancy, interviewed mothers about the advice they had received from physicians about postponing pregnancy. Significantly, they found that, regardless of the specific advice given, most mothers felt that their individual psychosocial situations had not been considered enough at the time. They noted that physicians and other caregivers may be most effective and helpful by educating parents about the advantages and disadvantages of postponing pregnancy, in order to help them make a more informed decision.

In a recent study, [Leitch and associates \(2000\)](#) assessed demographic data, obstetric history, experience of child loss, pregnancy and delivery complications, infant morbidity, family-child interaction, family support, and the relation of each of these factors to SIDS-related anxiety. They found a strong and significant relationship between previous experience of child loss and SIDS-related anxiety, and concluded that psychological help should be offered preventively to parents who have already experienced the loss of a child and are considering another pregnancy.

---

#### CASE ILLUSTRATION

A 19-year-old mother gave birth to a 4½-pound baby girl after a 36-week gestation. This was the mother's second pregnancy; there was a 2½-year-old brother at home at the time of the birth. The baby had been delivered by cesarean section because of premature onset of labor and fetal distress. There had been a possible history of alcohol or drug abuse; the mother tested negative for HIV infection. She had also been a cigarette smoker throughout the pregnancy. Apgar scores were 7 and 6, and the baby was observed for 3 days in the neonatal intensive care unit for labored breathing.

The infant was doing well until age 2 months, when she had several episodes of apnea at home, none requiring resuscitation. After a careful evaluation, it was decided not to place the child on a cardiorespiratory monitor.

At age 5 months, the older brother, now almost 3 years of age, discovered the baby not moving in her crib. He reported this to the mother, who impulsively yelled out "What did you do to her?" The boy had previously demonstrated some behavioral difficulties indicative of sibling rivalry. The baby was rushed to the pediatric emergency room, where she was pronounced dead. Counseling was recommended to the family at the time, but they did not seek help, and little outreach by hospital staff took place.

Several weeks later, the parents brought their son to the pediatric emergency room one evening, complaining that he had a cough and chest congestion that worried them. In the course of the evaluation, mother herself presented vague somatic complaints, stated she felt she was "going crazy" because she saw visions of her daughter choking, and feared she was losing control of her temper with the son. The child psychiatrist was consulted.

It was ascertained that the father was attempting to support his wife, but he indicated that he was in danger of losing his job if he kept attending to the problems at home. Extended family members were unavailable, and the parents felt rather isolated and helpless, particularly in relation to their son's behavioral problems. The child was also demonstrating nightmares and new animal phobias. Counseling was arranged for the child and family by the pediatric social worker, and the primary pediatrician made himself available for continuing support. One year after the death of the infant, all family members were functioning more adaptively, the brother was enrolled in nursery school, and the parents were considering another pregnancy.

#### Comment

This case presents a fairly classic paradigm of the problems SIDS families encounter. The families demonstrate the following general characteristics: The mothers tend to be young, multiparous, of low socioeconomic level, and cigarette smokers. The pregnancies are relatively complicated and are more prone to premature birth. The infants often present with difficulties at birth, which may resolve acutely, are discharged home, and later experience episodes of apnea that presage the sudden death.

The acute psychological reaction to such an event often involves displacement of blame onto a family member, such as an older sibling, or medical staff. Fathers frequently present as somewhat distant, stoic, and relatively unsupportive of the mother's emotional state.

Ideally speaking, follow-up visits should be planned at the time the infant arrives at the emergency room. However, these families are too often inadequately followed, and those without network support often experience delayed emotional sequelae. Typically, well-intentioned friends, family members, and physicians suggest premature replacement of the infant, which may lead to exacerbation of symptoms on the part of the parents. A sibling who feels guilt about the death may present with symptoms. The mothers frequently develop psychosomatic or depressive features.

Immediate psychological intervention is usually necessary; involvement of the father and surviving siblings is critically important. Continuous monitoring by the pediatrician and pediatric social worker is indicated, with psychiatric consultation as needed. Outcome and prognosis depend on premorbid adjustment as well as management by the interdisciplinary team.

---

## CONCLUSION

The immediate effect of potential and acute loss of an infant on the nuclear family is the major theme of this chapter. Each condition presents young and relatively inexperienced parents with a crisis for which they have usually had little preparation and no prior education. Furthermore, in our technologically and medically advanced culture, with its overinvestment in physical beauty, high intelligence, and medical expertise, the negative impact of prematurity, disability, and death tends to be exaggerated. It is almost impossible for the average American to comprehend that there are parts of the world where infant morbidity and mortality are daily experiences. Actually, this was, and in a few places still is, true of the United States in the 21st century. Universally, the potential or actual loss of an infant is a severe stressor for the family.

Prematurity represents a state of suspended animation for most parents. Even large premature infants with good prognoses induce anxiety and symbolize potential death and disability. Furthermore, the specter of mental retardation, an anathema in our society, presents parents with a long period of ambiguity and chronic anxiety. During this period, they must be helpless observers rather than active participants. Recent research has indicated that the active involvement of parents in the care of their premature infants can be helpful in alleviating both the guilt and anxiety related to loss and impairment. Even if the ultimate complexities of bonding have yet to be fully delineated, this is a practice and useful approach in the prematurity nursery. Clearly, child psychiatrists have important roles to fulfill both in helping staff members to deal with increased parental participation and in the direct management of family members with intense distress related to their infants' fragility.

Parents whose infants are born with congenital anomalies may face a lifetime of adjustment to a child who places special demands on them. Although some congenital anomalies are not obvious to the culture at large or are surgically remediable, those presenting visible deformities to the world or resulting in mental retardation place special emotional burdens on the parents. This situation usually requires the health care professional to deal with both chronic guilt and significant ambivalence on the part of one or both parents. In addition, considering the social and economic burdens that must be endured, major realistic stressors must be recognized and attended to if the family is to remain a viable unit.

Last, the literature on sudden infant death has been reviewed. Although infant mortality has been a reality throughout human history, the psychological study of families experiencing the death of an infant or child is a very recent endeavor. Mourning, in a secular society, has evolved from being a primary purview of the religious counselor to the legitimate scientific pursuit of the psychological investigator. Counseling efforts are now being introduced and implemented in hospitals and clinics to provide support for families with children who die suddenly at home or in the hospital. Child psychiatrists have important roles to fill at all levels of liaison activity regarding SIDS, be it in direct consultation and service or in training and supervision of other health care professionals.

It is clear that there will never be enough child and adolescent psychiatrists to treat all families of premature, disabled, and deceased infants. Knowledge of normative responses has advanced to the point where basic skills can be utilized by and transmitted to others who can provide basic services. However, there is much to be learned about the short- and long-term sequelae of such stressful situations on individuals and family systems with preexisting psychopathology. For such families, child and adolescent psychiatrists are uniquely suited to play a further role in research and treatment.

[Chapter References](#)

In the last 15 years, there has been significant progress in understanding the psychiatric and psychosocial aspects of cancer in children and adolescence, an important development given the persistence of childhood cancer as the leading cause of death from disease other than congenital illness ( [Haase et al., 1998](#)). The most common types of childhood cancers include leukemias, lymphomas, neural tumors, and sarcomas; and each has a specific age, sex, and racial distribution ( [Steinherz and Simone, 1998](#)). Pediatric cancers are distinguished from adult cancers in their tissue type, embryonic origin, and presumed causative factors ( [Steinherz and Simone, 1998](#)). Pediatric cancers also have higher survival rates, perhaps in part because of children's ability to tolerate more robust therapy ( [Steinherz and Simone, 1998](#)).

Survival of children is maximized when the children are part of treatment protocols sponsored by national pediatric cooperative groups ( [Haase et al., 1998](#)). The importance of a coordinated multidisciplinary approach that encompasses psychosocial aspects of treatment and survival cannot be overstated. The mortality from pediatric cancer underwent a significant decline between 1975 and 1995 ( [Gloeckler Ries, 1999a,b](#)), with mortality declining overall by 40%. When looking at cancer mortality statistics, it is important to look not only at pooled data, but also at data pertaining to individual cancers and age groups; for example, mortality rates in children 5 to 9 years of age declined most, and the mortality rate from acute lymphocytic leukemia (ALL), which represents about one-third of pediatric malignancies, fell by 50% between 1975 and 1995 ( [Gloeckler Ries, 1999b](#)). The survival rate for children under the age of 20 with ALL is now approximately 80%, Hodgkin's lymphoma is 91%, and non-Hodgkin's lymphoma is 72% ( [Ries et al., 1999](#)). Survival rates for central nervous system (CNS) tumors are considerably less.

Physical sequelae of illness and chemotherapy can include affects on cognition, growth/endocrine systems, liver, cardiac, and kidney function, sexual maturation and function; all can have psychological and cognitive correlates, including effects on academic achievement and social competence ( [Eiser, 1998](#); [Parsons and Brown, 1998](#)). Parsons reviewed studies showing a fourfold increased risk of school-related difficulties in this population ( [Mulhern et al., 1989](#); [Parsons and Brown, 1998](#); [Rubenstein et al., 1990](#); [Williams et al., 1991](#)). She cites one study that found that 50% of children surviving leukemia had academic problems at 5-year follow-up despite normal IQ ( [Deasy-Spinetta and Spinetta, 1980](#); [Parsons and Brown, 1998](#)), with 61% having attentional problems ( [Jannoun and Chessells, 1987](#)). Another study looking at pediatric ALL survivors found that 33% showed impaired cognitive functioning and 28% demonstrated impaired emotional functioning ( [Barr et al., 1993](#)).

Depression seems to be correlated with hospitalization and greater time since diagnosis ( [Mulhern et al., 1992](#)). Importantly, psychosocial functioning *may not* correlate with physical health and vice versa ( [Parsons and Brown, 1998](#)). The earlier the diagnosis and treatment, the greater is the likelihood of subsequent cognitive and behavioral sequelae ( [Eiser, 1998](#)).

Multimodal approaches, according to the American Cancer Society Task Force on Cancer in Children, hopefully will bring the overall cure rate of childhood cancer near 80%. The incidence rate is rising at 1% per year, and the cure rate is increasing at 1.4% yearly ( [Haase et al., 1998](#)), figures that are felt to be predicated on assurances of attention paid to "the physical, emotional, and social quality of life" ( [Haase et al., 1998](#), p. 822). The American Cancer Society organized a quality of life workshop in 1995 to address these issues, which noted that quality of life includes issues such as the family (siblings and parents) and community as well as the individual, with serial assessments over time. Specific aspects of the patient's life that must be included are education, insurability, development, and employment. Potential side effects of antineoplastic medication, including secondary malignancies and effects on growth and cognition, are important aspects to be considered. It was recommended also that the effects of managed care systems on reimbursement for medical costs be examined closely ( [Haase et al., 1998](#), pp. 822–823).

It was estimated that by the year 2000 there would be over 200,000 survivors of childhood cancer, which would represent 1% of the young work force in America ( [Haase et al., 1998](#)), with these children comprising "1% of the cancer incidence but . . . 100% of the future" ( [Haase et al., 1998](#), p. 823). Statistically, the loss of a child's life from cancer represents over 100,000 person-years of life lost annually, whereas survival of each child represents 400,000 person-years ( [Haase et al., 1998](#)). Critical ongoing investigations are necessary to evaluate the following:

1. Pediatric cancer control
2. Issues of cancer survivorship
3. Late effects of treatment
4. Psychosocial outcomes
5. Supportive and transitional care

Research findings have influenced the manner in which children are treated for cancer. As [Redd \(1994\)](#) notes in his summary of advances in psychosocial oncology, for example, an understanding of how central nervous system irradiation for leukemia affects neuropsychological function has informed how radiation treatment and intrathecal chemotherapy are delivered ( [Copeland, 1992](#)). Other major areas of research have been behavioral techniques to reduce distress associated with painful procedures, and the psychosocial effects of cancer treatment on children and their families. As [Redd \(1994\)](#) observed, recent research has demonstrated that cancer treatment does not seem to necessarily increase the risk of psychopathology. He noted specific factors that have promoted recent research in this area, and underscored that this area is amenable to the study of the interactive effect of psychological, social, and medical factors, such as the following:

1. Advances in research methodology (e.g., to assess distress reliably)
2. Increased interest in the study of children with cancer among professionals not otherwise associated with cancer
3. Wide availability of professional outlets for research findings
4. Support for psychosocial research by departments of pediatric oncology at major medical centers
5. Patient and parental cooperation
6. Efforts made by the American Cancer Society (ACS) and the National Institutes of Health (NIH) to support research and research training in psychosocial oncology

He also pointed to factors that interfere with continued movement in this direction, including the following:

1. Methods of psychosocial assessment
2. Clinical significance of research findings
3. Availability of appropriate comparison groups

4. Communication of research findings
5. Balance in conceptual focus

For example, although there have been advances in the ability to measure parameters of psychosocial function, less obvious effects may not be discerned. Also, certain research findings may not be clinically relevant. Identification and selection of appropriate comparison groups is a challenge because of the relatively small number of children being treated. There are relatively few researchers in this area, and there is a need for greater liaison with researchers in other fields as well as adequate communication of clinically relevant research results with health care workers primarily responsible for the care of these children. Last, Redd wishes that the focus of clinical work might include identification of strengths and protective factors in these patients as well as psychopathology.

In this chapter, a review of recent clinical and research findings is summarized, including the following:

1. Psychosocial impact of cancer
2. Assessment instruments
3. Individual psychological factors affecting adjustment and outcome
4. Family factors influencing adjustment and outcome
5. Pain and distress in the pediatric cancer patient
6. Cognitive sequelae of cancer treatment
7. Posttraumatic symptoms related to cancer treatment
8. Behavioral and psychosocial interventions
9. Psychopharmacology in the pediatric cancer patient
10. Hospice care and the terminal patient

## PSYCHOSOCIAL IMPACT OF CANCER

There has been a greater recent appreciation of the psychological sequelae of surviving cancer in childhood because of increasing survival rates ( [Die-Trill and Stuber, 1998](#)). The long-term effects of cancer survival have potential consequences on multiple parameters of the survivor's life, including growth and development, social relationships, body image, employment, marriage, and vulnerability to anxiety and depression ( [Hill and Stuber, 1998](#)). Conflicting reports of the prevalence of psychological problems in this population can be explained to a large degree by methodologic issues involving the definition of terms, samples, and measures used. There is ample evidence of a lasting psychological impact from cancer and its treatment ( [Hill and Stuber, 1998](#)). Locus of control may affect different patients in unique ways, either by combating a sense of helplessness in patients who are aided by feeling more in control of their illness, or absolving patients from the responsibility for the illness if they prefer to believe that doctors or fate determine the outcome ( [Hill and Stuber, 1998](#)). The psychological defenses of denial and repression may be adaptive in this population ( [Hill and Stuber, 1998](#); [Phipps et al., 1995](#); [Worchel et al., 1992](#)).

[Redd \(1994\)](#) and other authors ( [Katz et al., 1988](#)) have pointed out that issues facing children and adolescents who have been treated for cancer include those related to isolation from peers and reentry into school. It is important to understand the differential developmental impact of cancer on the preschooler struggling with issues of mastery of the environment, on the school-age child undergoing physical development, and the adolescent searching for a sense of identity ( [Die-Trill and Stuber, 1998](#)). Children under 6 years of age perhaps are less susceptible to the subsequent development of posttraumatic stress disorder (PTSD) but more vulnerable to the neuropsychological sequelae of CNS irradiation; patients diagnosed in adolescence seem to be more susceptible to adjustment problems ( [Hill and Stuber, 1998](#)).

Psychosexual sequelae of pediatric cancer also have been reviewed recently; they traverse physical, psychological, and interpersonal domains ( [Woolverton and Ostroff, 1998](#)). Physical sequelae include the impact on the timing (delays) or status of puberty (including the loss of previously acquired pubertal milestones such as fertility, menstruation, libido, erections, and pubic hair) ( [Grant and Demetriou, 1988](#); [Woolverton and Ostroff, 1998](#)). Sperm-banking in males, although quite ethically compelling, can pose unique stresses for the adolescent. Psychological effects include those on autonomy, one's concept of the future, and sexual self-concept (one's sense of identity related to physical attractiveness and sexual function). Effects on the latter are easily neglected by those involved in the care of the pediatric cancer patient. Effects on interpersonal aspects of psychosexual development proceed from the impact on peer group affiliation and dating caused by the isolating effects of cancer and its treatment. The social impact of cancer has both vertical (adult) and horizontal (peer group) impact ( [Woolverton and Ostroff, 1998](#)). Survivors experience the unique stress of cancer's differential effects on maturity, because they often have a precocious sense of empathy, responsibility, and appreciation for life, but delayed social and sexual development.

Effects on oral intake are common, both secondary to illness and chemotherapy, and as well can be ways in which the child or adolescent attempts to maintain some sense of control. The response to the physical limitations imposed by procedures, intravenous lines, feeding lines, and so on, exacerbate those resulting from pain, surgery, nausea, and vomiting, and can both interfere with development in the younger child or infant, as well as cause psychological regression and social isolation ( [Die-Trill and Stuber, 1998](#)). There seem to be developmental differences; younger children experience more social anxiety and shyness, and teenagers experience more social isolation, although not necessarily depression. Research indicates that social support is a crucial element in the adjustment of this latter group ( [Katz and Varni, 1993](#); [Katz et al., 1992](#); [Noll et al., 1993](#); [Varni et al., 1993, 1994, 1997](#)).

Although children with cancer often may return to school early in the outpatient treatment phase, they frequently experience fears about not being able to catch up with work, and how peers or school staff will react to their illness and its physical manifestations ( [Die-Trill and Stuber, 1998](#)). High rates of school absence are reported. Four groupings of school difficulties are noted in these patients:

1. Patients exhibit school anxiety secondary to the illness or its treatment-induced side effects (hair loss, weight changes, nausea and vomiting, surgical disfigurement).
2. Patients, parents, and schools have difficulty reintegrating the patients into school after prolonged absences.
3. Patients have illness-related learning disabilities requiring psychological evaluation and possible school arrangements.
4. Newly diagnosed patients require preventive intervention and guidance to be reintegrated.

Social stressors for pediatric cancer patients also include separation from peers, functional changes in physical ability, and responses from peers and adults, which can lead to diminished self-esteem ( [Die-Trill and Stuber, 1998](#)). One study found that children receiving social skills training noted higher levels of support from teachers and peers at 9 months following diagnosis compared with before treatment, and their parents noted a decrease in both internalizing and externalizing problems, along with improvements in school competence, during this interval ( [Varni et al., 1993](#)). [Varni and associates \(1994\)](#) noted that support from teachers, classmates, and friends correlated with lower psychological distress and higher self-esteem. Peer support has the greatest impact, which emphasizes the importance of the social network at school. In a later study, [Varni and Katz \(1997\)](#) found that "perceived stress" and social supports have significant impact, particularly at 9 months following diagnosis.

The importance of an orientation that looks at "transitions" in the life of the pediatric cancer patient has been underscored by an American Cancer Society Workshop on Quality of Life in Children's Cancer ( [MacLean et al., 1996](#)). These transitions include moving from active treatment into completion of a treatment protocol and from there to long-term survival, changes in health care providers associated with moving from pediatrics into adult medicine, and changes in the place of treatment delivery ( [MacLean et al., 1996](#)). Transitions often involve significant stress and anxiety because of accompanying changes in procedures. The psychological importance of acknowledging what such transitions mean to pediatric patients and their families is an important part of medical management. Obstacles to successfully negotiating these transitions can include the failure of such acknowledgment along with other factors such as lack of financial resources, inadequate education for health care providers, insufficient involvement of parents, or "unevenness" of care, such that psychosocial interventions are underrepresented ( [MacLean et al., 1996](#)).

Redd (1974) reviewed research suggesting that parents often have greater adjustment problems than their children, with 30% of parents experiencing depressive symptoms ( [Manne et al., 1993](#)) in the phase following diagnosis, and children expressing more context-specific distress around procedures ( [Manne et al., 1992, 1993](#)). One-fourth of husbands and wives report increased marital discord, related to individual distress, and differences between spouses with regard to anxiety or coping style ( [Dahlquist et al., 1993](#); [Katz et al., 1992](#)).

Elementary school-age children have a limited understanding of what causes cancer, less so than their comprehension of what causes colds, although the understanding of what causes cancer seems to increase with grade level. Misconceptions that casual contact and contagion are important etiologic factors persist into

preadolescence, underscoring the importance of education ([Chin et al., 1998](#)). This has obvious implications for both the child diagnosed with cancer, as well as the education of his or her peers.

Interventions designed to address these issues (see the following) must target the psychosocial, psychological, and neuropsychological sequelae of cancer and its treatment ([Hill and Stuber, 1998](#)).

## ASSESSMENT INSTRUMENTS

Quality of life in pediatric cancer patients has received increased scrutiny, and is being studied as part of Phase III Clinical Trials in order to better evaluate outcome ([Bradlyn et al., 1995](#); [Seid et al., 1999](#); [Varni et al., 1998a,b, 1999a,b](#)), although overall it remains understudied, perhaps largely because of methodologic challenges ([Parsons and Brown, 1998](#)). Important parameters to take into account in doing such research include the manner and validity in which such information is obtained (ideally from the child, teachers, parents, and health care providers), developmental factors, timing of the assessment, sensitivity and specificity of the instrument, importance of measuring function against reasonable norms for a given patient, and need to study different domains of functioning (academic, social, and family).

Unfortunately, earlier research has tended to focus on studying individual deficits or parameters of function ([Parsons and Brown, 1998](#)). Domains that are assessed must be altered from those used to evaluate adult quality of life, to account for the relative dependence of children on their parents, the emotional life of children, and the ability to modify assessment to account for longitudinal changes associated with development ([Bradlyn et al., 1995](#); [Parsons and Brown, 1998](#)). The lack of clarity regarding proxy assessment, especially in young children, has been identified as a major challenge in doing quality of life research, as is the importance of having adolescent patients treated by pediatric rather than adult oncologists, because of their close familiarity with developmental issues particular to adolescents ([Bradlyn et al., 1995](#)). A more recent instrument, the Pediatric Cancer Quality of Life Inventory (PCQL) ([Seid et al., 1999](#); [Varni et al., 1998a,b, 1999a,b](#)), has included disease-specific symptom modules (e.g., pain and nausea) and treatment-specific modules; patient and parent concordance on these measures is high. Other measures of quality of life also have been developed ([Feeny et al., 1998](#)).

Parsons notes that objective measures involving clinical status or academic performance should be used whenever possible. Significant variability in assessment of children among respondents is an important factor, a phenomenon mitigated especially by family dynamics, necessitating multiple informants and self-report ([Parsons and Brown, 1998](#)). Chronic illness necessitates longitudinal as opposed to cross-sectional assessments in order to be sensitive to long-term consequences of cancer and its treatment. The knowledge gained from studying long-term outcome can be used to help direct health care policy, given the fact that childhood cancer survivors live an average of seven decades following "cure," and continue to be affected by the psychological, physical, and cognitive effects of cancer and its treatment ([Parsons and Brown, 1998](#)), although they are outside the domain of the medical system. Therefore, it is vital to extend the scope of "cure" and assessment of patient needs beyond that of medical treatment and include the rest of life.

Body image instruments (Kopel et al., 1998; Mulhern, 1999) have been developed to measure this parameter in adolescents and young adults with cancer, and may be useful in screening adjustment difficulties that emerge from body image disturbance. Die-Trill and Stuber assess that

weight changes, hair loss, amputations, placement of catheters to facilitate treatment administration, surgical scars, and alterations in skin coloration and texture not only make the child feel different from peers, but may represent frightening changes in the body to the child and may impact self-esteem adversely. Fear that the body will never return to its original appearance, fears of not being recognized by others, or of being mistaken for an individual of the opposite sex (frequently experienced by adolescent girls who lose their hair) often lead to shame, social isolation, and regressive behavior ([Die-Trill and Stuber, 1998](#), p. 900).

Psychosocial assessment at the time of initial diagnosis should include an assessment of various domains, including development, socioeconomic and cultural issues, coping capacity, family cohesion and communication, and personal and family history ([Adams-Greenly, 1991](#)). [Feeny and associates \(1998\)](#) developed a tool designed to systematically assess health status in survivors of childhood cancer 7 years old and older that used seven attributes—including senses, mobility, emotion, cognition, self-care, pain, and fertility. This tool was used later in a study by [Billson and Walker \(1994\)](#). In their study of children who had completed treatment for cancer, 30% of the parents' and 40% of the doctors' assessments identified no deficits in any attributes. The attributes most often disagreed on between doctor and patient/parents were those of pain and emotion. Doctors generally noted fewer deficits in all categories compared with patient/parents, suggesting that doctors unfamiliar with the patient might underreport problems, and/or that parents might overreport them. The survivors of neuroaxial tumors tended to have the worst health status outcome of the 48 assessment pairs, although 66% of patient/parents reported being satisfied with their or their child's life overall.

## INDIVIDUAL FACTORS AFFECTING PSYCHOLOGICAL OUTCOME

Factors such as the effect of differing cognitive orientations toward achievement on response to cancer treatment ([Elkin et al., 1998](#)), as well as the effects of body image on social adjustment have been studied ([Pendley et al., 1997](#)). The latter study found that the effects of negative feelings about one's body or low self-worth as social anxiety may not manifest until several years after treatment is completed. In another study, avoidance coping, depressive attributional style, and social competence predicted almost half the variance in child depression. Anxiety in children was predicted by a depressive attributional style, parental anxiety, and socioeconomic status ([Frank et al., 1997](#)); based on these findings, interventions should foster more positive attributional and assertive styles, as well as support from friends and training in social skills.

Children who *both* perform more self-care *and* receive more dependent care from their mothers were found to have higher self-concept scores in one study ([Mosher and Moore, 1998](#)). One review examined the construct of the "sense of self" in children who survive cancer ([Woodgate and McClement, 1997](#)), encouraging an analysis of the child from multiple points of view of, including the following (borrowing from William James):

1. How the child defines himself or herself (the "Me-self")
2. The child as the subject, who experiences and organizes experience (the "I-self" or object)
3. The child within a social context (how the self mirrors the reactions of others)
4. The child in relation to feelings about himself or herself (self-reflection)
5. The child within a cultural context
6. The child in a self-evaluation context (self-concept, or how the child distinguishes himself or herself from others)
7. The child's self-esteem; that is, how the child feels about himself or herself, such as self-worth or feelings about competence

This construct is relevant to an understanding of how the child with cancer experiences himself or herself: How does the child conceptualize his or her illness? For example, does the child anticipate recovery?

Studies have suggested that adolescents with cancer attempt to maintain a sense of normalcy in their appearance, school attendance, and social connections ([Woodgate and McClement, 1997](#)). Adolescents may try to maintain a separation between the world of illness (cancer) and normalcy as a way of sustaining the integrity of their sense of self, although at the same time they can feel "different" because of the uniqueness of their experience and fortitude ([Rechner, 1990](#); [Woodgate and McClement, 1997](#)). Self-worth can positively influence affect, which in turn is related to the extent to which emotional reserves can be mobilized to allow the child to participate in life's activities. Self-esteem and self-confidence are believed to correlate with persistence and flexibility when faced with adversity ([Rutter, 1985](#)). Little research is available regarding how surviving cancer affects children's self-concepts ([Woodgate and McClement, 1997](#)). [Koocher and colleagues \(1980\)](#) found that developing an understanding of their experience and themselves related to successful coping strategies in three patients. Incorporating some assessment of the patient's sense of self into the evaluation of a child or adolescent newly diagnosed with cancer thus may be quite useful in developing an understanding of the patient's experience ([Damon and Hart, 1982](#); [Woodgate and McClement, 1997](#)). [Woodgate and McClement \(1997\)](#) reviewed [Damon and Hart's \(1982\)](#) interview techniques, which consist of: self-as-object items involve examining self-definition, self-evaluation, self in past and future, and self-interest and include questions such as the following:

1. What are you like?
2. What are you not like?
3. What do you like most about yourself?
4. What do you like least about yourself?
5. Do you think you'll be the same or different 5 years from now?
6. How about when you are an adult?

## 7. What do you want to be like?

Self-as-subject items involve examining aspects of continuity, agency, and distinctness, and include questions such as the following:

1. Do you change at all from year to year?
2. How did you get to be the way you are?
3. How did that make you the kind of person you are?
4. What makes you different from anyone you know? ([Damon and Hart, 1982](#); [Woodgate and McClement, 1997](#))

Cognitive and behavioral strategies designed to enhance self-worth and self-esteem can be targeted more accurately from such an understanding of the factors impacting on the child or adolescent's sense of self ([Woodgate and McClement, 1997](#)). Play and drawings must be used as tools for eliciting the same information in younger children. [Varni and coworkers \(1995\)](#) systematically studied this phenomenon. They found that perceived physical appearance in children with cancer had direct and indirect effects on depression and social anxiety, with the indirect effects proceeding from self-esteem. Perceptions of athletic, social, and academic competence were found to attenuate the effects of perceived body image on self-esteem to some degree. These findings highlight the importance of interventions such as those described by Varni in other papers that address social functioning and support ([Varni et al., 1994](#)), and cognitive interventions that might successfully address negative feelings about physical appearance.

## FAMILY FACTORS INFLUENCING ADJUSTMENT AND OUTCOME

Research has explored the effect of family factors on the psychological morbidity of cancer in children. This has been examined from a social-ecological perspective ([Shapiro et al., 1998](#)) in mothers of children diagnosed with leukemia, where both intrapsychic factors (caregiver adaptation as reflected by maternal depression and sense of burden) and instrumental adaptation (reflected by maternal ability to function successfully within the health care system) were affected by positive relationships in the family. Mothers who noted less depression and burden were more likely to report improved relationships and communication with their spouses; mothers noting more positive doctor–parent relationships also reported better relationships with both spouse and child. Others also have looked at adjustment and coping by parents of children with cancer ([Grootenhuis and Last, 1997](#)), examining psychological distress, marital distress, and family functioning, as well as the use of coping strategies such as social support, communication, search for meaning, and factors that affect adjustment.

Parents commonly experience feelings of isolation, incompetence, and self-blame. [Die-Trill and Stuber \(1998\)](#) reviewed two models of parental response to a diagnosis of cancer, one of which describes stages including the anxiety and disorganization of the impact of the diagnosis, denial, grief, focusing attention on the situation, and closure, which is marked by acceptance and adjustment to the ramifications of the illness on the family ([Fortier and Wanlass, 1984](#)). A second model frames potential response patterns of chronic sorrow ([Buschmann, 1988](#)), and is characterized by profound feelings of losing the “complete” child and his or her hopes over the long-term.

There have been conflicting reports on the specific effects of pediatric cancer on family functioning because of the lack of methodologic consistency in studies ([Die-Trill and Stuber, 1998](#)). Studies vary as to whether the child was on or off treatment, prospectively or retrospectively, or was involved in a specific phase of treatment (initial, inpatient, outpatient, or during remission), rather than longitudinally. It appears that preexisting family stressors—parental psychiatric illness, child neglect, divorce or marital conflict, conflict between parent and child, cultural and language barriers, and multiple losses within the family—put families at risk for adjustment difficulties ([Brown et al., 1992, 1993](#)). Acute emotional disturbance during the initial phase of diagnosis, including intense separation anxiety, sleep disturbance, and obsessive-compulsive symptoms, have been described in over 50% of parents, with the persistence of anxiety and depression 8 months later during remission, and sleep problems and depression 20 months later ([Magni et al., 1986](#)).

Positive parental adjustment has been found to correlate with marital satisfaction, family support, open communication, less stressors, family expressiveness, and a greater moral or religious emphasis ([Barbarin and Chesler, 1986](#); [Cassileth et al., 1985](#); [Die-Trill and Stuber, 1998](#); [Kupst et al., 1984](#); Spiegel et al., 1983). Siblings also can be specifically affected and experience ambivalent feelings, including intense fears about their ill sister or brother. Siblings also may develop feelings of abandonment and resentment because parental attention is focused on the ill sibling, with consequent feelings of guilt because of their anger or being the well child. Siblings may harbor shameful feelings about the appearance of their ill brother or sister, or develop somatic preoccupations ([Die-Trill and Stuber, 1998](#)).

[Manne and Miller \(1998\)](#) found that perceived conflict between adolescents and their mothers was associated with psychological distress; the magnitude of physical impairment accounted for most of the variance, supporting interventions that address this relationship. [Sahler and associates \(1997\)](#) found that mothers with dysfunctional siblings of a child with cancer displayed the lowest levels of well-being and were more likely to look for professional services, and least likely to benefit from social support, indicating that specific problem-solving training for mothers was likely to be more effective. [Hoekstra-Weebers and colleagues \(1999\)](#) found that trait anxiety, considered to be a personality factor, predicted risk most robustly for maladjustment to having a child with cancer, and social support seeking by fathers tended to mitigate risk. With regard to mothers, the experience of positive events that preceded the child's diagnosis and assertiveness seemed to reduce the risk of maladjustment. [Sawyer and coworkers \(1997\)](#) prospectively studied children aged 2 to 5 who were diagnosed with cancer and their families, and reported that considerable distress was reported in the period immediately following diagnosis, although this effect became attenuated during the year following diagnosis, approaching levels of problems seen in the general community. In a later paper, [Sawyer and coworkers \(1997\)](#) reported that maternal adjustment following the diagnosis of childhood cancer predicted the child's adjustment 2 years later; it was hypothesized that impaired maternal functioning from maladjustment might impact on the delivery of care for their children.

[Enskar and colleagues \(1997\)](#) described eight categories of problems faced by the families in their sample of 15 children and adolescents with cancer, including: (a) feelings of powerlessness associated with the child's suffering or reaction to the disease or treatment; (b) having their lives governed by the child's disease (e.g., with respect to work and finances); (c) shifting family dynamics, including the lack of privacy or integrity in the marital relationship, not devoting enough time to well siblings, and tendency to spoil or overprotect the sick child; (d) significant change in parental self-image governed by a shift in priorities, feelings of despair, sadness, and uncertainty; (e) attempts to cope; (f) dealing with the reactions of others; (g) finding support from others (including immediate family, friends, parents of other ill children, and health care staff); and (h) evaluating the quality of care, with an emphasis on professionalism of staff, organization of the delivery of care, information supplies, and types of equipment available for activities (e.g., VCR).

[Brown and associates \(1993\)](#) found that 34% of mothers with children diagnosed with ALL met the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition, revised (DSM-III-R) ([American Psychiatric Association, 1987](#)), criteria for at least one psychiatric disorder, and that psychopathology in either parent accounted for a major portion of the variance seen in the children's' psychological function. Children with mothers who had a psychiatric diagnosis noted more anxiety symptoms and were more likely to have a maladaptive attributional style; mothers with psychiatric diagnoses reported more internalizing symptoms in their children, although this could have represented biased reporting. The higher rates of psychiatric disorders in mothers in this sample as compared with the community at large seemed not to be explained simply on the basis of a stress response to the child's illness, and may have resulted from higher rates of premorbid disorders. The majority of the children in this sample did not evidence elevated rates of psychopathology, although the children who had parents with psychopathology did have greater adjustment difficulties; the direction of this relationship remained unclear, and the authors supported a multifactorial model including the interactive effects of chronic illness in the child and vulnerability to parental psychopathology. Other research in this area has found that the constructs of family cohesion and expressiveness most positively predicted favorable adjustment in pediatric cancer patients at 6 and 9 months following diagnosis ([Varni et al., 1996c](#)).

Treatment adherence in this population also has been reviewed ([Die-Trill and Stuber, 1998](#)), with 33% of children under 13 years of age and 59% of adolescents found to be noncompliant with oral medication; nonadherence is causally associated with poorer prognosis. Factors predictive of adherence differ by sex, anxiety (in female patients), and anxiety, anger, and obsessive-compulsive behavior (in parents of male patients) associated with greater adherence. Medication intake, number of siblings, and poor-self image also correlate negatively with adherence. Cultural differences also play an important role in adherence, and more intensive treatment, parental depression, and child behavioral problems are predictive for less adherence ([Die-Trill and Stuber, 1998](#)). Paradoxically evidence does not support increased adherence in more serious illnesses; those adolescents at risk seem to have less insight into causality and prognosis, and use denial more defensively ([Die-Trill and Stuber, 1998](#)).

Adherence has been found to relate to family factors ([Manne et al., 1993](#)). Problems with adherence were found to be more common in younger children (especially around procedures such as venipuncture, lumbar puncture, or bone marrow aspiration) and families with lower socioeconomic status (decreased adherence to appointments and the reporting of child's reactions to treatment). A more “supportive” parenting style seemed to be associated with greater adherence, which is perhaps mediated by the child's perception of the parent's receptivity to hearing complaints or concerns voiced by the child, or the parent responding more sensitively to child distress, such as a reluctance to get out of bed on the day of a clinic appointment. Treatment implications include interventions designed to behaviorally

assess and improve parental supportive functions. The success of specific types of behavioral interventions designed to treat noncompliance probably can be optimized by determining the acceptability of these measures by parents and nurses before instituting them ( [Miller et al., 1998](#)); in this study, positive reinforcement and reprimand were tolerable to parents, whereas response cost and time out were not.

## PAIN AND DISTRESS IN THE PEDIATRIC POPULATION

An understanding of the psychological meaning of pain within a developmental and individualized context is crucial to working with pediatric cancer patients, and can be associated with disease, procedures, or treatment ( [Frager and Shapiro, 1998](#)). Pain from disease can be somatic, visceral, or neuropathic in etiology; treatment-related pain includes mucositis, peripheral neuropathy, and obstipation; pain syndromes also can be specific for certain stages of treatment, including pain in the initially diagnosed patient, during relapses in the terminal patient, or chronic pain syndromes following treatment ( [Frager and Shapiro, 1998](#)). Children may minimize or deny pain symptoms owing to associations of pain complaints with procedures or doctor visits, out of fear of worrying their parents, or out of a sense of guilt for somehow being responsible for the pain. Procedural pain in and intense anxiety in anticipation of such procedures in particular is often highlighted as most distressing by these patients, yet this area is often one not given enough attention by health care professionals; this exacerbates the feelings of loss of control that accompanies cancer treatment. Parents also may minimize or deny the extent of their child's pain because it symbolically heralds a more ominous prognosis for the illness, or to protect them from experiencing the impact of their child's pain. Pain can worsen preexisting marital tension and lead to parents blaming each other for the suffering of their child; siblings may experience serious distress too, especially guilt about witnessing their brother or sister suffer ( [Frager and Shapiro, 1998](#)).

Guidelines recommended by [Frager and Shapiro \(1998\)](#) are: (a) including the entire family in intervention for pain; (b) viewing pain as an "emergency;" (c) addressing the physiologic, emotional, and social aspects of pain; (d) facilitating parental involvement in pain management; (e) frequently reassessing pain and the success of interventions; (f) using both pharmacologic and nonpharmacologic strategies; and (g) being vigilant to treatment-associated pain, both in advance and concurrent with treatment. They provide an excellent manual on the assessment and treatment of pain in this population, noting the need for a comprehensive initial pain assessment, with a detailed history and characterization of the pain complaints and coping strategies, and the use of self-report aided by visual analog scales as the "gold standard" ( [Frager and Shapiro, 1998](#)). They stress the importance of issues such as privacy during procedures, trust, and (safe time" when the child knows that procedures will not take place. The presence of an involved parent who can use transitional objects, story-telling, books, or other developmentally appropriate interventions specific to a child's interest can help these children tremendously. Pharmacologic interventions ( [Frager and Shapiro, 1998](#)) include nonsteroidal antiinflammatory drugs, acetaminophen, opioids, or adjuvants such as tricyclic antidepressants or anticonvulsants such as gabapentin, depending on the type of pain (acute versus chronic, neuropathic versus somatic or visceral, localized versus diffuse); topical analgesics include eutectic mixture lidocaine-prilocaine topical anaesthetic (EMLA) cream. An essential principle is that adequate pain management is given as "standing orders," not pro re nata (PRN) as needed. Patient-controlled analgesia is an extremely effective way to achieve around-the-clock pain management. Identification of comorbid conditions (e.g., anxiety, insomnia) can help guide the use of other adjuvant medication such as benzodiazepines.

The American Academy of Pediatrics published guidelines regarding the management of pain associated with procedures in children with cancer ( [Zeltzer et al., 1990](#)). Despite these guidelines, The American Pain Society noted in its 1995 Consensus Statement that pediatric pain continued to be an under treated phenomenon, owing to a lack of education in health care providers, misled concerns about addiction to opiates, state and federal regulations regarding the prescribing of controlled substances, and insurance reimbursement for the same ( [American Pain Society Quality of Care Committee, 1995](#)). In this statement, they reviewed the American Pain Society Guidelines for pain management, which had been established in 1991, and included: recognizing and treating pain promptly (including charting/displaying of pain self-report, identifying outcome variables, and documenting outcome); making information about analgesics readily available; promising patients attentive analgesic care; defining explicit policies for use of advanced analgesic technologies; and examining the process and outcomes of pain management with the goal of continuous improvement ( [American Pain Society, 1991](#)). These guidelines were revised in 1995 ( [American Pain Society, 1995](#)), noting five key elements: (a) assuring that a report of unrelieved pain raises a "red flag" that attracts clinicians' attention; (b) making information about analgesics convenient where orders are written; (c) promising patients responsive analgesic care and urging them to communicate pain; (d) implementing policies and safeguards for the use of modern analgesic technologies; and (e) coordinating and assessing implementation of these measures. The Agency for Health Care Policy and Research also published guidelines for the management of cancer pain (1994), and these guidelines have been applied to children ( [Buchanan et al., 1997](#); [Schmidt et al., 1994](#)).

Other guidelines relating specifically to children also have been published ( [McGrath et al., 1996](#)) that stress the combined modalities of behavioral, physical, and supportive therapies along with appropriate pharmacologic treatment, which should be given as a standing order (not a "PRN") to help children sleep through the night, and orally to avoid painful routes of administration.

Specific articles have been written about the use of local anesthetic agents such as EMLA cream ( [Kapelushnik et al., 1990](#)), such as in reducing pain associated with lumbar puncture. [Varni and associates \(1996a\)](#) described a "Multidimensional Biobehavioral Model of Pediatric Pain," and used this model to look at psychosocial mediators of pain, such as "perceived stress." Perceived stress is a construct that reflects the meaning of day-to-day events that are distressing to children, also referred to as "daily hassles" ( [Varni et al., 1996a](#)). Varni concluded that targeted cognitive-behavioral interventions could be effective in reducing pain, such as "cognitive refocusing" or "stress management techniques (progressive muscle relaxation, meditative breathing, and guided imagery)," would be effective in ameliorating pain, based on his model of "precipitating events" and "intervening variables," which mediate pain perception in children ( [Varni et al., 1996a](#)).

Standardized assessment of pediatric pain also has been an area of scrutiny ( [Varni et al., 1996b](#)). There is some evidence that different phenomenon might be measured depending on the informant (child, parent, or nurse). [Manne's \(1992\)](#) study found that during venipuncture in pediatric cancer patients, when compared with an independent rater, the child's report correlated most with chronologic age, the parents' report was based on their subjective perception of the child's pain, and the nurse's report reflected overt distress. Distress is five to ten times greater in children under 7 years of age ( [Jay et al., 1985](#); [Redd, 1994](#)). Some of this can be attributed to the cognitive level of the child, as the understanding of illness and procedures follows along piagetian lines ( [Perrin and Gerrity, 1981](#)). Young children often feel illness and/or procedures represent punishments for misdeeds, and may attribute malevolent intentions to health care providers, especially in the context of a procedure. A recent review of 13 treatment-outcome studies ( [Powers, 1999](#)) indicated that cognitive-behavioral intervention is a "well-established treatment" for pain accompanying procedures in children.

As [Redd \(1994\)](#) noted, parents may influence their child's emotional state during procedures via a "contagion" model; the child may read nonverbal cues indicating the presence of a threat and become as anxious as his or her parents. This phenomenon could result from a parent's anxiety or depression interfering with his or her support during a procedure, or from the lack of distress reducing skills (i.e., simply trying to reassure the child instead of using distraction or other behavioral techniques). Depending on the developmental level of the child, the parents can play a key role in using cognitive-behavioral interventions, which might include the child blowing on a party blower, the use of video games, guided imagery, or hypnosis, accompanied by positive reinforcement (stars, stickers, etc.) ( [Redd, 1994](#)). Behavioral interventions, including parent coaching, attentional distraction, and positive reinforcement can reduce distress during venipuncture, with less physical restraint needed ( [Manne, 1990](#)). Contingency management, hypnosis, systematic desensitization, modeling, and behavioral rehearsal allow parents to play an important part in these interventions ( [DuHamel et al., 1999](#)). Taken together, the data suggest that the emotional state of parents exerts a powerful effect on the way children's feelings are interpreted, and directly on psychological morbidity in children in and of itself.

Pediatric cancer patients undergo repetitive invasive, frightening, and painful procedures that are often sensitizing (i.e., the child does not necessarily "get used" to the procedure); and there may be resistance, refusal, and anticipatory fear because of cognitive limitations, especially in younger patients. Die-Trill and Stuber have described childhood manifestations of distress:

distress is usually manifested by crying, screaming, requesting emotional support or physical contact, verbal resistance, verbal expression of fear, information seeking, and requesting delays in the administration of the procedure. Common fears include disfigurement, losing all their blood or being overloaded with it during transfusions, and death. Shame for not being able to control oneself is frequently experienced by older children ( [Die-Trill and Stuber, 1998](#), p. 899).

Parents and staff alike may feel overwhelmed and guilty when observing such distress in a child.

## COGNITIVE SEQUELAE OF CANCER TREATMENT

Cancer also can impact on neuropsychological function directly, in the case of brain tumors and metastases, and indirectly, through the effects of infections, fever, medication, and complications ( [Silberfarb and Oxman, 1988](#); [Walch et al., 1998](#)). A significant mediator of the effect caused by brain tumors is younger age at diagnosis and treatment.

Work done in the last decade found that CNS irradiation and intrathecal administration of chemotherapeutic agents (e.g., methotrexate, which is used as prevention against disease spreading to the CNS in leukemia) could have adverse effects on cognitive function, although they improve survival rates dramatically. These effects are most commonly seen in performance skills, arithmetic, perceptual motor skills, visual processing, visual motor integration, sequencing ability, and short-term memory (Redd, 1994), although some researchers have argued that more specific individual neuropsychological batteries might measure effects more specifically and validly than overall global tests such as the Wechsler Intelligence Test for Children (WISC). The size of the effect has many determinants, including the child's age and sex, dose of radiation, size of the area irradiated, and dose schedule (Redd, 1994; Walch et al., 1998). It is notable that adverse effects may not be seen until years following treatment (Redd, 1994; Rubenstein et al., 1990).

## POSTTRAUMATIC SYMPTOMS RELATED TO CANCER TREATMENT

Many articles have been published recently about PTSD in pediatric cancer patients (Barakat et al., 1997; Butler et al., 1996; Hill and Stuber, 1998; Kazak et al., 1997; Manne et al., 1998; Smith et al., 1999; Stuber et al., 1997; Wintgens et al., 1997). This was in part because the stressor criterion was modified in DSM-IV to include life-threatening illnesses (Smith et al., 1999). The incidence of PTSD in pediatric cancer survivors in one study was 14.7% (Barakat et al., 1997), with parents also having significantly elevated PTSD symptoms associated with child symptoms and mediated by perceived life threat and family and social support resources. Stuber and associates (1997, p. 958) found that predictors of PTSD in 437 child and adolescent pediatric cancer survivors included the following:

1. The survivor's retrospective subjective appraisal of life threat at the time of treatment, and the degree to which the survivor experienced the treatment as "hard" or "scary" (This was mediated by the mother's perception of both the threat to life and the severity of treatment.)
2. The child's general level of anxiety
3. A history of other stressful experiences
4. The time since the termination of treatment (negative association)
5. Female gender
6. Family and social support

Stuber noted child-specific PTSD symptoms, including somatic indications such as stomachaches, nightmares, and repetitive play. The majority of survivors experience mild PTSD symptoms, although it was noted that these might not necessarily be maladaptive in all cases. Interestingly, neither exposure itself to life-threatening procedures such as bone marrow transplantation, nor the age of the child, nor the medical sequelae of treatment were predictive of the development of PTSD symptoms in and of themselves. The role of the mother's perception of life threat to the child and her anxiety level were found to be quite significant, which supports the importance of psychological interventions directed toward the mother. The social support finding was interesting from the point of view of how the survivor's perception of an upsetting response on the part of other family members and friends could impact on PTSD symptoms, underscoring the need for further work to help delineate how this effect is mediated, such as through empathy or guilt in the survivor as Stuber and associates (1997) suggest. Interventions during the acute phase of treatment could impact on the child and family's perception of life threat, help mold this view in a realistic but hopeful manner, and offer acute anxiety-reduction interventions for the child (Stuber et al., 1997).

In a literature review of PTSD studies of pediatric cancer patients and their parents, the children and adults involved in studies using a validated PTSD diagnostic tool experienced PTSD symptoms in all but one case (Smith et al., 1999). In one study, 6.2% of mothers of children who survived cancer had PTSD, and an additional 20% had subclinical PTSD (Manne et al., 1998). Twenty-five percent of mothers with PTSD also had an anxiety or depressive disorder. Reviews on this topic have noted research documenting that parents of adolescent survivors of cancer also have a heightened incidence of PTSD (Kazak et al., 1998; Pelcovitz et al., 1996; Stuber et al., 1997); the latter study noted the important predictive power of parental anxiety.

## OTHER BEHAVIORAL AND PSYCHOSOCIAL INTERVENTIONS

Behavioral interventions in this population have been reviewed recently (DuHamel et al., 1998). In addition to the specific interventions suggested in the preceding by research on PTSD and the cognitive-behavioral interventions designed specifically for pain, distraction and relaxation in particular have been found to be effective treatments in this population, especially for chemotherapy side effects such as nausea and vomiting (McQuaid and Nassau, 1999). Psychoeducation has been found to reduce distress levels in parents in this population (Hoekstra-Weebers et al., 1998). The potential positive impact of both individual and group psychotherapy has been reviewed recently (Sourkes, 1998; Woolverton and Ostroff, 1998), both from preventative and posttreatment perspectives. In particular, play therapy with younger children can be valuable in facilitating a sense of mastery and desensitizing children from procedure-related distress. School-based interventions, peer groups, and other interventions to address psychosexual concerns can be valuable for older children and adolescents (Woolverton and Ostroff, 1998).

Up to 29% of pediatric cancer patients receiving chemotherapy have been reported to experience nausea, and 20% develop vomiting in anticipation of chemotherapy, mediated by a classical conditioning model, and correlated with emetic potential of the offending agent. Children with greater anticipatory nausea and vomiting also tend to have parents who reassure and model healthy coping strategies less, and rely more on threats. The response to Ondansetron, an antiemetic agent, in controlling anticipatory nausea and vomiting prior to chemotherapy, is mediated by psychological factors such as expectations of vomiting following chemotherapy. This also implies that psychological intervention addressed at the cognitive component that interplays with the classical conditioning model could be helpful (Tyc et al., 1997).

Clowning has been investigated as a tool in reducing distress in children undergoing invasive medical procedures (Oppenheim et al., 1997). Two pilot studies examined the effect of specially trained clowns on distress in children undergoing medical procedures (Slater et al., 1998). In Study I, 27 6- to 20-year-old heart transplant recipients (mean age = 14.06 years) were observed during three consecutive biopsies during cardiac catheterization. Subjects were randomly assigned to clown versus no-clown conditions during their second visit. Baseline data were collected without the clowns present. Children and their caregivers completed self-report measures of distress and anxiety. Trained observers, caregivers, nurses, and physicians rated child distress. Results show a decrease in observed child distress ( $P = 0.054$ ), and significant decreases in child self-reported distress ( $P = 0.011$ ) and parent-rated child distress ( $P = 0.049$ ) with the clowns present. Doctors found the procedure easier to perform with the clowns present ( $P = 0.011$ ).

Study II was a crossover design, with 32 3- to 18-year-old children (mean age = 10.22 years) in a cancer day hospital who were randomly assigned to exposure to clown treatment at either visit 1 or visit 2 during invasive procedures. Children's distress was rated as in Study I. Results of Study II show no significant difference in child distress with clowns present. Doctors and nurses found procedures easier to perform with clowns present ( $P = 0.066$ ). The presence of specially trained clowns during invasive medical procedures significantly reduced children's distress during cardiac catheterization. Less robust findings in the oncology setting may be owing to the small number and pain-control measures already available in the oncology clinic. Future studies might focus on benefits of clowns with sick children in less frightening medical settings.

Support groups or family conferences for patients, their siblings, and parents, along with educational material disseminated to the patients, families, and schools also can be helpful (Whitsett et al., 1999). One-day programs for families of children with cancer also have been constructed and systematically evaluated, showing that they can reduce levels of anxiety and PTSD symptoms at 6-month follow-up (Kazak et al., 1999).

These issues have been written about in a multicultural context as well, stressing the importance of the relationship between family members and health care workers, as well as the relationship between families as a group and the health care team as a group (Masera et al., 1998). Salient points include the importance of the delivery of adequate psychosocial care, mutual respect, education, regular psychosocial team meetings, dealing with reentry issues following treatment (in school, work, and with friends), liaisons between medical teams, parent associations (which should be organized and directed by parents), and community-based efforts; as well, education must occur on a national and international level to heighten awareness of these issues. The emerging message is clear: Psychosocial interventions for these children and their families are imperative and *do* work (Kazak et al., 1995).

Interventions designed to reduce stress in pediatric oncology staff also have received recent attention (Grootenhuis et al., 1996). In this study, none of the staff underestimated the parents' need for support, which was even higher than the parents' estimated. There were gender effects, with female health care staff rating pain during three medical procedures higher than male staff, and the ratings of staff who had worked longer in oncology being less than those working for a lesser period of time. More experienced staff tended to see the patients in a more positive light, for example, perceiving them as stronger, which may represent a coping strategy for the staff. This study highlights the importance of health care workers being attuned to the evolution of their own attitudes regarding their patients.

The importance of an awareness of psychosocial issues in these children is also relevant to the radiologist (Gunderman, 2000). Recommendations include that

support staff not discuss radiologic findings with patients and families, and that the radiologist set aside time to meet with patients and families, certainly before the procedure or imaging study, to explain what will happen, and answer questions, although the radiologist probably should not be the physician who informs the patient of a diagnosis of cancer. However, the author makes the point that questions should be answered directly (in a private setting), and may even communicate concern about radiologic findings, although discussed in a general fashion, leaving the role of definitive diagnosis to the pediatric oncologist. The author underscores the importance of understanding negative reactions of patients and families to radiologic procedures and revisits (e.g., which may be accompanied by a fear of relapse), and to look for ways to help parents feel more in control during these procedures. The radiologist may allow parents to assist in positioning their children, administer oral contrast, and remain close by to give support. The use of developmentally appropriate explanations about the procedure to children, such as using dolls in younger children, is also essential. It is also important for the radiologist to administer sedation in a liberal fashion (as opposed to physically restraining the child), develop a relationship with the family, and be sensitive to the physical changes associated with illness and treatment.

The relevance of social support as a construct in pediatric cancer patients also has been reviewed recently ( [Woodgate, 1999](#)). Increased social support facilitates adjustment in these patients and their families, although there is an inexact appreciation for how these experiences are protective. The author concludes that there is a need for more comprehensive research efforts looking at social support from a family, sociocultural, and developmental perspective. Treatment implications proceed from this perspective as well as the understanding of social support needs as dynamic, time- and context-dependent, and patient-specific over the course of treatment.

The importance of spiritual care in pediatric cancer patients also has received comment in the literature ( [Hart and Schneider, 1997](#)). They reference spirituality in children as “the ability of a child through relationships with others to derive personal value and empowerment” ( [Taylor et al., 1995](#)). Such relationships occur both on a vertical (higher being) and horizontal level (self, others, and environment) ( [Fulton and Moore, 1995](#)). The approach to spiritual care first involves an assessment of religious needs (religious preference and activities) and receptivity to support groups, as well as the spiritual needs of the child. Using developmental theory, such as that espoused by Piaget ( [Ginsburg and Oppen, 1998](#)) and Erikson (1963), can allow nurses to intervene successfully to reduce distress, within a religious framework as well. An awareness of and sensitivity to losses specific to each child, the importance of interventions designed to facilitate a sense of normalcy, and the continuing role of nursing in the terminal stages of illness are also underscored.

Psychotherapy in this population has been reviewed, with three domains of focus identified: effects of cancer and its treatment on body image related to procedures and so on; effects on “normal” social, academic, and family functioning; and life, death, and grief issues ( [Sourkes, 1998](#)). Individual psychotherapy can address issues related to the trauma of the threat against survival and experience of illness, loss and helplessness, and need to rebuild one's life following treatment ( [Sourkes, 1998](#)). Sourkes stresses the importance of considerations of the cognitive, affective, and social impact of cancer on the child, and reviews the “props” needed, such as a dollhouse or stuffed animals. He also reviews the tools employed by the therapist, such as art techniques, lists made by the patient that identify areas of focus, mutual storytelling, or writing. Play psychotherapy can play a vital restorative function in these patients and facilitate a sense of mastery and partnership with the therapist.

Normalization of the emotional experience (common to cancer patients) can facilitate acceptance of the therapy; the goals are to enhance coping strategies, autonomy, and control ( [Sourkes, 1998](#)). Issues of confidentiality must be respected, because trust is the cornerstone of treatment. The importance for the therapist of developing a liaison with parents and other professionals caring for the patient and being attuned to countertransference is also underscored. The latter can include the impact of unresolved issues of loss in the therapist's life, and the need to walk a fine line between the intense suffering these children experience and the need to maintain a healthy distance that allows preservation of the therapist's emotional stability without compromising an empathic connection with the uniquely demanding nature of the child's emotional needs. Guilt over being healthy and anxiety about the child's life are common in therapists working with these children ( [Sourkes, 1998](#)). A therapist may develop displaced anxiety about her or his own health or the health of her or his own children as part of a countertransference phenomenon.

Brief psychotherapy in children with cancer also has received comment in the literature ( [Oppenheim and Hartmann, 2000](#)). In the four cases presented, the importance of the effects of parents' relationships with their own parents; the psychological status and ambivalent feelings of siblings; the symbolic aspects of disfigurement, body image, and self-concept; and the relevance of intense fears and fantasies were material ripe for psychotherapeutic intervention.

On a systems level, particularly in areas where there is a lack of academic medical centers doing oncologic research, “shared management” of pediatric cancer patients has been instituted, which divides care between the university medical center and community-based physicians ( [Kisker et al., 1997](#)). [Kisker and colleagues \(1997\)](#) reviewed the initial evaluation of this system, which indicated that treatment protocols were followed rigorously, that there were both direct (medical costs) and indirect (loss of work) savings, and no significantly higher rates of medical morbidity. The 15-year follow-up of this program had similar results. Comparable survival rates in the children and improved relationships between the academic center and primary care physicians were found. Such benefits can have potential “trickle down” benefits on the patients and families (personal comment).

The Children's Cancer Group (CCG), created in 1955 with 116 member institutions, is a pediatric clinical trials cooperative oncology group that is unparalleled in scope in North America ( [Kodish et al., 1998](#)). Informed consent in pediatric patients and their families has been researched ( [Kodish et al., 1998](#)), and it was found that clinicians tend to underestimate the amount of information parents prefer to know; the role of the child, equally important, was not studied in this instance. Informed consent is most accurately described as a process, not a singular occurrence. In this study, although parents generally were satisfied with the informed consent process, clinician-investigators were not, perhaps because of the overpowering nature of the informed consent process and its weight on parents.

## PSYCHOPHARMACOLOGY IN THE PEDIATRIC CANCER PATIENT

Psychopharmacology in this population was recently reviewed by [Spiegel \(1998\)](#), who noted a paucity of published work in this area. Use of tricyclic antidepressants for children with anxiety and depression and the use of alprazolam for anticipatory anxiety have been reported ( [Maisami et al., 1985](#); [Pfefferbaum et al., 1987](#); [Pfefferbaum-Levine et al., 1983](#)). [Spiegel \(1998\)](#) stresses the role of medication as complementing psychological and behavioral interventions, with a focus on treating specific symptoms as opposed to psychiatric disorders. The use of psychotropic medication in this population is hampered by our limited understanding of their interactions with oncologic medications and FDA approval for such usage, and the need to extrapolate from adult literature. It is essential that consideration of cytochrome P450 drug interactions be studied when using psychiatric medication in this population ( [Flockhart and Oosterheld, 2000](#)).

### Anxiety

[Spiegel \(1998\)](#) reviewed the literature documenting anxious and phobic symptoms in this population. Procedural phobias, separation anxiety, and PTSD have been described in the pediatric cancer patient. Emotional symptoms must be viewed within a developmental context and are intimately intertwined with physical illness, often making differentiation of the two challenging. For example, a procedural phobia can be a representation of incompletely treated pain, and anxiety can be a sequelae of sleep deprivation or represent a premorbid psychiatric condition that becomes exacerbated in the context of cancer and its treatment; all three phenomena could occur simultaneously. Anxiety also can occur secondary to delirium, medication side effects, infection, or other metabolic causes. The use of specific agents such as antidepressants, antihistamines, benzodiazepines, neuroleptics, and narcotic analgesics is guided by the intensity and time course of the anxiety and comorbid symptoms ( [Spiegel, 1998](#)). Posttraumatic stress disorder may be treated acutely with benzodiazepines and chronically with antidepressants. Antihistamines can be used for insomnia, sedation, and generalized anxiety, although they present risks because of anticholinergic toxicity in cognitively impaired or delirious patients. Benzodiazepines can be used for anxiety related to procedures, insomnia, and generalized anxiety, although side effects can include impaired cognition and disinhibition, especially in the presence of CNS disease or delirium. Routes of administration depend on the specific agent, with alprazolam given sublingually; lorazepam given orally; and lorazepam, midazolam, and diazepam given intramuscularly. Diazepam can be given intravenously; and clonazepam may be the most appropriate benzodiazepine for chronic use because of its long duration of action and twice-daily dosing.

Tricyclic antidepressants are effective in the treatment of insomnia, panic attacks, or generalized anxiety. Selective serotonin reuptake inhibitors have not been studied systematically, but anecdotally seem to be effective for both depression and anxiety in this population.

### Depressive Disorders

[Spiegel \(1998\)](#) underscored the difficulty of making a depression diagnosis in this population, given the preponderance of somatic symptoms (insomnia, anorexia, diminished energy) and the psychological responses to illness in children being treated for cancer. Undertreatment of pain, subsyndromal delirium, and PTSD can all present with depressive symptoms as well.

Low-dose tricyclic antidepressants are potentially valuable in treating specific depressive symptoms in this population, such as insomnia, and may increase appetite in these physically compromised patients. Side effects include anticholinergic effects (urinary retention, dry mouth, constipation, delirium) and effects on cardiac function

(hypotension, hypertension, EKG changes, and arrhythmias), although these are less likely on lower doses. Choice of agent is dependent on desired effect and route of administration, with amitriptyline being the most sedating, and nortriptyline available as an oral elixir.

Selective serotonin reuptake inhibitors, which have now been shown to be effective in pediatric depression in a controlled trial ( [Emslie et al., 1997](#)) and open trials ( [Rey-Sanchez and Gutierrez-Casares, 1997](#)), seem to be tolerated well in this population and appear to be superior to tricyclic antidepressants for the treatment of depression in this population, and may as well be effective for the treatment of PTSD ( [Spiegel, 1998](#)). Paroxetine may have the advantage of occasionally enhancing appetite. It is essential to monitor for pharmacologic interactions between selective serotonin reuptake inhibitors (SSRIs) and other medications pediatric cancer patients may be taking, given the potential for effects on the P450 enzyme system.

### Stimulants

Stimulant medications, the hallmark of treatment of attention deficit hyperactivity disorder (ADHD), are effective in this population in lower doses for enhancing energy state or counteracting the sedating effects of narcotic analgesics. Important side effects to monitor include insomnia and anorexia. Stimulants may be used in conjunction with anxiolytics, SSRIs, or tricyclic antidepressants.

### Delirium and Psychosis

Pediatric cancer patients are at risk for delirium owing to multiple factors, including the following ( [Spiegel, 1998](#)):

1. Primary effects of CNS tumors
2. Metabolic derangement
3. Drug withdrawal
4. Infection
5. Inadequately treated pain
6. Fever
7. Effects of radiation
8. Effects of chemotherapy and other medication (especially narcotics, medications with anticholinergic side effects, or drug-induced mania)

Delirium frequently goes unrecognized, and must be considered in the differential diagnosis of any acute change in a pediatric cancer patient's behavior, which might be manifested as anxiety, psychosis, aggression, or confusion. The mini-mental status examination, or more formal neuropsychological testing (if time permits) can be useful in formally assessing and following alterations in mental status; family recognition of a change in a child's behavior can be invaluable.

Low-dose treatment with high-potency neuroleptics, such as haloperidol or risperidone, can be quite effective in treating delirium and the accompanying behavioral agitation, so long as the underlying etiologies are also being investigated and treated. Intravenous haloperidol, although not an FDA-approved treatment, has been reported to be quite effective in appropriate circumstances ( [Spiegel, 1998](#)). Low-potency neuroleptics (e.g., chlorpromazine, thioridazine) may be used to treat insomnia or for sedation. Neuroleptics also may be used to treat aggressive behavior in this population, which may represent a symptom of delirium, an underlying psychiatric disorder, or a medication side effect.

Neuroleptics, when used in low dosages, tend to be fairly well tolerated in this population, although the treating clinician should be astute to extrapyramidal side effects such as dystonic reactions, Parkinsonism, and akathisia. Of note is that neuroleptics, including chlorpromazine, haloperidol, and risperidone, can all potentially prolong the QTc interval ( [Welch and Chue, 2000](#)). Risperidone has calcium-channel blocking properties. Other serious potential side effects include neuroleptic malignant syndrome.

### Pain

Tricyclic antidepressants (TCAs) and benzodiazepines can be useful adjuncts to the pharmacologic management of pain, particularly to treat comorbid anxiety and/or insomnia, or as premedication for procedures. Tricyclic antidepressants actually may potentiate the analgesic effects of narcotics, and psychostimulants may counteract the sedating effects of narcotics ( [Spiegel, 1998](#)).

### Comorbid Psychiatric Disorders

Unfortunately, some pediatric cancer patients may have preexisting psychiatric disorders that may require continued treatment with psychostimulant medication (ADHD), antidepressants, or mood stabilizers, although these treatments have not been systematically studied in this population. It is imperative to monitor for drug interactions with other medications the patient may be on. [Spiegel \(1998\)](#) notes the vulnerability of survivors to affective disorders, learning and attentional difficulties, and PTSD, to which the clinician must be attuned, and which may require pharmacologic treatment.

The treatment of the terminal patient also must not be overlooked. Longer-acting benzodiazepines (e.g., diazepam, clonazepam) minimize rebound anxiety and are effective in delirium, and neuroleptics are less likely to cause confusion in toxic states. High-potency neuroleptics may be used to preserve alertness, or low-potency neuroleptics may be used to enhance sedation, depending on the clinical situation ( [Spiegel, 1998](#)).

## HOSPICE CARE AND THE TERMINAL PATIENT

The issue of hospice care and death unfortunately cannot be ignored in pediatric oncology, and a familiarity with published material on these issues is essential to any professional working with these children ( [Davies, 1996](#); [Farrell, 1996](#); [Gillance et al., 1997](#); [Goldman, 1995](#); [Goldman and Christie, 1993](#); [Hill and Stuber, 1998](#); [Martinson, 1995a,b, 1996](#); [Pfund, 1998](#); [Thompson, 1998](#); [Wakai et al., 1996](#); [Wallace and Jackson, 1995](#); [Whiting, 1997](#)). The underlying premise of hospice care is that terminally ill children and their families can benefit from interventions designed to improve quality of life even in this phase ( [Davies, 1996](#)), most effectively delivered by a psychosocial team ( [Wallace and Jackson, 1995](#)). Hospice care has been written about from a developmental perspective, with the terminally ill adolescent patient presenting unique challenges to hospice staff owing to the physical changes associated with cancer and its treatment, and the need for the adolescent to maintain independence, which can lead to refusal of care in the setting of anger and denial ( [Klopfenstein, 1999](#)). Training programs in pediatric hospice care are felt to be a necessary component of a comprehensive treatment program for pediatric cancer by many authors ( [Papadatou, 1997](#)).

The issue of discussing death itself with children and adolescents also has been written about, with a direct, honest but sensitive approach generally advocated ( [Goldman and Christie, 1993](#)), although, only 19% of families openly discussed the child's approaching death with them in this study, and staff generally overestimated the extent to which such discussion was happening. Both families and staff may lack the requisite communication skills to have such a discussion, which could be enhanced. [Goldman and Christie \(1993\)](#) reviewed literature suggesting that even 3- or 4-year-old children can discuss death, and note that open communication about death is advantageous for families and children overall.

Pediatric palliative care recently was reviewed ( [Frager and Shapiro, 1998](#)); it was pointed out that the concepts of "cure" and "care" should not be mutually exclusive. A comprehensive model that allows for palliative care (including pain management and psychological services) and bereavement work must focus on issues related to loss and be present throughout the treatment of a child, and not merely follow the active phase of treatment. The central ethical orientation involving the care of the terminal child is "to consider all actual and potential benefits and burdens from the perspective of the child as patient" ( [Frager and Shapiro, 1998](#), p. 908; [Solomon et al., 1993](#)).

## CONCLUSION

Pediatric cancer has a myriad of psychological effects on the patient and his or her family, with the evolution of an understanding of this phenomenon encompassing the concept of quality of life when broadly defined. The diagnosis of cancer has acute psychological effects on the child and family system, with ripple effects that influence school and community. As cancer incidence has risen, so has cancer survival, resulting in a large population of survivors whose psychological, social, educational, and occupational needs must be addressed by society at large, and especially by those delivering psychological and behavioral care.

# 97 PSYCHIATRIC ISSUES IN PEDIATRIC BONE MARROW, STEM CELL, AND SOLID ORGAN TRANSPLANTATION

Jonathan A. Slater, M.D.

- [Chapter References](#)

Both bone marrow transplantation (BMT) and solid organ transplantation (SOT) have undergone a revolution in the past 20 to 30 years, evolving from primarily experimental procedures to accepted treatment for a variety of diseases and varieties of end-stage organ failure ( House and Thompson, 1988; Surman, 1989). The history of pediatric cardiac transplantation was reviewed by Addonizio (1990). Christiaan Barnard performed the first adult cardiac transplantation in 1967, although the patient lived only 17 days. In 1967, Kantrowitz transplanted a heart into a 2-week-old infant who survived for several hours, and in 1968, Denton Cooley transplanted a new heart and lungs into a 2-month-old, who also survived for several hours. Although government-sponsored treatment of end-stage renal disease was instituted in 1972, almost 20 years after the first successful renal transplantation in 1954 (using an identical twin as donor), poor success rates during the 1970s, due primarily to infection, rejection, and donor shortages, caused a relative moratorium on transplantation of other organs during this time ( Surman, 1989).

In the late 1970s, however, positive results at Stanford University, which had persisted with its heart transplant program, led to a resurgence of interest in heart transplantation. The experience with children and adolescents, however, remained quite limited. With the introduction of a new immunosuppressant, cyclosporine, in 1980, success rates began to improve because of both a decreased rate of infection and improved management of rejection episodes. After this, the number of centers performing heart transplantation soared, and the experiences with greater numbers of patients led to efforts at heart transplantation in infants and children. The progression from the laboratory into mainstream medicine thus was facilitated by the development of immunosuppressant medications, improvements in operative technique, more careful immunologic subtyping and matching, greater refinement in the candidate selection process, and growing experience in the medical management of transplant recipients (Parkman, 1986; Surman, 1989).

The historic “Baby Fae” xenograft (nonhuman donor) received much media attention in 1984. In 1985, Leonard Bailey successfully performed a neonatal cardiac allotransplantation (human heart as donor), and during the mid-1980s, the number of transplantations in children increased exponentially. Between 1984 and 1988, the International Heart Transplantation Registry recorded 583 cardiac transplantations in patients younger than 20 years of age; before 1980, there were fewer than five transplantations a year performed on patients in this age group ( Addonizio, 1990).

The first allogeneic BMT was reported in 1969, in a 5-year-old with severe combined immunodeficiency syndrome ( Meuwissen et al., 1969). For BMTs in particular, statistics have been cited that indicate that approximately half of all BMTs have taken place in the pediatric population ( Wiley and House, 1988). The number of BMTs rose as chemotherapy and immunologic techniques improved, and the types of illnesses treated extended to soft tissue tumors, immunologic and metabolic diseases, and leukemia (Stuber, 1993a). BMT is a mainstay of treatment for early acute lymphoblastic leukemia or acute myelogenous leukemia, chronic myelogenous leukemia, and some solid tumors in children (Parkman, 1986; Trigg, 1988). The application of transplant technology to the pediatric population thus often has been center stage in this process for both SOT and BMT, with an exponential rise in the number of transplantations performed ( Table 97.1A, Table 97.1B, Table 97.1C, Table 97.1D and Table 97.1E and Table 97.2).

**Table 97.2. Five-Year Survival Rates After Stem Cell Transplantation**

Research into the quality of posttransplantation life, which was reviewed by [Surman \(1989\)](#), helped push SOT transplantation into the forefront of accepted medical technology for end-stage or incurable conditions. The role of psychiatric involvement developed in the setting of the implicit ethical issues surrounding allocation of a resource (the donated organ) in which the demand far exceeds the supply; as psychosocial factors in candidate selection (such as the potential for nonadherence) became identified as important in affecting outcome; and as neuropsychiatric complications such as delirium, anxiety, depression, and the psychological impact of the transplantation process on the patient and family became recognizable.

The United Network for Organ Sharing (UNOS), an outgrowth of the National Transplant Act of 1984, is under the directorship of the Health Resources and Service Administration, which sets standards about transplantation success rates, criteria for review, and application to function as a transplantation center ( [Surman, 1989](#)). UNOS directs the national Organ Procurement and Transplantation Network (OPTN) and United States Scientific Registry on Organ Transplantation. All transplantation centers, organ procurement agencies, and tissue typing laboratories in the country participate. UNOS administers the allocation and distribution of organs using a computerized list that is managed by strict scientific criteria, including organ type, tissue match, blood type, length of time on the waiting list, geographic distance if applicable (heart, heart–lung, lung, liver, pancreas), and immune status.

Research into the psychiatric aspects of transplantation in children has been limited, although child psychiatric involvement in a consultation–liaison role represents a standard component of the transplantation team. It has become increasingly evident, however, that the psychiatric ramifications in the world of SOT and BMT represent paradigms of modern, high-technology medicine today that are generalizable to many pediatric medical conditions and treatments ( [Stuber et al., 1991](#)). Issues involving informed consent/assent, ethical and quality-of-life concerns, developmental considerations, pain and anxiety management, nonadherence, and the effects of acute and chronic illness on the patient and family transcend this particular field, although perhaps nowhere else are they all found in such a compelling, poignant manner.

In a similar way, the child psychiatrist's task in consulting to a transplantation team requires the use of all of the practitioner's professional skills in a setting where individual and family psychotherapy, psychopharmacologic intervention, behavior therapy, liaison to other staff, and the understanding of medical illness and procedures are required. This chapter reviews the psychiatric issues involved in pediatric SOT and BMT, with the overall focus being the role of the consultation–liaison child and adolescent psychiatrist. In the 6 years since the first edition of this chapter:

- The relative percentage of pediatric donors has increased from 19% of cadaveric donors in 1989 to 26% of donors in 1998.
- Survival rates for pediatric organ transplant recipients are comparable with adult survival rates.

- Pediatric patients usually have shorter waiting list times than adults because UNOS allocation policies tend to favor patients younger than 18 years of age (UNOS, 1999).

## GENERAL ISSUES IN THE PEDIATRIC TRANSPLANTATION POPULATION

The literature on the psychiatric aspects of transplantation in the pediatric population has been reviewed ( Sexson and Rubenow, 1992; Slater, 1994; Stuber, 1993a). Stuber (1993a) notes many of the salient aspects specific to transplantation in the pediatric population, including effects on donor supply secondary to size, longer waiting periods, and the ethical implications of using living-related donors or organs from anencephalic infants. The effects of transplantation on identity and self-concept formation are just beginning to be studied, and pediatric transplant recipients differ from many of their adult counterparts in that they are not regarded as having "caused" the conditions that necessitate transplantation ( Stuber, 1993a). Caring for these patients also has been reviewed from a primary care perspective (Kosmach et al., 1998). The effects of transplantation on maternal stress has been studied ( Rodrigue et al., 1997). It was found that after bone marrow, liver, kidney, or heart transplantation, more than one-half of mothers experienced significant stress at 1-month follow-up, and over a third still experienced significant stress at 6-month follow-up. These findings indicate that the psychological response to transplantation represents an ongoing stressful experience, even when the child is recovering.

Posttransplantation issues for mothers, who usually are the primary caretakers, include dealing with the feelings of well siblings who may feel neglected, care and potential noncompliance in the patient, reentry issues and social isolation, being responsible for appointments, and overseeing limitations placed on the children. Financial strain may increase months after transplantation when bills and prescription costs mount, and mothers with fewer financial resources exhibited greater levels of stress, greater family conflict, and less family support, indicating the need for special attention to this population. Extended family supports may be less available once the initial phase after transplantation is over. Medical factors seemed not to be associated with psychological functioning of mothers in this study. Specific programs to assist parents in development of coping strategies, increasing resources, and bolstering family stability are essential. The latter includes support groups, which have also been found to be valuable at this author's institution, where a multifamily heart transplant group is run monthly.

The authors point out that high stress levels may predispose to anxiety and depression in mothers, which can have potential effects on child care and compliance (Rodrigue et al., 1997). Successful coping strategies exercised by parents included information gathering, especially in the form of support groups and liaison with members of the transplantation team.

Solid organ transplantation has become recognized as a legitimate treatment for many types of end-stage organ failure ( Table 97.3). The number of children on waiting lists at the time of writing, the number of transplantations performed annually by organ, the number of children on the waiting lists for organs, and survival rates are detailed in Table 97.1A, Table 97.1B, Table 97.1C, Table 97.1D and Table 97.1E, Table 97.4 and Table 97.5A, Table 97.5B, Table 97.5C, Table 97.5D, respectively. Analogous data on BMT recipients are presented in Table 97.2. The dilemma in allocation of solid organ donations is presented in Table 97.6, which indicates how many children die on the waiting list.

Heart	Liver (Donor n, Recipient n, %)	Kidney (Donor n, Recipient n, %)	Lung (Donor n, Recipient n, %)
Congenital anomalies	End-stage liver disease	Ischemic cardiomyopathy	Cystic fibrosis
Cardiomyopathy	α-1-Antitrypsin deficiency	End-stage renal disease	Primary biliary cirrhosis
	End-stage liver disease	Chronic hepatitis	Interstitial disease
	Alcoholic cirrhosis	Hemochromatosis	Congenital heart disease
	Hemochromatosis	Hereditary spherocytosis	
	Chronic active hepatitis	Hereditary spherocytosis	
	Systemic	Hereditary spherocytosis	
	Primary biliary cirrhosis	Hereditary spherocytosis	
	Hemochromatosis	Hereditary spherocytosis

**Table 97.5A. Patient Survival Rates at 3 Months and at 1, 3, and 5 Years: Liver Transplants**

transplant is one probably mediated less by psychiatric factors. A multidisciplinary transplantation team represented by pediatrics, surgery, psychiatry/psychology, nursing, and social work is oriented more toward identifying risk factors for psychopathology and nonadherence, and ensuring that there are adequate social supports. The child and adolescent psychiatrist performs a dual function. As a consultant, he or she conducts a thorough psychiatric evaluation of the patient and family, with an emphasis on identifying psychopathology or potential risk factors for adjustment reactions or nonadherence. The consultant role also includes periodic neuropsychiatric assessment and the brief treatment of patients and families with a variety of modalities that may extend into the posttransplantation period, and perhaps should in many circumstances ([Stuber et al., 1991](#)).

As the psychiatric liaison, the child and adolescent psychiatrist performs an equally important function as an intermediary, communicating a level of understanding about the patient's and family's experience to the rest of the medical staff. In addition to this, however, the psychiatrist may serve a supportive or directive function for the other members of the transplantation team, who may struggle with feelings triggered by particular patients, clinical situations, or ethical dilemmas. He or she is very much a part of the "family" composed of the transplantation team, patient, and patient's family.

Transplantation teams comprise individuals who may conceptualize the psychiatrist's role in different ways, and expectations or priorities should be specified before evaluation or suggested interventions. For instance, lung transplantation in an adolescent patient with cystic fibrosis and a history of nonadherence will carry a particular focus. The evaluation of the family consisting of a 2-year-old and 5-month-old twins, where one of the twins has a serious cardiomyopathy requiring transplantation, will be different. The pediatrician's focus in the first case may be to try to develop a formulation of the causes of nonadherence and the likelihood of successful intervention to address this problem. In the latter case, the availability of family supports and the psychological state of the mother may be of more concern. Few data are available on parental factors that may correlate with postoperative morbidity, and more are needed ([Stuber, 1993a](#)).

Transplantation is all the more compelling because, with the exception of kidney transplantation, SOT and BMT are treatments of last resort, without which the patient would likely die. There is less urgency on the pediatric nephrology service because these children can survive on dialysis without transplantation, which therefore may be considered more electively.

---

#### CASE ILLUSTRATION

Psychiatric consultation was requested when the father of a child who received a cardiac transplant punched a hole in the wall and repeatedly threatened nursing staff in the aftermath of his son's cardiac arrest. Psychotherapy with this man was not possible because of what appeared to be his limited ability to gain insight into the underlying causes for his anger, which were believed to be a sense of helplessness and tremendous desperation, as well as the wish to fix blame on somebody or something for what had happened to his son. Although it was important to help the staff understand what this man was going through, it was perhaps more important to ensure they felt protected. Security was called, and definitive limits were set for this man with regard to verbal and nonverbal threats.

---

The pretransplantation evaluation should be part of the multidisciplinary assessment of the transplantation candidate, the purpose of which should be explained to the family by the primary physician. Psychiatric consultants may best be conceptualized as experts in child development, pain and anxiety management, and the psychological responses to transplantation. He or she is an important member of the transplantation team who can provide emotional support to the patient and family during an unusual crisis that anyone would find extremely distressing and help prepare them emotionally for transplantation. The child and adolescent psychiatrist also can serve a vital function in helping to communicate the child's needs to his or her family and the rest of the transplantation team. If framed in this manner by the primary physician, the evaluation rarely will be met with resistance by the family. It is important that there be continuity of care with respect to psychiatric services because the pretransplantation evaluation can form the basis for a trusting relationship that will affect the receptivity of future interventions and allow a greater depth of understanding in the patient's and family's experience.

The pretransplantation evaluation must encompass the standard elements of child psychiatric evaluation. In addition, however, the consultant must be familiar with the medical problems for which transplantation is being considered, as well as have a working understanding of transplantation itself from a medical and surgical perspective. In so doing, he or she will more likely be seen as an integral part of the transplantation team. The consultant should ascertain whether other members of the transplantation team have specific concerns about a patient or family.

The child or adolescent patient and his or her family have reactions simply to the fact that they are being evaluated for transplantation (see section on [Diagnosis](#), later). Such reactions may cover the range from denial to panic, with different family members often reacting differently. In some cases, extended family members or siblings are not told about the evaluation. In others, grandparents and siblings are present at the evaluation and clearly have an impact on the process itself. Evaluation often is complicated by the fact that it is occurring in an urgent setting with a critically ill child, and parents are required to digest relatively quickly a great deal of complicated information about a subject about which they know nothing, in the setting of acute anxiety and fear, leaving them overwhelmed, which often makes true informed consent impossible.

In other cases, small children with cardiomyopathies may not appear that ill, taxing the capabilities of parents to overcome the understandable inclination to use denial. These children nevertheless may have borderline cardiac function and be subject to fairly rapid decompensation. They therefore may be listed for transplantation because the relatively long waiting periods for small children could make organ procurement difficult. Parents later may look back on videotaped footage of their child before transplantation and wonder how they did not realize the child was sick. Listing the child early also may give the transplantation team more time to familiarize themselves with the family, and vice versa. Before meeting with the family, the psychiatric consultant can benefit from information concerning the reactions of the family to the evaluation procedure.

Parents and patients may ask the psychiatric consultant questions about medical or surgical aspects of transplantation, such as survival rates, that are best referred back to the pediatrician or surgeon. With prepubertal children, it often is helpful to meet with the parents first, as in a standard child psychiatric evaluation. Adolescents may wish to meet with the psychiatric consultant first, or with his or her parents; at some point, adolescents and children should be interviewed alone because they often will reveal feelings not expressed in the presence of their parents. The child and adolescent psychiatrist should begin the consultation by asking the parent or patient about conceptions and expectations about the psychiatric evaluation, to allow appropriate clarifications to be made.

The psychiatric pretransplantation evaluation can be diagnostic as well as educational and potentially therapeutic. Elements of this evaluation should include:

1. Getting to know the patient and family, and vice versa: Will they be able to function as part of a "team?"
2. How is the patient/family experiencing the pretransplantation evaluation and the prospect of transplantation? Significant "psychoeducation" may take place by helping to "normalize" the patient/family's reactions to the transplantation experience.
3. Obtaining a history of the medical/surgical problem, prior illness experience, and the "parallel" emotional or psychiatric history. This includes:
  - a. An assessment of the patient's and family's coping styles. Certain coping styles may be predictive of fewer adjustment problems in the setting of a chronic illness and include "positive self-talk, attention diversion, relaxation, thought stopping, task orientation, talk(ing) with someone, and good problem solving activity," as opposed to "catastrophizing" strategies such as the "focus on negative affect or fear, anxious anticipation, escape or avoidance, worry/rumination, self-denigration and self-blame, [and] fear of unlikely consequence" ([Olson et al., 1993](#)).
  - b. Obtaining a description of the temperament of the child/adolescent
  - c. Past and present psychopathology in patient, parents, siblings
  - d. Nature of past procedures, hospitalizations, and surgeries, and reactions to same, including "secondary" psychopathology, giving consideration to affective (depression, anxiety), cognitive (confusion, distortion), and behavioral (tantrums, oppositional behavior, nonadherence, posttraumatic phenomena) parameters
  - e. Risk factors for nonadherence
  - f. History of drug or alcohol abuse in the adolescent
4. Assessing the quality of the child/adolescent-caregiver(s) relationship and family dynamics
5. Detailed developmental, neuropsychiatric, social, and school history
6. Mental status examination and neurocognitive assessment of the child/adolescent
7. Assessment of how socioeconomic factors may have affected the management or course of the child/adolescent's illness, and how these factors may be of concern regarding life after transplantation. Are psychosocial supports adequate?
8. What the patient/family understand about the process of transplantation, from being listed, to the surgery itself, postoperative course, and immunosuppressant medication. Much of this information may not be given routinely to the patient until there is consideration for formal listing, but the family often has many misconceptions about this process, perhaps from what they have read or heard from other families. Are parents able to give informed consent, and is the child/adolescent able to give informed assent/consent? Is the family and adolescent accepting of long-term medication administration and care? [Modified from

[Slater \(1994\)](#), with permission.]

Other factors influence the response to hospitalization at the time of transplantation:

1. The age of the child and developmental level. Younger children are more prone to cognitive distortions common to the Piagetian preoperative stage, regression, fantasies of intended harm, mutilation, and separation fears. They are less likely to understand the rationale of procedures, nature of the pathophysiologic process, and course of an illness.
2. The number of prior hospitalizations early in life. Repeated hospitalizations between the ages of 6 months and 4 years may increase the risk of later psychiatric disorder ([Mrazek, 1984](#); [Quinton and Rutter, 1976](#)).
3. Hospital characteristics, such as visitation policies and quality of the child life department. [From [Slater JA \(1994\)](#), with permission.]

At the conclusion of the evaluation, which may take several interviews, a concise formulation should integrate data, which have been gathered into a form easily “digestible” by nonpsychiatric colleagues. This formulation should identify psychopathology, describe coping styles, and address possible predictors of resilience or nonadherence and the adequacy of social supports. The psychiatric consultant should indicate areas where misconceptions exist regarding information presented to the family by other members of the transplantation team and relay this back to his or her colleagues.

The diagnostic impressions and therapeutic recommendations should be communicated to both the referring physician as well as to the patient and family. This should be done both verbally and in the form of a written note, a copy of which may be given to the parents as well, if appropriate, which may help “demystify” the psychiatrist's role as well as educate. Recommendations should correlate with problem areas identified in the formulation and may include, for example, preparation for transplantation with play or videotapes, the teaching of relaxation techniques for anxiety reduction, social service intervention to clarify medical insurance, or contact with other transplant families.

Families commonly look forward to hearing suggestions from the psychiatrist for helping them through the arduous process of transplantation. If immediate follow-up is not thought to be necessary by the consultant and family, the family should be told how the consultant can be reached. If the patient is in the hospital, continued follow-up is advised. When the psychiatric consultant communicates with colleagues, judgment should be exercised with respect to patient confidentiality about issues not relevant to the transplantation process; this should be discussed with the patient and family. Care should be exercised about what is written in the hospital record because in many ways this is a public document.

## DIAGNOSIS

The reactions of the patient and family to the diagnosis of a medical problem serious enough to warrant transplantation occur in the context of the prior medical history. A chronically ill child who already has had several surgeries for congenital heart disease presents a different scenario from a previously well child who noticed a lump in his cheek initially assumed to be an abscess that turns out to be a Burkitt's lymphoma (see [Case Illustration](#), later). These differences may seem obvious, but what all patients and families come to share is an extreme fear of uncertainty associated with the unknown, fears of pain—emotional and physical—and on some level the fear of death.

Parents may react differently ([Gold et al., 1986](#)), some in more of an assertive, information-seeking mode, acting proactively for their children, and others with more passivity and increased reliance on medical staff for direction. The psychiatric consultant can be of great assistance in helping parents to act in their own (and the child's) best interests and to become more aware of how their individual coping styles affect them.

---

### CASE ILLUSTRATION

Adolescents themselves may have a powerful sense of denial. An adolescent, on being told that he needed a heart transplant, said: “Really how to figure how I felt back then, basically a thirteen year old kid is invincible in his own mind. I remember I was playing football and my dad pulled me over. He didn't want to tell me, but then he finally told me, and I'm like, ‘All right dad, can I go back in the game?’ And he was like, ‘Yeah, go ahead.’ Because at thirteen you don't think of what a transplant means. You don't know the dangers, the risks, or anything.” [From [Slater \(1994\)](#), with permission.] One adolescent with severe heart disease confided that when she was around her parents, she used to bite her lips to make them turn red, so they would not realize she was [cSlater.](#) ( [1994](#)).

---

### CASE ILLUSTRATION

The consultation–liaison child and adolescent psychiatrist was called by a senior colleague to see his relative, an 8-year-old boy with newly diagnosed Burkitt's lymphoma. The patient's father was in a state of shock, unable to believe that what he thought was a simple abscess was in actuality a malignancy for which his son would receive emergent BMT. The fact that, like many chemotherapy protocols, the one his son would receive was experimental further overwhelmed this man. In desperation, he began frantically calling different centers that do BMTs to compare protocols, and in fact he began to wonder if a mistake had been made when the pathology slides were read or that they had somehow been switched. He became irritable and sleep deprived, and to complicate matters further, he did not want his son told that he had a malignancy, fearing it would overwhelm and terrify him. The staff reacted powerfully to this scenario, and many meetings with the family and staff in various combinations were needed.

The psychiatrist was buffeted by many stresses, including the feelings associated with referral from a senior colleague, the need accurately to assess the father's mental status and intervene appropriately, the need to consider the best interests of the boy, and the need to liaison with other staff. All of this happened rapidly in the setting of a diagnosis leading to BMT within several days.

---

Diagnosis itself may thus represent a trauma that manifests posttraumatic symptoms, requiring intervention. Parental misconceptions about or lack of exposure to the process of transplantation, such as donor allocation and wait listing, further complicate matters. In this setting, parents are asked to organize themselves cognitively and make terribly difficult decisions in a short time that will affect the survival of their child; it often is an impossible quandary. They may find it difficult to communicate with one another openly about fears, owing to concerns over destabilizing the spouse, and may suffer in solitude. Parents may focus on concrete details like survival statistics to attempt to center themselves in the face of a feeling of overwhelming helplessness and anxiety over entrusting their child's life to people whom they barely know, who are recommending procedures about which parents may be completely ignorant. Illusions of control over the events of one's life seem to be obliterated.

Alternative treatments may be sought that potentially may delay medical intervention, such as the case of a family who made phone calls around the world: “Maybe somebody will tell us that there's a doctor in the Philippines who has found a papaya serum that can cure cardiomyopathy” ( [Slater, 1994](#)).

## BEING LISTED

If recommended, informed consent for transplantation is obtained after evaluation, when families are educated about the indications, risks and benefits, and process of transplantation. Being listed represents a “point of no return” ( [Slater, 1994](#)), and families typically experience great anxiety about the future that may include confusion over how UNOS manages the wait list for organs. Parents are in a sense formally committing their child's future to events and personnel over which they have little control, often with a feeling of blind faith that things will work out positively, knowing full well they might not. The “roller coaster” metaphor has been used by many families in describing the process of a building up of tension, followed by a fearful, perhaps exhilarating, but out-of-control descent ( [Slater, 1994](#)).

Parents of young children wonder how they should explain to their children what will be happening to them, and how to prepare them. Here, the child and adolescent psychiatrist can be of great assistance.

---

### CASE ILLUSTRATION

Steven, a 3½-year-old boy who had a cardiomyopathy, was listed for heart transplantation. The consulting psychiatrist, using dolls and stuffed animals, engaged Steven in a story about a little boy named “Chris” who had become ill. Using some elementary drawings and a heart cut from red construction paper, he explained what the heart did, and how it had become sick in this little boy. In the play, he told how the boy's heart was too sick even for medicine to help, but that he had to somehow be helped.

“What could we do?” asked the psychiatrist.

“I don't know,” responded Steven.

“Well, we could get him a new one,” said the psychiatrist.

After that, Steven and the psychiatrist acted out the heart operation many, many times over a period of days, using an actual anesthesia mask and as many “real” props as possible, including miniature intravenous poles, operating room tables, tape, bags of

intravenous solution, masks, gloves, and so forth. Each time Steven would become more involved, insisting on the operation, and emphasizing specific aspects of it, such as the use of the mask or saying good-bye to the mommy or daddy in the operating room.

At one point, the psychiatrist said, "You know, Steven, you are like the little boy in our story in some ways."

"How?"

"Well, you are in the hospital because your heart is sick too. And we have tried to give you medicine to make you better, but it isn't working, so, like Chris, we are going to have to give you a new heart."

Steven's reactions to the preceding play intervention were carefully discussed with his mother before the sessions with him, and at an appropriate pace, more details about the story were layered on in successive versions, incorporating aspects of Steven's experience, all within the play. Chris, for example, was so tired of waiting in the hospital for so long, but this was explained to be because he was too sick to go home. His new heart could come at any moment! He had an especially hard time saying good-bye to his mommy when she went home for Saturday night and his father stayed over with him, because he feared his mommy might never come back—but this was not true, for she always did.

Additional observations were made about Steven's negative reaction toward his father on these occasions, and his father's anger at this treatment, which his father took personally. Counseling with the father was directed at explaining how beneath Steven's rejecting behavior was anxiety over his mother's absence and his failing to understand and accept her need for a night's sleep. Specific suggestions were given to facilitate the "transfer" between parents, which included the father bringing something special with him on visits, phone contact with his mother on the nights when she was absent, coaching his mother to address Steven's underlying fears that she would not return, and helping his father adopt more of a "holding environment" for the boy's anger and frustration.

In the play, much of Steven's underlying anxieties were fleshed out in the character of Chris, and all of the details of surgery and postoperative care, including pain management and medication administration, were added. Steven would react excitedly to the psychiatrist's entrance, eagerly gathering his stuffed animals and recreating the stories over and over. In another version, it was "ET, the Extraterrestrial" who had the heart problem and was far from home, in the clutches of doctors who were trying to do him harm. Even ET eventually was successfully transplanted and returned home.

He often would ask the psychiatrist to supply voices:

"Have him [Chris] say 'good-bye' to his parents again," or "have his mommy tell him she will be coming back."

When the actual time of Steven's transplantation approached, after some initial reluctance, and to his mother's surprise, he said "Okay, let's go!" In the operating room, he calmly held the mask to his face himself, said good-bye to his parents, and was successfully transplanted.

Children and adolescents may react with mixtures of fear, anxiety, depression, confusion, and existential angst, which is mediated by cognitive level and the tendency to regress. This may take the form of oppositional behavior and irritability. They often wonder "Why is this happening to me? What did I do wrong?" (Slater, 1994).

---

---

#### CASE ILLUSTRATION

One 12-year-old girl was constantly in tears whenever the subject of transplantation came up: "I had never had surgery before, any kind. And just the thought of having your heart taken out. There were just so many questions: 'Am I going to live?' 'Is it going to hurt?' 'How long is it going to take?' 'How am I going to recover?' 'Am I going to be normal?'"

---

---

#### CASE ILLUSTRATION

An 8-year-old boy who came from a religious family and was refusing transplantation put his parents in an extremely difficult position. His mother felt tormented that if she signed the consent against his will and he did not survive, that she would never be able to forgive herself. After considerable work with a child psychiatrist, the underlying fear was revealed. The boy said that under no circumstances would he allow someone else to be killed so that he could have a new heart. With the help of a hospital chaplain, this boy's misconceptions were corrected, and he was successfully transplanted. [Both the preceding illustrations from Slater (1994), with permission.]

---

---

Older children and families may benefit from viewing a videotape about children and adolescents who have undergone transplantation. One such film about cardiac transplantation in children includes interviews with donor families, as well as a family who lost a child after transplantation (Slater, 1992). Seven families have watched the film before cardiac transplantation; all have had positive reactions. Samples have included:

"The first reaction was relief that these kids existed, that they were apparently healthy. Our son could survive. It really worked. When we actually saw the donor families talking, it was enormously sad and moving, but in a positive way that somehow helped me."

"I felt reassured that I had no choice and that it was the only decision possible, as I listened to the parents of the child who died wrestle with their guilt over having put her through the surgery, knowing she would die without it."

"It made me feel better even though I cried during certain parts. It helps but it hurts at the same time."

"It was a helpful film which confirmed the emotions we went through...it also provided firsthand knowledge of what we would go through...you realize that no matter who you are or what walk of life you come from, you all have the same concerns, fears, anxieties and questions."

"It was hard to see the donor parents' sadness, talking about their son. It is so hard to think about the donor family, yet it's something I always find myself thinking of."

#### WAITING

The waiting period, between the time a child is listed for a transplant and the arrival of the donor organ, can last from days to months. This can be tantamount to psychological torture because the transplantation can happen at any moment or not at all. Either alternative can be devastating. Intervening complications such as infection can temporarily remove the child from the waiting list. Mean waiting times to transplantation by organ are depicted in Table 97.8.

Waiting list	Age Group (yr)	Mean Waiting Time
Kidney registrants	6-10	300 days
	18-34	891 days
Liver registrants	6-10	237 days
	18-34	392 days
Heart registrants	6-10	51 days
	18-34	214 days

From UNOS Scientific Registry Data, 1999.

**Table 97.8. Mean Waiting Times to Transplantation**

---

---

#### CASE ILLUSTRATION

One parent commented that "waiting for the heart is like sitting in a tunnel with no light in either direction, there's nowhere to go."

Another described this period: "Waiting for the heart is a very helpless and scary feeling. You can't do anything. As a mother and as a parent, you're used to being able to take care of your children. If they have a fever you take them to the doctor, you put on cold soaks, you give them Tylenol. If they have colds you give them fluids. You can do a lot of things to cure little illnesses that they have. You can't do anything when you're waiting for a heart" (Slater, 1994, with permission.)

---

---

Parents may consider interfacing with the community, either to request assistance in meeting the extraordinary costs of transplantation or in an effort to publicize the need for a donor organ with the hope that this will make a difference. Such exposure can have costs for the family in terms of loss of privacy, but may be seen as necessary.

Parents often regard the issue of organ procurement with ambivalence, as they wrestle with conflicting feelings that arise from survivor guilt or identification with the family who lost their child. On an emotional level, many parents fear they are “wishing” for another child to die, although they “rationally” know they have no control over this event. On occasion, two children in the same hospital might need an organ of the same size and blood type, with one listed higher than the other because he or she is more critically ill, for example. Such a situation can cause tremendously conflicting feelings for parents who might feel they are in a sense “competing” for the same organ; guilty feelings often ensue.

As time goes by, the waiting period often seems to wear patients and families down. If the child is hospitalized, mothers often literally move into the hospital for weeks or months at a time, such that marital relationships are entirely disrupted. Emotional and physical reserves of parents often become so depleted during a turbulent medical course that their own basic needs are neglected. As they respond to day-to-day events, often in turbulent cycles, the parents have little time to reflect on what has happened or replenish their emotional and physical reserves. The psychiatrist often can detect this trend and advise accordingly with simple suggestions that may act as “permission” for a guilt-ridden parent to leave the hospital temporarily, for example, to get a night's sleep or a decent meal. Parents may experience a sense of support and validation of their experience from speaking with the psychiatrist.

Parents commonly feel torn between the responsibilities of other children, work, and the child in the hospital, and may feel guilty about “failing” to meet all these demands, although the task may be impossible to carry out completely. If the family does not live near the hospital, these feelings can be exacerbated, as siblings are shunted off to other family members, often leading to resentment toward the parents and sometimes toward the sibling in the hospital. Siblings may have a variety of adjustment reactions, and the psychiatric consultant's duties may extend to counseling parents about issues with their other children and, on occasion, the psychiatric evaluation of siblings.

Parents may become resentful of what has happened to their lives and describe being short-tempered with one another. The parent in the hospital with the child may become resentful toward the working parent, who is not with the child on a day-to-day basis, dealing with events in the hospital. Marital problems that were present before transplantation obviously are worsened, and parents may become clinically depressed or develop anxiety disorders, such as one parent who began to experience panic attacks that required treatment.

“False alarms” may add to the feeling of unpredictability and helplessness, when parents receive word about a possible donor organ that does not come to fruition. Such instances can be even more anticlimactic and potentially traumatizing if the parent has already said good-bye to the child, who is moved to the operating room. In one instance, a mother became seriously depressed, returned home, and could not leave her bed for a number of days.

The patients themselves may become progressively more irritable and obstinate, straining their relationships with parents, who often are the objects of angry outbursts that test their abilities both to empathize and set limits with their children. In some cases, the parents cannot take extended leave from work, and the child may spend much of his or her time in the hospital without visitors.

---

#### CASE ILLUSTRATION

In one such case, a 12-year-old boy developed strong, somewhat flirtatious attachments to some of the intensive care unit nurses, which became problematic when he began to engage in inappropriate behaviors, such as suddenly cutting the hair of one of the nurses with a scissors when she turned around. He later bit off the end of a glass thermometer, saying he was just “kidding around” (Slater, 1992). The consulting psychiatrist felt that fueling these behaviors was the boy's sense of frustration and helplessness at the long waiting period, exacerbated by his parents being unable to visit him during the daytime, and his being semiconscious during a witnessed cardiac arrest and resuscitation several days before these behaviors. Psychotherapy with the boy allowed him to discuss his lack of feeling safe in the intensive care unit, even in the presence of all the high-tech monitoring equipment. As a developing male adolescent, he felt his body becoming weaker and weaker, which severely affected his self-image and emerging sexual identity. The psychiatrist also assisted the intensive care unit staff in setting limits with this young man, which led to an abatement in these behaviors.

---

#### SURGERY

When parents are notified that a suitable organ donor has been found, many report ambivalent feelings. One parent thought “Oh my God, it's here. Well, I don't want to go. I just felt like saying, ‘Give it to the next person, we're not ready’” (Slater, 1994). On the way into the hospital, she and her husband felt the impulse to turn off the exit and return home with their daughter, who was listed for a heart transplant. Parents struggle with the responsibility they bear for committing their child to transplantation, knowing that there are operative and postoperative risks, and sometimes are tormented by the thought that somehow the child could almost magically survive without the transplant. The ambivalence usually is worse if the child is waiting for a transplant as an outpatient and is not critically ill at the time of transplantation. In either case, parents experience guilt over making decisions that expose the child to the potential trauma of hospitalization and surgery, despite knowing it is the only way to save their child. If the child does not fare well, parents need maximal support to help them cope with their sense of responsibility for the outcome, however “irrational” that might be.

The moment of separation just before surgery is a moment many parents recall as an indelible mark in their minds. As one parent described:

I kissed her good-bye, turned toward the door to the operating room, and never turned around. It was because you make that separation, even though you still hear sound... You just have to do it. If you turned around, I think the impulse would be so strong they'd probably have to restrain you and drag you out (Slater, 1992).

Another recalled: “We certainly felt that we were leaving her in very capable hands, but there's all of the unknown questions, you know: ‘Are you going to see this child again? Is everything going to go through okay?’ And just simply walking away from it was a hard thing to do. Somehow I felt if I could just stay there it would be okay” (Slater, 1992).

During surgery, time often is telescoped for these parents who sit waiting to hear word on their child's progress. A visit from the psychiatrist at this time can be quite supportive.

Parents should be prepared both visually and descriptively for what they will see in the intensive care unit after surgery. A preoperative visit and detailed description often can help defuse parents' acute shock at witnessing their child with an endotracheal tube, intravenous lines, indwelling chest tubes, and high-tech monitoring devices. Despite explanations before surgery, they often are overwhelmed and confused by the complicated medical management in the immediate postoperative setting, and this anxiety may be exacerbated by the presence of other critically ill children (Bradford, 1990).

The conduct and sensitivity of the intensive care unit staff can greatly affect parents' emotional state during this period, when postoperative sedation, analgesia, and the presence of an endotracheal tube make communication with their child difficult. As the child's level of awareness returns, he or she may be irritable, combative, or withdrawn, and the psychiatrist may assist in recommending pharmacologic intervention or other behavioral techniques to help the child. The psychiatrist can be invaluable in helping to explain the nature of the child's experience to parents, as well as to staff (Bradford, 1990), and should conduct serial neuropsychiatric assessments. Strokes, metabolic derangement, medication effects, delirium, and hypoxia are among the many events that may compromise mental status in the perioperative period.

A common tendency among families is to compare their postoperative course with that of other families whom they have met. Unfortunately, although kidney transplant recipients often can be discharged within a week (Stuber, 1993a), other SOT recipients may remain in the intensive care unit for that long and spend weeks or even months in the hospital, subject to unpredictable complications. In the often elated atmosphere of a successful transplantation, it is easy for parents to think ahead to discharge, setting themselves up for inevitable disappointment at the first postoperative complication. Such events, like mild rejection episodes and postoperative fevers, are common, and can “burst the bubble” of the “honeymoon” phase described by some families immediately after transplantation. This deflation may herald continuation of the “roller coaster” ride, with cycles of high hopes and expectations alternating with periods of intense fear and worry. As the sense of reality sets in that the transplant is really not a “cure,” patients and families may feel quite disillusioned. The psychiatrist can both help prepare them for this process, as well as allow expression of these feelings in a supportive setting.

Thus, speaking with other transplant recipients can have both positive and negative aspects. In one respect, feelings can be validated by others who have gone through the same experience. On the other hand, because these experiences inevitably are individualized and subject to so many variables, patients may experience

a sense of frustration, failure, or disappointment if their expectations, which are modeled by the experiences of others, are not met.

As tubes and lines are withdrawn, and analgesia reduced, children can benefit from more contact with visitors and the child life department. Parents can read to their children, and videotapes can be viewed. Behavioral interventions such as guided imagery, story telling, and self-relaxation, and games such as hand-held computer games can continue to play a role during this period and be used to help children tolerate postoperative procedures. Such practices may decrease the need for sedation ([Bradford, 1990](#); [Bullock and Shaddy, 1993](#)).

### Developmental Considerations

As [Stuber \(1993a 1993b\)](#) describes, developmental issues affect the child's and adolescent's experience of and response to transplantation in a manner different from that in adults. Parents must be involved in the decision-making process, and adolescent assent or consent also is essential. Developmental regressions compete with the demands for autonomy common to all phases of childhood. The impact of developmental factors on illness has been approached from many different models, including ego psychology, self-psychology, and cognitive psychology, and delineated by many, including [Anna Freud \(1952\)](#) and others ([Bauman, 1981](#); [Nagera, 1978](#); [Schowalter, 1971](#)). Other writers have applied theories of affective development in the infant-caregiver dyad ([Emde, 1989](#)) to help understand how illness can affect relationship formation ([Parmelee, 1989](#)). The application of Piagetian theory to the progression of the cognitive understanding of illness has been reviewed by [Schonfeld \(1991\)](#). [Thompson and Vernon \(1993\)](#) and [Vernon and Thompson \(1993\)](#) have reviewed the literature on the effects of hospitalization and directed interventions on children. Developmental theory has been applied specifically to transplantation as well ([Sexson and Rubenow, 1992](#); [Slater, 1994](#)) ([Table 97.9](#)).

**Table 97.9. Developmental Aspects of Transplantation**

The patient-family system is exposed to the multiple stresses of acute and chronic illness, intrusive high-tech procedures, surgery, and hospitalization, often in an unrelenting fashion. Ethical issues, involving solid organ or bone marrow donations by family members, and quality-of-life issues may further complicate this picture. A fundamental purpose of the child and adolescent psychiatrist is to translate childhood experience into terms adults can understand and therefore respond to empathically.

When transplantation occurs in the infancy or early childhood, children are more likely to incorporate physical sequelae such as the scar and medical management (chronic medication and medical follow-up) into their developing identity and self-image. The subject of transplantation may be dealt with in a similar manner to adoption, explaining to the child from an early age what has happened to him or her and helping the child develop a narrative and more complex understanding about who he or she is as time goes by. This openness and acceptance on the part of the parents that the transplant is not a “secret,” but an integral part of the child's identity, may help facilitate adjustment and the child's acceptance of the requirements of life as a transplant recipient. Such issues apply to BMT as well, which is covered later in the chapter.

Although children may experience cognitive distortions, such as using immanent justice theorizing to explain their illness as a punishment for misdeeds ([Schonfeld, 1991](#)), it is continually surprising to physicians and parents alike how much children do understand. For example, the parents of a 4-year-old who had undergone cardiac transplantation at 2 years of age felt that she had little recollection of the events and were amazed when she played out features of the hospitalization in exact detail when given miniature hospital props.

In communicating with a child or adolescent about his or her illness, transplantation, procedures, or other aspect of medical care, the accepted approach is to be honest within a developmental orientation. In the pediatric transplantation population, these distortions often occur alongside normal childhood curiosity. In the setting of heart transplantation, cultural symbols and metaphors invest this organ with tremendous meaning:

We tend, in the medical world, to think of a heart as a pump. We've got to be reminded, sometimes by the patient, that the heart is an organ with a lot of mystery to it, if you will, a lot of history to it. The heart loves, the heart represents not simply that organ which sends the blood around, but that organ which we associate with some of our most wonderful human attributes. I mean love, heart as courage. We'll talk about an athlete who has heart; identifying the heart with valiant, courageous impulses. The heart with sentiment, with affection. Do we really think that one can take out a heart, and replace it with another heart, and not set off an extraordinary chain of associations on the part of the recipient? Will my new heart be valiant? Will my new heart be loving? Am I the same person now that I have a new heart? Am I that other person? [From [Slater \(1994\)](#), with permission.]

Children may wonder, for example, if it matters whether the donated organ comes from a male or female, black or white donor. Others queries have included children asking “how they will know whom to love, for example, when they receive their new heart: Should they still love their parents, or the family from which the donor heart came? They think of the sayings, ‘I love you from the bottom of my heart,’ or that someone's heart can ‘break’ because they miss someone, and apply this to the transplant experience and become understandably confused” ([Slater, 1994](#)).

Under the influence of tremendous anxiety, cognitive distortions can be exacerbated. This interface became apparent when a child began refusing her endocardial biopsies because she believed that each time, more “pieces” of her heart were being removed, such that eventually it would fall into her stomach. In her play, she repeatedly tied her stuffed animals down to perform “biopsies” on them and soothed them by saying “it's going to be all right.” This posttraumatic repetition perhaps could be understood as helping the child master her helpless feelings during catheterization. In ego psychological terms, one might characterize her as “identifying with the aggressor” or “turning passive into active.”

Another child told his mother he was worried that other children in the playground would start coughing, as he did, if they overexerted themselves. This projection of one's own experience on that of others is typical of the egocentrism in the preoperational Piagetian phase.

Latency or school-age children also respond to transplantation within a developmental frame. Interference with physical prowess in boys, and relationship development with peers in girls, can result from repeated hospitalization and illness. Academic performance can be affected by school absence or the neurocognitive sequelae of treatment, such as cranial irradiation in BMT. The development of self-esteem can be affected by the decreased opportunities for mastery that normally are associated with important affirming responses from role models.

Adolescent transplant recipients present unique challenges to the physicians working with them because of the seriousness of nonadherence, which is more prevalent in this age group. Adolescents react to contingencies of their illness, which undermine developmental needs for independence and control. The enforced dependency, although in line with regressive forces brought about by serious illness, may result in more demanding and boisterous behavior.

The psychological issues in this population have been reviewed by [Stuber \(1993b\)](#), who addresses several important points, including ethical concerns about the adolescent's right to refuse treatment, the need for systematic research to identify psychosocial predictors for outcome, specific developmental considerations such as the parents' involvement in the adolescent's “personal body functions and decisions,” and the psychological reactions to implantation of a foreign organ. As Stuber notes, hearts may be imbued with more philosophical meaning. An adolescent who was approaching his birthday, for example, said that he felt strange that he would be turning 16, but his heart, which came from a donor 2 years younger, would be only 14. Over time he came to experience his new heart as an integral part of his

identity and body.

Illness and medication side effects can dramatically affect appearance and physical and sexual development, having a significant impact on the adolescent's identity and relationships, and making him or her more self-conscious. Prednisone can cause weight gain, acne, and a cushingoid appearance. Cyclosporine causes hirsutism. BMT is associated with hair loss and cachexia. Adolescents may desperately struggle with the need to be "normal" like their peers, while at the same time accepting that he or she is different. Their sense of a possible foreshortened future may interfere with plans for college, a career, and intimate relationships.

Adolescents may struggle with decisions about who to tell about the transplant. This question may have antecedents in failure to confide in friends about the illness leading to transplantation, such as an adolescent with cystic fibrosis who is listed for lung transplantation and has told her friends over the years that she has asthma. The issue of who to tell usually centers around concerns over peer acceptance and may have painful aspects, such as one adolescent whose boyfriend's mother told her son not to get involved with the patient because she was a transplant recipient and might not live a long life.

Making it "public knowledge" that one is a transplant recipient can lead to celebrity status in school initially for an adolescent, but also can lead to intrusive questions about sexual functioning and other naive questions that must be fielded about life as a transplant recipient. An adolescent reported that he was initially treated like an invalid, and one classmate asked whether he had to carry oxygen with him on a date. These questions reflect the transplant candidate's concerns early on as well, but often are not addressed unless the consultant raises them in a sensitive way.

Adolescents often describe feeling out of step with their contemporaries in terms of both concrete issues like missed social events, as well as in a sense that many of them describe that they have grown up too quickly and have lost a carefree quality they see in their friends:

I guess at that point I just felt they weren't taking life serious, as seriously as they should. But I think in reality I was just taking it too seriously, like I felt like every minute was my last minute. And I was trying to be the best I could be because I thought maybe it was because I was bad that it happened to me. And I found that I was given this second life and I was making a mess of it because I was so tight and wound up about everything ( [Slater, 1992](#)).

Transplant recipients often talk about entering a health-related profession or other field where they can feel useful to others. One adolescent joined the volunteer fire department and relished in the idea of carrying a beeper with him; in fact, he used his fire fighting "on-call" schedule as a rationale for missing clinic appointments at times. Several have confided in me that they would rather be nurses because they cannot see themselves as the one actually "causing" the pain, but understand what it is like to be the patient, and feel they could more sensitively soothe children in pain and fear. Many of their aspirations and specific commendations reflect on the importance of supportive care in the hospital and the important role of hospital staff at crucial junctures in their recovery.

### **Pain and Anxiety Management**

The topic of pain and anxiety management in the pediatric transplant population has not been well studied or described ( [Green, 1994](#)). There is a literature on this subject in the pediatric population, especially in the psychology and pediatrics journals ( [Abu-Saad, 1984](#); [Bush, 1987](#); [Kuttner et al., 1988](#); [Manne et al., 1988, 1990](#); [McGrath and Hillier, 1989](#); [Siegel and Smith, 1989](#); [Varni et al., 1987](#)). [Bush \(1987\)](#) reviewed the literature on analgesic use in children, which suggests that children are undermedicated for pain compared with adults undergoing similar procedures. Undermedication can exacerbate pain behaviors and disrupt the trust between the child and physician.

In addition, there is good reason to expect that this population can benefit greatly from cognitive-behavioral techniques designed to diminish pain and anxiety associated with biopsies, catheterizations, venipunctures and central line placement, surgery, bone marrow aspirations, lumbar punctures, and many other procedures that may occur in these patients. These techniques have been used for such procedures in different populations ( [Bush, 1987](#)), especially in pediatric patients with cancer ( [Kuttner et al., 1988](#); [Manne et al., 1990](#); [McGrath and Hillier, 1989](#)). [Manne et al. \(1990\)](#) described a behavioral approach designed to decrease anxiety in children with cancer who undergo repeated venipunctures (see also [Cardona, 1994](#)). A combination of parent coaching, distraction, and positive reinforcement was associated with a decrease in parental anxiety and report of the child's pain, and less distress for both child and parent.

One relevant study used such techniques during right ventricular endocardial biopsies in pediatric patients ( [Bullock and Shaddy, 1993](#)), which are used to monitor for episodes of rejection in the cardiac transplant population. The techniques described included preparation, reassurance, deep breathing, imagery, distraction, and muscle relaxation. By their sixth biopsy, all patients discontinued the use of benzodiazepines, felt more in control, and reported less pain (which was associated with decreased autonomic measures). In addition, the length of time required to do the biopsies was diminished.

[Bush \(1987\)](#) and [McGrath and Hillier \(1989\)](#) have reviewed this literature from a developmental point of view, recommending an interdisciplinary approach. Early impressions that infants do not experience pain have been refuted, and it is clear that from several weeks of age, infants react to pain in gradually more differentiated patterns of response. Specific responses to painful stimuli as well as anticipatory anxiety and avoidance behavior follow a typical developmental sequence along Piagetian lines. Cognitive factors affect pain intervention in multiple areas that include the subjective pain experience, how to describe pain intervention measures, how to evaluate pain, how to implement the pain reduction techniques, and how much children will retain after being taught techniques to help them manage pain ( [Bush, 1987](#)). Prior experiences with pain also are modulators of later pain response ( [McGrath and Hillier, 1989](#)).

Pain behaviors may serve communicative functions in families. Parental responses, including anxiety before to a procedure and expectation of the child's fear or uncooperativeness, can significantly affect the child's experience of a painful stimulus and subsequent behavior. Heightened parental anxiety thus can exacerbate distress for a child undergoing a procedure ( [Bush, 1987](#); [Manne et al., 1988](#)). Family patterns of pain response are learned through modeling and reinforcement, and operant conditioning models also have been used to describe responses that reinforce pain behaviors as predominant coping strategies. In line with a learning model, instruments or even people that are associated with pain induction can later independently elicit anxiety, fear, avoidance, and complaints of pain. Nevertheless, most clinicians working in this area oppose a differentiation of pain between "psychogenic" versus "organic." Such a distinction can disrupt therapeutic alliances and usually is not relevant or able to be substantiated diagnostically or therapeutically.

In assessing pediatric pain, [Bush \(1987\)](#) suggests focusing on diminishing anticipatory anxiety, the prior history of pain experiences, and the environmental responses to pain behaviors. [Varni et al. \(1987\)](#) underscore the importance of combining cognitive, behavioral, and physiologic data in evaluating pain. In children, self-reported distress during a procedure may not habituate after repeated exposure, although it may appear to lessen to an observer. Developmental and psychological factors, such as age and fearfulness, may be more operative ( [Manne et al., 1988](#)). Adaptive coping mechanisms may include distraction, desensitization, information seeking, and parental presence. Visual analog scales ( [Bush, 1987](#); [Varni et al., 1987](#)) or "word descriptors" ( [Abu-Saad, 1984](#)) have been used successfully in pain assessment in children to help quantify the fear or pain experience.

Psychological techniques in pain management have included hypnosis, distraction, and relaxation with the help of breathing exercises. Other interventions may address family factors that are operative in the child's pain experience. The preparation aspect of intervention may use a modeling principle in exposing children to educational videotapes or other children who are using adaptive coping mechanisms. Younger children may benefit more from "imaginative involvement," a technique that takes advantage of their active fantasy life in creating stories and using hypnotic suggestions, than distraction ( [Kuttner et al., 1988](#)).

In summary, the BMT, peripheral blood stem cell transplant, and SOT pediatric population undoubtedly can benefit from psychological techniques to assist with anxiety, fear, and pain associated with the myriad of procedures these patients experience. There may be long-term benefits as well, such as improved compliance and the possible decrease in potential posttraumatic symptomatology.

### **Posttransplantation Life and Nonadherence**

#### *THE FIRST YEAR*

Lifestyle is irrevocably changed after transplantation and evolves in parallel with the medical course and nature of follow-up. There seems to be a differentiation with respect to issues involved in early follow-up and late follow-up, and the end of the first year after transplantation may be an important marker.

Initially, there are frequent clinic visits and a necessary immersion in becoming versed with the requirements of transplant life. Complications may occur during the first year, as the immunosuppressant regimen is adjusted. One parent summed up this period by saying: "Life then was centered around the hospital. We lived

transplant, we ate, we slept transplant. We were totally removed from the rest of our lives" ([Slater, 1994](#)).

Patients and families are more closely followed and monitored during the first year and live in the aftermath of having survived an extraordinary ordeal; they often describe having more powerful family bonds and pride in having weathered the ordeal. Being closer in time to the pretransplantation and transplantation experiences, they may be more likely to treat their bodies and the new organ inside with respect. They are much more task focused as they learn about administering medication and recognizing signs and symptoms of illness. Many of the social sequelae may not yet be apparent because children and adolescents are just beginning to reenter their social milieu and still might be treated as quite special by peers, a time-limited but perhaps supportive influence on self-esteem. In addition, many of the physical side effects may not be fully in evidence. For all these reasons, adolescents may be less likely to be noncompliant during the first year.

Biopsies and catheterizations are more frequent in the early period after heart transplantation and tax the skills of most parents, who are used to having more latitude with respect to setting limits with their children. In the world of transplantation, there often is little room for negotiation: medication must be given, doctor's appointments must be kept, biopsies and catheterizations must be done.

#### LATE FOLLOW-UP POSTTRANSPLANTATION

The end of the first year often is marked by an anniversary celebration by patients and families, and as routine follow-up diminishes in frequency, many families describe a discomfort with being more on their own, "waiting for the other shoe to drop" ([Slater, 1994](#)).

The uncertainty of posttransplantation life is a background anxiety that some patients and families are better able to suppress than others, and unexpected complications, which can include rejection, seizures, alterations in renal function, infection, and posttransplantation lymphoproliferative disorder, for example, can be powerful reinforcers of a constant background dread that may seriously affect patients and families. Other potential chronic effects of immunosuppressive therapy include hypertension, coronary artery disease (cardiac transplant recipients), bone disease, cataracts, and growth reduction ([Moskop, 1989](#)).

[Stuber \(1993b\)](#) underscores salient clinical considerations in the adolescent population, such as anxiety, impaired self-esteem, nonadherence, depression, and posttraumatic stress disorder (PTSD). One adolescent told me that he was troubled by the discontinuity in his conscious experience of the transplantation because he did not "see" the actual operation, but simply awoke with a scar on his chest and a new heart inside. He developed intrusive images of what he felt the actual operation looked like, seeing his heart repeatedly lifted out of his chest and replaced by another. Eventually, the treating psychiatrist obtained some videotaped footage of an actual heart transplantation, which the adolescent eagerly watched, and later reported his intrusive thoughts had abated. He later brought this tape to school to show his classmates in health class.

Major depression can be differentiated from organic mental syndromes or constitutional symptoms secondary to depleting medical illness. Useful criteria in making this differentiation include the presence of cognitive correlates of depression, including hopelessness, guilt, low self-worth, and suicidal ideation, and the absence of signs and symptoms of delirium or encephalopathy on formal mental status examination ([Stuber, 1993b](#)).

Parents also may exhibit posttraumatic phenomena, such as a mother of a transplant recipient who nearly died waiting for an organ, who was tormented for months by intrusive images of her daughter's funeral.

Over time, parents struggle with normal developmental issues in relinquishing control and responsibility to their adolescent children, but this is exacerbated by heightened anxiety over whether the adolescent will be compliant and recognize physical signs and symptoms. Events such as the adolescent leaving for college can have profound impact on a parent. As one mother described: "I think that this whole transplant life, is a life, and you can get lost in it. When my daughter went to college, she said, 'Mom, you know, like get a life.'

"I said, 'But you are my life. I've been taking you back and forth, doing things with you, and watching you all this time—you have been my life.'

"She said, 'Yeah but mom, now you have to get a life'" ([Slater, 1992](#)).

There may continue to be residual issues among siblings and between healthy siblings and parents that originated in the need for the parents to be so preoccupied with the ill child. These feelings may have distorted relationship development in the family to such a degree that psychiatric treatment is warranted.

Outpatient individual or family psychotherapy can be of great assistance, especially during the first year after transplantation, when most of the acute adjustment to transplant life takes place, and psychiatric follow-up may be made easier by patients' frequent visits to the transplantation clinic. During rehospitalizations for complications or routine biopsies or catheterizations, the psychiatric consultant should reevaluate, looking for the presence of any intercurrent psychopathologic process in the patient or family members or risk factors for nonadherence. The consultant should assess social adaptation, compliance behaviors, and the overall level of family and patient functioning, including school attendance and presence of any cognitive impairment. Appropriate referrals for neuropsychological testing or Committee on Special Education evaluation can be made.

#### NONADHERENCE IN TRANSPLANT RECIPIENTS

Most of the literature on nonadherence in the transplant population involves adult renal transplant recipients or pooled data from adults and children ([DeLone et al., 1989](#); [Dunn et al., 1990](#); [Kiley et al., 1993](#); [Rovelli et al., 1989](#), [Rovelli et al., 1989b](#); [Schweizer, 1990](#)), although some studies have looked specifically at the pediatric population ([Beck et al., 1980](#); [Bunchman, 1999](#); [Foulkes et al., 1993](#); [Korsch et al., 1973, 1978](#); [Phipps and DeCuir-Whalley, 1990](#)); [Bunchman \(1999\)](#) cited data ([Blowey et al., 1997](#)) suggesting that lack of adherence in the pediatric renal population is responsible for 93% of the loss of all allografts, with 20% to 40% of children nonadherent with their medical regimens. Possible interventions to reduce nonadherence include the simplification of therapy, support groups, techniques to remind patients to take medication (alarms, pill boxes), once-daily dosing, transdermal preparations, and small pills or liquid preparations with reasonable taste ([Bunchman, 1999](#)). Diaries, logs, and frequent visits with health care specialists who can troubleshoot and monitor compliance also can be valuable. There is literature on general nonadherence issues in medically ill adolescents that has been reviewed ([Cromer and Tarnowski, 1989](#)).

Shapiro and Fingerth (unpublished data) reviewed the literature on nonadherence in the adult cardiac transplant population and found a robust association between nonadherence and both global psychiatric risk and personality disorders. Global psychiatric risk was estimated clinically as low, moderate, or high by the psychiatrist after reviewing the prior psychiatric history. Included among the items scrutinized were any history of substance abuse, cognitive impairment, personality disorder, social stressors, prior level of functioning, previous history of nonadherence, social supports, interpersonal problems with treating physicians, and knowledge/expectations about transplantation. For those patients with high global psychiatric risk, 50% were noncompliant. Personality disorders were diagnosed clinically as being nonexistent, mild, moderate, and severe, with patients having severe personality disorders noncompliant 100% of the time.

[Korsch et al. \(1973\)](#) examined the psychosocial outcome of 35 pediatric renal transplant recipients and found that, within a year, most normal family patterns had returned if the child was healthy, with most of the disruption in family functioning occurring during this year. Ten of the 35 patients had scores indicating maladjustment on personality measures, most apparent in the anxiety and self-esteem scales. Eight patients had psychopathology, with depression the "most specific test finding." Transplant recipients with personality disturbances were more likely to be noncompliant. Seventeen of 19 older adolescents were in college or working. Eleven of 16 younger patients were in school. Leisure activities were age appropriate. Anxiety over rejection and side effects of steroids emerged as significant clinical issues.

[Korsch et al. \(1978\)](#) found that risk factors for nonadherence with immunosuppressive medication included sex (female greater than male), adolescence, premorbid deviance on personality scores, absence of the father, and lack of community support and other resources.

[Beck et al. \(1980\)](#) reported a 43% prevalence of nonadherence in a sample of pediatric renal transplant recipients and found that all of the noncompliant patients were adolescent. The noncompliant patients seemed to have less parental involvement in supervising their medication and attending clinic visits. An intervention program including counseling and instruction resulted in five of the noncompliant patients becoming compliant. None of this latter group of patients lost their grafts, as was the case with six other noncompliant patients. Notebooks in which medication administration and laboratory results were recorded have facilitated compliance.

[Rovelli et al. \(1989a\)](#) found nonadherence in renal, heart, and liver transplant recipients to be higher in the age group younger than 20 years. After the initial 3-month period posttransplantation, it was reported that nonadherence caused graft loss more frequently than unmanageable rejection episodes in compliant patients.

[Schweizer \(1990\)](#) reported that clinic visit nonadherence was associated with medication nonadherence.

Factors that predict compliance in the outpatient setting also have not been well studied in the pediatric BMT population. One study in outpatient adolescents with cancer (not specific for BMT recipients) showed that nearly 50% were noncompliant with oral medication regimens ([McConville et al., 1990](#)). Risk factors for nonadherence included less developed concepts of illness, less perceived vulnerability, greater denial, and relatively decreased orientation toward the future ([Tamaroff et al., 1992](#)). A study that looked specifically at compliance in inpatient pediatric BMT recipients reported greater than 50% nonadherence rates as inpatients, most commonly found with oral antibiotics, and most prevalent in the preschool or school-age population ([Phipps and DeCuir-Whalley, 1990](#)). More research in this area is needed.

[Hesse et al. \(1990\)](#) suggested that nonadherence with corticosteroids may be more prevalent in the pediatric and adolescent population. [Foulkes et al. \(1993\)](#) found that compliance with different medications may vary within an individual's regimen and underscored the importance of assessing compliance to each medication.

[Bradford \(1990\)](#) reviewed other risk factors for nonadherence in patients with chronic renal failure, which included "side effects, duration, and complexity (of medication); the doctor-patient relationship; family factors: instability or discord, poor communication, lack of support from family members, maternal mood, poor maternal understanding of treatment, and lack of supervision; poor understanding, perceived vulnerability and doubts about the effectiveness of the treatment" ([Bradford, 1990](#)). Periodic psychosocial assessment of transplant recipients as outpatients was recommended.

In one series of 28 pediatric liver transplant recipients, 34 instances of nonadherence were documented, with a mean of 2.19 episodes of rejection before the nonadherence was identified ([Molmenti et al., 1999](#)). The mean age of transplantation was 9 years, with the mean age of nonadherence being 14.8 years. The authors conclude that the clinician should have a high index of suspicion for lack of adherence when adolescent patients present with repetitive episodes of rejection associated with low immunosuppressant levels.

Preliminary results from a study of nonadherence in pediatric heart transplant recipients found nonadherence in 13 of 64 (20%) patients and was significantly associated with adolescent age and "late" rejection occurring greater than 1 year after cardiac transplantation. In noncompliant patients, graft survival dropped off precipitously in stepwise fashion from 1 year posttransplantation, such that only 30% graft survival was present at 5 years in these patients ([Douglas et al., 1993](#)). This is alarming because eight of these patients lost their grafts (two retransplantations and six deaths). One of these patients maintained a powerful sense of denial and invincibility throughout the entire transplantation experience. He later became secretly noncompliant with his medication, rejected the first heart, and almost died before being retransplanted. He eventually died several years later. Because of this alarming statistic, in 1993, a noncompliance treatment plan was instituted that included:

- Pretransplantation and posttransplantation teaching, specifically about noncompliance
- Assignment of patients to a primary pharmacist who worked directly with the transplantation coordinator and family
- Demonstration of adherence to treatment while awaiting transplantation if there was a preoperative noncompliant history
- Mandatory psychiatric referral and follow-up
- Inpatient and outpatient retraining of patient and family
- Frequent (weekly or biweekly) immunotherapy drug monitoring and clinic visits
- Monthly peer support group meetings
- Daily home visiting nurse if indicated and feasible
- Paid transportation for visits
- Liaison with school nurse
- Transplantation coordinator pouring medications weekly
- Child welfare agency intervention

When these data were updated in 2000, it was found that of 156 children who had had heart transplantations since 1984, there were 129 survivors at a mean follow-up age of  $5.8 \pm 3.9$  years, with 23 surviving more than 10 years. Seventy-seven were attending school or college, 6 had graduated from college, and 11 were working. Despite the noncompliance treatment plan, 31 patients died after discharge, and noncompliance was the primary factor in the death of 50% of these patients. In these follow-up data, which looked at patients both before 1993 and after 1993:

- Compliant patients had a >90% overall survival rate after transplantation.
- The initial incidence of nonadherence had not changed despite an intensive prevention and treatment regimen.
- The frequency of nonadherence increases with time in long-term survivors, particularly when the young child reaches adolescence.
- Noncompliance is significantly associated with adolescent age.
- Rejection frequency and episodes of late rejection and hemodynamic compromise were significantly higher in all nonadherent patients.
- Although survival of nonadherent patients has improved with focused therapy (60%), it is still significantly less than in compliant patients (90%).
- Nonadherence continues to be the leading cause of late graft loss and death in pediatric cardiac transplant recipients.
- Adolescents are at constant risk despite previous compliance, and a high index of suspicion is warranted.
- Prevention and treatment of nonadherence is labor intensive but may improve survival.

Contrary to expectations, a significant number of patients who were transplanted before 1993, when they were preadolescents, and who were initially compliant, later as adolescents became noncompliant. This phenomenon seemed to counter the prevailing belief that children who "grew up" ill would be less likely to be noncompliant as teenagers. Based on this author's experience, some patients continued to have significant morbidity and mortality from nonadherence for the following reasons:

- They continued, despite the transplantation team's best efforts, to miss medical and psychiatric clinic visits and blood drawing for immunosuppressant blood levels, and in our experience, the transplantation team has little leverage to "force" patients to be compliant. Social service can be helpful at times to younger patients, although the adolescent sample remains the most difficult to control. Psychiatric hospitalization usually was an ineffective option in the treatment of such patients, even if a case could be made for the suicidal potential of nonadherence. This is because psychiatric hospitals in general are uncomfortable managing medical problems, or the patient's insurance plan had limited psychiatric inpatient coverage. In several instances in which patients could be admitted, the limited length of psychiatric admissions (1 to 2 weeks) did little to solve the problems causing nonadherence.
- Peer support groups were voluntary, and although viewed as quite necessary by the transplantation team, clearly are not sufficient to prevent nonadherence.
- It was difficult to mobilize appropriate psychiatric and social services that potentially would address factors contributing to nonadherence, such as conduct problems, family psychopathology, patient psychopathology, and psychosocial discord, especially when such factors occurred in combination. In the author's opinion, the type of intensive psychiatric service, either extended psychiatric partial hospitalization, or a residential facility with psychiatric, nursing, and medical follow-up, that might have a chance of treating these patients successfully *simply does not exist*. Intensive efforts to find such placements by our transplantation team, or even to create them, have not yet been met with success.

In a sample of 53 pediatric heart and heart-lung transplant recipients (mean age, 10.3 years), 30% were found prospectively to be nonadherent to the treatment regimen ([Serrano-Ikkos et al., 1998](#)). Interestingly, the heart-lung transplant group was significantly less adherent than the heart transplant group. A greater number of adolescents in the latter group may have explained this finding. However, pretransplantation adherence was not studied, and different chronic illnesses before transplantation in the heart-lung transplant group (e.g., cystic fibrosis) also may have contributed to this finding. Children living with both biological parents had higher adherence than children living in single-parent or blended families, suggesting the possible protective factor of support. These findings may help target specific interventions to families and patients who may be at higher risk for nonadherence.

---

#### CASE ILLUSTRATION

An adolescent young man who was secretly noncompliant as a 13-year-old later confided: "I guess when you're that age you think you're invincible, especially after going through a transplant. I mean hey, you were close to death and you made it. You're even more invincible now. I mean you were just a normal invincible thirteen year old before, now you kind of feel I guess, for lack of a better *immorta*. Yeah, you laughed in the face of death, big deal. But in the end, if you don't take your medicine, he's going to laugh back really hard. Probably why I needed a second transplant is one very big reason, stupidity: I was too proud to take my medicine in front of other kids. I had that, you know, the peer pressure, the look of someone turning around while I'm taking it. And it really got to me, it did. The reason I spoke up about not taking my medicine is that I realized I was hurting myself. I realized whether consciously or not I was committing suicide. Whether I actually thought of it that way or not, I was killing myself. So, while the doctors were going crazy trying to research every angle on this of why I could be getting sick, I just said, "Look, I wasn't taking my medicine, that's why I've been getting sick." I paid the price, losing a transplanted heart and having to go through it again was painful, not to mention I lost the trust of a lot of doctors." [From [Slater \(1994\)](#), with permission.]

---

---

Based on available data, it would appear that risk factors for nonadherence in the pediatric transplant population include:

1. Adolescence
2. Conduct disorder, sociopathy, or other significant personality disorder
3. Affective disorder, including major depression and perhaps other, more chronic, indolent depression with impaired self-esteem such as dysthymia; possibly the presence of another psychiatric disorder such as PTSD, which has been receiving more attention as an identifiable sequela in pediatric patients with cancer, and is reviewed in the [Chapter 96](#) in this volume
4. Family psychopathology, possibly an absent father, and poor supervision by parents
5. Prior history of nonadherence
6. Cognitive limitations and problems understanding the medication regimen by adolescents or parents
7. Low perceived vulnerability and expectation of benefit from treatment, including a sense of a foreshortened future the patient feels powerless to affect
8. Poor physician–patient relationship or continuity of care
9. Inadequate resources to meet treatment requirements (e.g., transportation, financial)
10. Poor understanding or acceptance of the need for commitment to treatment and follow-up

Warning signs for nonadherence in this population may include ( [Douglas et al., 1993](#)):

1. Late rejection
2. Variations in cyclosporine levels or reluctance to have them drawn
3. Casual reporting of missed doses of immunosuppressants
4. Missed or delayed clinic appointments
5. Not reporting illness

Management issues should include treating nonadherence as a phenomenon with a differential diagnosis ( [Cromer and Tarnowski, 1989](#)):

1. Direct physical assays should be used when possible to monitor compliance.
2. Interventions should be directed at presumed underlying causes and risk factors.
3. Nonadherence should be treated as an issue “shared” by the patient, family, and physicians and approached from a task-oriented, problem-solving point of view.
4. The clinician should combine interventions that use closer monitoring (more frequent clinic visits), and help the patient with organization strategies (use of alarm watch, pill boxes, carrying extra doses of medication at all times).
5. Psychiatric involvement and individual and/or family psychotherapy and pharmacotherapy should be used if appropriate.
6. Pain should be managed adequately.
7. Increased involvement of parents or parental surrogates should be considered.

Adolescent issues affected by transplantation should be anticipated even before surgery and discussed with the patient in an appropriate fashion to help identify potential problem areas. Nonadherence should be addressed early on with the patient and family as a major side effect of treatment and serious cause of graft loss and death. This discussion should continue after transplantation. Specific areas that might be addressed include concrete help with side effects (e.g., helping to establish diet and exercise regimens, advice on removing excess hair) or peer issues. Adolescents as young as 10 years of age, depending on their level of maturity, often can be taught to manage their own medication from the time they are in the hospital and should be put in touch with other transplant recipients who can provide opportunities for modeling coping behaviors.

For adolescent patients in particular, outpatient follow-up should be considered as a routine measure. An early alliance between an adolescent and mental health specialist may be of great value in facilitating work later, when the adolescent is at higher risk for nonadherence (see later), and allow early identification of risk factors and intervention.

In a study that looked at brittle diabetic patients ( [Moran et al., 1991](#)), many of whom are presumed to have psychosocial factors that exacerbate their medical course, intensive inpatient psychotherapy three to four times weekly, for an average duration of 15 weeks, was associated with improved diabetic control, which was maintained at 1-year follow-up. One might extrapolate from such a preliminary study and suggest that severely noncompliant adolescent transplant recipients should be hospitalized for a period of weeks to months in a medical facility that can provide a multidisciplinary approach to treatment that includes a strong psychiatric component. It is hoped that insurance companies will reimburse such services, which may have a strong impact on patient survival.

## SPECIFIC ORGAN SYSTEMS

### Bone Marrow Transplantation and Peripheral Blood Stem Cell Transplantation

#### OVERVIEW

The psychiatric aspects of BMT were reviewed in two articles by [Andrykowski \(1994\)](#) and [Wolcott and Stuber \(1992\)](#), and in a more recent paper by [Andrykowski and McQuellon \(1998\)](#). The use of BMT has undergone a rapid increase since the late 1970s because of better survival rates, the expansion of its use to treat a greater variety of illnesses, and the growth of alternative donor pools besides an identical twin sibling.

The procedure itself is offered only as a final option in diseases where conventional treatments will not or have not sufficed and that include leukemias, lymphomas, breast cancer, neuroblastoma, ovarian cancer, germ cell tumors, melanoma, multiple myeloma, and malignant gliomas ( [Abramowicz, 1992](#); [Andrykowski, 1994](#); [Trigg, 1988](#); [Wolcott and Stuber, 1992](#)). In the pediatric population, BMTs also have been used to treat aplastic anemia and congenital metabolic and immunologic disorders. Cytotoxic drugs, often in combination with total-body irradiation (TBI), are used to wipe out the patient's own bone marrow over a 4- to 10-day period while the patient remains in relative isolation, often in specialized laminar air-flow rooms, with visitors usually required to wear gowns, gloves, and masks. Healthy marrow is then delivered by intravenous infusion. BMTs are categorized by the source of the marrow to be transplanted, which is either autologous, allogeneic, or syngeneic.

Autologous BMTs use the patient's own marrow or peripheral blood progenitor (stem) cells, which are harvested before BMT and reinfused after high-dose chemotherapy, and is used in lymphomas, sarcomas, and advanced breast cancer ( [Andrykowski, 1994](#); [Andrykowski and McQuellon, 1998](#)). Stem cells are harvested on an outpatient basis by passing peripheral blood through a machine that collects white blood cells, which have progenitor cell function, with the remaining blood returned to the patient, and blood growth factors sometimes are used to stimulate production of white blood cells before the collecting of stem cells ( [Andrykowski and McQuellon, 1998](#)). Immunosuppressant medication is not necessary, and there is less risk of graft-versus-host disease (GVHD), where the infused white blood cells react to the host as being foreign and mount an immune reaction. Ninety percent of children receiving BMT undergo significant pain secondary to the mucosal damage and desquamation after high-dose chemotherapy, which produces oropharyngeal inflammation, ulceration, and oral mucositis ( [Pederson and Parran, 1999](#)). Research indicates that continuous infusion of opioids at milligram per kilogram dosage levels that may need to exceed that administered to adults ( [Pederson and Parran, 1999](#)). This higher dosing may be secondary to the more rapid tolerance that develops in children compared with adults, and the relatively higher doses of mucotoxic chemotherapy regimens used in children, as well as the greater attention paid to behavioral indicators of pain; the importance of using self-reports was emphasized. These authors reviewed literature suggesting that patients receiving peripheral blood stem cell transplants may undergo mucositis for shorter periods because of more rapid bone marrow recovery, possibly due to the use of different chemotherapeutic regimens than in BMT.

Allogeneic transplants are used to treat hematologic malignancies and immune disorders ( [Andrykowski, 1994](#)) and use human lymphocyte antigen (HLA)–matched marrow from a family member or other donor, with the benefit that tumor cells are not part of the infused marrow ( [Abramowicz, 1992](#)). GVHD is more common than with autologous BMTs. Syngeneic transplants use marrow from an identical sibling donor.

Bone marrow transplantation typically involves a hospitalization of at least 5 to 6 weeks and can require a much more lengthy hospitalization of several months because of the high rate of complications, with a mortality rate of 5% to 20% with autologous transplants and 10% to 30% with allogeneic transplants ( [Abramowicz, 1992](#); [Andrykowski, 1994](#)). In general, patients with leukemia fare better than those with solid tumors, with disease-free survival rate at 2 years approaching 60% with early leukemia ( [Table 97.2](#)). Many factors have been associated with survival rates, including the type of tumor, stage of tumor before treatment, age and physical

state of the recipient, origin of the marrow, type of chemotherapy used before transplantation, the actual transplantation protocol used, and the experience of the transplantation center itself ([Abramowicz, 1992](#)).

After discharge, patients often are in an immunocompromised state, with normal immune function not returning for up to 1 to 2 years posttransplantation, thus placing the patient at moderate risk for dangerous infections and requiring a strict care regimen on the part of the patient and family. Acute GVHD occurs and runs its course within 30 to 100 days posttransplantation and commonly affects the liver, gastrointestinal tract, and skin. GVHD is differentiated from rejection in SOT, where the host is mounting the immune response. Chronic GVHD occurs later and does not resolve, although it can be managed medically ([Andrykowski, 1994](#)).

Thus, even though the patient may survive the initial malignancy, postoperative morbidity may include infections, GVHD, graft failure, primary malignancy relapse, secondary malignancies, and a multitude of treatment-associated side effects that may affect a variety of organ systems, including cognitive function ([Andrykowski, 1994](#); [Wolcott and Stuber, 1992](#)). Recovery thus can be broken down into the acute phase in the hospital, a slower, subacute phase that may last months after discharge, and a significantly prolonged stage of "adjustment and rehabilitation" ([Wolcott and Stuber, 1992](#)). Conceptualization of the process in phases, as in SOT, can lend itself to a better understanding of the psychological sequelae.

Psychosocial or psychiatric evaluation of BMT candidates may play a less crucial role in the selection process because bone marrow is a "renewable resource" whose supply is not limited as in SOT. Nevertheless, because of the expense of the procedure, its significant medical and psychological morbidity, and debate over the allocation of health care resources, there may be increasing pressure to establish priorities along guidelines that take into account survival rates and quality of life ([Andrykowski, 1994](#)). Research has been extremely limited, especially in the pediatric population, in looking at psychosocial variables that may predict compliance and medical/psychological outcome in patients and families.

#### PSYCHIATRIC SEQUELAE AND INTERVENTIONS

A body of literature addresses the neuropsychiatric sequelae and psychological adjustments in pediatric BMT recipients and their families ([Andrykowski, 1994](#); [Arvidson et al., 1999](#); [Dermatis and Lesko, 1990](#); [Gardner et al., 1977](#); [Kramer et al., 1992](#); [McConville et al., 1990](#); [Parkman, 1986](#); [Patenaude et al., 1979](#); [Pfefferbaum et al., 1977, 1978](#); [Pot-Mees, 1987](#); [Smedler et al., 1990](#); [Stuber, 1993b](#); [Stuber et al., 1991](#); [Trigg, 1988](#); [Wiley and House, 1988](#); [Wolcott and Stuber, 1992](#); [Wolcott et al., 1987](#)).

Pediatric patients receiving BMT are thought to be at higher risk for cognitive deficits than children receiving standard cancer therapy because they typically receive initial chemotherapy, followed by a conditioning regimen consisting of TBI, chemotherapy, or both ([Arvidson et al., 1999](#)). [Arvidson et al. \(1999\)](#) noted that although children treated with autologous BMT tested for general intelligence in the average range, such testing was insufficient to categorize learning problems whose identification required more specific neuropsychological testing. They found more learning difficulties in children receiving cranial radiation with young age at diagnosis and that a long follow-up time correlated with lower performance on neuropsychological testing, and recommended that specific tests evaluating attention and memory be administered.

[Arvidson et al. \(1999\)](#) cite a study ([Kramer et al., 1997](#)) that found that there was a 5-point decline in IQ 1 year after BMT, in which the authors suggested that psychosocial factors may be important. Long-term follow-up studies are few, although one found deficits in perceptual function and fine motor speed ([Smedler et al., 1995](#)). An interesting study in the adult population ([Gregurek et al., 1996](#)) suggests that anxiety may be related to the incidence and severity of acute GVHD through potential immunomodulatory mechanisms.

A study ([Cool, 1996](#)) examining the effects of BMT on neuropsychological function in children, found that prior cranial radiation therapy, although improving survival rates in acute lymphoblastic leukemia, caused effects on cognition (lower IQ scores and effects on memory) even before BMT. The TBI and chemotherapy regimens that prepare a child for BMT seemed not to have significant independent effects on cognition at 1-year follow-up post-BMT, although as a whole, the BMT group showed lower achievement, and a subgroup of children did evidence declines in verbal IQ. Longer-term follow-up of BMT recipients found declining IQ scores over time, with greater effects seen in younger children and those with prior cranial radiation therapy. This has implications for remedial services, which should target memory and organization skills during school reentry, as well as for in-hospital or at-home schooling before the child is able to return to school. Follow-up testing should go beyond 5 years because many effects occur late.

In a neuropsychological study of patients after BMT, children who had received chemotherapy only did not differ significantly from those receiving chemotherapy and TBI ([Simms et al., 1998](#)). These authors note, however, that there does appear to be a subset of children 1 to 5 years after BMT who appear to have significant declines in neuropsychological function. Cognitive effects on children younger than 3 years of age tend to be more variable across studies.

The first year after BMT may be a time when children are especially vulnerable to emotional difficulties, with effects on social competence and self-esteem, and may represent an opportunity for psychological intervention ([Phipps et al., 1995](#)); in this particular study, no significant declines in neuropsychological function were found, although 21 of the 25 posttransplantation survivors in the sample were 6 years of age or older.

The experience of pediatric BMT can be conceptualized in terms of emotional stages ([Patenaude et al., 1979](#); [Pfefferbaum et al., 1978](#)). [Pfefferbaum et al. \(1978\)](#) describe a 10-stage process, with implications for the need for psychological management. Many of these stages have correlates in SOT, as discussed previously. Chronologic hallmarks include:

1. The exigencies of the informed consent/assent process and living donor considerations such as putting a healthy sibling at risk. Many authors note the unrealistic expectations on the part of the patient and family that often accompany this stage ([Patenaude et al., 1979](#); [Pfefferbaum et al., 1978](#)). Psychological distress in parents during this stage has been studied ([Dermatis and Lesko, 1990](#)) and suggests that parents experience a variety of psychiatric symptoms that may inversely correlate with the quality of the communication between parents and the physician. Parents may not fully grasp all aspects of the informed consent process, and single parents may be more at risk for psychiatric symptoms. Psychological intervention may be especially important during this stage to facilitate communication and the use of coping strategies.
2. Pretransplantation evaluation (similar to that in SOT).
3. Effects of separation from school, home, and friends.
4. The intense feelings of separation and helplessness during the child's isolation for several hours for TBI and the inevitable chills, nausea/vomiting, and diarrhea that follow.
5. Transplantation day, with the specific risks of general anesthesia and bleeding for the donor. The bone marrow infusion itself may be a somewhat "anticlimactic event, greater in symbolic than immediate medical significance" ([Patenaude et al., 1979](#)). The isolation of the sterile room may pose a significant stressor.
6. The waiting period, during which time the family "settles in" to the hospital, and parents may attempt to counter feelings of helplessness by carefully following blood counts with attendant anxieties.
7. Watching for the donated marrow to "take," approximately 2 weeks after the infusion, with children sometimes feeling a sense of "responsibility for the outcome,... assuming blame for infiltrated intravenous lines, unsuccessful venipunctures, nausea, diarrhea, and even results of blood counts." [Patenaude et al. \(1979\)](#) describe the "vacillation between...fear and hope."
8. Medical complications and psychological reactions to "waiting again" for marrow activity to stabilize, with children perhaps most prone to withdrawal, depression, and irritability; and parents feeling "rejected and embarrassed"; and the possible decrease in support from family members, who may become less available, as well as from the staff itself.
9. Anxiety over reentering the social milieu as discharge approaches, owing to the change in physical appearance (hair loss, weight loss, cushingoid changes), and the inevitable disappointment that the child is not "well."
10. The relative isolation, dietary restrictions, chronic medication administration, and uncertainty that characterizes life after discharge ([Pfefferbaum, et al., 1978](#)). BMT survivors may be even more compromised physically than SOT recipients. The enforced dependency and reliance of the child on a single figure, often the mother, poses a significant stressor for the entire family ([Patenaude et al., 1979](#)).

The child and adolescent psychiatrist is perhaps best used as an integral member of the BMT team who makes contact with the family during their initial evaluation and serves as a liaison to the rest of the hematology–oncology team. Pretransplantation evaluation of the patient, family, and living related donor, as well as neuropsychiatric assessment and family support during the procedure, also are important avenues for both treatment and prevention of psychiatric morbidity. Attention should be paid to the relationship between the referring physician or institution and the hospital administering the BMT because the patient may likely return to the original hospital at some point, and families may experience complicated feelings about the two institutions, with potential feelings of abandonment, issues over

transferring care, or possible splitting mechanisms ([Atkins and Patenaude, 1987](#)).

A waiting period between the decision to transplant and the BMT procedure itself may occur because of the availability of hospital beds, financial factors, or failure to identify suitable unrelated or related donors. Like the waiting period in SOT, this can be associated with ambivalence about the procedure, significant anxiety over intercurrent survival or progression of illness, and the psychological consequences of possibly not living near the transplantation center ([Andrykowski, 1994](#)). In the case of a living related donor, donor-related feelings may be less ambivalent because an organ is not being "sacrificed" ([Gardner et al., 1977](#)), compared with kidney donation, for example, where recipient guilt is common. In BMTs, the donors nevertheless may experience guilt and perhaps added pressure because the request for marrow donation does not involve the irretrievable loss of an organ. Solid organ donation may represent a sacrifice that makes absolution from further responsibility, or ambivalence about donating, more "justifiable" ([Gardner et al., 1977](#)). Other siblings may feel "relief" as well as feeling "left out" ([Patenaude et al., 1979](#)). All these factors have an impact on parents, siblings, and patients alike ([Pot-Mees, 1987](#)), and mothers of BMT recipients may be particularly prone to these sequelae because they may spend an extraordinary amount of time in the hospital with their child.

Simply identifying and assisting the family in coping with the extensive array of individual stressors can represent tremendously supportive interventions. These stressors may alter family roles and finances and include long geographic distance from home, the tremendous fear of death, and the tendency for attention to center around the BMT recipient to the exclusion of other family members. The latter can evoke feelings of both guilt and resentment over individual needs not being met ([Andrykowski, 1994](#)). Addressing these problems is paramount because psychiatric sequelae can affect the relationships between the members of the team working with the child and his or her family network, which can have deleterious effects on the BMT recipient ([Andrykowski, 1994](#)). The psychiatric consultant can be of great help in assisting the rest of the medical staff in their understanding and management of the patient and family. He or she also may be of great assistance to parents in helping them to manage both their own feelings and the reactions of their children. [Nelson et al. \(1997\)](#) studied the effects of stem cell transplantation on the mothers of pediatric recipients, concluding that maternal anxiety during this treatment approximates anxiety in the unstable, acutely ill patient with cancer, and surmising that this is the second time mothers experience an acute risk to their child's life (the first being the diagnosis). An awareness of maternal anxiety is paramount in assisting clinicians in intervening because such anxiety may affect supportive functions for the child, as well as the reporting of childhood problems by the mother. Heightened depressive scores in mothers also were noted, and this phenomenon had an equivalent impact on care of the child. Intrusion coping, consisting of the parent reviewing feelings and information associated with the transplantation, seemed to be adaptive and was encouraged by the authors. Perception of adequate social support seemed to correlate inversely with depressive symptoms.

Behavioral and affective responses in pediatric BMT recipients may include depression, sleep difficulties, anxiety, apathy, withdrawal, irritability, and regression, as well as organic mental syndromes from neurotoxic central nervous system irradiation, chemotherapy, and infectious and metabolic effects ([Andrykowski, 1994](#)). Children often experience a gradually decreasing tolerance of and increasing opposition to procedures, along with increasing fearfulness and separation anxiety, all of which may cause havoc for parents ([Gardner et al., 1977](#); [McConville et al., 1990](#)). For the child, the need for intravenous hyperalimentation due to decreased oral intake, the denial of symptoms due to the (legitimate) fear of further intervention, and pronounced helplessness and dependency may further complicate the medical aspects of the procedure ([McConville et al., 1990](#)).

One study suggests that, over the long term, pediatric patients who undergo allogeneic stem cell transplantation are at risk for emotional difficulties ([Felder-Puig et al., 1999](#)). The sample consisted of patients between 14 and 30 years of age who had undergone stem cell transplantation at least 2 years before the assessment. Thirty-five percent had significant levels of anxiety, with 62% showing elevated levels of sensitivity and vulnerability (both perhaps etiologically related to the history of multiple invasive procedures and the fear of relapse), which were higher than those of the bone cancer survivor control group. Thirty-five percent of stem cell transplantation survivors reported dissatisfaction with their romantic lives (perhaps related to effects of their treatment on sexual function, diminished opportunities for meeting people, or negative effects of treatment on body image). Only 12% had major problems academically or occupationally, although the 12% were more dissatisfied with their performance compared with a control group of bone cancer survivors. Stem cell transplantation survivors did not differ from control subjects in multiple other domains that were evaluated, nor was the maladjustment rate greater than in the general population. Eighty-five percent of stem cell transplantation survivors were able to return to their schools or jobs. However, restrictions in physical activities were the main problems reported, and were greater than those in the bone cancer survivor group.

One study looked at children's perception of pain during BMT ([Pederson et al., 2000](#)). Important points included the ability of children accurately to self-report pain, the need for frequent serial assessments, the need specifically for nursing to use analog pain scales that assess for the intensity, type, and location of pain, as well as the need to include children in the choice of intervention strategies to help empower them. Despite receiving preparatory information about the pain they might experience before BMT, few children were able either to recall or assimilate this information. This fact suggested the need for feedback from children after their being given information to determine what they have retained, as well as a continuing teaching effort. Children noted the value of nonpharmacologic interventions, which emphasizes the need for staff to pay attention to these interventions even before BMT to help orient them to what will be most effective for an individual child. The practice of the child self-reporting pain should be fostered by staff.

In a series of 15 children undergoing BMT, the children appeared to adapt to the demands of BMT ([Gunter et al., 1999](#)). On a conscious level, they tended to become mildly depressed and generally to avoid the issue of what they were experiencing, with mild regressive trends, referred to by the authors as a type of "overnormalization." Projective testing, on the other hand, suggested that the children were dealing with more intense issues of death, depression, loneliness, anger, and feelings of guilt and punishment. More significant adjustment reactions, which were in the minority, were characterized by three varieties of reactions, including temper tantrums, regression, and depression reactions with noncompliance; such reactions seemed to be predicted by a history of "neurotic developments" or family conflict. The importance of recognizing the adaptive defensive structure of the individual child, as well as stressing the acceptance of expressed feelings of depression and anger, was underscored.

Another study noted that family cohesion and family expressiveness were protective factors for resilience in this population ([Phipps and Mulhern, 1995](#)), underscoring the importance of the family milieu in these patients. These findings potentially can provide a focus for the necessary psychosocial intervention for these children and their families. Mental status assessment often may be complicated by the presence of a dynamic interplay of these factors. BMT recipients are acutely affected by the medical course of other, similar patients in the hospital and, in the setting of another patient's death, may undergo a complex series of reactions that include denial and distancing, a heightened fear of death due to identification, and survivor guilt ([Patenaude and Rapoport, 1982](#)); psychological intervention is indicated in such circumstances. Decompensation and death provide unique challenges to all involved in the care of the child and adolescent. Concerns over quality of life and minimizing the suffering of a child compete with the wish to save the child and may present conflicts among staff and family members.

There also are psychological effects on the patient and family that relate to the source of the marrow and the subsequent success or failure of the graft, which may resemble analogous issues in living related organ donation in kidney or liver transplantation ([Wolcott and Stuber, 1992](#)). Death of the BMT recipient presents unique psychological sequelae for a family member who has donated marrow and may feel guilty that somehow his or her marrow was faulty ([Freund and Siegel, 1986](#)) or that he or she failed to save the recipient.

Recently, the psychological effects of BMT on siblings have become better appreciated ([Packman, 1999](#); [Packman et al., 1997](#); [Spinetta et al., 1999](#)). Sibling donors exhibited greater anxiety, lower self-esteem, and more adaptive skills in the academic setting, compared with nondonor siblings ([Packman et al., 1997](#)). One-third of the siblings in either group exhibited a significant degree of PTSD symptoms, which was a critical observation, and these symptoms occurred at 3- and 6-month follow-ups, suggesting the continuing impact of these experiences over time. Donor siblings experience the effects of an invasive procedure and the subsequent impact of continuing stresses; they may experience pressure to donate and feelings of loneliness and a tendency to withdraw emotionally after donation, along with a closer bond to the recipient after BMT. Packman notes that even a sibling who does not donate marrow must deal with two family members undergoing a medical procedure (assuming another family member is the donor), and that these symptoms could be better understood if seen as arising through a mechanism of "contagion," or simply by viewing the posttraumatic exposure as consisting of what the victim "felt" rather than what they experienced first-hand. Repeated interventions over time with siblings, rather than single interventions, should prove to be more effective, and should use multiple strategies, including sibling support groups. The effects of psychological interventions on siblings should be systematically studied ([Packman, 1999](#)). Guidelines for assistance to siblings of children with cancer have been published by the SIOP Working Committee on Psychosocial Issues in Pediatric Oncology ([Spinetta et al., 1999](#)). These guidelines stress:

- The importance of the involvement and education of siblings, including explanations about testing for potential bone marrow donation
- That siblings are not responsible for the cancer
- The need for sibling visits to the patient
- The value of support groups
- The need for siblings to remain informed about effects of cancer treatment during different phases

In the author's experience, BMT may be more stressful for the transplantation team, with guilty feelings perhaps more easily aroused because the children necessarily

are made so visibly sick by this extended procedure. Many SOT recipients, in contrast, may look significantly better soon after transplantation. Heart transplant recipients, for example, no longer appear cyanotic and may be out of the intensive care unit in several days, soon enjoying relatively greater physical activity compared with what may have been possible in a fairly compromised pretransplantation state. The physical changes secondary to immunosuppressant medication, so distressing to the adolescent patient, appear later.

Psychopharmacologic and psychotherapeutic intervention in the pediatric cancer population was reviewed by [McConville et al. \(1990\)](#) and [Spiegel \(1998\)](#). Medications have included anxiolytics, antidepressants, and low-dose neuroleptics to manage anxiety and depressive symptomatology during both the acute and terminal phases of illness; pharmacologic intervention in the pediatric patient with cancer is reviewed in another chapter in this volume.

Psychotherapeutic techniques range from working with the family, to teaching hypnosis and behavioral relaxation exercises to help patients tolerate painful procedures and decrease overall anxiety levels. Especially with respect to the latter, supportive collaboration with other medical staff is an essential aspect of the psychiatrist's role. Therapeutic play has been anecdotally reported to be quite helpful for pediatric BMT recipients, particularly when specific issues and goals are identified and used to guide the interventions ([Kuntz et al., 1996](#)).

Hospital staff can play a significant role in helping the patient and family prepare for discharge realistically and assist in concrete planning about resuming activities, helping parents understand the likely reactions of siblings and anticipate the effects of changes in marital roles ([Freund and Siegel, 1986](#)). Discharge from the hospital also is accompanied by stressors that are associated with the return home and reentry into the social milieu. These issues are similar to those confronted by SOT recipients, but complicated by the fact that recovery may be slower in the BMT population. Patients are not physically well and often exhibit the continuation of adjustment reactions, with consequent effects on siblings. There is a required preoccupation with cleanliness and minimizing exposure to potential pathogens that represents a constant reminder of the precarious line that is being traversed. These concerns often take on a compulsive quality.

Disruption of the marital relationship is common owing to the enforced separation during hospitalization, the reformulation of roles, and potentially conflicting coping styles, and preexisting difficulties are magnified tremendously ([Freund and Siegel, 1986](#)). A sense of "anger and betrayal" may be evoked in the patient and family when the transplant has not provided a cure ([Atkins and Patenaude, 1987](#)). This feeling may be exacerbated in the setting of post-BMT complications. Depression and impaired self-esteem may result when expectations meet with disappointment ([Freund and Siegel, 1986](#)). Individual psychotherapy, including play therapy with younger children, may facilitate psychological adjustment and the expression of feelings associated with the illness and procedure ([Atkins and Patenaude, 1987](#)). "Open communication, maintenance of hope, and the positive use of denial" may predict a more positive outcome, although clinical course may be a powerful predictor of psychopathology ([McConville et al., 1990](#)).

Although denial may be adaptive in children and adolescents in helping to maintain self-esteem, caregivers can play a significant role in addressing issues that would not be raised voluntarily and provide guidance as to the timing of education concerning these issues for the child/adolescent and family ([Wolcott and Stuber, 1992](#)).

Denial, however, may not necessarily be adaptive. [Stuber et al. \(1991\)](#) noted persistent symptoms of posttraumatic stress in 3- to 7-year-olds for more than 1 year post-BMT. Symptomatology appeared most pronounced around the time immediately after discharge from the hospital, when anxiety over survival is high. Denial and avoidance were the most prominent PTSD symptoms. Stuber et al. theorize that the more "chronic, nonimminent" nature of a threat that is internal and not external may be more likely to lead to denial and avoidance. This reaction "may seem the only possible response when the traumatic event is perpetrated by adults who are said to be acting in the child's interest, with the permission and assistance of parents." They also suggest that the simple fact of asking children about symptoms may be therapeutic. Intrusive, repetitive preoccupation may be evident only in the child's play. If the psychiatrist does not ask about symptoms or observe the play of these children, necessary treatment may be delayed because of the nature of this phenomenon, where symptoms are less dramatic and more insidious, and early intervention thus will be compromised.

These data should guide future early psychiatric treatment in this patient population and probably others who experience life-threatening illness with high-tech, dramatic, invasive interventions. It also has implications for follow-up care because of the probability that denial will affect how and when medical help is accessed. The occurrence of late psychological effects of BMT calls into question the view expressed by some to put "the BMT experience behind them," and suggests a more direct approach to dealing with issues surrounding the illness and its sequelae.

Specific sequelae for pediatric BMT recipients may include learning disabilities, growth retardation, and infertility. Significant motor delays and subtle impairments of performance in perceptual and fine motor tasks have been reported in children between 3 and 11 years of age treated with BMT accompanied by TBI ([Smedler et al., 1990](#)). Children in this age group were more significantly subject to these effects than were older children and adolescents, and cranial irradiation may be the significant factor in predisposing to neurocognitive deficits ([Kramer et al., 1992](#)). Cognitive deficits seem to be related to the dose of cranial irradiation or intrathecal methotrexate, and such sequelae can have significant effects on the developing child's school performance and self-esteem. Low-dose cranial irradiation may be associated with fewer cognitive sequelae ([Kramer et al., 1992](#)). Other long-term sequelae include sterility in most patients after BMT, with consequent effects on sexual identity and romantic relationships, as well as self-esteem. Sexual dysfunction also is common, such as problems in vaginal lubrication in women and impotence or retarded ejaculation in men ([Andrykowski, 1994](#)). Psychological intervention may address these effects and provide appropriate counseling, which may mitigate and help differentiate between effects that are secondary to treatment/illness and social or psychological factors such as affective illness ([Andrykowski, 1994](#)).

## **Kidney Transplantation**

Adjustment after kidney transplantation seems to be influenced by developmental factors. Preschool children exhibit the most rapid rates of growth and improved social functioning, with adolescents experiencing the greatest degree of social and emotional problems. [Bernstein \(1977\)](#) reported risk-taking behavior, school phobia, and depression in 4 adolescents of the 32 renal transplant recipients he studied. [Korsch \(1973\)](#) examined outcome in pediatric renal transplant recipients and found that most negative effects on family functioning occurred during the first year. A subset of patients (10/35) had maladjustment on personality measures that consisted of problems with anxiety and self-esteem; these patients were at higher risk for nonadherence. Depression was the "most specific test finding." Seventeen of 19 adolescents were working or in college, and 11 of 16 younger patients were in school. Important concerns in this population included steroid-induced side effects and apprehension about rejection.

One study of 19 adolescent renal transplant recipients found that 21% of the patients took less than 80% of their prescribed medication ([Blowey et al., 1997](#)). A review noted that lack of adherence, or noncompliance, has a mean prevalence across studies of approximately 40% in children and adolescents, with one-third of the authors' sample reporting "psychologically meaningful" reasons for noncompliance; the authors recommended that, rather than emphasizing individual patient characteristics when addressing noncompliance, that one should look specifically at the patient's psychological experience of chronic illness ([Wolff et al., 1998](#)). Patient satisfaction, or how the patient's expectations correlate with reality, was suggested to be a major factor in compliance. In this series of adolescents, there was a 69% incidence of medication noncompliance, with 24% of the patients showing improved compliance after the resolution of crises in their lives that were found to be influencing compliance. Lack of adherence usually was found to have multiple causative factors, including the burden of the illness, lack of understanding, and feelings of dependency, not being taken seriously, or being uninfluential; a significant number of patients also tended to blame the health care providers, feeling disappointment, a lack of trust or insufficient time spent with them, a sense of not having been given enough information, or that health care providers had "given up" on the patients, for example. An important concept in this article was the view that the medical requirements of transplantation conflicted with the needs of self-determination—to some degree, inevitably—and that noncompliance often was precipitated by crises in the patients' lives. The approach to dealing with noncompliance should be less judgmental, with a greater attempt to communicate with the patient and to understand the psychological underpinnings for not complying with treatment.

There have been attempts to quantify the relative risk for nonadherence. The score on a psychological scale based on assessments of IQ, schooling, psychomotor development, emotional development, and social development was found to correlate with renal graft survival during the first year after transplantation in one study ([Mongeau et al., 1997](#)).

Several studies have indicated that quality of life improves after renal transplantation in the pediatric population ([Almond et al., 1991](#); [Brownbridge and Fielding, 1991](#); [Cole, 1991](#); [Khan et al., 1971](#); [Krmr et al., 1997](#); [Poznanski et al., 1978](#); [Reynolds et al., 1991](#)). Denial seems operative as a defense against fears of rejection and may lessen as patients enter their third decade. Disturbances in autonomous functioning associated with enforced dependency on adults may lead to social isolation, impaired self-esteem, and depression. In particular, impaired social functioning may put children at risk and may be exacerbated by prolonged school absence ([Khan et al., 1971](#)). The continuation of peer relationships is especially important in adolescents, and specific interventions might focus on the maintenance of "social networks" ([Melzer et al., 1989](#)). One follow-up study of 17 kidney transplant recipients who retained their grafts found that 59% were "completely satisfied" with their lives, with 94% reporting no interference of their health with family life 10 or more years after transplantation in childhood ([Krmr et al., 1997](#)); of note, however, in this

sample, was that 21 of the original 40 children in the sample eventually lost their grafts.

There may be a role for preemptive transplantation before the progression to end-stage renal disease requiring dialysis, to attempt to avoid the metabolic and psychological impact of chronic renal disease (Cole, 1991), and transplantation has been advocated as the preferred treatment in end-stage organ failure (Almond et al., 1991; Brownbridge and Fielding, 1991). Improved physical health after transplantation has been postulated to have a positive effect on psychosocial outcome in the patient and family (Reynolds et al., 1991). Brownbridge and Fielding (1991) found psychosocial adjustment in transplant recipients to be superior to that in patients on hemodialysis or peritoneal dialysis.

However, despite reports of improved physical, emotional, and cognitive functioning, renal transplant recipients continue to experience the problems associated with chronic immunosuppression, impaired growth, anxiety over rejection, and delayed sexual maturation (Reinhart and Kempf, 1988). Cognitive deficits may persist, especially if the onset of disease was at an earlier age, and there was a longer time with end-stage organ failure before transplantation (Sexson and Rubenow, 1992), as is the case with liver failure (see later). Child psychiatry has been described as having a significant role in addressing these issues and in helping to facilitate adjustment.

One study found that there were improvements in mental processing speed and sustained attention in children after renal transplantation when individual children's pretransplantation and posttransplantation performance was compared (Mendley and Zelko, 1999). The authors emphasized the importance of "within-subject comparisons," noting that if they had merely compared groups, there would not have been any positive findings.

Family cohesion was found to correlate with daily living skills in a study of pediatric renal transplant recipients (Davis et al., 1996), suggesting the importance of family support for the functioning of these children. Impaired socialization skills also were correlated with lack of adherence to medication regimens. Eighty-two percent of the transplant recipients in this study exhibited maladaptive behavior (defined by frequency of temper tantrums). However, these patients, although skewed in age toward early adolescence, were found to be compliant with medication and diet much of the time.

### Liver and Intestinal Transplantation

The role of the consultation–liaison psychiatrist in liver transplantation cases has been described by Pinard and Minde (1991), Krener (1987), and Surman (1994). Psychosocial effects have been discussed by Bradford (1991), who noted that competition for organs, maternal overprotectiveness, and enhanced dependency by the child on parents may have a significant impact on the family. Cognitive deficits may persist, although posttransplantation life in general is marked by fewer hospitalizations, shorter lengths of stay, and fewer medications. Outcome has been commented on by Stone et al. (1997), who noted that 93% of transplanted children in a series of 20 patients experienced an acceleration in growth velocity that allowed them to catch up after transplantation. At 5- to 10-year follow-ups posttransplantation, 100% attended school, with 70% not in special education, 80% participating in sports, and 85% in other extracurricular activities. Children's Global Assessment Scale (C-GAS) scores indicated 75% were functioning in the normal range, and Global Assessment of Relational Functioning scale (GARF) scores indicated that 70% of families were functioning normally. The authors note that a comprehensive psychosocial support program throughout all stages of the transplantation experience, along with specific efforts at reintegration (with few restrictions on the children), limiting visits to the transplantation center, and using the lowest possible effective immunosuppressant dosages were important factors in the aforementioned statistics. Windsorova et al. (1991) studied the emotional adaptation of pediatric liver transplant recipients and found that, as a group, they did not display any more behavioral disturbance, anxiety, depression, or effects on self-concept than did a control group of diabetic children. Compared with normative data, however, the liver transplant recipients showed indications of greater anxiety and depression on projective testing. Multidimensional assessments of psychosocial functioning were deemed more sensitive for identifying such phenomena than was parental or patient report.

Others have assessed quality of life in liver transplant recipients (Chin et al., 1991; Windsorova et al., 1991). In Chin's sample (1991), all but one school-age child had returned to school, with quality of life described as good or excellent in all. However, in 7 of 12 children older than 5 years of age, maladaptive behavior was reported, which may have been related to the degree of hepatic encephalopathy that persisted after transplantation. Zamberlan (1992) identified problems in socialization and peer relations, which were associated with feelings of loneliness and vulnerability, in the 20 school-age liver transplant recipients she studied. Psychiatric intervention, especially during the first year posttransplantation, has been recommended (Sexson and Rubenow, 1992; Zamberlan, 1992).

Mastroyannopoulou et al. (1998) addressed the prevailing trend in consultation–liaison to begin to look more at factors predisposing to a greater ability to cope and adapt, rather than risk factors for poor psychological outcome. The use of varied coping strategies is thought to be adaptive and is based on an increased capacity for flexibility and change. Overall, normal children, children with chronic liver disease, and liver transplant recipients used similar coping strategies. It was found that, compared with children with chronic liver disease who had not been transplanted, transplant recipients tended to have a greater sense of control over their illness; in addition, the transplanted group saw themselves as less "ill," and in fact many viewed themselves as "cured." Both of these groups seemed to use wishful thinking and distraction as effective coping strategies, defenses that might be considered more maladaptive in an otherwise healthy population, highlighting the need to appreciate differences in what constitutes adaptive psychological functioning in this population.

The most comprehensive data on neuropsychological outcome in pediatric liver transplant recipients have been published by Stewart et al. (1989, 1991a, 1991b). In one series (Stewart et al., 1989), 15 of 29 children had delays in cognitive or motor function before transplantation that were associated with earlier onset of liver disease. After transplantation, 4 of 11 patients with cognitive delays and 5 of 10 with motor delays had improvements great enough to place them within the normal range at 1-year follow-up. As a group, improvement in cognitive function did not reach significance. Improvement on the Social Scale of the Child Behavior Checklist (Achenbach and Edelbrock, 1983) was found at 1-year follow-up in children who were transplanted at 4 years of age or older. Enhanced functioning was reported with peers, in sports, and in the ability to take on greater home responsibilities. Prednisone exerted robust effects on linear growth, and gains in head circumference were most notable in children younger in chronologic age.

Neuropsychological deficits were found in these patients Stewart et al., (1991a, 1991b). When matched against a control group of patients with cystic fibrosis (Stewart et al., 1991b), the liver transplant recipients had greater impairments in intellectual/academic function, learning and memory, abstraction and concept formation, visual-spatial function, and motor skills. Significantly more liver transplant recipients were receiving special services in school, although less than a third were receiving the services they needed. The greater impairment in functioning in the liver transplant recipients was postulated to be related to the effects of hepatotoxins on the developing brain, although other factors, such as acute illness requiring invasive surgery, were not controlled for. Liver transplantation can potentially prevent the irreversible effects of hyperammonemia on cerebral function in children with arginosuccinic acid synthetase deficiency (citrullinemia), a urea cycle defect (Fletcher et al., 1999).

More recently, the academic functioning of 50 pediatric liver transplant recipients was studied 3 or more years after transplantation (Kennard et al., 1999). This study found that these patients did not make statistically significant gains in intellectual functioning after transplantation, highlighting the effects of illness on mental functioning. In addition, compared with the normal population, academic achievement was lower in this population, although three subgroups were identified: 56% of the children who were performing on standardized academic tests within 1 standard deviation (SD) of their full-scale IQ (FSIQ) scores, and greater than half of this subgroup were performing above expectation, indicating the presence of facilitating factors that would be useful to identify; 26% of children performing greater than 1 SD below their FSIQ scores; and 18% performing in the mentally deficient range. Although 48% of the sample received special education services, only 38% of the children with learning difficulties were recipients of these services, which is quite problematic. The most common difficulties in children who were not intellectually impaired were in the areas of math and written language, which is interesting in light of the visual-spatial difficulties cited in earlier studies. Potential factors that might account for the variability in intellectual function include those related to the underlying disease itself (patients with biliary atresia tended to do more poorly) and the relationship of encephalopathy to the child's developmental status; the severity of pretransplantation illness and duration of posttransplantation immunosuppression; and "facilitative" factors such as motivation and persistence. Several important conclusions by these authors include the need for routine psychoeducational evaluations and the awareness that achievement can be enhanced with special education services.

Ethical factors involving living related liver donation, often from a parent to the child, were reviewed by Singer et al. (1989). Emond (1993) points out that approximately 40% of children in need of a liver transplant might be appropriate for a living related graft, and notes the significant advantage of not being dependent on the cadaver waiting list. UNOS Scientific Registry Data indicate that the number of living liver donors has been increasing since 1989, when 2 were reported, to 1993, when 35 such donors were recorded. Emond (1993) also comments on the ethical issues surrounding living related liver donation. Even though the risk of donor morbidity is relatively low, there have been reported cases of bile duct injury, nerve apraxia, or wound infection. He also noted several cases of donation made by unrelated living donors, which raises additional ethical issues. In an additional case evaluated by this author's consultation–liaison service, a school teacher who knew the recipient intimately agreed to be the donor, although it appeared as if her wish to donate was motivated greatly by issues of guilt in her own life deriving from the loss of her own child. Her investment in the donation as a means of personal psychological reparation seemed to make the consequences of an unsuccessful

outcome potentially devastating for this teacher.

Intestinal transplantation in children was reviewed by [Reyes et al. \(1996\)](#) and cited as having a 70% survival rate, with a 60% survival rate for combined liver–intestinal transplants. The psychosocial effects on parents of liver or intestinal transplantation also has been reviewed ( [Tarbell and Kosmach, 1998](#)), with significant psychological distress in both parents found perioperatively, and with fathers exhibiting greater distress than mothers. Stress appeared to be higher when the transplant recipient was younger or male, or there were fewer people in the household. The study underscores the importance of including fathers in psychosocial assessments.

### Heart Transplantation

Neuropsychological function in cardiac transplant recipients has been reviewed in the adult population ( [Nussbaum and Goldstein, 1992](#)), but few studies exist in the pediatric population. In one series of 54 infants with congenital heart disease who were transplanted at 4 months of age or younger, 80% of these infants survived the first year, and 89% were neurologically normal at 14 months posttransplantation ( [Trimm, 1991](#)). Normal language functioning was found in the 77% old enough to be assessed, and normal audiologic function was found in 90%. The Bayley Scale of Infant Development was administered sequentially, and when their scores were averaged, all but two infants fell within 2 SD of the mean on the Mental Developmental Index, and all but two infants fell within 2 SD of the mean on the Psychomotor Developmental Index.

Like other chronically ill children, adolescents with congenital heart disease that was surgically corrected earlier in childhood may be at higher risk for later behavior and adjustment problems ( [Utens et al., 1993](#)). Studies examining the psychosocial outcome of pediatric cardiac transplantation are limited, but in a multicenter study, [Uzark et al. \(1992\)](#) reported that these children's level of function approaches that of their peers, with 93% attending school and able to participate in athletics. Nevertheless, this sample of 49 children, who averaged 21 months posttransplantation and whose mean age was 10.4 years, showed less social competence and more frequent behavior problems relative to the norm on the Child Behavior Checklist ( [Achenbach and Edelbrock, 1983](#)). Such problems were associated with impaired self-concept and higher anxiety levels, as well as the inclination not to discuss feelings. The authors hypothesized that depression and behavior problems were related to personality and interpersonal factors, such as the adolescent's not feeling accepted by or communicating well with peers. Families experienced relatively high stress levels without a concomitant increase in resources to assist in coping with the stress. Psychosocial assessments, enhancing communication between family members, and cognitive work with adolescents were suggested.

Other authors have looked at psychosocial adaptation in this population ( [DeMaso et al., 1995](#); [Gold et al., 1986](#); [Hanton, 1998](#); [Lawrence and Fricker, 1987](#); [Suszycki, 1988](#); [Uzark and Crowley, 1989](#)) or addressed clinical issues more descriptively ( [Slater, 1994](#)). [Lawrence and Fricker \(1987\)](#) found that quality of life in seven children who had received heart transplants was characterized by a return to normality. [Uzark and Crowley \(1989\)](#) note that pretransplantation stress levels secondary to chronic and sometimes life-threatening illness are superimposed on the transplantation scenario, resulting in powerful effects on family function that relate to doubts about the child's vitality, financial pressure, marital tension, and potential distance from the social milieu. Multidisciplinary intervention from social work, nursing, and mental health workers can be of enormous help. [Hanton \(1998\)](#) commented specifically on the role of nursing care in the transplantation of a preadolescent girl.

[DeMaso et al. \(1995\)](#) found that 78% of pediatric heart transplant recipients who were transplanted between 3 and 20 years of age had improved psychological functioning in the normal range posttransplantation, with pretransplantation and posttransplantation scores correlating. Children with higher pretransplantation and posttransplantation emotional functioning had fewer posttransplantation hospitalizations. From a diagnostic standpoint, Psychological Symptoms Affecting the Medical Condition were diagnosed in 35% of the pretransplantation patients, as opposed to 4% of the posttransplantation patients. Mood disorders secondary to medical status were found in 13% of pretransplantation patients and 0% of posttransplantation patients. As well, after transplantation, children with congenital heart disease adjusted as successfully as children with acquired cardiac illness. Family functioning correlated with the child's pretransplantation and posttransplantation psychological functioning. DeMaso and colleagues underscore the importance of psychological intervention before transplantation, given these findings.

### Heart–Lung and Lung Transplantation

[Warner \(1991\)](#) published data from a series of pediatric patients in end-stage respiratory failure referred for heart–lung transplantation and found that two-thirds died at some point during the referral, evaluation, or surgery process. He emphasized the necessity for careful screening of these patients to avoid putting them through additional trauma that would be associated only with a poor outcome, although for some children heart–lung transplantation represents a desperate but viable final option. Five children of 10 transplanted had returned to school and other age-appropriate activities. Psychosocial morbidity in children awaiting heart or heart–lung transplantation was studied prospectively ( [Serrano-Ikkos et al., 1997](#)). Twenty-five percent of children met criteria for a psychiatric diagnosis, and over 50% exhibited impaired psychosocial functioning, which the author attributes to the effects of chronic illness rather than the specific effects of awaiting transplantation. Interestingly, the well siblings displayed the same amount of emotional or behavioral difficulties as the ill children. Severely ill children had higher depression scores compared with their well siblings. Marital and family difficulties were common, with 57% of families being “moderately” or “poorly” adjusted.

Research on psychosocial or neuropsychiatric outcome in lung or double-lung transplantation is quite sparse. In one series, four of the seven pediatric patients who underwent heart–lung or lung transplantation currently are alive, with all school-age children back at school and doing well emotionally ( [Quitell, personal communication, 1993](#)). Indications for transplantation included decompensation in the context of pseudotruncus type 6, pulmonary hypertension, pulmonary fibrosis, and pulmonary atresia.

---

#### CASE ILLUSTRATION

One of the children who received a single-lung transplant at 16 months of age is currently approximately 18 months postsurgery. He was reportedly delayed neurodevelopmentally before transplantation, but has made significant gains since his surgery. After his birth, he had spent only 2 months at home before being admitted to the hospital, where he spent the next 14 months until he was transferred to another medical center and transplanted.

At that time, the medical staff was concerned about the lack of time that his parents spent with him. It almost seemed as if they had “dropped him off” to have a transplant, and there were large stretches of time that the baby was alone in his hospital room, unlike many of the other children whose parents literally hovered by the child's bedside and never left. The staff became concerned about whether this constituted neglect, but after transplantation, it became apparent that the parents had been completely misjudged because they became model parents, “never skipping a beat,” according to their pediatrician.

In retrospect, on further evaluation, it became apparent that these parents had never had the opportunity to bond with their child because he had been admitted to the hospital in an extremely compromised state so soon after birth. His mother had been completely overwhelmed and had never had the opportunity to “feel like a mother.” With the multitude of nurses who were necessarily caring for her baby, she felt without a role. A follow-up conversation with this family disclosed a beaming father, proud of and loving toward his son, who was reported as “just like any other 3-year old” except for some speech and language problems. [[Slater \(1994\)](#), with permission.]

#### Comment

This case illustrates the importance of impaired maternal/paternal–infant bonding in the case of some severely impaired infant transplant candidates, and the need both to help the parents develop some role in their care, and to use this knowledge in assessing the relationship between caregivers and their child.

---

In summary, available neuropsychiatric and psychosocial follow-up studies in this population indicate that the quality of life usually is improved after transplantation; many of these children, in fact, would not be alive without transplantation. After surgery, many have increased levels of physical activity and school attendance, and cognitive function may be improved in some. Nevertheless, many have persistent cognitive deficits because of the effects of chronic illness and circulating neurotoxins during brain development. Transplantation is another stressor superimposed on a stressed family system, with sequelae for siblings and marital relationships. For the transplant recipient, studies suggest that they are at risk for depression, behavioral problems, and impaired self-esteem, which probably relate to the social problems for which these patients also are at risk. Anxiety symptomatology, including school refusal and posttraumatic symptomatology, also may be more common in this population. For these reasons, neuropsychological testing and early psychiatric evaluation and intervention are recommended.

### PSYCHOPHARMACOLOGIC ASPECTS OF TRANSPLANTATION

Neuropsychiatric side effects of immunosuppressant and antiinfectious agents used in transplantation and aspects of psychopharmacologic intervention in this population were reviewed by [Trzepacz \(1993a, 1993b\)](#) ([Table 97.10](#) and [Table 97.11](#)). Important considerations of drug use in this population include altered pharmacokinetics due to drug interactions and impaired hepatic, renal, or cardiac function. Children have altered pharmacodynamics because of both developmental

Cognitive factors obviously play a powerful role with respect to informed consent earlier in childhood. However, as children mature, an “absence of dissent” can be determined, and the level of “assent,” or “emotional consent,” the nature of the child’s emotional response to what is being asked, can be ascertained ( [Slater, 1994](#)).

Ethical issues surround solid organ or bone marrow donation. Psychologically, all transplant recipients have reactions to the donation process, and specific feelings about the donor have been studied in the adult population ( [Bunzel et al., 1992](#)). From the point of view of the recipient, feelings include guilt, a sense of responsibility, and identification with the donor family.

The wish for contact between donor and recipient is a phenomenon that occurs from both directions. Psychologically, the donor–recipient connection is imbued with tremendous meaning. One adolescent organ recipient felt that “they [the donor’s family] are my family inside. I have their blood running through my veins” ( [Slater, 1994](#)).

The parent of a child who had received a cardiac transplant reflected: “It’s really impossible to put into words the way you feel about what they went through. I mean it’s a true, deep empathy, except you know you didn’t quite cross that line. And you’re grateful you didn’t, but you feel badly enough getting as close to that line as you did. I can’t imagine what it would be like to lose a child, or maybe the problem is that I can, and that’s what’s so frightening, and that’s what’s so hard.” [From [Slater \(1994\)](#), with permission.]

Although the right to privacy is protected, anonymous contact is possible under certain circumstances. Sympathy cards, thank-you notes, and photographs have been sent. Many donor families simply wish to know that the recipient is doing well, and often the recipient is curious about from where the organ came. Nevertheless, the two parties may not share the same wishes for giving or receiving information. For the donor’s family, it may be too painful to be exposed to the child that has lived while theirs has died. For the recipient, it might be too difficult to have contact with the family who donated their child’s organs to allow him to live and is mourning their own child’s death.

As [Rothman \(1992\)](#) notes, one stands in awe of donor families, who in the midst of such tragedy and traumatic loss are able to think of the welfare of another child and family. A mother who donated the organs of her deceased son recounted her feelings:

At first there was a little apprehension, but the apprehension is more than compensated with compassion, and that any of your fears that you do have, which are right to feel, would really be smoothed over tremendously by making your child available in a sense to being a donor; and that it is such a wonderful gift. There is no greater gift of giving life to someone else. And its rewards are not just—in a sense, they will never be monetary—but it’s more precious than gold. And it’s the wisdom to be able to ... you’re not really giving up anything. That’s what love really is about, it’s being able to give. [From [Slater \(1994\)](#), with permission.]

With respect to living-related organ or bone marrow donation, can the decision to donate ever be “voluntary” ( [Lewis, 1974](#); [Lowy and Martin, 1992](#); [Singer et al., 1989](#))? What about situations where two children in the same family require donor kidneys but only one parent is immunologically compatible? Other considerations include the morbidity and risk associated with making the donation, and the effect on family relationships for both the sibling who donates and the siblings who do not ( [Lewis, 1974](#); [Sexson and Rubenow, 1992](#)). The feelings surrounding the death of a child reached dramatic proportions when a parent once pleaded with me to allow her to donate her own heart to her dying daughter.

[Lewis \(1974\)](#) wrote extensively on the case of an identical twin confronting the decision to donate a kidney to her sister, where it appeared that overt refusal was an impossibility. In this situation, the child psychiatrist had to consider the impact of this decision on the relationship between the sisters, the donor’s current state and later development, and the emotional state of the family. All of this was felt difficult to predict ( [Lewis, 1974](#)):

She might have a nagging sense of loss, emptiness, and resentment at losing her kidney; but she might feel a greater sense of loss if she were to lose her sister. She might develop a fantasy of being anatomically united with her sister; on the other hand, she might experience a precipitous increase in individuation if her sister were to become more and more different and eventually die. She might feel a sense of increased self-esteem from giving her kidney, and might feel guilty later if she had not given her kidney.

Both girls initially did well, although persistent somatic anxiety developed in the donor, and somatization symptomatology developed in other family members as well. When [Lewis \(1993\)](#) reported anecdotally on follow-up 14 years later, the twins had drifted apart both geographically and emotionally. The donor twin continued to have a fantasy that because she and her sister were twins, each having one functioning kidney, the donor symbolically still had two kidneys.

Bereavement work is an inevitable consequence for the child and adolescent consultation–liaison psychiatrist in this setting and represents perhaps the most difficult task the clinician could face. Feelings of tremendous loss, sadness, and impotence often are engendered in the psychiatrist, who nevertheless can play an enormously supportive role simply by his or her presence. One family later thanked the child psychiatrist for being at the bedside so their child did not die alone. Involvement with these families is different from the typical work in child psychiatry. I have personally attended funerals and received cards from such families years later.

Last, consideration given to transplanting a child while he or she is still relatively stable and not in dire need of the organ has ethical implications as well. Transplanting a child earlier in the course of what appears to be a disease that will result in end-stage organ failure also may decrease the persistent cognitive deficits presumably caused by circulating neurotoxins, by shortening the time that the child is exposed to them. It also lessens the chances that the child will die waiting for an organ.

## CONCLUDING COMMENT

Transplantation inexorably alters life for the patient and family who endure it. A change in perspective or philosophy inevitably accompanies adjustment to posttransplantation life. Many adolescents describe a change in priorities, such that they are not as troubled by trivial matters and are better able to appreciate life. At the same time, however, these patients and their families often live life day-by-day, with an omnipresent uncertainty lurking in the background. As one adolescent described, “I was worried about what to wear, and now, you know, I’m worried about whether I’m going to live” ( [Slater, 1994](#)).

The role of the child and adolescent psychiatrist in this drama may be as deep as he or she is willing to allow. There exists the opportunity for much collaboration with physician colleagues and a flexibility of roles in the physician–patient relationship that may be unique to this type of work, in which the psychiatrist truly can function as a member of a “family” composed of the transplantation team, patient, and patient’s family. Being around this “family” can be awe-inspiring at times and quite painful at others. In a sense, it is a privilege to be involved with these children and adolescents. More systematic research obviously is needed to help identify risk factors for nonadherence and other secondary psychiatric morbidity, to develop a clearer understanding of psychosocial and neuropsychiatric sequelae, and to help formulate intervention strategies.

“There is a strange heroism and poignancy to their stories, some sense that a miracle has taken place, but also the lament of two childhoods lost in the act of one being saved. Perhaps this is the ultimate paradox of organ transplantation in children” ( [Slater, 1994](#)).

The epidemic of acquired immunodeficiency syndrome (AIDS) represents a major world crisis affecting the health and psychological well being of tens of millions of persons, causing devastation among families, and threatening the social welfare of communities. There is a widening gap between the developed and developing countries of the world. In countries such as the United States, where newer, expensive therapies are available, there have been significant decreases in morbidity and mortality; countries with more limited resources are experiencing horrifying escalations in the spread and effects of the epidemic. This contrast is particularly true for children. In the developed world, where interventions aimed at reducing perinatal transmission are readily affordable, there has been a dramatic decrease in the number of perinatally infected children. In the developing world, where resources are lacking, reduction in perinatal transmission has not yet become a reality. However, throughout the world, the increasing focus is on adolescents and youth, because they are the age cohorts experiencing the highest rate of new infections.

## WORLD VIEW OF THE EPIDEMIC

According to estimates from the Joint United Nations Programme on HIV/AIDS (UNAIDS), by the end of 1999, approximately 34.3 million people were living with human immunodeficiency virus (HIV) infection, of whom 95% were in the developing world. Approximately 5.4 million persons were infected in 1999 alone, and one-tenth of them were less than 15 years of age ([UNAIDS, 2000](#)). Since the epidemic began, 19 million adults and children have already died. In 1998, AIDS rose to become the fourth leading cause of death worldwide, after being ranked seventh just 1 year previously ([UNAIDS, 1999b](#)).

Sub-Saharan Africa continues to dominate the world AIDS epidemic in sheer numbers. Approximately 75% of all new infections in 1999 occurred in the region, with 2.2 million AIDS-related deaths. In the face of this devastation, another 23.4 million adults and 1 million children are expected to die prematurely if they are not provided access to therapy. Southern Africa is particularly hard hit: in most countries, the rates of infection are between 20% and 26% of those aged 15 to 49 years; in Botswana, the infection rate among young adults is as high as 36%. It is predicted that more than one-third of all youth now aged 15 years will eventually die of AIDS in many sub-Saharan countries ([UNAIDS, 2000](#)). Amid such dire statistics, there is promise that some countries may be successfully turning the tide of the epidemic. Most prominent is Uganda, in which a strong national prevention campaign has reduced the rate of infection to slightly more than 8%, from a peak of 14% in the early 1990s.

Although rates of infection are relatively lower in other parts of the world, the numbers remain significant and show a rapid increase in some areas. By the end of 1999, there were approximately 5.6 million infected people in South and Southeast Asia, and approximately one-fifth of these were infected within the last year alone ([UNAIDS, 1999a](#); [UNAIDS, 2000](#)). Spread of the epidemic is affected by changing economics, with people moving from rural to urban areas as economies expand and then moving back to rural areas as unemployment rises. In addition, the growing numbers of young women who engage in prostitution for their livelihood are affecting the increased rate of transmission. In some of the major cities in India, nearly half of the prostitutes are younger than 18 years of age, and more than one-fourth of them have been found to be HIV infected.

The HIV epidemic in Latin America is highly diverse; heterosexual transmission predominates in some countries, particularly those in Central America and on the Caribbean coast, whereas in other countries, such as Mexico, Argentina, and Colombia, injecting drug use and homosexual transmission are significant contributing factors. Rates of infection in some Caribbean islands are the highest of any area outside of sub-Saharan Africa. For example, in Haiti, more than 5% of adults are infected, and in the Bahamas the rate of infection exceeds 4% ([UNAIDS, 2000](#)).

Countries in Eastern Europe and Central Asia have rapidly emerging epidemics that are largely related to injecting drug use ([UNAIDS, 1999c](#)). The number of cases in Eastern Europe increased ninefold in just 3 years, from fewer than 30,000 cases in 1995 to 270,000 cases by the end of 1998. The spread of the epidemic in these countries is related to serious economic failure and concomitant increases in poverty and the disenfranchisement of young people, which lead to higher rates of injecting drug use and greater reliance on prostitution as a means of livelihood ([Dehne et al., 1999](#)).

## Epidemic in the United States

In the United States, 1996 marked a major turning point in the epidemic when the introduction of new therapies slowed the progression of HIV disease and led to a reduction in the number of cases of AIDS and a dramatic decrease in HIV-related deaths. AIDS was the leading cause of death for those aged 25 to 44 years in 1995, but by 1997, it had fallen to the fifth leading cause of death in this age group.

There continue to be other changes in the epidemic as it progresses, and these changes disproportionately affect women and minorities. In 1999, women represented 32% of all those reported with HIV, compared with 7% of those reported with AIDS in the first 5 years of the epidemic (Centers for Disease Control and Prevention, 2000). Blacks and Hispanics have had markedly higher rates of infection than whites. Since 1996, blacks have outnumbered whites in new AIDS diagnoses. Statistics on AIDS fail to portray the true nature of the epidemic; with the advent of more effective therapies that delay or prevent the onset of AIDS, many HIV-positive persons may go unreported because they do not meet criteria for an AIDS diagnosis. As a result, tracking cases of HIV infection is now a more accurate way of monitoring the spread of the epidemic than tracking statistics on AIDS. In particular, because of the delay between the time of infection and the development of AIDS, data on HIV infection provide more pertinent and potentially useful information on the spread of the disease among youth. It is significant that, unlike the declining rates of AIDS, the rate of spread of HIV infection remains fairly constant.

## CHILDREN AND AIDS

Changes in the incidence of AIDS have been even more dramatic among children than among adults. For example, in 1999, only 263 children were reported to the Centers for Disease Control and Prevention with perinatally acquired AIDS, less than one-third of the number of cases reported in 1992 (Centers for Disease Control and Prevention, 2000). Although some of this reduction is the result of therapeutic advances, the greater contribution to this decline is the success of decreasing perinatal transmission from mother to child through treatment of HIV-infected pregnant women with antiretroviral therapy ([Connor et al., 1994](#)). This approach, together with delivery by elective cesarean section, has had a rapid and dramatic effect on decreasing rates of HIV transmission ([European Mode of Delivery Collaboration, 1999](#); [International Perinatal HIV Group, 1999](#)). Before 1994, the rate of transmission of HIV infection from an infected mother to her child was approximately 25%; this rate has now fallen to less than 5% ([Blattner et al., 2000](#)). Estimates from one study suggest that fewer than 250 children were born with HIV infection in the United States in 1997, compared with approximately 1,260 cases of infection just 5 years previously ([Lindgren et al., 2000](#)).

Similar successes have not been seen in poorer countries, where the protocols used for treatment of pregnant women in developed countries are unaffordable. This picture is further complicated by the finding that HIV is also transmitted by breast-feeding, and this results in infection of an additional 10% to 20% of infants ([Dunn et](#)

al., 1992). Substituting infant formula for breast-feeding not only is too expensive in many countries, but also it is associated with an increased risk of morbidity and mortality from other infectious causes (Butz et al., 1984; Kuhn and Stein, 1997). Some studies have demonstrated that shorter, less expensive courses of treatment with antiretroviral medications can be efficacious in decreasing transmission of infection from mother to child ( Dabis et al., 1999; De Cock et al., 2000; Saba et al., 1999; Shaffer et al., 1999; Wiktor et al., 1999). Among these, perhaps the most important is the HIVNET 012 Trial, which demonstrated that just two doses of the antiretroviral medication, nevirapine, one given to the mother at the beginning of labor and one given to the baby after birth, had the effect of almost halving the rate of transmission (Guay et al., 1999).

Whether the countries that have the highest rates of HIV disease can successfully introduce programs to prevent perinatal transmission remains to be seen. Implementation of such interventions requires access to affordable medications and a sound system for providing prenatal and perinatal care, as well as HIV testing and counseling. Even when women agree to be tested, many may not return for the results (Cartoux et al., 1998). Fears of stigmatization and, even worse, fear of abuse or being thrown out of their homes prevent women from being tested or returning for test results. Even when formula feeding is a viable option for an infected woman, she may choose to breast-feed to avoid suspicion that she is HIV infected ( Farquhar et al., 2000).

## Orphans

Although a real opportunity exists to decrease the number of children being infected with HIV, the number of infected adults worldwide continues to increase, resulting in a rapidly escalating number of children orphaned by the epidemic. According to UNAIDS statistics, by the end of 1999, approximately 13.2 million children less than 15 years of age had lost their mothers, or possibly both parents, to AIDS, and one-third of these children were less than 5 years old. More than 95% of these orphans live in sub-Saharan Africa (UNAIDS, 2000). Before AIDS, about 2% of children in developing countries were orphans, but by 1997, this figure had risen to 7% in most African countries and in some cases had reached as high as 11%. Orphaned children are often looked after by family members, frequently aging grandparents, and sometimes adolescent siblings. However, as the infection rate in a community increases, there are fewer working adults, and the result is a decrease in the resources available to care for orphaned children. In the United States, early projections that the number of motherless children and adolescents would exceed 80,000 by the end of the 20th century (Michaels and Levine, 1992) have not been completely borne out because HIV-infected parents are living longer. Nonetheless, many children are living in families seriously affected by the disease.

## Adolescents and Youth

It is now estimated that about half of all new HIV infections worldwide occur in people less than 25 years old ( UNAIDS, 1998; UNAIDS, 2000). The infection rate is increasing more rapidly among youth than it is among older persons. In the United States, even though there is a decline in AIDS incidence, there has not been a comparable decline in the number of newly diagnosed cases of HIV infection among young people ( Centers for Disease Control and Prevention, 1998c; 1999). HIV infection in adolescence tends to be more prevalent among girls than among boys because young women tend to have sex with older men. Among young men with HIV infection, homosexual transmission accounts for the single largest risk group. Evidence indicates that the advent of antiretroviral therapies sparked a resurgence of unsafe sexual practices among gay men, particularly among those less than 25 years of age ( UNAIDS, 2000).

Rates of infection with other sexually transmitted diseases (STDs) continue to be very high among youth and serve as indicators of their elevated risk of HIV infection. Of the 12 million cases of STDs that occur each year in the United States, one-fourth occur among teenagers, and two-thirds are acquired by 25 years of age (Chabon and Futterman, 1999). Drug use among adolescents can also increase the risk of HIV infection, not only through direct infection from injecting drug use, but also through increased risk for unsafe sex when inhibitions are lowered by alcohol or drugs. There is some evidence, however, that young people may be more likely to adopt safer sex practices than older persons. Studies carried out in Chile and Brazil show that compared with older adults, more young people use condoms, and in the United States, the proportion of high school students reporting either abstinence or the use of condoms has increased ( Centers for Disease Control and Prevention, 1998b).

## Clinical Manifestations of HIV in Children

Because of newer therapies, the prognosis of HIV-infected children is significantly improved compared with just a few years ago and can no longer be predicted with any certainty. Early studies documented that, unlike adults, children become symptomatic very quickly. For example, one study found that approximately 70% of infected children were symptomatic by 1 year of age (European Collaborative Study, 1991; Forsyth et al., 1996; Scott et al., 1989). The presentation of illness tends to be bimodal; some children become seriously ill in infancy (referred to as *rapid progressors*), whereas others remain relatively healthy for a prolonged period (referred to as *slow progressors*) (Blanche et al., 1990; Commenges et al., 1992).

In general, the clinical characteristics of HIV disease in children are similar to those in adults, although there are several important differences. Regarding opportunistic infections, the most significant difference relates to the timing of infection with *Pneumocystis carinii* pneumonia (PCP). Unlike in adults, in whom PCP generally occurs late in the course of disease, HIV-infected children tend to present with PCP very early (median age, 5 months). PCP used to be the leading cause of death in HIV-infected children; however, with present-day management, PCP is now less prevalent, and mortality from PCP has decreased significantly. Of the other opportunistic infections, *Mycobacterium avium* complex disease is the most prevalent among children. This usually presents as a generalized illness, often with fever, night sweats, weight loss, and diarrhea.

HIV-infected children also have a higher incidence of serious bacterial infections, such as sepsis, pneumonia, and meningitis. *Lymphoid interstitial pneumonia*, a condition affecting children, occurs only rarely in adults. This chronic interstitial lung disease usually presents in the second or third year of life and is reported to result from the coexistence of infection with Epstein-Barr virus and HIV. The course is often relapsing, but acute exacerbations generally respond well to therapy with steroids. Other manifestations of HIV disease are extremely varied and can affect all organ systems ( Forsyth, 1995). These include the lymphoreticular system, hematologic abnormalities, gastrointestinal and hepatobiliary disease, cardiomyopathies, and renal disease. The malignant diseases most frequently associated with HIV disease in children are lymphomas; Kaposi's sarcoma occurs only rarely. Growth stunting is one of the central effects of HIV disease ( Center for Disease Control and Prevention, 1999; McKinney et al., 1993); the result is that many infected children approaching adolescence are delayed in their physical development and are smaller than their peers, and they struggle to adapt to their unusual appearance and their physical immaturity. It is expected that, with improvement in disease management, growth problems will become less prevalent.

## Central Nervous System Disease

Early studies of central nervous system (CNS) manifestations of HIV disease suggested that between 40% and 90% of infected children had some degree of neurologic involvement (Belman, 1988; Epstein, 1986). These studies, however, were conducted in cohorts of children with more advanced disease. Later prospective studies documented rates of serious neurologic signs of 8% to 13% in HIV-infected children and of 19% to 31% in children diagnosed with AIDS ( Blanche et al., 1989; European Collaborative Group, 1990; Lobato et al., 1995; Msellati et al. 1993). The occurrence of CNS disease tends to parallel the bimodal progression described previously; children who develop severe disease and have opportunistic infections in infancy are those who are most likely to develop severe encephalopathy, whereas those who are *slow progressors* tend to be relatively spared and present with milder forms of CNS disease. Now that HIV-infected children are growing into their teenage years, there is likely a trimodal progression of disease. Some children, who were spared symptomatic disease earlier in life, may later develop CNS disease that is more comparable to HIV disease in adults ( Belman, 1992).

### EARLY-ONSET ENCEPHALOPATHY

Three-fourths of children with encephalopathy are diagnosed before the age of 36 months ( Lobato et al., 1995). Clinical manifestations include a decrease in head growth, loss of developmental milestones or failure to achieve new milestones, and progressive development of CNS signs. These signs include weakness and flaccidity, which, in time, progress to spastic paraparesis or quadriplegia, possibly with pseudobulbar palsy. Disorders of movement such as dystonic posturing or extrapyramidal tremors are less frequent, as are cerebellar signs ( Belman, 1992). There is often a characteristic facial expression marked by a paucity of facial movements, despite the child's appearing alert and wide eyed. The progression of disease is often rapid, occurring over 1 to 2 months, or it may fluctuate with periods of relative stability. If death does not occur from another cause, there is generally a decreasing responsiveness to the environment, and, in the end, the child is mute and quadriplegic.

Another group of infected children includes those who have more static encephalopathy. They do not lose milestones, but as they grow older, deficits in development become more evident, and new skills are acquired at a slower rate than normal. There can be abnormalities in either motor or cognitive development, or both. Some

children may show improvement over time, whereas others have little change.

#### LATE-ONSET ENCEPHALOPATHY

The risk of developing HIV-related signs of CNS disease later in childhood has not been adequately assessed. Early signs of CNS disease in older children include a decline in academic performance, emotional lability, problems with attention or worsening of attention deficit hyperactivity disorder, and possibly conduct disorders, although these same symptoms may represent manifestations of multiple causes unrelated to HIV (Belman, 1992). Cognitive deficits are more frequent than motor deficits, and impairments may become evident on tests involving quantitative, verbal, memory, visual-spatial, and time-orientation abilities (Exhenry and Nadal, 1996). Within the realm of language, expressive skills are more likely to be impaired than receptive skills (Wolters et al., 1995).

#### OTHER CENTRAL NERVOUS SYSTEM DISORDERS IN HIV DISEASE

Other manifestations of CNS disease in HIV-infected children include neoplasms, opportunistic infections, and strokes. Primary brain lymphoma or lymphoma arising elsewhere and metastasizing to the brain may occur at all ages. Presenting signs may include seizures, changes in behavior, or the appearance of focal deficits.

HIV-infected children are at increased risk of CNS infection with the usual childhood pathogens that cause bacterial meningitis. The most frequent opportunistic infections affecting the CNS in children are cytomegaloviral encephalitis, *Candida albicans* meningitis, and infection with *Mycobacterium avium-intracellulare* (Belman, 1992). Opportunistic infections of the CNS with *Cryptococcus*, *Toxoplasma gondii*, and cytomegalovirus occur less frequently in children than they do in HIV-infected adults, likely because in adults these infections are most often a reactivation of latent infection, which is not true for children. Congenitally acquired toxoplasmosis and cytomegaloviral infection have been described, but only rarely. Progressive multifocal leukoencephalopathy, a progressive demyelinating disease of the brain caused by the JC virus, which has been reported in adults with HIV disease, is now being reported in children and may occur more commonly as the population of HIV-infected children ages (Vandersteenhoven et al. 1992).

Children with HIV disease have an increased incidence of strokes which include both hemorrhagic and nonhemorrhagic causes. Hemorrhage is usually associated with immune-mediated thrombocytopenia, whereas nonhemorrhagic causes include abnormalities of cerebral blood vessels, meningeal infections, and cardiomyopathy (Belman, 1992; Park et al., 1988).

#### EVALUATION OF CENTRAL NERVOUS SYSTEM ABNORMALITIES IN HIV-INFECTED CHILDREN

An extensive history focusing on developmental milestones and a detailed neurologic examination are most important in alerting the clinician to the possibility of progressive encephalopathy. A full neurodevelopmental assessment is warranted when there is any suggestion of developmental abnormalities or sign of neurologic disease. Neuropsychological testing can be useful in establishing an initial baseline, monitoring subsequent alterations in cognitive processing secondary to CNS involvement, and devising appropriate rehabilitative interventions.

In general, results of cerebrospinal fluid studies are normal in HIV encephalopathy, although there may be slightly elevated protein and a mild, predominantly lymphocytic pleocytosis. Abnormalities associated with HIV encephalopathy are nonspecific and include enlargement of the ventricles, cortical atrophy, attenuation of periventricular white matter, and cerebral calcifications (Exhenry and Nadal, 1996). The calcifications, when they occur, are usually symmetrical and are located in the basal ganglia and periventricular frontal white matter, or occasionally in the cerebellar regions. Computed tomography scanning is most helpful in demonstrating cerebral calcifications, whereas magnetic resonance imaging is better at detecting the abnormalities in white matter. Abnormalities can be seen on neuroimaging studies, even in the absence of other signs of encephalopathy; however, repeated assessments are usually helpful in assessing progression of disease in an individual patient.

#### Treatment of HIV Infection

In the mid 1990s, because of a greater understanding of the pathophysiology of HIV disease and the advent of protease inhibitors, a class of antiretroviral medications, there were changes in the approach to treatment of HIV disease and a dramatic improvement in associated mortality and morbidity. Formerly, the approach had been to reserve the use of antiretroviral medications for patients who already had fairly advanced disease, as evidenced by a decline in CD4 cells or the development of symptoms of their disease. However, once it was understood that the period that preceded clinical signs of disease was not a period of latency, but, in fact, a period characterized by continuous replication of the virus and destruction of the immune system, newer recommendations for treatment were developed (Perelson et al., 1996; Saag et al., 1996). It is now recommended that the level of viral replication be used to inform decisions regarding treatment, such as when best to start treatment and when to change pharmacologic agents because a therapeutic regimen is not sufficiently effective. The extent of viral replication, commonly referred to as the *viral load*, is quantified by measuring the HIV ribonucleic acid (RNA) by polymerase chain reaction amplification.

The present treatment approach, referred to as *HAART* (highly active antiretroviral therapy), includes starting treatment early and achieving maximal suppression of viral replication using a combination of at least three different antiretroviral medications. Unfortunately, there is a potential for the virus to develop resistance to antiretroviral medications, particularly if someone has already been treated with a single medication before starting triple therapy. In such cases, once there is a rebound in the viral load, the virus is likely to be resistant to all three medications, and all three will need to be changed. In addition, within the different classes of medications is a tendency for cross-resistance to develop: if the virus is resistant to one medication in a class, it may also be resistant to others within the same class. Thus, even in this era of multiple medications from which to choose, the choices become limited once viral resistance has developed. Despite this limitation, some evidence indicates that although patients may have a rebound in viral load measurements on triple therapy, they continue to do better and have a slower progression of disease than would otherwise be expected (Kaufmann et al., 1998). As with other manifestations of HIV disease in children, advances in management are almost certainly having an effect on decreasing the prevalence and severity of CNS disease among children. Such a decrease in CNS manifestations of HIV disease has been well documented in adults, but it awaits further study in children (Mascke et al., 2000).

#### ADVERSE EFFECTS OF MEDICATIONS

All the antiretroviral medications have adverse effects, some of which may be potentiated by the use of other medications, including psychotropic medications. The finding that antiretroviral medications, particularly the protease inhibitors, can cause significant derangements in metabolic processes resulting in abnormal lipid profiles and glucose levels, and alterations in body composition are among the most important adverse effects (Carr et al., 1999). This latter, referred to as the *lipodystrophy syndrome*, may be very distressing to patients because of the changes in physical appearance. There is wasting and disappearance of fat from the face and limbs but an increase in fat in the abdominal region and over the lower part of posterior neck, referred to as a *buffalo hump*.

#### ADHERENCE TO MEDICATIONS

A major challenge posed by the advances in therapy of HIV disease has been the need to ensure that patients are able to take their medicines. Treatment regimens often call for a large number of medications, taken at regular intervals each day. Some of the medications are available only as large capsules that are difficult to swallow; others have a particularly bad taste. Meanwhile, studies have shown that missing doses of medications can lead to the faster development of viral resistance. One study reported a linear association between self-reported adherence and level of HIV viral suppression. Patients taking fewer than 80% of their prescribed doses of antiretroviral medications had a significant increase in viral load measurements compared with those who took more of their medications (Haubrich et al., 1999).

#### Development, Psychopathology, and Pediatric HIV

Intervention for children infected with or affected by HIV disease requires a comprehensive approach in which medical interventions are delivered with attention to the complex psychological and social needs of these children and their families and are provided within a developmental frame of reference. As with their overall cognitive development and capacity for logical reasoning, children's understanding of HIV and AIDS follows a predictable sequence. Preschool and early school-age children explain AIDS in terms of contiguous events. At this age, children may recognize that symptoms are the result of an underlying illness, but they are likely unable to explain the cause of HIV as a virus that is contracted in specific ways. With development, the causation of AIDS can be described as a sequential process related to internal sources, including sexual behavior, blood exposure, or external sources such as drug use. Typically, these explanations may provide later school-age children with a factually accurate account of how HIV and AIDS may be contracted; yet the explanation remains based on a series of events culminating in illness. The final stage of understanding is based on the expanded capacity for abstract reasoning that accompanies adolescence. Youth become able to describe the origins of

HIV and AIDS in terms of its underlying disease origin ([Walsh and Bibace, 1991](#)). Findings of an expectable developmental progression in children's understanding of HIV and AIDS should inform pediatric prevention and intervention efforts, because they highlight the importance of practices that are tailored to children's psychological, emotional, and cognitive capacities.

### *INFANTS AND TODDLERS*

Theorists from a variety of perspectives agree that development undergoes its most intensive period within the first few years of life and in the context of the child's relationship with a primary caregiver. The quality of attachment between infant and caregiver sets the stage for later development and influences how children progress in terms of their sense of self, their capacity for relationships with others, and their emotional resilience.

Preoccupation with the medical and psychological demands of coping with HIV disease may deplete families of the energy and psychological resources available to attend to normative aspects of early childhood development. For example, parents of an HIV-infected infant may be overcome with anxiety and remorse at having transmitted the virus to their child, and they may, in turn, become less responsive to the infant's cues related to basic needs involving nurturance, warmth, or sustenance. Although most caregivers remain able to provide for their infant's basic needs, for others, HIV may interfere with the establishment of a predictable and reciprocal pattern of interaction between caregiver and their infected or affected babies, and the result may be episodic and irregular dyadic engagement.

Infancy is a time of intimate contact between child and caregiver. Bodily fluids are routinely exchanged, although HIV-positive mothers may be advised to forego the intimacy of breast feeding, a problematic issue in developing nations, where a mother's breast milk represents a needed source of nutrition that cannot be easily replaced with costly formula that is difficult to procure. The expectable acts of defiance and desires for separation that mark toddlerhood may heighten unconscious fears of loss and permanent separation for affected children. The anger and defiance of the toddler represent developmentally appropriate and necessary assertions of autonomy and distinctness from a parent or primary caregiver ([Mayes and Cohen, 1993](#)). Infected, symptomatic young children require an enhanced degree of caretaking and protection that may constrict the expression of their normal drives toward the external world.

### *EARLY CHILDHOOD AND PRESCHOOL YEARS*

Arguably the most important developmental accomplishment of the young child involves the capacity for imaginative or pretense play ([Marans and Cohen, 1996](#)), which forms the leading edge of symbolic development and predates the use of complex language to mediate between internal states and action. At this age, play, which is intimately connected to language and cognitive development, represents a primary means for integrating internal thoughts and feelings with external experiences. The play of a child affected by HIV may involve repeated scenarios related to illness or loss, even though the same child may never be able to verbalize these concerns. Although children may gradually be able to understand basic facts about HIV illness and death, their ideas will likely remain concrete and specific to their life experiences. Metaphors about death may engender greater confusion, because young children are unable to abstract the basic concept that death represents a final cessation of life. For these reasons, the therapeutic use of play represents a significant means of assisting young children to cope with the feelings of guilt, loss, and abandonment that they cannot express.

Relationships with parents become intensified by a youngster's heightened feelings of power and pleasure in bodily sensations. When HIV becomes involved at this stage of development, emotional conflicts involving the simultaneous experience of holding both loving and rivalrous or aggressive feelings that may become especially threatening and upsetting. Parents with HIV or AIDS may be too psychologically and physically fragile for a child to express these concerns freely. The egocentric orientation of this stage may potentiate feelings of guilt and responsibility, because children may assume that their actions play a causal role in a parent's illness. Emotions may be undifferentiated, and the ability to recognize the possibility of holding varied and perhaps conflicting feelings contemporaneously will be compromised. When efforts to emulate the parent or caregiver are usually internalized as values and standards for personal behavior that are extended into a broader social world, strivings for independence based on these parental identifications may be unbearable for a child struggling with the implications of familial HIV. Independence and engagement with peers and a broader social world may be experienced as a rejection of the already fragile caregiver, and some children may find themselves unable to negotiate this expectable developmental step.

### *MIDDLE CHILDHOOD AND SCHOOL-AGE CHILDREN*

[Erikson \(1968\)](#) describes the stage of "industry versus inferiority" at which time children's sense of self becomes tied to their accomplishments involving school, peer groups, and age-appropriate activities. To develop a sense of "industry," children must negotiate earlier developmental tasks involving the development of a distinct sense of self that is connected to, yet relatively less dependent on, their primary caregivers. Children who have been unable to resolve conflicting feelings concerning medically compromised parents may remain tied to their caregivers in a manner that precludes their developmentally appropriate ventures into the world of peers and school. Although far from the physical and psychological maturity of adolescence and adulthood with its expectations of caring for oneself and others, the school-age child, one hopes, becomes an "agent" of his or her own actions. However, HIV-affected child may be unable to take a stance that carries an implicit rejection of a parent who may be ill.

Entry into elementary school, with its expectations for applied problem solving and learning, coincides with the child's enhanced capacity for problem solving and logical thought. Mastery of basic logical principles allows a child to infer cause-and-effect relationships, to devise alternate solutions to problems, and to comprehend reciprocal relationships. These advances may be invaluable as children attempt to understand their own illness or that of their parent. Language serves a regulatory as well as a communicative function; a child who can put words to his or her feelings is able to refrain from acting on those feelings and acquires greater mastery over his or her experiences. Unresolved anxiety about separation from a parent or caregiver who is ill not only may compromise these capacities but also may interfere with the development of relationships with peers and teachers. Preoccupation with illness may interfere with problem solving, learning, and academic performance.

### *ADOLESCENCE*

HIV infection has become an increasing problem among adolescents, particularly those who engage in high levels of risk-taking behaviors. In the 1 year from July 1995 to July 1996, more than 2,600 new cases of AIDS were reported among 13 to 24 year olds ([Centers for Disease Control and Prevention, 1999](#)). Because existing prevention and intervention programs have resulted in significant decrements in prenatal and perinatal HIV infection, many of these new cases may involve persons who contracted HIV during adolescence. As in the general population, HIV infection among adolescents is expected to affect young women and youth of African-American and Latino descent disproportionately ([Anderson and Morris, 1993](#)).

Many adolescents experiment with new behaviors in an attempt to fashion a separate identity and to establish their own autonomy from their families. Among affected youth for whom childhood has not been a normative process, the tasks of adolescence are still more challenging. These adolescents appear at greater risk of poor health outcomes as well as maladaptive behaviors leading to truancy, high-risk sexual behavior, criminal activity, substance abuse, and psychiatric disturbances ([Brown et al., 1997](#)). This cohort of adolescents rarely seeks needed medical treatment, thus increasing their own risk of contracting both STDs and HIV. Moreover, youth who are truant or who withdraw from school prematurely miss receiving information promoting healthy behaviors and preventing STDs ([Slonim-Nevo et al., 1995](#)). Adolescents within the criminal justice system, who present with high reported rates of infectious diseases, including HIV infection and AIDS, and limited histories of primary prevention and health care are thought to be among those at highest risk ([Hammett et al., 1998](#)).

For youth who are either infected with or affected by HIV or AIDS, the "second individuation process" ([Blos, 1962](#)) of adolescence may go awry as a result of chronic concerns about isolation, illness, and death. Although most adolescents strive to loosen the ties of childhood dependency by substituting intimate and romantic relationships with peers ([Freud, 1965](#)), those who must contend with personal or familial HIV may be unable to engage in these behaviors in the service of adolescent individuation and the formation of an independent sense of self. For these youth, the expectable rule transgressions and rebellions against parental strictures also become fraught with danger, real and imagined, about the potential consequences of their emerging sexuality and the strength of their angry, hostile, or defiant feelings.

As adolescents contend with their desire for adult sexuality and relationships, they now do so in the context of the potential for HIV infection. Peers have been found to exert a strong influence on adolescents' attitudes toward the practice of safer sex, and peer attitudes that favor or discourage condom use are strong predictors of their actual use ([Brown et al., 1997](#)). Adolescents, out of their own discomfort, may be unlikely to approach parents with these concerns, especially if these relationships are already marked by conflict, dispute, or unexpressed concerns about HIV disease. Although avoidance of topics related to HIV may reduce immediate feelings of discomfort and may prolong a wish to protect teenagers through an extended and protected childhood, adolescents continue to engage in and experiment with sexual activity at ever younger ages. Initial sexual encounters among teens are rarely planned, and this spontaneity decreases the likelihood of their using birth control or engaging in sexual practices aimed at reducing the chances of HIV transmission. Normative sexual exploration with same-sex and opposite-sex peers and

questions about gender orientation may also heighten the risk of HIV, as well as other STDs, and may limit an adolescent's attention to issues of risk amelioration ([Brown et al., 1997](#); [Hein et al., 1995](#)).

### **Psychopathology and HIV Disease**

Adolescents diagnosed with psychiatric disorders may engage in a range of behaviors that potentiates their risk of contracting HIV ([Brown et al., 1997](#)). Compared with nonpsychiatrically disordered peers adolescents with comorbid psychiatric disorders engage in more frequent substance abuse, including injecting drug abuse, unprotected sexual intercourse, and sexual activity with partners of unknown risk history. They also contract STDs with greater frequency than nonpsychiatrically impaired youth. [Brown and colleagues \(1997\)](#) note the lack of prevalence estimates for HIV infection among adolescents with psychiatric disorders but suggest seroprevalence rates in excess of the 0.2% to 2.2% rates among adolescents of indeterminate psychiatric status. This has been the case for psychiatrically compromised adults, in whom prevalence rates have ranged from 5.5% to 14%, a finding suggesting that psychiatric symptoms increase the likelihood of engaging in activities that pose particular risks for HIV infection.

Whether they arise from separate causes or result from the associated stress of HIV infection, comorbid psychiatric disorders further compromise the functioning and quality of life for youth infected with HIV ([Sherbourne et al., 2000](#)). Sherbourne and her colleagues conducted a psychiatric screening in a large national probability sample of 2,864 adults with HIV infection and found elevated 12-month incidence rates of major depression (36%), dysthymic disorder (26%), generalized anxiety disorder (16%), substance dependence (12%), and panic disorder (11%). Those with comorbid mood and anxiety disorders reported a poorer quality of life in terms of psychological functioning and medical status than HIV infected persons without evidence of a psychiatric disorder, a finding that warrants verification in youth samples.

Among HIV-positive adults, depression has been consistently associated with continued practice of unprotected sexual intercourse. HIV-positive adults who engage in high-risk sexual behavior appear more pessimistic and hopeless about their future and possess fewer strategies for coping with stress. As a result, they appear less likely to disclose their serostatus to potential sex partners or to initiate discussion of safer sex practices. Both negative affect and positive affect have been associated with unsafe sexual practices among HIV-positive adults, a finding suggesting to some investigators that high-risk sexual practices may represent an attempt to modulate affective experiences. From this perspective, positive moods may be associated with the decision to engage in unprotected sexual activity, perhaps fueled by denial and a wish to minimize awareness of personal HIV status. Subsequent negative moods then increase the likelihood that sexual activity may be used to ameliorate affective distress.

Studies have also shown that adolescents diagnosed with conduct disorder or a depressive disorder engage in higher rates of substance abuse, including intravenous drug abuse, and unprotected sexual activity, including prostitution ([Stiffman et al., 1992](#)). Efforts at primary prevention among depressed adolescents who may have acquired knowledge of HIV transmission may be confounded by their compromised sense of self-worth. Their pessimistic outlook may interfere with their ability to apply the information they have received to their behaviors ([Brown et al., 1997](#)). High-risk sexual behavior or drug abuse may also be symptomatic of a depressive disorder, in which the behavior represents a self-destructive act or an attempt to escape from an intolerable affective disturbance, a finding that has received empirical support among adult samples ([Brown et al., 1997](#)). Disorders associated with impulsivity or sexual preoccupation, such as bipolar disorder, borderline personality disorder, or impulse control disorders, may also interfere with the use of safer sexual practices ([Kalichman, 2000](#); [Sherbourne et al., 2000](#)).

Children with attention deficit hyperactivity disorder or conduct disorder are more likely to engage in impulsive actions that increase their risk of HIV infection ([Booth and Zhang, 1997](#)). Adolescents with conduct disorder abuse substances at higher levels, engage in sexual activity with a greater number of partners, and more frequently contract STDs relative to nondisordered youth. Even among runaway and homeless adolescents, who are much more likely than most adolescents to engage in high-risk sexual activity and injecting drug use, those with a comorbid diagnosis of conduct disorder are still more likely to have engaged in an exchange of sexual activity in return for money or drugs and to have unprotected sex with multiple partners. A diagnosis of conduct disorder increases the likelihood of injecting drug use by more than a 2:1 margin (odds ratio, 2.28) and the likelihood of exchanging sex for drugs or money by almost a 3:1 margin (odds ratio, 2.82). Adolescents who know someone infected with HIV are also at greater risk of drug injection (odds ratio, 1.40) or sexual exchange (odds ratio, 1.29) ([Brown et al., 1997](#)).

In addition to coping with the normative press of adolescent sexuality and identity formation, adolescents with cognitive deficits may also be at heightened risk of contracting HIV. Youth with mental retardation or borderline intellectual functioning may lack important skills related to judgment and logical decision making that would allow them to conduct accurate appraisals of the risks associated with a range of behaviors, including those related to sexual activity and substance use. They may lack accurate information about prevention and routes of HIV transmission, which may lead to erroneous conclusions about HIV. Their judgments may mirror those of younger children, who may overgeneralize their risk to common situations such as physical touching and sharing utensils ([Brown et al., 1997](#)).

### **SEXUAL ABUSE AND HIV TRANSMISSION**

Although HIV infection has been found to be a sequela of sexual abuse, the extent to which this has occurred is difficult to quantify. For example, a study of 9,136 cases of HIV infection reported to the Centers for Disease Control and Prevention through 1996 identified only 26 cases attributed to sexual abuse ([Lindgren et al., 1998](#)). In contrast, 14 (14.6%) of 96 children diagnosed with HIV infection at a single institution were confirmed to have been sexually abused ([Gutman et al., 1991](#)). Factors that put children at greater risk of HIV disease, such as substance abuse, social and economic marginalization, and dysfunctional lifestyle, are the same factors that put them at greater risk of sexual abuse. Some evidence indicates that the experience of sexual abuse in childhood may result in increased sexual risk taking and drug use in adolescence and adulthood, thus increasing a person's lifetime risk of HIV infection ([Allers et al., 1993](#); [Gellert et al., 1993](#); [Johnsen and Herlow, 1996](#); [Mullings et al., 2000](#)).

There are certain barriers to HIV testing of children who are being evaluated for sexual abuse, and recommendations vary from testing all children undergoing evaluation to testing only those for whom information suggests an increased risk of exposure to HIV ([Gellert and Berkowitz, 1994](#); [Gutman et al., 1993](#)). Risk of transmission of HIV should be a particular consideration if a child is evaluated immediately after an incident of sexual abuse, because of the possibility of providing prophylactic antiretroviral medications to prevent transmission. Such postexposure prophylaxis has been shown to be beneficial in needlesticks and other types of occupational accidents ([Henderson, 1999](#)), and it is now being used with persons who have been raped or have put themselves at risk of sexual transmission ([Centers for Disease Control and Prevention, 1998a](#)).

### **EFFECTS OF HIV/AIDS ON FAMILY FUNCTIONING**

HIV affects families across generations, as children, parents, and grandparents confront illness and premature loss of loved ones. HIV-infected children must contend not only with multiple losses and relationship disruptions resulting from the illness of their parents, but also with effects of their own illness that may remove them from normative childhood activities and may destabilize their world. Families with HIV-infected children tend to be socially isolated, with fewer available supportive relationships at times of crisis or acute illness. Uninfected siblings, grandparents, and other family members must cope with uncertainty, guilt, and the fear of anticipated and premature loss, as well as the social and psychological burden of caring for chronically or terminally ill relatives ([Mellins and Ehrhardt, 1994](#)). Family structures are often disrupted by parental illness, and children may be forced to change caregivers frequently as they move within or beyond their family networks.

### **CHILDREN AFFECTED BY HIV AND AIDS**

The numbers of children affected by parents or caregivers with HIV disease will continue to rise, with substantial rates of HIV infection among young, minority women, 50% of whom are estimated to bear children ([Family Health Project Research Group, 1998](#); [Pilowsky et al., 2000](#)). Unfortunately, family members as well as professionals may fail to recognize the unique concerns and obstacles that threaten the development of these children. As witnesses to repeated periods of acute, incapacitating parental illness, these children anticipate the death of one or both parents and worry about who will take care of them when their parents are no longer available. They may be left to contend with feelings of sorrow, anger, guilt, and confusion in isolation as other family members turn their attention to the infected adult or struggle with their own histories of loss ([Gewirtz and Gossart-Walker, 2000](#); [Ickovics et al., 1998](#)). Children in HIV-affected families face additional burdens related to parental incarceration, family and residential instability, exposure to violence, caregiver substance abuse, and social isolation ([Gewirtz and Gossart-Walker, 2000](#); [Maman et al., 2000](#); [Nagler et al., 1995](#)). Family and caregiver relationships, including those with fathers, may be unstable, marked by erratic and unpredictable contact ([Wright and Draimin, 2000](#)).

In an effort to redress the paucity of data on the functioning of HIV-affected children, Forehand and his colleagues developed a multidisciplinary, longitudinal study of HIV-infected mothers and their affected, HIV-negative children ([Family Health Project Research Group, 1998](#)). Researchers followed an urban sample of 107 6- to 11-year-old HIV-affected African-American children and a matched comparison group of 150 mothers and children from the same locale. After controlling for the

severity of AIDS symptoms, 3-year results indicate higher levels of internalizing and externalizing psychiatric symptoms among the HIV-infected mothers and their affected children, as well as greater impairments in children's social competence.

The unpredictable nature of HIV disease, marked by multiple episodes of relapse and recovery and a chronic course of illness, limits parents' ability to provide consistent and stable care and perpetuates a sense of anxiety and dread among their children ( [Gossart-Walker and Moss, 1998](#)) ( [Rotheram-Borus et al., 1998](#)). Ironically, many parents may neglect their own health as they focus on the pressing needs of their children, and children's longer-term needs for permanency and security may be sacrificed by their parent's unwitting neglect of their own important health issues ( [Wiener et al., 1994](#)).

Children who confront HIV disease in a parent or caregiver are often unable to express their expectable feelings of anger and guilt because of an unrecognized fear that they may become overwhelmed by their distress or may hasten the death of their loved one ( [Gossart-Walker and Moss, 1998](#)). Many HIV-affected children contend with a sense of foreboding about their future and that of their caregivers that can neither be expressed nor anticipated. Adolescents affected by parental HIV infection and AIDS are particularly vulnerable. As [Zayas and Romano \(1994\)](#) noted, "Perhaps no group of children in modern time has been more battered by the combination of social and familial decay and a devastating illness, coupled with the normal storms of adolescence." Adolescents residing with a parent diagnosed with AIDS consistently report high levels of parent-child conflict, academic failure, peer relationship problems, and criminal behavior, with estimates that 25% to 73% of HIV-affected adolescents present with clinically significant difficulties ( [Rotheram-Borus et al., 1998](#)).

#### STIGMA AND SECRECY

The psychological disability secondary to the guilt, shame, and anxiety of living with a family member whose illness may not be discussed or even revealed represents a notable challenge to the development of HIV-affected youth ( [Nagler et al., 1995](#)). The secrecy and stigma surrounding an HIV diagnosis, as well as its uncertain course, compromise a developmental trajectory already affected by inconsistent caregiving and the specter of loss and abandonment. Psychological forces of denial and shame conspire to leave parents and children isolated and overwhelmed. Although children know of the parent's illness, they may not be provided with opportunities for identifying the illness and discussing its ramifications, processes that allow them to organize their ideas, fears, and feelings ( [Nagler et al., 1995](#)). Should death occur in the absence of disclosure about the illness, children may be unable to metabolize their complex reactions and may be left to struggle with their poorly understood and painful memories and feelings. Ironically, even though many parents are reluctant to inform their children of their HIV infection, some adolescents become caregivers to sick parents and younger siblings without ever being able to name the illness that has debilitated them.

Societal ramifications in the form of stigma and shame combine to marginalize affected families further and to reinforce their need for secrecy. Families must manage a chronic, incurable disease in the context of a society that adopts a punitive stance toward the behaviors that result in HIV infection ( [Nagler et al., 1995](#)). In the presence of this social disapprobation, many parents elect to keep their diagnosis secret from family, friends, and society as a whole. Self-imposed secrecy and reactions to social stigma may preclude families from procuring necessary treatment, seeking assistance with permanency planning for affected children, and obtaining needed forms of social support ( [Gewirtz and Gossart-Walker, 2000](#)). Although children's development may go awry in the face of the inexorable stressors associated with the illness, these psychiatric complications cannot be addressed adequately when they represent manifestations of unacknowledged HIV infection or AIDS.

#### LOSS AND BEREAVEMENT

Children, whether infected or affected by HIV, anticipate and experience bereavement on a continual basis. As with other types of trauma, the adjustment of children who lose one or both parents to HIV infection or AIDS remains heavily influenced by premorbid functioning and the stability of subsequent caregiving relationships ( [Forehand et al., 1999](#)). Although debates about children's ability to mourn continue among psychological theorists, most agree that mourning, particularly in relation to the loss of a parent, requires the prior establishment of object constancy, a sustained mental representation of the caregiving relationship. For many HIV-affected children and youth, the death of a parent has been preceded by multiple disruptions of attachments because of the instability and relapses attributable to the progression of the disease. As a result, the internal representations held by these children related to caregiving lack the necessary features of predictability and responsiveness that allow mourning to take place and serve to promote healthy adaptation to loss.

#### DISCLOSURE

Despite emerging findings for the benefits of disclosure, many parents are unable to reveal an HIV diagnosis to an affected or infected child. As [Nagler, Adnopolz, and Forsyth \(1995\)](#) observed, children "represent parents' replacements and hope for immortality," yet these aspirations become untenable in the presence of HIV disease and AIDS. Parents may be overcome by guilt and beset by self-recrimination at having transmitted the virus to their children. Disclosure forces parents to confront their personal responsibility and to acknowledge the negatively sanctioned behaviors related to substance abuse or sexual activity ( [Lipson, 1993](#); [Lipson, 1994](#)). Unable to tolerate their own remorse and psychological pain, parents may withdraw and may deny an illness that is evident to their children and loved ones ( [Faithfull, 1997](#)). Other parents struggle with their knowledge of HIV but equate disclosure with harming their children and instead attempt to protect children from this painful knowledge, to preserve the mystique of childhood innocence. [Lipson \(1993\)](#) suggests that the conscious fear that children cannot understand the ramifications of HIV masks a deeper fear that children will indeed grasp its fatal implications.

#### Prevalence of Disclosure

Despite interest in disclosure and its potential implications for intervention with HIV-infected and affected children, few studies have examined parental decisions about revealing their diagnosis to their children. In the early 1990s, relatively few HIV-infected children were informed of their diagnosis ( [Lipson, 1993](#)). Several years later, [Rotheram-Borus and her colleagues \(1997\)](#) reported a disclosure rate of approximately 75% by HIV-infected parents. Older children were more likely to be told of a personal or parental diagnosis of HIV infection or AIDS; infected parents tended to disclose increased information as they became more symptomatic ( [Armistead et al., 1997](#); [Ledlie, 1999](#)).

The issues of disclosure and permanency planning become still more important with the ongoing evolution of the HIV and AIDS epidemic from an acute, fatal illness to a chronic condition that nevertheless portends a foreshortened life span as children experience the painful consequences regardless of their specific knowledge about the disease ( [Murphy, 2000](#)). Clinicians have come to accept the axiom that knowledge is preferable to the fantasies that children may construct about their illness or their parent's illness. For some children, disclosure may dispel erroneous beliefs about personal responsibility for the illness, yet it may also heighten fears and anxieties related to abandonment. Although secrecy can represent a burden for child and parent alike, openness may accentuate their shared anxiety because of the unpredictable trajectory of the disease ( [Nagler et al., 1995](#)). Thus, disclosure should represent a process that neither begins nor ends with the actual revelation of HIV infection.

#### Stages of Disclosure

A model of disclosure, based on more than a decade of clinical intervention, has emerged from the work of the Yale Child Study Center Program for HIV Affected Children and Families ( [Adnopolz, 2000](#); [Geballe et al., 1995](#); [Murphy, 2000](#)). The program informed and enriched Tasker's five-stage model of disclosure ( [Tasker, 1995](#)) with a developmental perspective that clarifies and integrates factors favoring and mitigating against disclosure.

As previously noted, many parents, whether through conscious or unconscious choice, do not inform their children of an HIV diagnosis. Tasker has identified a *secrecy phase* during which parents struggle with their own acceptance of the illness and their wish to deny its implications. Their unwillingness to reveal their health status may also be influenced by the negative associations among HIV and AIDS, promiscuous sexual activity, and the use of illicit substances. Rather than share any knowledge of their illness, parents may look to their health and mental health providers for repeated reassurance that their serostatus remains confidential. Children whose parents are unable to move beyond this phase are left to cope with reactions to their overwhelming sense of loss, guilt, and abandonment in secrecy and isolation.

Parents in the second, *exploratory phase* demonstrate ambivalence about disclosing their HIV diagnosis, although the need to guard against revelation diminishes over time. The Yale program found that the average time between parent's receipt of the diagnosis of HIV and actual disclosure of their status to their children is 2½ years. The exploratory phase generally progresses from secrecy and denial of HIV to tentative attempts to name the disease through the use of euphemisms. Some parents may admit to being "sick," without further amplification, whereas others may report secondary illnesses associated with HIV. For example, one youngster was told that he had a heart condition serious enough to require frequent medical visits, but he was not told of his HIV diagnosis.

As parents move closer to revealing an HIV diagnosis, they enter the *readiness phase* of disclosure in which they rehearse possible disclosure scenarios, either in fantasy or explicitly, with a trusted friend or professional helping to guide them through the process. Practicing the form, timing, and content of disclosure provides opportunities for parents to consider the possible reactions of their children and to identify strategies to assist their coping responses.

The *disclosure phase* begins at the time children are told of an HIV or AIDS diagnosis. Disclosure provides the child with the words to name a condition that is pervasive in its effects but cannot be discussed openly. It allows menacing secrets to be replaced by knowledge, and it shifts the developmental tasks toward coping with the painful reality (Nagler et al., 1995). The following case vignette from the Yale program illustrates the importance of disclosure.

The patient was a 16-year-old perinatally infected boy who had never been told his diagnosis even though he had lost both his parents and several other relatives to AIDS and he had received his medical care from a pediatric HIV specialty clinic since birth. Disclosure was prompted by a period of medication noncompliance and resulted initially in feelings of shock and despair. However, in time he was able to develop an important therapeutic alliance in which he was able to address the tumultuous feelings associated with his own illness and begin the process of grieving his multiple losses.

Although the American Academy of Pediatrics has recommended that HIV-infected children be informed of their diagnosis (American Academy of Pediatrics, 1999), there are few protocols to guide the clinician and family through the ambivalence and regret preceding the actual disclosure. Studies of HIV-infected children report diminished parental depression and improved family functioning after disclosure (Wiener et al., 1998). The effects on children's psychological functioning appear more equivocal. Although disclosure of other life-threatening illnesses, such as cancer, appears to alleviate anxiety (Lipson, 1993; Reeve and Kline, 1995), the increased burden of social stigma and isolation associated with HIV infection may cause some children to experience heightened levels of distress. Symptoms may abate as children are afforded continued opportunities for discussion and expression with family members, mental health workers, and pediatric providers. Once additional stressors are accounted for, disclosure of an HIV diagnosis does not appear to result in further decrements in children's emotional or social functioning. Instead, disclosure may alleviate the burden of unspoken fears and may become a basis for further integration of painful knowledge and a foundation for permanency planning efforts. However, clinical experience suggests that external support before and after disclosure is essential for the adults providing the information and the children who receive it.

With the burgeoning rates of HIV infection among adolescents, disclosure will increasingly become a decision that will be made by youth as well as their adult caregivers. A comparison of mother-child dyads in which the child had a positive HIV status found that children who had disclosed their diagnosis to similarly aged friends reported no decrements in their behavior or self-concept. Importantly, children who disclosed their status to their peers experienced a statistically significant increase in their immune response (CD4 percent) relative to their nondisclosing, HIV-positive peers, a difference that was apparent regardless of age or medication regimen (Sherman et al., 2000). Although both content and context dictate responses to disclosure by children, families, and friends, the study by Sherman and her colleagues adds weight to recommendations stressing the importance that children become aware of their diagnosis and exert control over the management of their illness, when possible.

#### PERMANENCY PLANNING

For many families, disclosure of HIV can be seen as preparation for the task of permanency planning for children who will be orphaned by the disease. Long considered the most appropriate mechanisms for child rearing, families offer children the nurturance, protection, and guidance essential for healthy development. Within a stable, secure, and consistent family environment, children acquire a set of beliefs and values, learn standards of behavior, develop expectations for the future, and gain knowledge about themselves and the world (Adnopolz, 2000). According to Solnit and his colleagues (Goldstein et al., 1996; Solnit, 1976), the family serves as "the bridge from the past to the future," offering children a sense of being rooted in time and place. This process, which suffuses development, underscores the centrality of long-term family stability and coherence.

Permanency planning with affected families includes efforts to assist parents to identify a familiar and accepted surrogate caregiver able to offer children affective support, reassurance, and understanding during periods of the parent's acute illness and after their deaths. However, it is not surprising to find that most parents have great difficulty making realistic plans for the future of their children. Parents may approach the possibility of premature death with untested assumptions about their children's future. They may assume that a relative or older sibling will take custody of younger children, yet they may be unaware that without specific planning these assumptions easily go awry. The process of developing a workable plan that names adults who will serve as parental replacements and calls into view a future for children in which parents will not participate is long and painful. Although efforts can be made to identify a potential guardian earlier in the disease process, most frequently this work does not begin in earnest until the terminal stages of the disease. Many states now provide legal remedies designed to ease the strain on parents of making custodial decisions and to allow for a more flexible approach to guardianship. It is now possible for children to be cared for by a temporary guardian who is responsible only when parents are too ill to fulfill their familial obligations. Guardianship reverts to parents as their acute symptoms remit and they are able to resume responsibility. Standby guardianship and coguardianship are additional legal options that have been developed in response to the special needs of HIV-affected children and families and as AIDS has come to resemble other chronic illnesses with unpredictable periods of relapse and recovery lasting over time.

The caregivers selected by parents most frequently are members of the extended family who represent the most realistic option for supporting the psychological and physical development of affected children and providing continuity in the midst of loss (Adnopolz, 2000; Geballe, 2000). The multiple functions served by extended families include maintenance of the child's ties to family history, culture, and beliefs (Wilson, 1989). Although strenuous attempts may be made to place children who lose a parent to AIDS in the care of relatives or others known to them through their family's social networks, siblings remain together in fewer than 50% of these cases (Draimin, 1995). The separation from other siblings can be experienced as a replication of the loss of the parent, a situation that could be avoided with careful planning and a commitment to maintaining the integrity of sibling groups.

The interrelationship between disclosure and permanency planning was demonstrated in a study of 151 HIV-infected parents and their 171 adolescent children (Rotheram-Borus et al., 1997). Almost three-fourths of the teens in the study had been told of their parent's HIV diagnosis, and most were aware of plans for their future custody. Virtually all parents who made a permanency plan consulted the potential guardian, and almost all plans were agreed to by the chosen guardian. Legal custody arrangements were rare, however, occurring in less than one-fourth of cases, a statistic attesting to the difficulty parents experience in taking the final step toward the release of their custodial interest in their children. The high rates of permanency planning attempts are encouraging, because they indicate that many parents are able to address their children's needs in a planned and thoughtful manner. However, the relative lack of legally sanctioned custody arrangements raises concern. Without legal intervention, it is quite possible that the plan developed by the parent may be jeopardized by the trauma, stress, anger, frustration, and disorganization that frequently follow the trauma of the parent's death. Helping parents to embed their custodial preferences in law remains an important aspect of permanency planning.

#### Mental Health Interventions

HIV disease exacts a dire toll on families and often compromises their ability to use available mental health care. Traditional modalities of office and clinic based care may be ill suited to families who must contend with multiple medical appointments and complex treatment regimens within a sometimes disorganized and overstressed family environment. The myriad burdens associated with HIV infection and AIDS may overwhelm even the most concerned parents. In light of these obstacles to traditional service use, we advocate a comprehensive, home- and community-based approach to the mental health care of children and families beset by HIV infection and AIDS.

The Yale Child Study Center Program for HIV-Affected Children and Families was created to provide home-based psychiatric services to children and their families affected by HIV and AIDS (Adnopolz, 2000; Adnopolz et al., 1994; Gewirtz and Gossart-Walker, 2000; Murphy, 2000; Nagler et al., 1995). The program serves children, adolescents, and families who are either infected with or affected by HIV or AIDS. Clinical services are distinguished by their comprehensive and flexible nature; duration, intensity, and location of treatment are determined based on a thorough evaluation of the needs of each child and family. Specific interventions include home- and community-based clinically informed case management, psychotherapy, psychiatric consultation and medication management, psychological assessment, support groups, family stabilization, 24-hour emergency consultation, and coordination of medical providers for biological, extended, and foster care families. Clients are referred from hospital- and community-based programs, including pediatric and adult AIDS providers, social service agencies, juvenile justice personnel, and community police officers; caseloads consist of families with multiple medical, psychological, social, and economic problems related to HIV disease. A staff of pediatric AIDS providers, psychiatrists, psychologists, social workers, and family support workers provides home- and community-based treatment to more than 70 families each year. Since its inception in 1989, the program has served more than 475 children and families.

A clinical team consisting of a social worker or psychologist, paired with a case manager with experience within the target community, coordinates services for each

family. Teams provide in-home individual, group, and family therapy to children and their families, as well as concrete assistance in the form of case management, parent guidance, and practical assistance with housing, entitlements, and coordination with other systems of care. The treatment team is able to work with families for extended periods, ranging from several months to many years. In addition to the variable length of intervention, which is tailored to the ongoing treatment needs of children and families and includes attention to medical compliance, family stabilization, and permanency planning, clinical providers remain available to families on a 24-hour basis through an emergency pager service. Significantly, the team is able to respond directly to families at times of medical or psychological crisis, thus ensuring continuity of treatment relationships and overall care.

The intensity of intervention is reviewed through formal supervision and case presentation, as well as through regular review of treatment plans with the families. Some families may have daily contact with the team at time of acute crisis and need, whereas for others, contact is maintained at a minimum to solidify already achieved therapeutic gains. Beyond the utility of coordinated therapeutic and case management services, the use of a clinical team serves an important role in terms of the professional development of its members. The sharing of their professional experience provides an ongoing source of support and consolation in the face of the inevitable losses that confront them.

#### *SPECIALIZED INTERVENTION FOR HIGH-RISK ADOLESCENTS*

Adolescents have been cited as a high-risk group for HIV infection and AIDS, with concerns about their welfare moving to the forefront as rates of prenatal and perinatal HIV infection have diminished. From limited research, the relationship of knowledge about HIV and AIDS and risk behavior remains unclear; investigators report contradictory results about the application of relevant knowledge to adolescent risk behaviors. [Rotheram-Borus et al. \(1997\)](#) note an increase in high-risk behavior among adolescents who have been informed of their parents' HIV infection. Clinicians in the Yale program have observed similar situations in which affected teens engage in multiple instances of unprotected sexual activity, a finding suggesting that denial may be a predominant mechanism by which adolescents cope with the complex emotional sequelae of HIV infection in themselves or in loved ones. In these instances, detachment and avoidance of emotion provide defenses against the overwhelming chaos and anxiety that multiple losses present. Reenactment of the very behaviors that led their parents to contract HIV may emerge from the age-appropriate feelings of invincibility and may represent a means to control the internal distress and external chaos experienced by adolescents who themselves must confront their own heightened sexual drives. These behaviors may also represent expressions of internalized rage against parents for their impending abandonment.

Adolescents as a group may engage in additional activities that increase their risk of contracting HIV. Recognized risk factors include relationships with multiple sexual partners, teenage pregnancy, prostitution, substance abuse, criminal activity, and school truancy. The presence of several known risk factors has been found to be more detrimental to psychological and developmental outcomes than the presence of a single risk factor, with an exponential relationship between number of risk factors and severity of psychosocial impairment. This documented comorbidity of HIV and other risk factors in vulnerable families implies a greater likelihood of finding adolescents affected by HIV within impoverished, marginalized urban neighborhoods or nonnormative settings, such as within the juvenile justice and mental health systems.

Despite predictions of a rising incidence of HIV infection among adolescents, appropriate prevention efforts and clinical responses have often been lacking ([Kalichman, 2000](#)). Prevention curricula based on a psychoeducational and problem-solving approach to sexual and other risk behaviors have demonstrated a range of positive outcomes in general school and community settings, including increased condom use during sexual intercourse, decreased high-risk (unprotected) sexual behavior, decreased sexual activity with multiple partners, increased age at time of first intercourse, and increased discussion of sexual practices between parents and children ([Jemmott et al., 1992](#); [Lefkowitz et al., 2000](#); [Main et al., 1994](#); [St. Lawrence et al., 1995](#)). The extent to which primary preventive approaches may generalize to high-risk, psychiatrically impaired, or juvenile delinquent cohorts outside these mainstream settings remains untested ([Schoeberlein et al., 2000](#); [Schonfeld, 2000](#)), yet those at greatest risk of contracting HIV or AIDS tend to be these same adolescents whose isolation from traditional health and mental health treatment systems complicates their receptivity to primary and secondary prevention efforts.

Clinical and case management services provided in collaboration with the juvenile justice system, in which other prevention efforts have made little headway, have the potential for decreasing the behaviors of adolescents that place them at risk of contracting HIV. Given the treatment-refractory nature of this population, the goals of ameliorating psychological impairment, reducing the incidence of high-risk behaviors, and providing access to appropriate medical and mental health care can be best accomplished through home- and community-based services. Changes in the juvenile justice system toward community-based probation, with its emphasis on alternative sanctions, have made inroads in providing structured, therapeutic programming as a component of court sanctions. Home-based providers with existing collaborative relationships with law enforcement, juvenile justice, school, and medical personnel can serve as a focal point for coordinated psychosocial and medical interventions for youth who are most likely to engage in the high-risk behaviors that may culminate in HIV infection.

At the Yale Child Study Center, home-based clinical services have been integrated with community juvenile probation in an effort to provide acute community psychiatric care to youth who appear at greatest risk of contracting HIV through their own risk behavior. Risk factors that result in a referral from a community-based probation officer include: (a) a caregiver with HIV infection or AIDS, (b) high-risk sexual behavior (teen pregnancy, prostitution, diagnosis of an STD, multiple sexual partners, unprotected sexual contact), (c) significant drug abuse, or (d) any history of injecting drug use. Youth and families are assigned to a clinical team consisting of a psychiatric social worker and a paraprofessional case manager with extensive community experience. The core of the intervention consists of the coordinated efforts of the clinical team who forges a consistent and supportive relationship with the family. A focus on specific risk behaviors and their amelioration occurs in the context of the clinical relationship, which itself serves a catalytic function in promoting family change. Further pragmatic and discrete interventions assist the family in supporting changes in the adolescent's behavior by providing adolescents and their families with access to affordable health insurance and ongoing medical and mental health care. The collaboration between the clinical staff and personnel from juvenile probation is critical to the intervention. For delinquent youth, who may present with little intrinsic motivation to alter their behavior or to comply with necessary medical or psychiatric treatment, the probation officer represents an important figure of benevolent authority and containment. Thus, probation officers reduce delinquent youths' feelings of anonymity in their communities and can complement community-based clinical interventions that would be unlikely to succeed in a clinic-based setting.

---

#### CASE ILLUSTRATION

Raymond is a 16-year-old youngster who lives with his mother and her boyfriend. His mother contracted HIV during his early childhood through injecting drug abuse. Her continued drug use and sporadic compliance with HIV medications compromised her health to the extent that she often lacks the energy and motivation to leave the house or participate in daily activities. Despite the encouragement of the home-based clinical team, she has not been able to discuss her illness with Raymond, nor has she addressed questions related to permanency planning. In the meantime, Raymond has become increasingly depressed. He is often truant from school and instead remains in his bedroom throughout the day. He has withdrawn from friendships and has become increasingly hostile to his mother. Coordinated responses by the clinician-family support worker team and the community probation officer have resulted in improved school attendance this year. His clinician conducts regular sessions with Raymond during the school day, facilitates school attendance and educational planning, and attempts to address his increasing despondency through individual and family interventions. The family support worker works with his mother to address her own illness and her capacity to plan for her son's future. Meanwhile, the probation officer has become a benign authority figure known to Raymond, his family, and school personnel as committed to his school attendance, treatment participation, and involvement in prosocial activities.

---

#### CONCLUSIONS

In the decades since the identification of HIV disease, advances in medical treatments, particularly antiretroviral pharmacotherapy, have transformed the disease from an acute illness with a vastly foreshortened life span to an entity with the characteristics of a serious chronic illness. These hard-won gains have improved the quality of life for many infected persons, yet for others throughout the world, HIV infection continues to proliferate at truly epidemic proportions. Within the United States, perinatally acquired HIV has diminished from approximately 25% to less than 2% of births to HIV-infected women. Like the virus itself, the demographics of HIV have mutated and evolved. Most new HIV infections appear among persons less than 25 years of age, with women of childbearing age and minority communities experiencing a disproportionate share of newly diagnosed infections. Although fewer American infants and children will be infected with HIV infection or AIDS, increasing numbers will be affected by the illness of their parents or others who play significant roles in their lives. Data now suggest that affected children are at increased risk of becoming infected as adolescents because of their own risk-taking behaviors.

Reports issued by the Institute of Medicine ([Institute of Medicine, 2000](#)) and the Office of National AIDS Policy in conjunction with the White House ([Office of National AIDS Policy and the White House, 2000](#)) highlight these worrisome developments in the HIV and AIDS epidemic that require a coordinated national and international effort toward prevention of new HIV infection and provision of care to those who are already infected. A comprehensive strategy to ameliorate the effects of HIV disease on children and adolescents should arise from a concerted, national strategy focusing on both prevention of new HIV infection and treatment provision to HIV-positive youth. Research will be needed to evaluate the transportability of prevention programs from school and clinic settings to community settings, such as the juvenile justice system, in which youth at greatest risk are likely to be found. The availability of effective treatment for HIV disease does not, at present, portend a cure. Nonetheless, counseling and testing remain crucial ingredients in a public health approach to HIV infection and service provision. Given the myriad

psychosocial stressors encountered by HIV-infected and affected children and youth, comprehensive and effective medical and mental health services remain crucial. Access to care must be extended to children, adolescents, and families who have traditionally existed at the margins of the health care delivery system. Psychiatric treatment must address children's well-being in the context of their families, so interventions address children's need for stability of caregiving relationships and safety through a comprehensive strategy that addresses the medical and mental health needs of individual children, supports family functioning, addresses permanency planning for infected and affected youth, and coordinates care among psychiatric, medical, and social service providers ( [Burr and Lewis, 2000](#); [Casey Family Services, 1999](#)).

Fire over the ages has inspired awe, wonder, fear, allegory, and myth from Hephaestus, the Greek god of fire, peaceful but ugly and deformed and wed to the beautiful Aphrodite, to Daedalus, flying too near to the sun, losing his wings, and plunging to his death. The Jews escaped Egypt through a miracle: “the Lord went before them by day in a pillar of a cloud, to lead them the way; and by night in a pillar of fire, to give them light” ( [Exodus 13:21](#)). A Mother Goose nursery rhyme catches the child’s wish for a mother’s rescue with “Ladybug, ladybug, fly away home. Your house is on fire, and your children will burn.” For authors and poets, fire can be an image of mental awakening, as in *A World Lit Only by Fire* ([Manchester, 1992](#)) and “The Poets light but lamps...” ( [Dickinson, No. 883](#)), and feelings, “Some say the world will end in fire, some say in ice. From what I’ve tasted of desire, I hold with those who favor fire...” ( [Frost, 1923](#)). Also pertinent is Tennyson, as he catches the power of language to assuage with “But for the unquiet heart and brain/A use in measured language lies; The sad mechanic exercise, Like dull narcotics numbing pain” ( *In Memoriam*, 5, st 2). We feel these evocative images, such as fear and rescue, ugliness and beauty, death and miracle, each day in the care of burned children.

## HISTORY

The era of intensive research and treatment of burns began during World War II, at the Massachusetts General Hospital after the Cocoman Grove Fire in Boston on November 28, 1942. Cobb and Lindemann chronicled the posttraumatic reactions of the survivors of that fire ( [Cobb and Lindemann, 1943](#)). Lindemann, in a classic article about them, also described the symptoms and management of their and their relatives acute grief ( [Lindemann, 1944](#)). Since then, images of war have made plain for all to see the catastrophe wrought by fire. Drawings by child and adult survivors of Hiroshima, televised images from Vietnam, films depicting a nuclear holocaust, and the terrorist attacks of Sept. 11, 2001, have riveted the world’s attention. Such images evoke terror but also compassion, and a positive benefit of such compassion is the near-miraculous care now available for children with burns.

In Boston, the Shriners Hospitals joined with the Massachusetts General Hospital and Harvard Medical School in 1968 to build the Shriners Burns Hospital, recently rebuilt, where care is provided at no cost to burned children and their families. The Shriners have also built pediatric burn hospitals in Cincinnati, Galveston, and at the University of California at Davis. Awareness in the 1960s and 1970s of the high rate of burns to children led to the founding of trauma centers including pediatric burn units in children’s hospitals and general hospitals throughout the United States and Canada. There are now designated burn centers for children in most major cities of the United States, Canada, Europe, and many other countries. Research has led to improved methods of resuscitation and transport, pain management (Stoddard et al., 2002), excision and grafting ( [Sheridan et al., 1994c](#)), cardiovascular and infection control, artificial skin and skin substitutes ( [Sheridan et al., 1994a](#)), plastic surgical techniques ( [Salisbury, 1992](#)), and other advances. Together, these have improved survival rates and outcomes ( [Blakeney, et al., 1998](#); [Ryan et al., 1998](#); [Sheridan et al., 2000](#)).

Child psychiatrists, such as Norman Bernstein ( [Bernstein, 1976](#)) and Richard Galdston ( [Galdston, 1972](#)), a child psychoanalyst, were pioneers in the psychiatric care of burned children, their families, and in work with the “burn team.” [Stoddard \(1982a\)](#) initially highlighted a developmental approach to pain of burned children, and an adult psychiatrist, Samuel Perry, and colleagues spearheaded the focus on undertreatment of pain in children and adults through a national survey of burn units ( [Perry and Heidrich, 1982](#)). Trauma surgeons and plastic surgeons, nurses, anesthesiologists, pediatricians, psychologists, social workers, physical therapists, burn survivors, and many others have contributed to major advances in prevention, education, research, and treatment. Although acute care of serious burns is specialized, most mental health professionals, at some time in their careers, provide or supervise treatment for patients who have been burned, as well as caring for their siblings and families.

## ORGANIZATIONAL AND RESEARCH ISSUES

The organization of care differs from some other pediatric areas: in large centers, burns tend to be a subspecialty in many of the fields mentioned earlier. As managed care forces increased generalization of services, more acutely burned children are transferred to specialized burn centers from hospitals without these services. After recovery, follow-up services are provided where the child lives, with periodic reevaluation or surgery at the burn center. The American Burn Association and the International Society for Burn Injuries are the principal scientific organizations sponsoring meetings to educate physicians, nurses, other professionals, and the public. The Phoenix Society, the international self-help group for children and adults with burns and their families, has been instrumental in advancing the care and understanding of burned patients.

Psychological aspects of burns are an active research area, especially pain outcome studies. As surgical research and improved treatment increased survival rates, there was new focus on pain as a crucial variable increasing stress and adversely affecting psychological outcome ( [Patterson et al., 1993](#)). Improving pain relief (U.S. Department of Health and Human Services, 1992) and increasing focus on psychological interventions provide increased hope to children and their families and may be improving outcomes, but pain remains undertreated in many centers ( [Marvin et al., 1991](#)). As comprehensive care improves, burn care personnel and the families are helping disfigured children and adolescents to resume normal lives and may enable them to adapt to handicaps. Research with burned children can pose ethical and human studies dilemmas because the research benefits to them and others are balanced against risks of their age, critical condition, and exposure to many procedures. Levine ( [Chapter 131](#)) wisely presents an ethical overview pertinent to such research with children, including sections on informed consent, on a cognitive basis for assent by children aged 7 to 14 years, and on parental permission.

## EPIDEMIOLOGY

There were an estimated 1.25 million burn injuries in the United States in 1992 and an estimated 5,500 deaths in 1991 ( [Brigham and McLoughlin, 1996](#)), of which about 35% were in children. Time trends reveal significant decreases from 1971 to 1991, with decreases in deaths and hospitalizations for burn injury both about 50%. Although in the previous edition of this text, I wrote that the United States had one of the highest rates of burn injury in the world, it has decreased into the midrange. This progress coincides with major efforts in burn prevention including smoke detectors, sprinkler systems, burn prevention education, improved regulation of consumer product and occupational safety, and other societal changes such as reduced smoking and alcohol abuse. In addition, regional burn treatment centers have been established in major population areas, and these centers improve outcomes after burn injury. Fire and burn injuries are the third leading cause of

accidental death in children 1 to 4 years old and the fourth leading cause of death in those 1 to 19 years old ( [Guyer et al., 1998](#)). Most burns are preventable. Preventive public health laws for fire-retardant sleepwear and lowered hot water temperatures in public housing have reduced burns to children. However, further laws are needed. Many infants and young children are burned by scalds by extremely hot water. Other common types of burns are flame, electrical, ingestion, and chemical ( [McLaughlin and Crawford, 1985](#)). These may be the result of poor housing, overcrowding, child abuse or neglect, sensorimotor deficits ( [Ramirez et al., 1998](#)), parental substance abuse or depression, risk-taking behavior, smoking, match play or firesetting ( [Chapter 57](#)), suicide attempts ( [Table 99.1](#)), or war.

**Table 99.1. Adolescent Survivors of Self-Inflicted Burns**

Child neglect or abuse ( [Chapter 100](#)) is a frequent cause of burns. The child psychiatrist collaborates with the surgeon, nurse, and social worker in suspected cases, and psychiatric assessment skills may confirm neglect or abuse when other methods fail to do so. This type of burn is common; neglect or abuse accounts for 6% to 20% of pediatric burns in different units, including some fatalities. Hight et al. ( [Renz and Sherman, 1993](#)) found 13 to 24 months to be the period of maximum risk of abuse. The most common type of inflicted burn is a scald, with other types (cigarette, hot iron, or radiator) much less common. [Renz and Sherman \(1993\)](#) prospectively studied abusive scald burns and found that all 30 children, at a mean age of 22.5 months, had buttocks burns, 80% had complications, and four died of sepsis. Indicators suggesting abuse include a changing history of what occurred, a past history of “accidents,” an inattentive parent, a consistently passive, withdrawn child who is “numb” to pain, and physical findings suggestive of abuse, such as a burn distribution not consistent with the history, other physical signs of abuse, and fractures. When abuse is suspected, reporting to the appropriate state social agency is mandated, and an investigation follows, with subsequent interventions as indicated. When support and explanation are provided to the parents or caretakers regarding why filing a report is required, they often accept counseling as part of burn care, although in some cases they withdraw from unit staff. Recognition of neglect or abuse is very important because these children are at increased risk of subsequent injury and death.

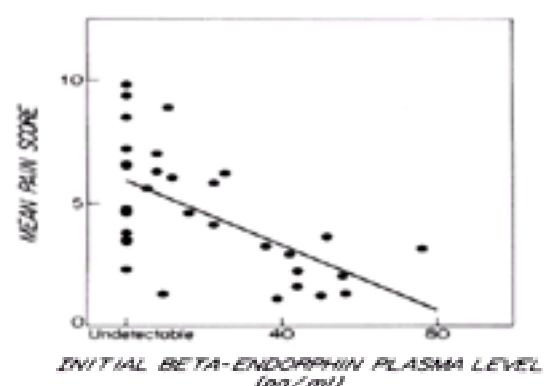

## UNDERMEDICATION FOR PAIN

Pain is very severe during acute treatment, especially during débridement of the burn wound (dressing changes, “tubbing” or “tanking”), but pain management and protocols have improved reducing staff conflict. Although the reasons are not fully understood, some reasons for undermedication by doctors and nurses seem to be (a) lack of education about pain management, (b) fear of respiratory depression and other side effects, (c) reluctance to obtain self-ratings of pain systematically, (d) false confidence (“I know what pain in children looks like”), and (e) lack of attention to adequate doses of opiates required with curariform drugs. [Perry \(1984\)](#), in a reflective article about this issue with adult burn unit staff, found that (a) preservation of the patient’s pain unconsciously preserved the boundary of the patient as a definable being, separate from staff, and (b) pain responses helped to confirm for the staff that the patient was alive; it was *not* a sadistic wish to cause pain but, rather, a reluctance to eliminate it. He suggested that consultants be aware of possible unconscious factors, identify and differentiate them from pain management, and encourage appropriate levels of analgesic use. Hospital pain protocols ( [Table 99.2](#)), collaboratively developed, and monitored, and revised regularly, may reduce this problem.

**Table 99.2. Pain Management Protocol from Shriners Burns Hospital, Boston**

## PAIN MANAGEMENT

The pain problems for burn patients are mainly acute rather than chronic. Before treatment of pain, physicians and nurses identify the location and source of pain, its usual intensity, course, and duration, and its response to prior treatment. Pain does correlate with endorphin levels ( [Fig. 99.1](#)) and with the extent and depth of burn in children ( [Carr et al., 1993](#)). Several years ago, analgesics were withheld from a hateful adolescent girl with massive self-inflicted burns and a history of drug abuse, because her constant complaining about pain was viewed as manipulative; a research study later revealed that her endorphin levels had been negligible and that she should have been receiving high doses of morphine. Unfortunately, endorphin levels are not rapidly available, but self-ratings are usually sufficient. For infants, behavioral measures (facial expression, body movement, behavioral state, and cry), as well as physiologic parameters (heart rate, blood pressure, respiratory rate, and oxygen saturation, if available, and epinephrine, norepinephrine, growth hormone, and cortisol), are used to monitor pain response ( [Porter, 1993](#)). Pain relief in infants improves surgical outcomes (not yet studied in burns), and it is enhanced with the use of pain rating scales ( [Anand et al., 1997](#)).

**Figure 99.1.** Mean pain score versus initial b-endorphin level during burn dressing change. The relationship of the initial (before analgesic and burn dressing change) b-endorphin plasma immunoactivity and mean pain score for the time of burn dressing change. (From [Szyfelbein SK, Osgood PF, Carr DB](#): The assessment of pain and plasma b-endorphin immunoactivity in burned children. *Pain* 22:173, 1985, with permission.)

For any child who cannot communicate, for example, because of the use of curariform drugs or intubation, estimates of maximum analgesic requirement for body weight are made. The only easily used assessment for pain and pain relief for conscious patients is self-rated pain ratings, preferably recorded on each shift and at each dressing change. When such ratings or pain questionnaires, performed consistently and reliably, are not present, there is little basis for evaluation of pain treatment, although clinical judgment and nurses' ratings are still used. [Matthews et al. \(1993\)](#) point to limitations of each but indicate particular strengths of self-report measures such as the Faces Pain Scale, Visual Analog Scale, and Oucher Scale. Of observational scales, these authors favor the Childrens Hospital of Eastern Ontario Pain Scale (CHEOPS). The most easily used self-rating scale is a simple 1 to 10 visual analog scale rating or asking the child to rate the pain from 0 to 10, with 0 as none and 10 as the most severe pain ([Szyfelbein et al., 1985](#)). Various scales are in use for young children, such as the Faces Pain Scale, which pictures faces rated from 0, a happy face that "doesn't hurt at all," through 5, a sad crying face "hurting as much as you can imagine." The range of developmentally targeted approaches for use in managing pain is shown in [Table 99.3](#).

**Table 99.3. Developmentally Targeted Approaches to Pain and Anxiety Treatment**

Of the psychological methods, the cognitive-behavioral method involving the child's participation was designed to increase the "locus of control" in burned children themselves ([Kavanaugh et al., 1991](#)). The method involves preparation for each step of the burn dressing change and gives the children greater psychologic control over their pain experience by encouraging their help in removing bandages and in other steps. It leads to fewer maladaptive behaviors, improved outcomes, and lower dosages of narcotics. [Kuttner \(1993\)](#), following Olness and Gardner, highlights the effectiveness and practicality of *hypnosis* for burn pain in children and notes that education of parents and encouraging their presence are desirable. She describes practical hypnotic methods in 3 to 6 year olds and in older children, states that maximum hypnotizability occurs in children, advocates its rapid, short-term use, and indicates that capacity for self-hypnosis is the ideal end point, to give maximal control. This method is underused, given its relative ease with children. [Foertsch et al. \(1998\)](#) and [Martin-Herz et al. \(2000\)](#) address hypnosis with burned children in major burn centers. Their findings suggest that although effective, hypnosis is less generally reliable for rapid relief of severe burn or procedural pain than are opiates and other drugs.

### Pharmacologic Treatment

Pharmacologic treatment is the primary intervention to relieve pain in burned children. Pain treatment is important for biological as well as psychological reasons: the stress pain causes disrupts metabolic, autonomic, and thermoregulatory as well as immune functions; it also can "adversely affect morbidity and mortality" ([Carr et al., 1993](#)). One study of burned children found that those receiving more morphine developed significantly less burn-induced posttraumatic stress disorder (PTSD) ([Saxe et al., submitted for publication](#)). Studies have clarified the effectiveness of morphine in relieving pediatric pain, by using either intravenous or oral administration of the drug ([Carr et al., 1993](#)). The doses used are much higher than doses used for most other purposes, as demonstrated in [Table 99.2](#), which is a protocol incorporating current research on pharmacologic pain and anxiety management. However, other pediatric centers have different protocols and often lower dosages. [Gaukroger \(1993\)](#) reviewed *patient-controlled analgesia* (PCA) and noted its unsuitability for preschool and mentally retarded children. [Berde et al. \(1991\)](#) evaluated PCA in a randomized, prospective comparison with intramuscular administration of morphine for postoperative analgesia and found excellent results for PCA with children 6 to 18 years old. [Doyle et al. \(1994\)](#) studied children after surgery (not burns), with the findings that those treated with higher-dose morphine had less pain and the lower-dose group had more hypoxemic episodes. [Carr et al. \(1993\)](#) state that "although PCA has been successfully used in acutely burned children, it lends itself more easily to the more manageable postoperative pain of patients returning for reconstructive surgery."

Haloperidol, droperidol, and the newer short-acting agent, propofol, potentiate the analgesic and sedative effects of morphine, but the latter two require monitoring by an anesthesiologist because of potential serious side effects and toxicity. These drugs can be very helpful for children in severe pain who are agitated ([Stoddard et al., 1997](#)).

Adjuvants, which enhance the effect of opiates, can make the difference between the presence and absence of pain relief. Most common in current use are low-dose benzodiazepines, acetaminophen ([Meyer et al., 1997](#)), and nonsteroidal antiinflammatory drugs, and less common are low-dose methylphenidate, amphetamine, tricyclic antidepressants, and haloperidol. Except for benzodiazepines, adjuvants have had no formal study in treatment of pain in burned children.

The benzodiazepines in common use, depending on pain severity and duration of action desired, include the following: of the *short-acting* agents, midazolam ([Sheridan et al., 1994b](#)), lorazepam, oxazepam, and triazolam; and of the *long-acting* agents, chlordiazepoxide, diazepam, clonazepam, and flurazepam. In a study of three acutely burned children at our center, clonazepam caused excessive sedation and anorexia in combination with morphine in two children but was effective in the third, a child with a family history of panic disorder.

There are few indications for use of psychotropic drugs with acutely burned children other than management of pain, anxiety ([Table 99.2](#)), or delirium. Using an algorithm to differentiate complex comorbid psychiatric disorders is essential to care. These include delirium or other psychosis, intractable pain, phobia or panic, sleep deprivation or sleep disorder, acute stress disorder (ASD), acute depression, medication side effects, or the toxic effects of sepsis, alcohol, or drugs.

On rare occasions, major tranquilizers are necessary to control severe burn delirium, agitation, aggression, or severe insomnia. In the rare instances when benzodiazepines are unsuccessful, or paradoxically cause disinhibition or agitation, the drug of choice for acutely burned children who are more than 12 years old is intravenous haloperidol on a short-term basis, usually in low doses (0.5 to 2.0 mg slow push) for only 24 to 48 hours, while the cause (e.g., sepsis, metabolic change, etc.) is being identified and treated. This drug has few cardiovascular effects and is rapidly effective. However, it may have adverse effects. In my experience in two of approximately 75 cases, rapid infusion of haloperidol appeared to cause brief reversible hypotension in children, and these two children were less than 10 years old. Continuous electrocardiographic and blood pressure monitoring at the time of administration is indicated if this drug is used in young children. Although dystonia can occur with continued use and may require an antiparkinsonian agent, that has not occurred with short periods of intravenous use, whereas the therapeutic benefits are marked. One study of haloperidol use in children with burns found it to be useful ([Brown et al., 1996](#)). Risperidone, a newer antipsychotic, is preferable if the child can take oral medication, and it may also assist weight gain, which is important in burn recovery.

Despite wide use in acutely burned children, the major studies to date of symptom response to psychotropic agents have been with analgesics and benzodiazepines. Occasional children with attention deficit hyperactivity disorder who were previously taking a stimulant may require it in the course of burn treatment; a side benefit is that it can enhance analgesics as well. The reasons for generally not using other psychotropic agents are possible interactions or toxic effects, such as from lithium, further compromising acute burn treatment.

During early acute burn care, other psychotropic agents should be used with great caution because of potential interactions or toxic effects. When these drugs are needed, they should be carefully monitored with serum levels, blood pressure, and cardiac monitoring. Special considerations that should influence the psychotropic drug selected and dosing are pharmacokinetics and the presence of common complications such as fluid and electrolyte shifts, acute respiratory distress syndrome from pulmonary burns, and hepatic or renal impairment. With drugs such as lithium or tricyclic antidepressants, there may be risk of intoxication or cardiovascular complications. The selective serotonin reuptake inhibitors (SSRIs) interact with a number of other drugs and reduce excretion of many through hepatic P-450 enzyme

blockade. Despite these caveats and those that follow, judiciously selected and monitored psychotropic agents may assist in management of the acute burn patient.

Drug side effects and, rarely, toxicity occur, especially with opiates, benzodiazepines, droperidol, haloperidol, and propofol ( [Kane and Lieberman, 1992](#)). Neuroleptic malignant syndrome may occur, and symptoms can be almost the same as malignant hyperthermia from anesthetics. Opiate or benzodiazepine tolerance, dependence, and withdrawal do occur. Some patients remain sedated and minimally responsive for too long because of high doses, impaired excretion, or a combination. The withdrawal syndrome from opiates includes abdominal cramps, vomiting, diarrhea, tachycardia, hypertension, diaphoresis, restlessness, and insomnia; it is reversed by opiate agonists. Abrupt withdrawal from benzodiazepines may cause anxiety, dysphoria, or insomnia but also full-scale withdrawal with abdominal cramps, vomiting, sweating, tremors, and convulsions. Some symptoms occur even several days later after gradual withdrawal. Resuming and then slowly tapering the benzodiazepine usually reverse the withdrawal symptoms. Although some patients become dependent on opiates and benzodiazepines, *addiction (i.e., severe drug abuse) is hardly ever caused by analgesia for burn pain*, despite the concerns of many staff members about this, especially with adolescents. Dependence is effectively managed, once the patient no longer needs the medication, by gradual tapering, including with occasional adolescent substance abusers who may have required higher doses of opiates at first than others. The use of a clonidine patch has been effective in eliminating moderate opiate withdrawal symptoms. In children, the combination of opiates and benzodiazepines may contribute to respiratory depression, delirium, anorexia, and excess sedation ( [American Psychiatric Association, 1990](#)). Severe opiate side effects can be reversed by naloxone, and benzodiazepine toxicity can be reversed by flumazenil, but this drug may cause seizures. Taking these risks into account, the judicious use of medications and careful monitoring normally result in predictable and reliable reductions in pain and anxiety.

## PHASES OF BURN RECOVERY

Three recovery phases occur after a burn, and they have both neurobiological and psychological features ( [Watkins et al., 1988](#)). These are *acute*, *intermediate*, and *rehabilitative*. Psychiatric assessment and treatment are adapted to each phase. The full range of psychiatric knowledge and skills is used in work with burned infants, children, adolescents, and their families.

### Acute Phase

#### DIAGNOSTIC ASSESSMENT

From the time of admission, assessment and treatment proceed together. Orientation, explanation, and preparation for what has occurred and is to come are linked with assessment of the child's and parent's responses to these interventions. Communication is best when it is at the child's stage of development ( [Gaffney, 1993](#); [Stoddard, 1982a](#)) and in the child's and parents' language ( [Table 99.3](#)). Because the child is often confused in the strange burn unit setting, is afraid of dying regardless of wound severity, and is anxious about pain, the initial history may be obtained from others, but it is important to elicit it from the child when possible. The child responds positively to reassurance about his or her condition and efforts to create familiarity and comfort. Relief of pain lessens fear and confusion. When parents understand and feel support and reassurance, they can assist and be successful in calming their child. Once an initial secure and trusting staff–parent alliance is established, additional history emerges that may clarify preburn risk factors such as a toddler's new motor skills, homelessness or poverty, firesetting, child neglect or abuse, and parental substance abuse, mental disorder, or criminality ( [Kolko and Kazdin, 1992](#)). Similarly, postburn emotional reactions such as fear, guilt, denial, grief, or withdrawal become evident.

An important early diagnosis to be alert for is *delirium* because the confused, agitated, or aggressive patient can cause self-injury by abrupt events such as unplanned pulmonary extubation or pulling out of intravenous lines. Electroencephalographic abnormalities associated with burn delirium have been demonstrated in adults ( [Andreasen et al., 1977](#)), and [Antoon et al. \(1972\)](#) described seizures in 10 of 20 burned children. Delirium in burned children can be common and “alerts staff to the patient's unstable medical condition and can be the first indicator of opiate side effects, sepsis, metabolic disturbance, CNS injury, or a combination of these. Prompt diagnostic evaluation of the delirious child, treatment of the causative factors, symptomatic relief, environmental change, and increased personal contact with staff and family are indicated” ( [Stoddard, 1990](#)). [Antoon et al. \(1972\)](#) studied the origin of burn encephalopathy in 20 children and found the cause to be hypoxia from smoke inhalation in six cases, sepsis in four, a combination of the two in two, and hyponatremia in four cases; of the survivors, only one had residual neurologic impairment; 10 patients died, and five had complete neuropathologic examinations, one with *Pseudomonas* meningitis, one with sepsis, and three with minimal findings. Although delirium remains a sign of complications, modern treatment has reduced the mortality rate to a fraction of what it was in most burn centers.

The stress of an acute moderate or severe burn is extraordinary, a shock that may involve loss of possessions and of loved ones, as well as injury to the child's own body. Many children with burns manifest ASD. This was found in nearly 40% of burned children by [Saxe et al. \(1999\)](#). The burn unit offers an opportunity for case identification, assessment, and intervention including referrals for developmental, neurologic, and educational evaluation of at risk children who would otherwise not receive them. For this reason, it is important to complete an initial assessment even during brief hospitalizations when indicated.

The basis for psychiatric diagnosis is the text revision of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) ( [American Psychiatric Association, 2000](#)), as well as the classification set forth in the *Child and Adolescent Mental Disorders—Primary Care* ( [American Psychiatric Association, 1995](#)).

#### DEVELOPMENTAL NEUROBIOLOGY

The child's body may be able to respond remarkably to trauma such as a massive burn, but it is becoming clear that the child's neurobiological response leaves him or her vulnerable emotionally. “A massive catecholamine release occurs immediately after burn injury both from the adrenal medulla and the autonomic nervous system” ( [Demling, 1990](#)). The body goes through three phases. First, an acute shock or resuscitation phase occurs, with decreased metabolism, dulling of severe pain, and many other acute changes requiring intensive treatment, especially fluid replacement. Second, after a few days, is a hypermetabolic or recovery phase, with an increase in the metabolic rate of about twice normal, during which the hypothalamus seems to select a higher temperature set point and that is associated with increases in plasma catecholamines, cortisol, glucagon, and growth hormone. In the presence of pain and anxiety, the brain can increase the hypermetabolic response ( [Demling, 1990](#); [Wilmore et al., 1974](#)). In infants and children today, unless complications occur, the excision of burn-damaged tissue and coverage of the burn wounds with skin grafts result in healing often in 1 to 3 months, even with large wounds. The acute and intermediate treatments are often accompanied by severe chronobiological changes, including for some a disruption of normal sleep stage distribution ( [Gottschlich et al., 1994](#)) and reversal of the day–night sleep–wake cycle because of around-the-clock treatments, pain, itching, and other factors, although the cause of disordered sleep in burn patients is not yet understood fully. As healing progresses, the sleep–wake cycle gradually returns to its preburn pattern, although sleep disorders, day napping, and enuresis are common postburn symptoms ( [Kravitz et al., 1993](#); [Lawrence et al., 1998a](#); [Murphy et al., 1989](#)). Third, during the rehabilitative phase, wound healing is completed, and metabolism gradually returns to normal a few months after discharge.

#### NEUROBIOLOGICAL POSTBURN PHASES: ACUTE STRESS DISORDER

The physiologic changes briefly outlined earlier appear to be mirrored by changes in brain function and mental status in those patients who are not so sedated that they cannot be evaluated. Some of the mental states commonly seen during acute treatment, which may reflect or relate to the systemic phases described earlier, include anxiety, confusion, pain syndromes, insomnia, depression, and recovery, which may be rapid or gradual.

After a burn, stress disorder symptoms are very common. The differences between symptoms expressed in the proximal and distal aftermath of a trauma are formalized in the DSM-IV-TR, with the distinction between ASD and PTSD. ASD describes the psychopathologic response in the immediate aftermath occurring up until 1 month after the trauma, whereas PTSD describes the psychopathology that persists after 1 month. ASD and PTSD are also distinguished by prominent dissociative symptoms. Children with ASD often have significant dissociative symptoms, numbness, a decrease in emotional responsiveness, and difficulty in recalling elements of the traumatic event. These children tend to reexperience the traumatic event, avoid reminders, and become hyperaroused to reminders of the event. Newer findings indicate that burned children who manifest the dissociative symptoms of ASD after the injury are at high risk to develop PTSD ( [Daviss et al., 2000](#); [Saxe et al., 1999](#)).

Sleep disorders are also common after burns, and they may be a symptom of stress or represent a comorbid disorder ( [Stoddard et al., 1996](#)). Sleep terror disorder is not rare, acutely, after burns, including reexperiencing but without recall of the burn experience. Insomnia and nightmares are often related to awakenings for dressing changes, medications, itching, and prior history of sleep disorders or family history. Sleep deprivation in burned children can be a cause of other psychopathology including stress disorders, depression, and disruptive behavior.

Neuroimaging studies provide evidence of lasting neurobiological abnormalities, such as reduced hippocampal size associated with PTSD, although this has not been studied in patients with burns ([Carr, 1998](#); [Rauch et al., 1996](#)). The hypermetabolic response may appear as a pseudomaniac delirious state with confusion, anxiety, and agitation; later, associated with catecholamine depletion, a state of depression usually develops, with depressive mood, interpersonal withdrawal, and decreased appetite ([Gold et al., 1988](#)). This is not true in all cases, and some children, whose pain and anxiety are controlled, are mentally clear and conversant as deep fascial excisions or amputations of burned areas are about to be or have just been done; in all cases, psychiatric assessment, surgical preparation, and psychotherapeutic support are essential.

In the child, adequate relief of pain and anxiety, together with rapid healing, may lessen the probability of ASD or depression. [Charney et al. \(1993\)](#) describe a model that shows a central role for the locus ceruleus, ventral tegmental area, and especially the amygdala in facilitating the “encoding of traumatic memories” through “fear conditioning, extinction, and sensitization.” Interestingly, the postulated neurotransmitter systems involve norepinephrine, dopamine, opioids, and corticotropin-releasing factor. These are some of the same systems activated in severe burns, and drugs affecting these systems are frequently required for complications arising during burn treatment: cardiovascular, renal, pain, and metabolic disturbances. However, studies reflecting central neurobiological effects in burned children have included mainly endorphins and cortisol. Current research is attempting to discover ways of preempting the processes resulting in PTSD ([Stoddard and Todres, 2001](#)).

Some of the common phenomena in acute burn treatment affecting and being affected by neurobiological systems include the following: neurotoxins (anoxia, carbon monoxide); delirium; catecholamine depletion and depression; opiate dependence, side effects, and withdrawal; and benzodiazepine dependence, side effects, and withdrawal. Endorphins, and probably endogenous benzodiazepines ([Hyman and Nestler, 1996](#); [Rothstein et al., 1992](#)), and the receptor systems involved affect the response of the amygdala to fear, to anxiety, and to medications ([Davis, 1992](#)). It is not known whether residual neurodevelopmental abnormalities follow burn trauma treated by modern methods.

## Intermediate Phase

### NEUROBIOLOGY

This phase, after the patient has survived and is healing, is only somewhat less stressful. Physiologic responses such as a conservation-withdrawal reaction or postacute stress depression seem to be normal after burn trauma. Hospitalization is not free of stress, and it is this period for which the term *continuous traumatic stress* may be most fitting ([Gilboa et al., 1994](#)). Stress occurs throughout burn treatment, not only acutely and then after it is all over (PTSD), but continuously to varying degrees. Vulnerable children with prior comorbid conditions, such as anxiety, affective, or disruptive behavior disorders, may have special difficulty in adapting to the frequent stresses of burn care and may benefit from resumption of psychotropic medications if they were temporarily stopped. Children requiring limb amputations benefit from diagnostic and therapeutic care to cope with severe or intractable pain, acknowledgment and adaptation to the loss, phantom limb, and posttraumatic stress ([Atalar and Carter, 1992](#); [Billig and Weaver, 1996](#); [Thomas et al., 2000](#); [Varni et al., 1991](#)). Other neurobiological changes occur commonly in burn care secondary to acute surgical use of potent agents such as dopamine, curare, analgesics, or ketamine. Complications may emerge including infection, organ failure, or metabolic disturbance, any of which can contribute to the occurrence of delirium.

A special problem in burn care is human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome ([Blumenfeld and Schoeps, 1993](#)). Children are less commonly infected than adult burn patients, but when a burned child is infected, it is doubly tragic. The improved antiviral treatments and overall case management are major advances offering hope. It is important for staff members to adhere strictly to universal precautions. Generally, acute burn treatment takes precedence over HIV interventions. Adverse events such as needlesticks may occur; such events and staff fears are addressed using standard hospital policies and procedures.

### POSTTRAUMATIC STRESS DISORDER AND COMORBID DISORDERS

In the assessment of neurobiological sequelae of burns, the child psychiatrist's medical expertise and skills in diagnosis and treatment become important. There are only a few psychiatric studies of injured children ([Stoddard and Saxe, 2001](#)), but research is progressively delineating the risks to neurobiological development and resulting developmental psychopathology, as well as evidence of resilience. Studies assessing physical or gross developmental but not psychopathologic outcomes, as is true of some outcome studies, may provide falsely optimistic results.

PTSD and other disorders are beginning to be studied in young burned children, but they are well defined in older children. It is not yet proven just what the symptoms of PTSD are in very young children because there are only a few clinical studies ([Scheeringa et al., 1995](#); [Terr, 1988](#)). Based on these studies, the symptoms of PTSD in children less than 4 years old seem to include reexperiencing of the burn demonstrated in posttraumatic play, nightmares, numbing of responsiveness, constriction of play or feelings, loss of acquired skills such as language regression or toilet training if achieved, increased arousal including night terrors and exaggerated startle response, and new fears (e.g., fear of the dark or separation anxiety) or new aggression. Children may also develop language delays ([Gorga et al., 1999](#)) or attachment disorders because the traumatic event may threaten their sense of security. Some more recent studies ([Alfred, 1999](#); [Johnson et al., 1998](#); [Meyer et al., 1999](#)), but not all past studies ([Sawyer et al., 1983](#)), of very young burned children support these findings. DSM-IV-TR criteria include “disorganized or agitated behavior” in the response to trauma, and posttraumatic play, “frightening dreams without recognizable content,” and “trauma-specific reenactment” as evidence of reexperiencing ([American Psychiatric Association, 2000](#)).

PTSD has been little studied with burned children; the largest study is a follow-up of 60 children aged 7 to 19 years with mean burn size of 38% body surface area (F.J. Stoddard, J.M. Murphy, L. Rizzone, 1994, unpublished data). The findings are consistent with the investigators' earlier study demonstrating that for children with burns at various ages who were assessed when older, between 25% and 33% of children eventually develop PTSD, and more than 50% manifest “partial” PTSD ([Stoddard et al., 1989a](#)). Although it may be surprising that the rates are not higher, these prevalence rates are consistent with other studies of burned children and adults. [Kravitz et al. \(1993\)](#) have consistent findings, with a similar incidence of sleep disorders. They studied sleep disorders in 82 children (mean duration after burn, 7.3 years), 41 boys and 41 girls, with a mean burn size of 44% (range, 2% to 91% of total body surface). They found that a subgroup of 30 children reported nightmares. Of the 55 reporting dreams, 45 reported normal childhood topics, six reported burn injury–related topics, and five related burn treatment–related topics. Some of the “normal” topics may be burn related also, such as monsters, kidnapping, being killed, scary movies, dying, being locked up, parents dying, or a sibling harmed. Topics clearly related to the burn were reliving of the event, smelling smoke, dreaming of others who died in the fire, and screaming “Fire.” Topics related to treatment included pain from dressing changes, anesthesia induction, fear of dying in the operating room, dreaming that scars are gone, and fearing a burned hand will be amputated. In that study, nightmares involved clear disorders of arousal with screaming, thrashing, sweating, and yelling. They found sleepwalking in 7% of the children. Similar to [Stoddard et al. \(1989a\)](#) and [\(1989b\)](#), these investigators found a history of enuresis in 24% of the children studied. The outcome of untreated PTSD after burns is not yet known, although studies suggest some attenuation of symptoms after the first few months.

### Psychotherapy

Ongoing psychotherapeutic intervention, with brief focused visits, is directed toward emotional adaptation to the burn and posttraumatic symptoms. This treatment may reduce symptoms without medication. Parents and family are essential participants. Psychotherapy should combine developmental psychodynamic principles, eliciting the patient's narrative when feasible, educating about what to expect in burn treatment, and supporting positive coping. Although cognitive–behavioral therapy has been used for pain ([Lasoff and McEttrick, 1986](#); [Kavanaugh et al., 1991](#)) but not yet formally for PTSD in burned children, the principles of cognitive–behavioral therapy for PTSD such as anxiety management, exposure-based interventions, coping with anger, and cognitive restructuring form the core for the practice of cognitive–behavioral therapy with burned children with PTSD ([Deblinger et al., 1990](#); [March et al., 1998](#); [Solomon et al., 1992](#)). PTSD is not the only mental disorder afflicting burned children, and psychotherapy may focus on comorbid disorders, such as phobia, depression ([Stoddard et al., 1992](#)), enuresis, or behavior disorders. Sleep disorders may be aggravated by itching, and in addition to antihistamines, massage may have a useful role. Massage therapy relieved pain, anxiety, and itching in an outpatient study of 20 adults by [Field et al. \(2000\)](#), but this has not been formally studied in children.

### Psychopharmacology

In addition to pain management, psychopharmacologic treatment may begin unless there are contraindications because of the patient's critical condition ([Marshall and Pierce, 2000](#)). Several agents are in common use in patients with burn injuries, particularly benzodiazepines. The introduction of short-acting parenteral agents, such as midazolam and lorazepam, made it feasible to target anxiety symptoms without the chronic sedation caused by diazepam and to monitor symptom ratings in response acute interventions. As a result of treating anxiety as well as pain, it is clear that one can trigger, reinforce, or exacerbate the other. Although some

researchers question the use of benzodiazepines for patients with PTSD, both the critical care literature and broad experience with injured patients suggest that short-acting benzodiazepines are very effective acutely in reducing stress, and they may improve outcomes ( [Stoddard et al., 1997](#)). For very severe confusion, anxiety, agitation, or aggression that can accompany delirium, panic, or PTSD, antipsychotic agents, such as haloperidol or (if oral medication is possible) risperidone, may rarely be indicated. Depression is often comorbid with PTSD in injured patients. Most acute depressive symptoms are responsive to supportive psychotherapy alone. SSRIs are often contraindicated because of drug interactions (P-450 enzyme blockade) in early acute care, but not always for smaller burns. Some patients are diagnosed with acute depression early in treatment, and delay in instituting psychopharmacologic treatment may slow recovery and participation in physical rehabilitation. Although a pilot study demonstrating effectiveness of imipramine for ASD is one of the few psychopharmacologic studies in acutely burned children, indications for its use are limited ( [Robert et al., 1999](#)). Strengths of imipramine are that this one agent may reduce pain, ASD, PTSD, insomnia, and enuresis. Liabilities include risks of hypotension, which we have seen in young children, and cardiac arrhythmias ( [Biederman, 1991](#); [Biederman et al., 1995](#)). Although the risks may be low, SSRIs offer many benefits with little risk, and for this reason they have displaced tricyclic antidepressants in psychopharmacology. The SSRIs in common use for depressive diagnoses or PTSD include sertraline, fluoxetine, and others ( [Hughes et al., 1999](#)). Other potentially beneficial agents include clonidine and  $\beta$ -blockers.

## EFFECTS ON PSYCHOLOGICAL DEVELOPMENT

### *Psychological Interventions*

**Individual Therapy.** There is a shift from the acute into the intermediate phase once survival is ensured and most burn wounds are grafted, although the patient may not be ambulatory. During this period, it is possible to assess mental status more fully and to begin differentiating issues of mourning the prior body image, grief over loss of loved ones, depression, and PTSD. In addition, assessment and diagnosis of neurologic or preexisting psychiatric impairment become feasible. The child's or adolescent's emerging awareness of their functional losses and cosmetic disfigurement are eased by responsive staff and supportive, informed family members. "Healing well" or "looking good" surgically does not mean that the child or parent will see the raw wounds or new grafts in the same way, especially if they expected a return to previous appearance. When a child requests a mirror, the curiosity and emerging self-awareness about facial burns and appearance can unsettle a nurse or parent and can lead to the question whether the child is ready or may react with too much anxiety or depression. Although each situation must be individually assessed, in most cases children benefit when such requests are honored, but with exploration of their expectation and adequate support and explanation nearby when they first view themselves. Modes of intervention usually include brief consultative checks, and, for those in most distress, several sessions of 15 to 30 minutes per week focused on the issues mentioned earlier as well as preparation for forthcoming surgery, return to home and school, and rehabilitation.

**Family Therapy.** Adaptation of the parents and family usually follows the course of the child's recovery. Remarkably similar feelings and defensive responses are observed in the child and family. Psychotherapeutic support, especially regarding guilt feelings, and grief work with parents, often in several sessions per week, during the intermediate phase assist the parents and enable them to support the child's coping through this phase ( [Kaslow et al., 1994](#)).

**Group Therapy.** Some hospitals with many burned children provide groups varying from brief psychotherapy to education to rehabilitation. At the Shriners Burns Hospital in Boston, three types of group interventions have been used. I have conducted an inpatient *children's group* with a resident, nurse, or teacher, for children 2 to 12 years old, which varies from preschoolers to school-age children to preadolescents, depending on which children are in the hospital. This is a semistructured play group in which children introduce themselves, say why they are in the hospital and how they were burned, play with puppets and toys, draw, and then clean up the toys and prepare to say good-bye. The children readily express their feelings and fantasies in displacement to the consistent "Curious George" puppet, who, while a troublemaker, is very curious about the children's puppets' understanding of their burns, pain, surgery, dreams, scars, peer ridicule, and other issues. Although children are hesitant to participate at first, they become attached to the group. When they are again readmitted, they ask for the "children's group"; once they become adolescents, they remember it with a smile because they usually enjoyed it despite occasional painful topics. An *adolescent group* for hospitalized adolescents and a *parent group* for parents of acute patients are also provided, to focus on education about treatment, grief, response to hospitalization, surgery, stigmatization, family and school issues, and discharge and reentry issues. In England, [Rivlin et al. \(1986\)](#) conducted similar groups, which the parents rated as helpful, using a multidisciplinary approach.

### *Indications for Transfer to a Psychiatric Inpatient Unit*

The hospitalization for burns may be the only opportunity for skilled psychiatric diagnosis and the initiation of appropriate psychiatric treatment. Transfer or commitment to an inpatient psychiatric treatment unit is rarely necessary for children and adolescents (after acute and intermediate treatment) who are suicidal, violent, severely depressed, or who fail to respond to consultative psychiatric treatment in the surgical setting. Psychiatric inpatient units require consultation regarding burn-related psychopathology, and they benefit from burn surgical and nursing consultation regarding any remaining wound care and surgical follow-up.

## Rehabilitative Phase

### *BODY IMAGE AND PLASTIC AND RECONSTRUCTIVE SURGERY*

After the child has survived and healed from the burn, the child's surgical follow-up care is transferred to the plastic and reconstructive surgeon, if not previously involved. The acute surgical service and plastic and reconstructive surgical services are often linked, and this assists transition from one to the other ( [Chedekel et al., 1998](#)). The child psychiatrist and mental health team learn through their patients and the plastic surgeons about the various surgical and nonsurgical options available for scars, disfigurement, functional impairment or loss, and amputations. Plastic surgeons of necessity develop psychological skills in evaluating burned patients and may seek psychiatric consultation for some cases ( [Goin and Goin, 1981](#)). Because much of acute treatment, even with recent changes, is outside the control of the child and family, a central psychological goal at this point in care is to increase the child's and parents' roles in the choice of treatment, its timing, and the long-term plan. Although staff responses assist the patient in seeing himself or herself anew ( [Solnit and Priel, 1975](#)), the consultant in turn, through the eyes of the child, becomes aware of the experience of being burned.

### *Seeing Through the Eyes of a Burned Child: The Developing Body Image*

Interviewing a burned child and observing the child's play provide a window on the child's body image development, the interference in that development caused by the burn and painful treatments, and, usually, the psychological adaptation and recovery that follow. The early concept was summarized by Fenichel as "the sum of the mental representations of the body and its organs, the so-called body image, [which] constitutes the idea of I and is of basic importance for the future formation of the ego" ( [Stoddard, 1982b](#)). A more contemporary definition derives from the functions of body image and the developmental levels at which it operates ( [Shontz, 1974](#)). The functions it serves are sensory register, instrument for actions, source of drives, a stimulus to the self (as in arousal, pain, and proprioceptive experiences), a stimulus to others (appearance identifies attractiveness or can be a stigma), an expressive instrument, and a private world. Disorders may occur at any cognitive level of body image experience including body schemata, body self, body fantasy, or body concept, and there are associated defense patterns and symptoms. Parental and peer attitudes toward the child's physical defects help to shape body image development. Some scarred persons have no disorder of body image, whereas others with little or no scar may have significant body image disorder (body dysmorphic disorder, in which there is no necessary relationship between external appearance and internalized body image).

The issue of "how first was the body imaged?" is of practical relevance in the care of burned children. Research on infancy ( [Chapter 22](#)) pertains to the impact of burns on children from birth to 3 years old and on older children. Intricate attachment processes begin prenatally and continue seamlessly in the mother-child relationship after birth. Observations reveal that a burned infant is emotionally traumatized in the following ways: pain is felt and localized, the sense of safety and security in attachment to the mother is threatened or even shattered, and the recovery from that experience or those experiences depends on the reestablishment of the attachment and the signs of responsivity present before the burn. What does this imply for body image development? A disturbance results from disruption of the protective mother-infant dyad for development of body image with its attendant affects and relational interactions. Such a disturbance may constitute an early disorder of body image. That appears in behavior as follows: increased helplessness, sleep and feeding disturbances, and affective withdrawal in infants; social restriction and loss of acquired skills in the toddler; and problems in development of control over new fears and other feelings in 2- to 3-year-old children, such as aggression, problems with excretory functions, nightmares, play constriction, and play reenactment of the burn trauma or burn treatments ( [Scheeringa et al., 1995](#)).

Hospitalization for a burn is often an early separation experience, which reveals the child's capacity to form and be consoled bodily by transitional objects, including a father or nurse who may represent a transitional relationship or surrogate. The capacity to create such relationships bodes well for the prognosis of the child and resembles hypnosis in its intensity and capacity to soothe. Body image is a relatively stable part of the self-concept by age 2 to 3 years and is modified by growth, puberty, trauma, and aging. Burns in childhood and adolescence may leave an emotional scar as well as the physical one and may profoundly alter the subsequent

body image, self-esteem, and interpersonal relations as well as ego functioning. Body image development is affected by gender, parental support, medical and surgical care, and developmental changes in adolescence ( [McQuaid et al., 2000](#)). However, body image disturbance may not be inevitable, as suggested by a study of children ages 5 to 15 years with matched controls using human figure drawings, which did not find significant differences in body image, except for increasing body image disturbance in both burned and unburned adolescents ( [Jessee et al., 1992](#)).

A change in the child's body image and associated feelings such as sadness, shame, or pride may be seen in self-portraits ( [Fig. 99.2](#), [Fig. 99.3](#) and [Fig. 99.4](#)). In addition, body image revision occurs through plastic surgery and often allows another stage of reintegration of body image and optimally a degree of healing of the prior damage to appearance and self-image. Focused short-term supportive and educational psychotherapy is helpful, and there are protocols for short-term therapy addressing body image issues such as coping with stigma and learning to manage staring or teasing and other reactions to facial disfigurement ( [Pruzinsky and Doctor, 1994](#); [Robinson et al., 1996](#)). Scales to assess satisfaction with appearance are available ( [Lawrence et al., 1998](#)).

**Figure 99.2.** Portraits, including self, by a facially burned girl.

**Figure 99.3.** Accurate self-portrait by boy with severe burns with his hand surgically attached to his groin during a phase of a reconstructive procedure.

**Figure 99.4.** Self-portrait by boy with facial and hand burns.

#### *Psychological Trauma: Burns, Body Image, and Reintegration*

Facially burned persons have become commonplace on television, in movies (*Nightmare on Elm Street*), and in plays (*Phantom of the Opera*), but only occasionally with compassion or explanation, and most commonly in horror films. An exception is an award-winning pediatric film by Andrew Maguire, *Here's Looking at You, Kid*, a documentary about a boy with facial burns and his and his mother's experiences afterward. Television and film have familiarized the public with scarring from burns. Notwithstanding, or sometimes because of, publicity, children are subjected to ridicule with epithets such as "monster," "French fry," and "Freddie Krueger." Clear explanation by children with burns to peers about their injuries and unequivocal leadership and support by teachers and parents directly addressing such problems may reduce the frequency of these attacks.

---

#### CASE ILLUSTRATION: Sibling Stigmatization Reduced by Outreach to the School

Paul is a Caucasian boy who sustained deep, full-thickness burns over 90% of his body, an inhalation injury, and renal failure at age 19 months in a house fire, and he survived only because of heroic measures and 6 months of hospitalization. Three years later, his older brother, Bobby, was brought to a local clinic by his mother because Bobby was being isolated by his peers and had been beaten up severely by neighborhood boys who ridiculed him because his disfigured little brother "was a monster." Bobby was fighting with his peers about this and at the same time deeply resenting Paul and all the special attention he had received. Their mother felt helpless and sought child psychiatric assistance after Bobby slammed the door on Paul to prevent children who were passing by from seeing him. In addition to caring for Paul, this single mother on welfare was caring for younger twins requiring constant medical care for respiratory distress syndrome. They lived in a tough, low-income, suburban neighborhood.

The clinic child psychiatrist, together with the special education outreach team from the hospital and Bobby's school, arranged a school outreach presentation about burns, disfigurement, and burn prevention. The hospital teacher, who conducted the presentation, told a special assembly of 300 first and second graders and teachers how Paul had survived almost miraculously through use of skin grafts. She also explained about "same and different" using *We're Different We're the Same* and illustrated that M & M candies are different colors but taste the same. She emphasized how different each child's feelings may be and "what it feels like to be teased." She reported that the faculty and students were very receptive to her presentation and that Bobby's class looked forward to helping Paul feel welcome when he entered school next year. The boys' mother soon reported that children were now coming to their house to visit the boys, and they looked forward to coming to Bobby's birthday party, whereas before, none of the children had socialized with them at all.

---

MacGregor and Bernstein reported that social isolation or *social death* was common among the severely disfigured ([Bernstein, 1976](#)). More recent studies do not confirm this finding, at least in the United States, and this may mean that they and others succeeded in helping to lessen the stigma of burns by stimulating improved surgical and psychological techniques and by advocating vigorously for equal social, educational, and occupational opportunity. However, social stigmatization is prevalent in cultures where disfigurement is seen "as a form of punishment. The individual with disfigurement, his or her family, or an ancestor, according to the particular belief system, has been either cursed by God or the Gods, sinned or violated a taboo. . . . Others may seek to distance themselves from those who have incurred such 'evil' " ([Groce and Zola, 1993](#)).

*Note to the Reader: Figure 99.5, Figure 99.6, Figure 99.7, Figure 99.8 and Figure 99.9 are included not to offend but to inform and usefully prepare the consultant for feelings associated with seeing and talking with burned children. Most burns are much less severe. Although such images are seen in surgical texts or on rounds, they are rare in psychiatric writing. The reader may progress through feelings of shock, revulsion, disgust, sadness, and even despair on viewing them—all normal reactions of new staff on ward rounds, and these are reactions that scarred children and adolescents also experience from others at home, school, and, at times, in intimate relationships. Consultants may feel at first unable to comprehend or discuss these kinds of injuries or disfigurements, which many children and families survive and cope with effectively. Being able to discuss the appearance of burn wounds and scars is a key consultative step in helping burned children to find words for their suffering and how they look. These cases all demonstrate positive emotional recoveries that are common today after severe burns. Such pictures are “dehumanized,” standing alone, and, therefore, more upsetting than talking with the child. A child psychiatry fellow, completing his 3-month rotation, observed thoughtfully that he no longer “sees,” that is, reacts to, the scarring because he relates to the children as people. This gradual adaptation is a common experience among burn unit staff.*

**Figure 99.5.** Facial burns before and after reconstructive surgery in a girl at ages 6 and 16 years.

**Figure 99.6.** An 8-year-old girl, who became a pianist, with healed hand burns, amputated digits, but no reconstruction.

**Figure 99.7. A:** Healed breast burns in a 14-year-old patient. **B:** Breasts being reconstructed through use of tissue expanders (balloons inflated with saline). **C:** Postoperative result at age 15 years, after reconstruction.

**Figure 99.8. A:** Burn to the penis in a 3-year-old boy. **B:** His healed perineal scar at 15 years, with full recovery of function.

**Figure 99.9.** Burn causing severe genital and leg scarring in an 8-year-old girl who had no reconstruction, accepted her scars with the help of supportive parents, and later married and gave birth to a child.

**Figure 99.9.** Burn causing severe genital and leg scarring in an 8-year-old girl who had no reconstruction, accepted her scars with the help of supportive parents, and later married and gave birth to a child.

One need only see a child with facial burns ([Fig. 99.5](#)), amputated fingers ([Fig. 99.6](#)), and breast ([Fig. 99.7](#)) or genital scars ([Fig. 99.8](#) and [Fig. 99.9](#)) to appreciate some of the damage to appearance and to internalized body image, as well as the suffering endured, and to realize how irrational thinking and prejudice can be elicited in response. Yet burn treatment and subsequent plastic and reconstructive surgery are remarkably effective in preserving life, in reducing suffering, and in restoring appearance and function. Burns do not inevitably cause psychopathology, but they can, especially in vulnerable children whose burn care and familial support do not meet their emotional needs.

#### HOSPITAL READMISSION FOR PLASTIC AND RECONSTRUCTIVE SURGERY

What are the key questions in child psychiatric evaluation before plastic and reconstructive surgery? What issues are involved perioperatively? Of primary importance are *secure relationships* with the family and with the doctor and treatment team. Another factor is the *capacity to tolerate fear and anxiety* associated with rehospitalization. Other factors involve the *results of preparation and consent for surgery*: (a) realistic awareness of scars and functional impairments, that is, the indications for surgery; (b) the child's wish or willingness to have the surgery at this time; (c) the parents' wish for the child to have surgery at this time; and (d) understanding of the procedure and the capacity to communicate it. It is essential for the consulting psychiatrist to ask the surgeon what the surgical procedure will be, how much time it requires, and what the expected usual emotional and physical sequelae may be. Anxiety often blocks a child's understanding, and multiple explanations may be necessary. If there is significant psychopathology ([Table 99.1](#)), review of records and preoperative assessment are indicated to reduce complications. Suicide is very rare in patients who were not suicidal before the burn injury ([Stoddard, 1993](#); [Wiechman et al., 2000](#)), and the rate appears to be the same or less than in the general population. However, screening for suicide risk is important in all cases of depression and also for those enduring long, stressful, or potentially disfiguring procedures or complications. On occasion, a child will refuse surgery at the operating room door because of acute anticipatory anxiety. This will often have a basis in reality, such as prior serious operative complications or having witnessed those of another patient. Emotional support and benzodiazepines given early often relieve this anxiety, while one makes certain that the child participates in choosing "if, when, and what" surgical procedure to have if the child's wishes were not a part of the original decision. Other preoperative problems include unrealistic expectations of "perfect" surgical results, embarrassment or shame related to severe disfigurement, and resurgence of PTSD symptoms such as flashbacks or nightmares. Supportive, reality-oriented preoperative psychotherapeutic interventions usually allow the patient to cope and progress with a reasonable and hopeful attitude toward surgery.

To perform a psychiatric consultation, some understanding of the surgical procedure—whether it is standard or newly developed—is essential ([Feldman, 1984](#); [May and Moses, 1988](#); [Salisbury, 1992](#)). This includes split-thickness skin grafts and releases of contractures and such dramatic advances as facial resurfacing, restoration of scalp and hair with scalp expanders and flaps, laser surgery, microsurgery to the hand with reconstruction of usable opposition and other digits, breast reconstruction with or without expanders or implants, amputations and prosthetic placement, and even penile or scrotal or vaginal repair or reconstruction. The reason for a consultation, although seemingly broad, often narrowly concerns the patient's reactions to a recent surgical procedure and its success or failure in the child's, parent's, nurses or doctor's eyes. Children undergoing such procedures benefit from psychiatric consultation, reassessment, support, and, at times, treatment.

#### SEXUAL DEVELOPMENT

As children with burns approach and pass puberty, they, like others their age, become more concerned with attractiveness, loving and being loved, and sexuality. Their sense of self is revised, and some become very self-conscious, covering their scars and avoiding being seen in public such as in locker rooms and beaches. Others become counterphobic and may be promiscuous or abuse substances in an effort to cope with conflict over self-image and self-esteem. Their requests for surgery involve wishes to appear normal, such as to repair scalp scars and have normal hair, to have asymmetrical breasts repaired and made symmetrical ([Fig. 99.7](#)), or to repair a facial scar that may cause peer ridicule. Most adolescents, including those with genital burns, which usually heal well ([Fig. 99.8](#) and [Fig. 99.9](#)), become sexually active, and many become parents. Finding a supportive partner, accepting of their burn injuries, aids in sexual adjustment ([Fig. 99.9](#)). Some studies indicate that women with burns have a lower level of sexual satisfaction than men, but this was not found in a small study of adolescents ([Robert et al., 1998](#)). Continued individual, family, and group psychotherapy assists with difficult personal, sexual, social, educational, and occupational transitions. Those who have not had such services or who live far from the centers where they are available may benefit from burn camps in their region ([Doctor, 1992](#)). Although some of these adolescents are followed in medical centers for plastic and reconstructive surgery, many do not receive counseling to assist them emotionally or with education about drugs, contraception, HIV, childbirth education, or parenting skills.

Since the 1980s, most centers have provided "reentry programs" after discharge through the hospital social service, special education, and other departments to assist with prompt return to school of burned children after discharge, rather than home tutoring, which was formerly common and increased morbidity and social isolation. This often involves school outreach educational programs to reduce peers', parents', and teachers' fears of disfigured children and to support reentry. This support is essential for some children, especially those with facial disfigurement, to return to school and to begin effective rehabilitation.

### LONG-TERM TREATMENT

#### Psychological Interventions

##### INDIVIDUAL THERAPY

Many children are not seen for psychological follow-up after their acute burn injury. This group may be most likely to have unexpressed feelings that may shape development, influencing avoidance behavior, and, in some cases, learning problems, phobia, or depression. The most common psychiatric consultations are in plastic surgical clinics, during rehospitalization, or in groups. These medically oriented follow-ups address specific burn-related concerns and encourage the child's and family's mastery over new, often developmentally related issues. Collaborative long-term monitoring with plastic surgeons is indicated for at-risk children. Referral to outside agencies is necessary for those with emotional difficulties or who require psychopharmacologic treatment. A few patients receive long-term weekly insight-oriented psychotherapy. Those therapies are directed toward enhancing self-esteem, body image, interpersonal relatedness, and autonomy, and this often occurs for children who are separated from or have lost their parents. On request, mental health teams at regional burn centers can provide supervisory guidance to therapists in distant locations who are unfamiliar or uncomfortable treating children who have been burned.

##### FAMILY THERAPY

Parents and families may be at greater risk of impairment than the children themselves. Siblings are at increased risk because attention is diverted from them to the burned child, and some siblings share responsibility for the burn. Parental guilt for the injury is a most painful, persistent emotion. Parents often blame themselves rather than attributing a burn to fate or the improbable. Although this defends against feelings of helplessness, it creates a diminished sense of worth as a parent ([Cahners and Kartiganer, 1990](#)). Guilt impedes coping and parental emotional recovery. [Cella et al. \(1988\)](#) find a high rate of depression in mothers years after the burn injury. [Rizzone et al. \(1994\)](#) find an incidence of PTSD of 52% in mothers of burned children, which is higher than that in any study of children or adults with burns. [Meyer et al. \(1994\)](#) find increased stress in mothers, a finding correlating with increased stress in their children who survived burns and in earlier studies that family support and the family value of autonomy are critical to the child's adjustment. [Fukunishi \(1998\)](#) has similar findings with mothers of scalded children. Over many years, parents seen during follow-up clinic visits in group are able to benefit from catharsis and mutual support in outpatient parent groups focused on relief of anxiety and guilt feelings, grief work, feelings about the scars, and improvement of family coping skills. Parents who are in fact responsible for the burn may suffer severe guilt and may be even more difficult to help through this trauma.

##### GROUP THERAPY

In some clinics and camps, groups are led by social workers, psychologists, or child psychiatrists. For instance, a weekly outpatient *group* for 13- to 21-year-old patients provides support for teenagers as they return and focuses on their family lives, body image, peer relations, school, drugs, sexuality, and choices for surgical reconstruction or the specialized cosmetics available. Social workers conduct *groups for parents* addressing how to parent a burned child, guilt, grief, assistance with feelings about plastic surgery, rehabilitation issues, resolution of unrealistic expectations from surgery, and help with referrals to social, educational, or occupational resources in their areas. Salient information from the groups is shared in weekly psychosocial rounds. Social workers and volunteers have also used self-help groups by mail and by telephone.

## Psychopharmacologic Treatment

During readmission for plastic and reconstructive surgery, other indicators for psychopharmacologic treatment are anxiety disorders, anticipatory phobic reactions preoperatively, PTSD, depression, attention deficit hyperactivity disorder, and enuresis. Treatment is based on the diagnosis differs little from that in outpatient psychopharmacology clinics. Agents include the full range of stimulants, anxiolytics, antidepressants, mood stabilizers, and antipsychotics. Because enuresis is common among burned children, behavioral interventions and the bell and pad are the initial interventions, but intranasal aqueous vasopressin and imipramine are also treatment options. Skin rashes, which can be caused by any drug, have the potential of complicating burn care and should be monitored.

## OUTCOME AFTER CHILDHOOD BURN INJURIES

This is a challenging subject for review. There are many small studies varying in quality and a few larger ones. The quality of burn and reconstructive treatment has improved since the mid-1970s, and this makes earlier studies invalid in predicting outcomes for recently treated children and young adults. There are two viewpoints on the outcome data: [Tarnowski et al. \(1991\)](#), in their review, assert that “collectively, findings indicate that there exists little empirical data to support the contention that the majority of pediatric burn victims exhibit severe poor post-burn adjustment,” and [Blakeney et al. \(1993\)](#) essentially agree. The current longitudinal study of [Saxe et al. \(1999\)](#) confirms and extends our earlier findings regarding high lifetime occurrence of ASD and PTSD. My colleagues and I ([Murphy et al., 1989](#); [Stoddard et al. 1989a, 1989b](#)), in a cross-sectional follow-up study of severely burned children, found that a majority of children manifested mental disorders (anxiety including PTSD, depression, disruptive behavior, enuresis), and 20% had no disorders; although some disorders existed before the burn injury, the study's aim was to identify disorders at the time and not to differentiate preburn and postburn psychopathology. In this study, although lifetime prevalence of psychopathology was high, it was low at long-term follow-up. No other study of burned children has used comprehensive structural diagnostic interviews. The longitudinal follow-up study by [Blakeney et al. \(1998\)](#) of children surviving burns over 80% of their body surface area found adjustment within the “norms” for most of the group, but not all. Even using the review by Tarnowski et al., these authors' assertion is premature that few data support severe postburn adjustment, and it may depend on what is considered “severe.” Many studies ([Table 99.4](#)) have found symptoms of postburn anxiety, depression, and behavior problems. Several found burned adolescents to be especially vulnerable to depression, but this is true of the adolescent population at large as well. Several, but not all studies, have found positive correlations between psychopathologic symptoms and visible disfigurement (especially facial) and the size of burn injury. Although several studies are satisfactory, few are excellent. There is need for longitudinal research with structured diagnostic interviews, not only mailed surveys, and large sample sizes including large and small burns, matched controls, and especially inclusion of surgical, psychological, and other treatment variables.

**Table 99.4. Outcome Studies of Burned Children**

What are the likely explanations for somewhat conflicting findings regarding outcomes? First, *preburn psychopathology* does not disappear after the burn injury, but it is difficult to measure reliably retrospectively: It is rarely reported. Second, *selection bias* is present in many studies, and it is difficult to eliminate in tertiary referral centers. Third, *many common instruments do not provide diagnostic data on mental disorders*. Fourth, *other pediatric handicaps and chronic illnesses* have been shown to be associated with increased psychopathology ([Perrin and MacLean, 1988](#)), and this could be true for burns, as our outcome study suggested. Fifth, *treatment interventions of all kinds are rarely described and their effects analyzed*.

## DEATH OF A CHILD

A child's death from burns is a most tragic loss of life resulting from a usually preventable injury. End-of-life care should be planned with the burn team for any critically burned child ([Schnitzer et al., 2000](#); [Stoddard and Saxe, 2001](#)) ([Chapter 104](#)). Parents and family members may have little preparation if the death occurs quickly, as it can from massive burns, respiratory burns, or sepsis. Their grief can be almost unbearable, and the presence of empathic staff members is especially consoling. When there is more time for parental participation and preparation, such as in cases of slow brain death, the grieving process can proceed in stages. Sensitive emotional and ethical ([Chapter 104](#)) issues arise with consent for do-not-resuscitate orders and organ donation, as reuse of body tissues for transplants increases ([Fratianne et al., 1992](#); [King et al., 1993](#); [Hammond and Ward, 1989](#); [Petro and Salzberg, 1992](#)). Such decisions are made with the burn team, led by the surgeon, together with the family. The burn team, supported by the mental health team, provides much needed support after the death to the grieving family and assists with their transition to gaining support from friends and community. Follow-up, by the attending surgeon and social worker, is sustaining to the family both soon after the death and on monthly follow-up consultations and anniversaries. Other children and their parents present in the burn unit may react with alarm, sadness, somatization, posttraumatic play, and fear of their own death. Sensitivity and developmentally appropriate responses to the child aid their coping with yet another unexpected trauma.

## STAFF SUPPORT

The burn unit is a most challenging place to work, and psychiatric consultative skills are highly valued. An understanding of consultative principles, models, impediments, and process is useful before initiating consultation ([Lewis, 1994](#)). Witnessing horribly injured children, seeing, smelling, and touching their burned flesh, and causing pain as part of treatment for an infant or child may evoke anxiety, sadness, and guilt, but also satisfaction and pride in providing needed treatment to an injured child ([Ravenscroft, 1982](#)). Turnover can be frequent in stressed units, but it is reduced by appropriate administrative leadership and staff support, and loyalty develops. Although some units may appear focused on technology to the exclusion of feelings, women physicians in all specialties as well as women in allied professions have contributed to a greater focus on emotional sustenance of both children and staff. The burn unit offers unparalleled opportunities to learn, provide treatment, and teach in areas such as pain, stress, grief, healing, consultation, and diagnosis and treatment in the acute care setting.

The aura of the burn unit is special and, for many, intimidating at first. Strong staff cohesion may make the burn team like the elite “Marine Corps” or battlefield station of the medical center, with a staff “tough enough” to treat such severe, frightening injuries. The image of the patient in the burn unit is of a “monster,” frightening to see and whose handicaps can be crippling—an image at great variance from the real child who speaks, feels, creates, and has relationships, whether with minimal or extensive scarring. Other scary images associated with the burn unit are of death and burning in hell, but also more hopeful ones of rebirth, as in the phoenix rising up from the ashes. The surgeon and others on the team may be both pitied (“how can you stand to work there?”) and idealized as a superhero, savior, or god invested with the magical powers of healing science.

## Entry by New Staff

Arrival at the burn unit may be a culture shock for doctor, nurse, patient, and family alike. New staff, trainees, medical students, and graduate students alternately tend naturally to withdraw emotionally or to identify with the child's suffering, at times overly so. For example, a new researcher said of a boy with massive healed burns, “He must be in so much pain.” On being asked about it later, the boy said that he had no pain and was only concerned with his computer game. There is a usual sequence of emotional adaptation after arrival on a burn unit: shock and dismay, curiosity and fear, frustration and helplessness, and sadness with often persistent feelings and images on return home, appearing as anxiety dreams, and even for some, a questioning of professional identity and goals ([Jellinek et al., 1993](#)). [Bernstein \(1976\)](#) pointed out how the feelings of shock are often adaptive and mobilize staff to use their skills on behalf of the patients and thereby to master their

fear, frustration, and sadness.

When new staff members arrive, it is helpful when they are prepared to expect feelings such as those mentioned earlier. One resident said how it had helped to have heard from me that I, too, even after many years there, feel the stress of the burn unit. It is also helpful to them to know that the feelings of horror wane as they come to know the children and their families and join the burn team, enhancing feelings of competence. Knowing about the usual course of the three phases postburn (acute, intermediate, recovery or rehabilitative) is a hopeful approach in the presence of such stress. They learn, too, that preparation of patients and families for these phases assists in their transitions and hopefulness. Further, it is helpful to provide assurance that mentors are available to listen and provide validation or advice when needed.

### Teaching Empathy

The psychiatrist and other mental health professionals demonstrate listening skills, communication, compassion, reflection, and constructive therapeutic action. Sensitivity to shame and embarrassment ([Lazare, 1987](#)) during rounds when the children's or adolescents' bodies are exposed to groups of staff, or where discussions may be overheard, is crucial to prevent humiliation or involuntary exposure to unwelcome information. It is important to encourage empathy in those "stepped" against feelings and also to convey understanding of inevitable overidentifications with children or their relatives, who evoke feelings reminiscent of their own children, families, or of their own life experience. Such transference and countertransference experiences are frequent, and supervision and experience can assist with these intimate feelings. For instance, a primary nurse transiently wept with grief over the suffering of a child to whom she had to cause pain. This child reminded her of her own, and she was grateful to share her feelings off the unit and then return to her work. In another instance, a doctor became the target of much fear, blame, and rage over a child's disruptive behavior and had to voice his feelings of frustration, despair, and inadequacy before resuming his work. Others can be less aware of their feelings and may act them out within the clinical situation or at home. Such feelings are easily aroused when parents' rage is evoked, when disruptive boys resist helpful nurses and insult them, or when staff members are in conflict over what course of action to take, such as with critically ill or dying children. In such situations, group consultation is most effective ([Jellinek et al., 1993](#)).

### Staff Consultation

The presence of the psychiatrist validates attention to emotional and diagnostic and treatment issues that may otherwise be avoided, often with adverse effects on patient and family care and staff morale. An overall goal is to support staff cohesion and prevent burnout, which may be more likely for staff in burn units and may relate to individual coping skills or "hardiness" ([DePew et al., 1999](#)). A working alliance and frequent communication with the surgical and nursing directors are important for effective consultation. Scrubbing and gowning and entering isolation areas or the operating room convey a willingness to talk with the patient or surgical staff "where they are." The consultative approach is ideally informed, consistent, flexible, and responsive to the situation. Admitting ignorance, reviewing the cases, and helping implement constructive recommendations are effective ways to join the burn team. The consultant models developmental and family assessment skills, and respect and advocacy for children, because surgical trainees may have limited experience with infants and children.

In the situations of staff conflict, various interventions are possible. The psychiatrist reflects on his or her own feelings and realizes that another team member reacts similarly, sometimes also carrying home feelings of fear, helplessness, or dread at returning the next day. Although the ultimate responsibility for treatment is the surgeon's, the spoken or unspoken burdens are shared with nurses, who are often "in the middle" ([Jameton, 1992](#)), and with all other staff. The nurse is more likely to know the child's situation but may feel conflict between duty and irritation when decisions are made or not made that do not agree with her or his sense of what is good care. Routine teaching rounds, psychosocial rounds, or informal or formal acute or plastic surgical rounds, separately or in combination, may be effective for "venting" feelings and working through the issues. Support groups for nurses or other staff members are held to discuss and process stress and morale issues together. The primary nursing management system seeks to achieve that aim within the nursing care team.

Communication is enhanced in many ways. Because consultation is rarely continuously available, staff is sustained by knowing when the consultant is available and the times of next meetings. Crises call for special meetings, including surgeon, nurse, and consultant, the other involved team members, and at times the family and patient. Respect for defenses, which can interfere with empathy, but which are necessary for staff to cope, is important. Defenses include denial, transient regressions, distancing from the situation, and overinvolvement and are often bridged by more senior members of the burn team who help master the situation. Having the psychiatrist on the team "puts behavior into a positive developmental and group-process perspective. Through emphasis on the normal and expectable phases of burn trauma recovery, the usual course of burn hospitalization for different age groups, and the impact of various burn treatments on children and families with different backgrounds and styles," the psychiatrist increases levels of mental health expertise among burn team members ([Ravenscroft, 1982](#)).

### Departure from the Burn Team

When staff members leave the burn unit, their leavings demonstrate their attachment and sense of involvement. The collected staff members often tell residents and trainees in rounds how they will be missed. When seasoned senior staff members leave, the departure can be so painful that those in the unit may react wondering "how will we manage without them?" The farewells and testimonials are proof of their dedication and the appreciation for their work and convey to those who continue that their efforts are worth the hardships. Sensitivity to administrative changes, team cohesion, losses, and the staff's adaptation is useful in maintaining the consultative alliance.

## CONCLUSIONS

Burn injuries are prevalent worldwide among infants, children, and adolescents. Treatment of burns has progressed since the 1940s to a point where most children currently treated in the best burn units survive even massive burn injuries. The priorities in psychiatric care throughout the postburn phases are pain management, diagnosis and treatment of delirium, stress disorders and depression, coping with disfigurement, psychotherapeutic support for the child and family through later plastic and reconstructive surgery, and end-of-life care, including family follow-up. A reflective attitude assists the consultant's gradual adaptation to the stresses of being in the burn unit. Critical psychological interventions are infant-parent support, patient and parent education, encouraging participation by the child in burn dressing changes, aiding in school reentry, aiding in adaptation to body image change, and aiding in social mastery during stressful developmental periods such as adolescence. Rehospitalization for plastic and reconstructive surgery, although stressful, is also an opportunity for emotional processing and reintegration. The child psychiatrist and mental health team experience, along with the other burn team members, significant emotional stress and also the many satisfactions from care of children and their families in the burn unit.

#### [Conclusions](#)

#### [Chapter References](#)

The physical abuse and neglect of children and adolescents continue to be major public health problems. The latest child maltreatment prevalence data were reported by the National Incidence Study-3, which sampled child protective services, law enforcement, juvenile probation, public health, hospital, school, day care, and mental health and social services agencies for a 3-month period during 1993 ( [Sedlak and Broadhurst, 1996](#) ) and by *Child Maltreatment 1998: Reports from the States to the National Child Abuse and Neglect Data System* ( [U.S. Department of Health and Human Services, 2000](#) ), which compiled summary case data from state child protective services.

The Third National Incidence Study ( [Sedlak and Broadhurst, 1996](#) ), using a harm (injury of child documented) standard, found that physical abuse had increased to 5.7 per 1,000 (381,700) children from the First National Incidence Study (1980; [U.S. Department of Health and Human Services, 1981](#) ), when the incidence was 3.1 per 1,000 (199,100) children, and from the Second National Incidence Study (1986; [U.S. Department of Health and Human Services, 1988](#) ), when the incidence was 4.3 per 1,000 (269,700) children.

The abuse of children has been associated with subsequent emotional and behavioral problems, including violent behavior by victims. Aggressive behaviors by victims that have been reported include those directed toward others ( [Alfaro, 1978](#); [Dodge et al., 1990](#); [Herrenkohl et al., 1997](#); [Kashani et al., 1992](#); [Klimes-Dougan and Kistner, 1990](#); [Lewis, 1992](#); [Lewis, 1985](#); [Lewis et al., 1979](#); [Widom, 1989](#) ), toward other family members ( [Kaufman and Zigler, 1987](#); [Oliver, 1993](#); [Straus and Gelles, 1986](#); [Straus et al., 1980](#) ), and toward themselves ( [Deykin et al., 1985](#); [Garnefski et al., 1992](#); [Green, 1978b](#); [Livingston et al., 1993](#); [Pfeffer, 1986](#); [Rotheram and Bradley, 1987](#) ).

Cruelty toward children has been described throughout history, with children viewed as parental property ( [Wolfe, 1987](#) ). However, in the United States, medicine has focused on child maltreatment only since 1946, when Caffey described fractures of the long bones in multiple stages of healing in children with subdural hematomas ( [Caffey, 1946](#) ). Early efforts on behalf of maltreated children focused on advocating for and implementing legislation to protect children. Child maltreatment reporting laws became instituted in all 50 states.

Kempe, a pediatrician, and his colleague Steele, a child and adolescent psychiatrist, both at the University of Colorado, were largely responsible for the current focus on child maltreatment by American medicine, including psychiatry ( [Steele and Pollack, 1968](#) ). They with their colleagues Silverman, Droegenmueller, and Silver reported the *battered child syndrome* in 1962 ( [Kempe et al., 1962](#) ). However, psychiatric studies of and services for maltreated children and their families continue to remain in the early stages of development.

## PHYSICAL ABUSE

### Definitions

*Physical abuse* definitions vary according to (a) cultural practices regarding corporal punishment, (b) cultural values (i.e., privacy versus interdependence), and (c) biological predispositions, such as the higher activity levels of U.S. neonates versus Chinese neonates ( [Gabarino and Etaba, 1983](#) ). Straus and Gelles, the principal investigators of the National Incidence Studies of Violence in America, define child abuse as the use by a parent of any of the acts of the Severe Violence Index of the Conflict Tactics Scale. *Severe violence* is defined by this scale as kicking, biting, hitting with a fist, hitting or trying to hit with something, beating up, threatening with a gun or a knife, or using a gun or a knife ( [Straus, Gelles, and Steinmetz, 1980](#) ). Using this definition, [Straus and Gelles \(1986\)](#) found that 6.9 million children are physically abused each year. They also reported that 97% of children from 0 to 3 years old are physically punished.

Physical abuse has been defined by the Child Abuse Prevention, Adoption, and Family Services Act of 1988 (Public Law 100-294) as “the physical injury of a child under 18 years of age by a person who is responsible for the child’s welfare, under circumstances which indicate that the child’s health or welfare is harmed or threatened thereby, as determined in accordance with regulations prescribed by the Secretary of Health and Human Services.” Persons responsible for a child’s welfare include employees of a residential facility, any staff of a facility, or any staff providing out-of-home care. The New York State Family Court Act (1976) defines physical abuse as “the situation which results when a parent or other person legally responsible for a child less than 18 inflicts or allows to be inflicted upon such child physical injury by other than accidental means” ( [Family Court Act, 1971](#) ).

### Incidence

During 1998, there were an estimated 903,000 victims of child maltreatment nationwide. The 1998 rate of victimization was 12.9 per 1,000 children. Neglect involved 53.5%, physical abuse involved 22.7%, and sexual abuse involved 11.5% of child maltreatment victims. One-fourth (25.3%) of victims were reported as being victims

of more than one type of maltreatment ([U.S. Department of Health and Human Services, 2000](#)).

The exact incidence of child abuse in the United States is unknown, as a result of reporting biases and investigatory procedural constraints. The probability that an abuse report will be filed is increased for ethnic minorities, the poor, urban residents, and those who use public rather than private sources of health care. The ability of a child protective service to document or substantiate abuse also varies with the source of the report.

In 1998, 29.2% of investigated reports were legally documented as involving child maltreatment. Physicians' reports have been found to be most likely to be substantiated by investigatory agencies ([Eckenrode et al., 1988](#)). Sources of 1998 child maltreatment information included, in descending order, educators, legal law enforcement and criminal justice personnel, anonymous reporters, social services, relatives, physical health personnel, and mental health personnel ([U.S. Department of Health and Human Services, 2000](#)).

### Age of Onset of Abuse

Severity of abuse found by the 1993 Child Abuse and Neglect Incidence and Prevalence Study varied inversely with the age of the child victim. Most fatalities occurred in younger children ([U.S. Department of Health and Human Services, 1998](#)). [Daro and Mitchel \(1990\)](#) reported that more than 50% of fatalities involved children less than 1 year old. Child abuse involving prepubertal children is most often reported in single-parent, ethnic minority, low-income families, whereas the majority of adolescents reported as abused in the United States during 1977 were white and from intact two-parent families who earned at that time more than \$11,000 per year ([U.S. Department of Health and Human Services, 1981](#)). Fathers are more often indicated as the perpetrators of physical abuse of adolescents, whereas mothers are more often indicated as perpetrators of physical abuse of prepubertal children ([Straus et al., 1980](#)). Most studies of abuse involving adolescents report that, although such abuse sometimes begins in early childhood and is continued into adolescence, in the majority of cases the onset of abuse begins during adolescence ([Libbey and Bybee, 1979](#); [Lourie, 1979](#); [Straus et al., 1980](#)).

The onset of abuse during adolescence has been explained by [Lourie \(1979\)](#), [Libbey and Bybee \(1979\)](#), [Garbarino et al. \(1984\)](#), and [Pelcovitz et al. \(1984\)](#) to relate most often to interpersonal conflicts around adolescent developmental tasks and parental midlife crises, rather than as a result of socioeconomic stress, as is often the case with the abuse of younger children. Parental psychopathology, as hypothesized in study by the Pelcovitz et al., is an additional risk factor for abuse in families of abused adolescents ([Pelcovitz et al., 1984](#)).

### Physical Examination Findings

Every child suspected of being physically abused or neglected should be given a physical examination ([American Medical Association, 1992](#); [Kessler and Hayden, 1991](#)). The American Medical Association *Diagnostic and Treatment Guidelines Concerning Child Abuse and Neglect* ([Council on Scientific Affairs, American Medical Association, 1985](#)) state the following in terms of diagnostic physical findings: "Characteristically, the injuries are more severe than those that could reasonably be attributed to the claimed cause" ([Council on Scientific Affairs, American Medical Association, 1985](#)).

Physical signs of abuse include the following: bruises and welts on the face, lips, mouth, ears, eyes, neck, head, trunk, back, buttocks, thighs, or extremities that form regular patterns often resembling the shape of the article used to inflict the injury (e.g., hand, teeth, belt buckle, or electrical cord); burns inflicted with cigars or cigarettes, especially on the soles, palms, back, or buttocks; immersion burns (stockinglike or glovelike on extremities, doughnut shaped on buttocks or genitals) or patterned burns resembling an electrical appliance (e.g., iron, burner, or grill); fractures of the skull, ribs, nose, facial structures, or long bones, frequently with multiple or spiral fractures in various stages of healing; lacerations or abrasions; rope burns on wrists, ankles, neck, torso, palate, mouth, gums, lips, eyes, ears, or external genitalia; bruises of the abdominal wall; intramural hematoma of the duodenum or proximal jejunum; intestinal perforation; ruptured liver, pancreas, or spleen; ruptured blood vessels, kidney, or bladder; and central nervous system injuries, including subdural hematoma (often a product of blunt trauma or violent shaking), retinal hemorrhage, or subarachnoid hemorrhage (often a product of shaking) ([Council on Scientific Affairs, American Medical Association, 1985](#)).

### Etiology

The prevailing model of the origin of abuse is the ecologic model ([Belsky, 1980](#)), which views child abuse as the consequence of the interactions of parental vulnerabilities (mental illness, substance abuse), child vulnerabilities (low birth weight, difficult temperament), a particular developmental stage (adolescence, toddler), and social stressors (lack of social supports, poverty, single parenthood, minority ethnicity, lack of acculturation, presence of four or more children in a family, young parental age, stressful events, exposure to family violence) ([Belsky, 1980](#); [U.S. Department of Health and Human Services, 1988](#)).

### Physically Abused Children and Adolescents

Studies of psychiatric disturbance in victims of child abuse who are referred for treatment have found the children to be impulsive, hyperactive ([Martin and Beezley, 1977](#)), depressed ([Green, 1978a](#); [Kaplan et al., 1986](#)), conduct disordered ([Kaplan et al., 1986](#); [Kinard, 1980](#)), learning impaired (Kline and Christiansen, 1975; [Salzinger et al., 1984](#)), and, frequently, to abuse substances ([Kaplan et al., 1986](#)). Studies of children and adolescents recruited directly from child protective services (state agencies responsible for investigating and documenting abuse) have found depression, conduct disorders, and substance abuse in victims ([Kaplan et al., 1998](#)). Studies of child and adolescent psychiatric populations have often found these children to have histories of physical child abuse ([Kashani et al., 1987a](#); [Kashani et al., 1987b](#)). Lewis and associates ([Lewis, 1985](#); [Lewis et al., 1979](#); [Lewis et al., 1992](#)) and [Alfaro \(1978\)](#) find that delinquent and violent adolescents also frequently, have histories of physical abuse. More specifically, children with symptoms of depression are more likely to have been physically abused than nondepressive children ([Allen and Tarnowski, 1989](#); [Kazdin et al., 1985](#)). [Kaufman \(1991\)](#) finds that 18% of her sample of maltreated children (abused or neglected) meet criteria of major depression and 25% meet criteria for dysthymia.

[Salzinger et al. \(1984\)](#) found that victims of maltreatment who were referred for treatment, and to a lesser extent their siblings, showed significantly more conduct disturbance, hyperactivity, tension, and anxiety than did a nonmaltreated comparison group. In an analysis of data using the Diagnostic Interview for Children and Adolescents ([Herjanic and Reich, 1982](#); [Reich et al., 1982](#)) on a referred sample, investigators found that abused children and adolescents were significantly more often diagnosed as having depression, alcohol abuse, conduct disorders, and attention deficit disorders than were a comparison group of nonmaltreated children and adolescents ([Kaplan et al., 1986](#)).

[Kaufman \(1991\)](#) found a prevalence of 18% of 56 maltreated children being diagnosed as having major depressive disorder and 25% as having dysthymic disorder. [Kaplan et al. \(1998\)](#) reported in a comparison study of physically abused adolescents and nonabused adolescents, who were not referred for treatment, that the abused adolescents were more often diagnosed as having depressive disorders and conduct disorders than were the nonabused adolescents.

None of the previously mentioned studies of behavioral dysfunction include any analyses of commonly suggested risk factors for child psychopathology, such as parental psychopathology ([Weissman et al., 1984](#); [Wolkind and Rutter, 1985](#)), lack of family cohesion and adaptability ([Wolkind and Rutter, 1985](#)), lack of perceived parental supportiveness ([Keller et al., 1986](#)), marital discord ([Illfeld, 1977](#)), prolonged separation of a child from a parent ([Rutter, 1971](#); [Wolkind and Rutter, 1973](#)), or head trauma ([Rutter et al., 1983](#)). The studies by [Kaplan et al. \(1986, 1998\)](#) are the only studies that did analyses of psychiatric illness in parents of abused children as risk factors. In their 1986 study, abused children of psychiatrically disturbed parents were more often diagnosed as having a psychiatric disorder than were nonabused children with a psychiatrically disturbed parent. Because these risk factors are frequently present in child abuse, research on the association of child mental illness and abuse will be improved by adjusting for the presence of these risk factors.

### Suicide and Abuse

An association between abuse and suicide has been found in studies of abused children and adolescents, of adolescent suicide attempters, and of mothers who attempt suicide. Self-mutilation is reported in abused and neglected children by [Green \(1978b\)](#). Deykin has reported that adolescents who attempt suicide have more often been reported as abuse victims than have adolescents who have not attempted suicide ([Deykin et al., 1985](#)). [Pfeffer \(1986\)](#) reports frequent child abuse in families of children who attempted suicide, and [Farber et al. \(1984\)](#), [Kaplan \(1986\)](#), and [Rotheram and Bradley \(1987\)](#) report high rates of suicide attempts in adolescent runaways. Garbarino and Farber report high rates of adolescent abuse in runaway youth ([Farber et al., 1984](#); [Garbarino et al., 1984](#)).

In a preliminary report on adolescent suicide of New York City metropolitan area adolescents, [Shaffer \(1987\)](#) reported that conduct disorders, substance abuse, and, less frequently, depression, as well as family discord and family histories of suicide and other exposure to suicide appear to be risk factors for adolescent suicide. These same psychiatric disorders have been reported in child and adolescent victims of abuse ([Kaplan et al., 1986](#); [Kaplan et al., 1998](#)). Child-abusive behaviors

were also found more often in mothers who attempted suicide than in a comparison group of nonsuicidal mothers ([Hawton et al., 1985](#)). Parental suicide attempts are known to be major risk factors for adolescent suicide ([Shaffer, 1989](#)).

The origin of the association between suicidal behavior and physical abuse remains to be studied. It may be secondary to modeling of aggressive behavior within the family or to exposure to the suicidal behavior of family members. It may also be secondary to increased biological risk in these families for disorders highly associated with suicide: affective disorders, substance abuse, and impulsive conduct disorders ([Kaplan et al., 1983](#); [Kaplan et al., 1986](#); [Shaffer, 1987](#)). Finally, the adolescent as well as his or her parents and family may be socially isolated and therefore at increased risk of suicide ([Salzinger et al., 1983](#); [Shaffer and Fisher, 1974](#); [Spinetta and Rigler, 1972](#)). [Kaplan et al. \(1997\)](#) find that physically abused adolescents have significantly more risk factors for suicide than do nonabused adolescents.

### Psychopathology of Parents of Maltreated Children

Comparative studies, although reporting an increased incidence of psychopathology in abusive parents, have been limited by the failure to use structured diagnostic interviews ([Estroff et al., 1985](#); [Paulson et al., 1976](#); [Smith et al., 1973](#)), by study populations inadequately defined as abusive ([Bland and Orn, 1986](#)), by relying on cases referred for treatment, and by indiscriminately combining parents of child and adolescent abuse victims. These studies have reported maltreating parents as depressed ([Bland and Orn, 1986](#); [Kaplan et al., 1983](#); [Wolfe, 1985](#)), aggressive ([Kaplan et al., 1983](#); [Wolfe, 1985](#)), having increased somatic concerns, exhibiting an imbalance in the proportion of negative to positive and aversive control behaviors when interacting with the target child, having more physical and verbal aggressive behaviors when interacting with the child, and having increased arousal and reactivity to any aversive child stimuli when compared with nonmaltreating parents ([Wolfe, 1985](#)).

In a study of a referred sample that used diagnostic structured interviews and distinguished between parents of abused children and parents of abused adolescents, investigators found significantly more diagnosed psychopathology in maltreating parents than in nonmaltreating parents. Mothers in abusive families were more frequently diagnosed as having a depressive disorder, whereas fathers, usually the perpetrating parent, were more often diagnosed as having alcoholism, antisocial personality disorders, or labile personalities. Mothers of maltreated children were more often diagnosed as having drug abuse than were mothers of maltreated adolescents ([Kaplan et al., 1983](#)).

The temporal relationship of the onset of child maltreatment with that of the onset of parental mental disorders has been reported in a study of physically abused adolescents. This pilot study suggests the importance of increased focus on supporting the parenting of adults with mental illness as a child maltreatment prevention strategy. Very few treatment programs for adults with mental disorders include any services specifically designed to enhance parent-child dyadic functioning.

### Intergenerational Transmission of Abuse

Abuse during childhood has been associated with increased risk that its victims will abuse their own children ([Kaufman and Zigler, 1987](#); [Oliver, 1993](#); [Straus et al., 1980](#)). In a critical review of this area, [Kaufman and Zigler \(1987\)](#) suggest that approximately one-third of those who are physically abused, sexually abused, or severely neglected will maltreat their offspring. They report that the presence of one supportive parent during childhood, a supportive spousal relationship, and fewer stressful events during adulthood may buffer against the intergenerational transmission of abuse.

### Social Isolation of Abusive Families

Social competence has been found to be impaired both in child abuse victims and in their parents ([Salzinger et al., 1983](#); [Salzinger et al., 1984](#)). Mothers of abused children and adolescents are less often employed outside their homes and are more socially isolated, particularly with respect to peers. As a result, outsiders are found to have less access to the family interactions of abusive families than to those of comparison families ([Salzinger et al., 1983](#)). This type of social isolation may be hypothesized to lead to a lack of child-rearing acculturation of the abusive parent ([Salzinger et al., 1983](#)). In addition, maltreated children have been demonstrated to have impaired social functioning and to be less popular when compared with their nonabused peers. ([Salzinger et al., 1993](#))

## EMOTIONAL ABUSE

*Emotional abuse* has been defined in the Study of the National Incidence and Prevalence of Child Abuse and Neglect ([U.S. Department of Health and Human Services, 1988](#)) as described in the following sections:

### Close Confinement (Tying or Binding and Other Forms)

This consists of tortuous restriction of movement, as by tying a child's arms or legs together or binding a child to a chair, bed, or other object or confining a child to an enclosed area (e.g., a closet) as a means of punishment.

### Verbal or Emotional Assault

This involves habitual patterns of belittling, denigrating, scapegoating, or other nonphysical forms of overtly hostile or rejecting treatment, as well as threats of other forms of maltreatment (e.g., threats of beating, sexual assault, abandonment).

### Other or Unknown Abuse

This consists of overtly punitive, exploitative, or abusive treatment other than that specified under other forms of abuse or unspecified abusive treatment. This form includes attempted or potential physical or sexual assault, deliberate withholding of food, shelter, sleep, or other necessities as a form of punishment, economic exploitation, and unspecified abusive actions.

Garbarino et al. further define emotional abuse and apply a developmental approach as clarification. They view emotional abuse as a pattern of psychically destructive behavior inflicted by an adult on a child. This pattern may take five forms: rejecting, isolating, terrorizing, ignoring, or corrupting ([Garbarino et al., 1986](#)). Garbarino et al. illustrate these patterns according to stages of child development, as follows:

1. Rejecting
  - a. *Infant*: The parent refuses to accept an infant's primary attachment.
  - b. *Preschooler*: The parent excludes the child from family activities.
  - c. *School-age child*: The parent conveys negative definitions of self to the child.
  - d. *Adolescent*: The parent refuses to acknowledge the changing social roles expected of the child.
2. Terrorizing
  - a. *Infant*: The parent intentionally violates the child's tolerance for change and intense stimuli.
  - b. *Preschooler*: The parent uses extreme gestures to threaten or intimidate the child.
  - c. *School-age child*: The parent places the child in a double bind ("Damned if you do, damned if you don't") ([Garbarino et al., 1986](#)).
  - d. *Adolescent*: The parent threatens to expose and humiliate the child.
3. Ignoring
  - a. *Infant*: The parent fails to respond contingently to the infant's spontaneous behavior.
  - b. *Preschooler*: The parent displays a lack of affect toward and does not engage the child in activities of socialization.
  - c. *School-age child*: The parent does not protect the child or intervene on the child's behalf when made aware of the need for help.
  - d. *Adolescent*: The parent abdicates the parental role and does not have an interest in the child.
4. Isolating
  - a. *Infant*: The parent withholds from the child interactions with parents or other parenting persons.
  - b. *Preschooler*: The parent teaches the child to avoid contact other than with the parent.
  - c. *School-age child*: The parent discourages peer relationships.
  - d. *Adolescent*: The parent attempts to prevent socialization by prohibiting organized and other activities outside the home.
5. Corrupting
  - a. *Infant*: The parent reinforces the development of inappropriate behavior (e.g., sexual) or creates an addiction (exposure to drugs, alcohol).

- b. *Preschooler*: The parent reinforces aggressive or sexualized behaviors.
- c. *School-age child*: The parent reinforces aggressive, sexualized criminal behaviors, or the abuse of substances.
- d. *Adolescent*: The parent promotes in the child socially prohibited forms of sexual, aggressive, criminal, or substance-abusing behaviors.

## **Incidence**

In 1998, 0.7 per 1,000 children or 6% of all children documented as maltreated were found to be psychologically abused ( [U.S. Department of Health and Human Services, 2000](#)).

## **Sequelae**

Emotional maltreatment has been found to be a stronger predictor than physical maltreatment of internalizing and externalizing behavior problems, low self-esteem, suicidal behavior, social impairment, and psychiatric diagnoses and hospitalizations ( [McGee et al., 1997](#); [Vissing et al., 1991](#)).

## **NEGLECT**

### **Definitions**

[Giovannoni \(1988\)](#) generally defined *child neglect* as follows: Whereas abuse is considered an act of “commission,” neglect is considered an act of “omission.” Neglect is perpetrated by caretakers of children who fail to fulfill their caretaker obligations to children. Neglect occurs in the following three situations:

1. Neglect is the result of a parenting problem.
2. Neglect results from social deviance of the caretaker secondary to caretaker problems such as substance abuse, mental retardation, mental illness, criminality, or other problems.
3. Neglect is associated with the physical abuse or sexual abuse of the child.

This definition may be further broken down into the following three categories, discussed at length in the next sections: physical neglect, educational neglect, and emotional neglect ( [U.S. Department of Health and Human Services, 1988](#)).

### *PHYSICAL NEGLECT*

#### *Refusal of Health Care*

This consists of failure to provide or allow needed care in accordance with recommendations of a competent health care professional for a physical injury, illness, medical condition, or impairment.

#### *Delay in Health Care*

This involves failure to seek timely and appropriate medical care for a serious health problem that any reasonable lay person would have recognized as needing professional medical attention.

#### *Abandonment*

This is desertion of a child without arranging for reasonable care and supervision. This category includes cases in which children are not claimed within 2 days and those in which children are left by parents or substitutes who give no (or false) information about their whereabouts.

#### *Expulsion*

This consists of other blatant refusals of custody, such as permanent or indefinite expulsion of a child from the home without adequate arrangement for care by others, or refusal to accept custody of a returned runaway.

#### *Other Custody Issues*

This category involves custody-related forms of inattention to the child's needs other than those covered by abandonment or expulsion, for example, repeated shuttling of a child from one household to another because of an apparent unwillingness to maintain custody or chronically and repeatedly leaving a child with others for days or weeks at a time.

#### *Inadequate Supervision*

In this case, the child is left unsupervised or is inadequately supervised for extended periods or is allowed to remain away from home overnight without the parent or substitute's knowing (or attempting to determine) the child's whereabouts.

#### *Other Physical Neglect*

This involves conspicuous inattention to avoidable hazards in the home, inadequate nutrition, clothing, or hygiene, and other forms of reckless disregard of the child's safety and welfare, such as driving with the child while intoxicated, leaving a young child unattended in a motor vehicle, and so forth.

### *EDUCATIONAL NEGLECT*

#### *Permitted Chronic Truancy*

Habitual truancy averaging at least 5 days a month is classifiable under this form of maltreatment if the parent or guardian has been informed of the problem and has not attempted to intervene.

#### *Failure to Enroll or Other Truancy*

This involves failure to register or enroll a child of mandatory school age in school, causing the child to miss at least 1 month of school, or a pattern of keeping a school-age child home for nonlegitimate reasons (e.g., to work, to care for siblings) an average of at least 3 days a month.

#### *Inattention to Special Educational Need*

This consists of refusal to allow or failure to obtain recommended remedial educational services or neglect in obtaining or following through with treatment for a child's diagnosed learning disorder or other special education need without reasonable cause.

### *EMOTIONAL NEGLECT*

Emotional neglect is defined by the 1986 National Center on Child Abuse study as “a parent providing inadequate nurturance/affection, exposing a child to chronic or extreme spouse abuse, permitting a child to abuse drugs or alcohol, permitting other maladaptive behavior, or refusing a child psychological care” ( [U.S. Department](#)

[of Health and Human Services, 1988](#)).

## Incidence

In 1998, 53.5% (6.8 per 1,000 U.S. children) of documented child maltreatment victims suffered neglect ([U.S. Department of Health and Human Services, 2000](#)).

## Physical Examination Findings

Typical findings are as follows:

1. *Physical neglect*: Malnutrition, repeated pica, constant fatigue, poor hygiene, clothing inappropriate for weather or setting ([Council on Scientific Affairs, American Medical Association, 1985](#))
2. *Medical neglect*: Lack of appropriate medical care for chronic illness, absence of appropriate immunizations or medications, absence of dental care, absence of necessary prostheses such as eyeglasses or hearing aid, discharge from treatment against medical advice
3. *Emotional neglect*: Delays in physical development and failure to thrive ([Council on Scientific Affairs, American Medical Association, 1985](#))

## Psychopathology of the Neglected Child

The effects of neglect have been studied even less frequently than those of abuse. In one of the very few studies on neglect, [Egeland \(1985\)](#) reported that physically neglected children at 12 months were more likely than nonneglected children to have insecure attachments. At 24 months, neglected children were more likely to be noncompliant and easily frustrated, as compared with controls. At 42 months, they were rated as more likely to have low self-esteem and self-assertion, less flexibility, and less self-control and to have a difficult time dealing with frustration. They lacked persistence and enthusiasm on educational tasks. They were more dependent and lacked enthusiasm and interest in the preschool environment. In elementary school, they had attentional problems, low self-assertion, low self-esteem, and greater internalizing behaviors. They were also reported as socially isolated by teachers. Egeland found emotionally neglected children more likely than control children to show declines on cognitive testing, insecure attachment, avoidance of emotional contact, depression, and aggressive behavior. [Bolger et al. \(1998\)](#) found neglected children to have problems with social functioning, including conflict with friends. Neglected children have also been reported to have difficulties in understanding appropriate affective emotional responses to interpersonal situations and to have limited social problem-solving skills ([Haskett, 1990](#); [Rogosch et al., 1995](#)). Greater expressive and receptive language deficits and poorer mathematics and language achievement test scores have been found in neglected than in abused children ([Culp et al., 1991](#); [Eckenrode et al., 1993](#); [Wodarski et al., 1990](#)).

In the United States during 1985, 58 per 1,000 couples experienced severe assault (spouse abuse), which included kicking, biting, punching, hitting with an object, beatings, and threats or harm with guns or knives ([Straus and Gelles, 1986](#)). Children often witness the spouse abuse incidents of their parents. These children are, according to child treatment reporting laws, considered to be victims of emotional neglect by virtue of this exposure. Child witnesses of spouse abuse have been described as having separation anxiety, sleep disturbances, psychosomatic symptoms ([Wolfe, 1987](#)), generalized fearfulness and withdrawal from conflict, impaired social competence, and conduct disorders ([Jaffee et al., 1990](#); [Wolfe et al., 1986](#)). [Pelcovitz et al. \(2000\)](#) found that adolescent exposure to domestic violence, more so than being a victim of physical abuse, increased the risk of the development of posttraumatic stress disorder during adolescence. Witnessing spouse abuse during childhood has also been associated with increased risk for becoming either a perpetrator or a victim of spouse abuse ([Straus et al., 1980](#)).

## Psychopathology of Neglectful Parents

Neglectful mothers are found to be less verbally responsive to their children than nonneglectful mothers ([Aragona and Eyberg, 1981](#)). Neglectful mothers are also found by Aragona and Eyberg to use more direct commands, less verbal praise or acknowledgment, and more critical statements when interacting with their children than are nonneglectful mothers ([Aragona and Eyberg, 1981](#)).

[Zuravin \(1988\)](#) reports that maternal depression is more often associated with physical neglect than with physical abuse of children. [Gaudin et al. \(1993\)](#) find neglectful parents to be more depressed and more socially isolated than are nonneglectful parents. Parents who perpetuate spouse abuse have been frequently found to have substance abuse disorders ([Kaplan, 1989b](#)), whereas their nonviolent spouses frequently had been diagnosed as having depressive disorders ([Kaplan et al., 1988](#)).

## EXPOSURE TO SUBSTANCES IN UTERO

Currently, there is a U.S. epidemic of children being born to mothers who abuse substances. The U.S. [General Accounting Office \(1990\)](#) reports that 325,000 prenatally drug-exposed infants are born annually in the United States, and approximately 100,000 of these infants are exposed to cocaine as well as to other illicit drugs and alcohol used with cocaine.

Reports have noted that infants exposed to substances *in utero* have smaller head circumferences than infants who are not exposed to drugs ([Griffith et al., 1993](#)) and have problems with hyperarousability with prolonged crying, sleeping and feeding difficulties, tonic and attentional problems, low birth weight, and seizures ([Chasnoff et al., 1989](#)). [Rodning et al. \(1989\)](#) report that preschoolers exposed to illicit substances *in utero* when compared with non-substance-exposed preschoolers have lower developmental quotient results on the Bayley Developmental Assessment Test, deficits in spontaneous play and representational play, less secure attachment behaviors, attentional problems with a disorganization of intentionality, and an absence of the impression of delight and pleasure.

Treatment and assessment needs of the *in utero* substance-exposed infant and preschooler include comprehensive programs for parents and children with the following available services: cognitive, language, and mental health assessments of infants and children; dyadic assessment of infant or child-parent attachment; parenting and extended family functioning enhancement strategies; special education, speech and language, and mental health services for children; and substance abuse, mental health, and vocational assessments and programs for parents.

## TREATMENT OF CHILD ABUSE AND NEGLECT

Because parental psychopathology is a high-risk factor for child or adolescent psychopathology in violent families, treatment programs for these families must include treatment for parental mental illness, including substance abuse, as well as treatment for the abused child or adolescent. Specific treatment and prevention strategies for both family violence and adolescent psychopathology and suicidal behavior will be improved, based on further understanding of their association. In fact, the low rate of compliance with treatment in cases of adolescent suicide attempts suggests that adolescents who attempt suicide may come from families that are very similar to families of abused adolescents, and they may therefore require treatment strategies similar to those designed for child abuse. Despite a considerable literature on the diagnosis of child abuse and the initial phases of management, there is a dearth of information regarding long-term psychotherapeutic management. There are virtually no empirical studies evaluating the effectiveness of therapeutic modalities or techniques with this population.

Most child abuse treatment programs have, as their major focus, treatment of the abusing parent, with little treatment of the maltreated child. This model views abuse and neglect as consequences only of parental psychopathology. In contrast, a multidimensional or "ecological" view of child abuse ([Belsky, 1980](#)) defines treatment needs more broadly than the parental psychopathology model. [Main and Goldwyn \(1988\)](#) and [Wolfe \(1987\)](#) emphasize the importance of focusing on the interactive aspect of the cycle of maltreatment and the importance of changing the negative mode of parent-child interactions. In addition to possible emotional disturbances in parents, other variables are seen as contributors to abuse and neglect. These include vulnerability of the child, family dysfunction, and environmental stress factors such as parental unemployment and the degree to which social support systems exist and operate for parents. In this view, child abuse occurs as a function of the degree to which the parents' environment tends to enhance or to undermine good parenting. When support is adequate, parental propensities toward violence are controlled. When there is little social support, violent propensities manifest themselves.

Effective treatment programs recognize the multidimensional nature of the origin of family violence. The multidisciplinary treatment team needs to aim its interventions at variables operating at all levels of the problem: individual psychopathology, family dysfunction, stress, and lack of social supports. In a study done from 1979 to 1981 of 19 child maltreatment clinical demonstration programs funded by the National Center on Child Abuse and Neglect, serving 1,000 families, [Daro \(1988\)](#) found that clinicians rated families who received family therapy and group therapy for 13 to 18 months of treatment as having made the most progress and being the least likely to have a relapse of child maltreatment necessitating rereporting. Parental substance abuse was associated inversely with treatment progress, as were greater

numbers of types of maltreatment exhibited by a family before referral.

In a study of physically abusive families who had a child in out-of-home placement because of abuse, low socioeconomic status, older age of child, greater severity of abuse, or the victim's school behavioral problem predicted poor outcome of social service agency rehabilitative effort and the need for permanent out-of-home care for victims ([Barth et al., 1985–1986](#)).

### Parent Treatment

There is an unusually high dropout rate when abusive parents are referred to traditional community mental health clinics. Given the probability that the parents came from a family environment in which needs for nurturance and dependency were often met with rejection and violence, it is not surprising that these parents often view authority figures with suspicion and mistrust. Initial resistance and missed appointments should be viewed as almost inevitable components of early phases of therapy. To move beyond the parents' lack of basic trust, outreach to these families must be made in a manner not usually needed with nonabusive parents. This includes availability to these parents of the staff on a 24-hour basis and the availability of evening treatment time, to involve both parents. The psychotherapy of the parents is viewed as having two primary components. The first is the provision of intense emotional support and positive models of parenting. The tendency of these parents to make unrealistic demands on their children is dealt with directly by teaching them appropriate developmental expectations and effective, nonpunitive child-rearing techniques. The second component is traditional psychotherapy aimed at insight and conflict resolution. Until a solid, trusting therapeutic relationship is established, this is often done in the context of individual psychotherapy. In later stages, conjoint family sessions deal with the interactional issues, such as the scapegoating of the abused child and marital conflict ([Kaplan et al., 1981](#)).

### Child Treatment

Abused children are at risk of serious behavioral and emotional disorders, developmental disorders, and learning problems. To screen for these problems, complete medical, developmental, and psychiatric evaluations should be performed on all abused and neglected children. School records should be reviewed. Referral for more appropriate educational placement is frequently indicated, as is referral for individual psychotherapy. The goal in psychotherapy is not only to overcome the emotional problems of abuse but also to facilitate emotional development in a manner that will overcome the intergenerational cycle of abuse.

Abuse-focused treatments provided in therapeutic day programs for treatment of young victims have been found to improve social and cognitive skills and to enhance self-esteem ([Culp et al., 1991](#)). Nonabused peers have been used in play therapies that focus on helping socially withdrawn, physically abused, or neglected children ([Fantuzzo et al., 1996](#)). [Urquiza and McNeil \(1996\)](#) and [Borrego et al. \(1999\)](#) find therapy with intensive parent-child interaction therapy (mother-child dyadic therapy) to be effective in families at higher risk of abuse.

### Pharmacotherapy

There have been few studies of the efficacy of medications for abused children. Propranolol was found to lessen hyperarousal and hypervigilance of abused children ([Famularo et al., 1988](#)). [Harmon and Riggs \(1996\)](#) found that clonidine reduced symptoms of aggression, hyperarousal, and sleeping problems of abused preschool children with severe posttraumatic stress disorder. Both these studies used small samples and open medication trial methods and were considered preliminary by their authors.

## LEGAL ASPECTS OF ABUSE AND NEGLECT

All states have reporting laws mandating that professionals in the areas of health care, social service, law enforcement, and education report suspected cases of child abuse or neglect. In approximately 20% of reported cases, children alleged to be abused or neglected become involved in court proceedings ([Besharov, 1971](#)). The purposes of these proceedings are to determine whether abuse or neglect occurred, the services required for family rehabilitation, and the need for custodial disposition.

In most states, abused and neglected children involved in court proceedings receive court-appointed attorneys called *law guardians or guardians ad litem*. The Federal Child Abuse Prevention and Treatment Act of 1974 mandates that states must provide children with representation independent of that of their parents for those children involved in judicial proceedings. The role of these attorneys is to act as advocates for the rights of the child client and the desires of that child. The duty of the law guardian is to permit inclusion of all relevant evidence and argument on behalf of the child client.

## HOSPITAL MANAGEMENT

Child abuse and neglect are frequently diagnosed and reported by hospitals, with children routinely hospitalized after these reports. Many hospitals have developed child protection teams to assess cases of child abuse and neglect. These teams, which often include mental health professionals, cooperate with the state agencies responsible for receiving and investigating child abuse reports and formulating treatment recommendations.

---

### CASE ILLUSTRATION

James, a 14-year-old seventh-grade student, was reported by his local police department to child protective services as having been physically abused. Officers in a police car saw him sitting on his front steps with bruises on his face and a swollen left eye. James informed them that his father hit him on the face with a baseball bat after his father saw his report card.

James and his family were referred for evaluation to an interdisciplinary child and adolescent psychiatric outpatient program for families with violence. James, his parents, and his entire family conjointly were psychiatrically evaluated. James' school and pediatrician were contacted after written authorization was obtained from James' mother. James' mother and father were found, respectively, to have major depressive disorder and alcohol abuse. James was found to have attention deficit hyperactivity disorder. James' school indicated that it had been suggested to James' parents that he receive psychotherapy and medication for his attention deficit hyperactivity disorder. However, James' parents had previously been unwilling to obtain mental health services for James, and James did not receive such help. After the evaluation of James and his parents, individual and family psychotherapy and medication were recommended for James. Mr. and Mrs. Smith, James' parents, were given couples therapy for marital problems. James' mother received individual therapy and medication for her depression. James' father was referred to a substance abuse treatment program for his substance abuse problem. James and his parents participated in family therapy, with an emphasis on disciplining James without corporal punishment. James' parents worked in therapy on their relationship and on resolving conflicts over James. Both parents were encouraged to relate to friends outside the family as well as to rekindle relationships with their extended families. They were also encouraged to permit James to be treated for his attention deficit hyperactivity disorder with medication and group psychotherapy. James and his parents complied with therapy, James became less provocative to his parents, and corporal punishment ceased. James' grades improved, and he made his first "best friend." Therapy lasted for 40 sessions. James graduated from high school.

---

## PREVENTION

Three types of child maltreatment primary prevention strategies are currently used. The first is competency enhancement, such as parent education programs. The second is preventing the onset of maltreating behaviors through, for instance, media campaigns, crisis hotlines, and community socialization programs for parents. The third is the targeting of high-risk groups, such as single, adolescent, parents of low socioeconomic status and those with complicated pregnancies and deliveries, to attend programs that increase parent-child contact and provide family support, such as visiting nurses or home visiting parent aides ([Britner and Repucci, 1997](#); [Rosenberg and Repucci, 1985](#)). The effectiveness of these programs still remains to be studied because little prevention outcome research has been done using comparison groups.

One methodologically sophisticated study of high-risk mothers indicates that providing visiting nurses reduces the rates of maltreatment, enhances parents' positive perceptions of their infants, improves the health of high-risk mothers, and reduces prematurity rates for their children, as compared with those who do not receive these services ([Rosenberg and Repucci, 1985](#)). [Olds et al. \(1997\)](#) report that high-risk mothers who are part of an intense nurse home visitation program are less likely to be reported for child abuse or neglect than are high-risk mothers who do not receive this service.

## ROLE OF THE PSYCHIATRIST

Psychiatrists can make important contributions to child abuse and neglect case management by consulting with social service agencies, hospitals, and courts, as well as by establishing and participating in treatment programs designed for these families.

Children and parents in child maltreatment cases are often not routinely screened for psychopathology and substance abuse, so the prevalence of psychopathology

and substance abuse has probably been underestimated and untreated. In a survey of hospitals with pediatric beds and of child protective services in the New York City metropolitan area, [Kaplan and Zitrin \(1983a, 1983b\)](#) find that most abused and neglected children and their parents are not assessed by psychiatrists or psychologists, nor are psychiatrists or psychologists members of child protection committees in most hospitals surveyed ([Kaplan and Zitrin, 1983b](#)). In a study of abused children and their parents in cases reaching the Manhattan Family Court, more than half of these children and more than half of their parents have not had psychiatric evaluations before court proceedings, despite having been known to multiple social agencies before court referral. When psychiatric consultation was available to law guardians in family court proceedings, their initial legal custody plans for the children were modified after psychiatric consultation in 21 of 40 cases ([Kaplan, 1981](#)). It is therefore recommended that psychiatrists become involved as members of hospital child protection committees and that routine psychiatric evaluations of parents and children, as well as frequent psychological testing to screen for developmental and learning disabilities and regular review of school records, should be done by agencies involved in planning for these families.

Child maltreatment poses a particular challenge to psychiatry. Child and adolescent mental health treatment compliance depends on parental as well as child and adolescent motivation. Medical neglect reports should be considered by psychiatry when treatment compliance problems exist. This route to overcome resistance to essential mental health treatments for children and adolescents is often overlooked by psychiatrists.

## CONCLUSIONS

Child psychiatric efforts directed at understanding, preventing, and intervening in the area of child maltreatment remain at an early stage. Maltreated children, their parents, and their relatives have been found to have an increased risk of the development of mental disorders, substance abuse, and aggressive behaviors. In addition to the need to advocate for the improvement of environmental stressors, the cessation of exposure of children to family violence, improved parenting, and child development education for parents and children, psychiatry must advocate for an increase in much needed child maltreatment mental health services.

Child sexual abuse continues to be a major public health problem. During 1998, 1.6 per 1,000 (a total of 103,845) children and adolescents in the United States were sexually abused ([U.S. Department of Health and Human Services, 2000](#)). Research has informed clinical practice by clarifying correlates of sexual abuse and by studying the efficacy of approaches for its assessment and treatment. Professional organizational guidelines pertinent to the mental health care of sexually abused children and adolescents also have been developed.

## DEFINITIONS

The following definition of sexual abuse, used in the most recent National Incidence Study (NIS-3) ([U.S. Department of Health and Human Services, 1996](#)), is used throughout this chapter: Child and adolescent sexual abuse involves a child younger than 18 years of age having experienced one of the following types of sexual acts: intrusion as evidence of oral, anal, or genital penile penetration or anal or genital digital or other penetration; molestation with genital contact, but without evidence of intrusion; or other acts that involved contact with nongenital areas of a child's body (e.g., fondling of breasts or buttocks, exposure) or inadequate or inappropriate supervision of sexual activities when the perpetrator was a parent, parent substitute, or other.

## EPIDEMIOLOGY

There are three major sources of national epidemiologic data on child maltreatment. One is the NIS-3. This study sampled child protective services, law enforcement, juvenile probation, public health, hospital, school, day care, and mental health and social service agencies in counties throughout the United States for a 3-month period during 1993 ([U.S. Department of Health and Human Services, 1996](#)). The incidence of sexual abuse reported by this study was increased compared with that of the two previous incidence studies of 1980 and 1986. Sexual abuse estimates in 1993 increased to 217,700 (3.2/1,000 children) from 119,200 (1.9/1,000 children) in 1986 and 42,900 (0.7/1,000 children) in 1980 ([U.S. Department of Health and Human Services, 1996](#)). Girls were estimated in 1993 to have been targets of sexual abuse more often than boys (4.9/1,000 female children versus 1.6/1,000 male children) ([U.S. Department of Health and Human Services, 1996](#)).

The second major source of national epidemiologic child maltreatment data is represented most recently by *Child Maltreatment 1998: Reports from the States to the National Child Abuse and Neglect Data System* ([U.S. Department of Health and Human Services, 2000](#)). This study, as well as its earlier versions, presents data collected by state child protective service agencies, but not from multiple types of agencies, as did NIS-1 through NIS-3 ([U.S. Department of Health and Human Services, 2000](#)). During 1998, 1.6 per 1,000 (a total of 103,845) children and adolescents in the United States were found to be sexually abused by child protective services. This represented 11.5% of the total 903,000 documented maltreated children and adolescents that year. That year, the rate of sexual abuse was 2.3 female victims per 1,000 female children, compared with 0.6 male victims per 1,000 male children in the population. More than half (55.9%) of the child sexual abuse victims were abused by male parents, male relatives, or other men; 3.8% were sexually abused by female parents only, 12% were sexually abused by both parents, 11.2% were abused by mothers together with others, and 2.2% were abused by female relatives or other women. The average ages of 1998 sexual abuse victims were 10.4 years for girls and 8.6 years for boys ([U.S. Department of Health and Human Services, 2000](#)).

The third major source of national epidemiologic child abuse data consists of population surveys. In a recently published national survey of the child disciplinary practices of 1,000 parents, 5.7% reported that their children had been sexually abused at any time before the survey, and 1.9% reported that their children had been sexually abused in the year before the survey. Sexual abuse was reported as equal in frequency for boys and girls. The sexual abuse cases of this survey were more likely to have been disclosed if parents had been sexually abused themselves, and if families were from lower socioeconomic groups and contained single parents ([Finkelhor et al., 1997](#)).

### Risk Factors for Child Sexual Abuse

Epidemiological studies of the prevalence of child sexual abuse often include a focus on population factors which co-occur with sexual abuse exposure and are therefore considered to increase the risk of sexual abuse. In a survey of women 21 years of age and older, risk factors for child sexual abuse included maternal and paternal alcohol abuse, children's perceptions of mothers and fathers as rejecting and not nurturing, and children not living with both biological parents by 16 years of age ([Vogeltanz et al., 1999](#)). In the 1998 Survey of Child Protective Services' documented sexual abuse cases, risk factors for child sexual abuse included female sex and being approximately 10 years of age if female and approximately 9 years of age if male ([U.S. Department of Health and Human Services, 2000](#)). As mentioned previously, [Finkelhor et al. \(1997\)](#), in their survey of disciplinary practices, found lower socioeconomic status, single parenthood, and parental history of childhood sexual abuse to be risk factors for the sexual abuse of children.

### Recantation of Child Sexual Abuse

After disclosure and documentation of abuse, children may recant. Of 249 state-validated child sexual abuse cases, 4% were found to recant after disclosure of abuse. Half of these occurred in response to pressure from a caretaker ([Bradley and Wood, 1996](#)). [Gonzalez et al. \(1993\)](#) reported that 27% of children who disclosed sexual abuse in therapy later recanted.

## CLINICAL ASPECTS

It is essential that all children and adolescents suspected of being sexually abused be given assessments that include physical examinations by clinicians with training in forensic data collection and interviews by persons with special training in specific methods of interviewing using nonsuggestive methods. If sexual abuse is documented, child and adolescent psychiatric evaluations to define mental health problems and to obtain any needed mental health interventions for the child and the child's caretakers also are essential.

### Physical Examination Findings

Abrasions or bruises of the external genitalia, distortion or attenuation of the hymen, alterations in anorectal tone, sexually transmissible diseases, and pregnancy all

may be findings when sexually abused children are examined ([American Medical Association, 1994](#)).

## Mental Health Correlates of Sexual Abuse

[Kendall-Tackett and colleagues' \(1993\)](#) review of research studies of the effects of child sexual abuse reported that 21% to 36% of child sex abuse victims had no short-term symptoms, and that 64% to 79% of child sex abuse victims had varied patterns of symptomatology. These included, in descending order of frequency, sexualized behaviors, posttraumatic stress disorder (PTSD), poor self-esteem, anxiety, fear, depression, suicidal ideation, somatic complaints, aggressive behavior, running away, and substance abuse.

Posttraumatic stress disorder has been reported as a correlate of sexual abuse during childhood ([Avery et al., 2000](#)). Although sufficient constellations of symptoms frequently are not present to warrant a diagnosis of PTSD using the criteria delineated in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; [American Psychiatric Association, 1994](#)), victims of sexual abuse often present with a constellation of symptoms similar to that seen in victims of other types of interpersonal trauma ([Herman, 1992](#)). *Complex PTSD* ([Herman, 1992](#); [Van der Kolk et al., 1996](#)) often is used to describe this constellation. Complex PTSD symptoms include difficulties with affect regulation, self-concept, and relations with others, dissociative symptoms, and somatization.

Depression also has been reported to be associated with child sexual abuse ([Koverola et al., 1993](#)). Women who were sexually abused as children have been reported also to have increased risk for depression as adults ([Zuravin and Fontanella, 1999](#)). A strong association of suicidal behavior has been reported in survivors of intrafamilial sexual abuse ([Dinwiddie et al., 2000](#), [Wozencraft et al., 1991](#)).

Aggression has been reported frequently in adolescent victims of sexual abuse ([Fergusson and Horwood, 1999](#)) and in adults who were sexually abused as children ([Widom and Ames, 1994](#)). [Lewis \(1992\)](#) hypothesized that child physical or sexual abuse exacerbates preexisting psychobiological vulnerabilities.

Difficulty modulating sexual impulses also has been reported frequently in victims of sexual abuse. Studies of sexually abused children ([Friedrich, 1993](#)) and adolescents ([Trickett and Putnam, 1993](#)) have found these children to differ significantly from their nonabused peers in their displays of unusual sexual behaviors and attitudes.

Risk taking by abused children has been conceptualized to relate to difficulties these children have in modulating their levels of arousal (Cicchetti, 1991). Both sexually and physically abused children have been noted to be more likely than their nonabused counterparts to take part in high-risk behaviors, such as cigarette smoking and alcohol and drug abuse ([Riggs et al., 1990](#)).

Sexually abused children have been found to have fewer close friends and more conflict with parents than nonabused children. They also have been found to have greater numbers of sexual partners, earlier onset of sexual activity, and more frequent unprotected sex than nonabused children ([Johnson, 1996](#)).

Impaired self-concepts in sexually abused children have been reported and have been found to be more evident in older children than in younger children ([Barnett et al., 1996](#); [Cole and Putnam, 1992](#)). Sexually abused children also have been reported to blame themselves for abuse ([Spacarelli, 1994](#)). [Friedrich \(1994\)](#) has hypothesized that increased somatic symptoms in survivors of both physical and sexual abuse in childhood (e.g., [Leserman et al., 1996](#)) are related to the heightened and distorted focus on the physical self that follows abusive experiences.

Dissociation and traumatic amnesia as responses to sexual abuse often have been reported (Putnam et al., 1996; Ross, 1996). Trancelike states, in which a child stares and is inattentive and unresponsive, are the most common dissociation symptoms in children. Dissociation enables the young child to avoid the frightening and overwhelming feelings that accompany abuse. [Ross \(1994\)](#) concluded that over 90% of adults who carried a diagnosis of dissociative identity disorder have a childhood history of physical or sexual abuse. Although dissociation initially may be helpful to the traumatized child, it also may interfere with recovery by interfering with cognitive processing of strong emotions and cognitions associated with the abuse. Dissociation also has been found to interfere with cognitive performance, including school functioning ([Putnam, 1990](#)).

## PSYCHIATRIC DISORDERS

Victims of child sexual abuse also have been found to be at increased risk for a variety of DSM-IV psychiatric diagnoses, most notably major depressive disorders ([Flisher et al., 1997](#)), conduct disorder ([Livingston et al., 1993](#)), and somatization disorder ([Pribor et al., 1993](#)). There is some indication that childhood sexual abuse is associated with disordered eating behavior, particularly bulimia ([Douzinas et al., 1994](#)). PTSD is perhaps the most consistently reported diagnosis in childhood victims of sexual abuse ([Wolfe et al., 1994](#)).

[Friedrich \(1997\)](#) reported that the severity of sexualized behavioral problems associated with sexual abuse is increased if physical as well as sexual abuse occurred. Poor mother–daughter relationship was found by [Hazzard et al. \(1995\)](#) to be the only significant predictor of internalizing and behavioral externalizing problems. Maternal psychiatric status also was found to predict outcome of sexually abused children ([Paradise et al., 1994](#)). PTSD may be predicted by the number of family-related stressors to which the sexually abused child was exposed ([Livingston et al., 1993](#)). Family adaptability and the intensity of parental response to sexual abuse disclosure also were found to predict the intensity of the child victim symptoms ([Mannarino and Cohen, 1996](#)). Adolescent age at the time of sexual abuse also has been found to be associated with increased severity of emotional and behavioral symptoms ([Feiring et al., 1999](#)).

Studies of physically and sexually abused children have documented impaired cognitive and language abilities and school functioning. These problems have included delays in verbal development, impaired academic achievement, and higher rates of school absenteeism, retention, and special class placement ([Eckenrode et al., 1993](#)).

## BIOLOGICAL STUDIES

There have been few studies of the biological correlates of abuse that have included children or adolescents as subjects. Biological studies of traumatized adults have reported that people with PTSD respond to chronic trauma with a state of hyperarousal, including increased heart rate ([Pitman et al., 1990](#)).

[Ito et al. \(1993\)](#) found that when physically or sexually abused children were compared with nonabused children admitted to child and adolescent psychiatric inpatient services, the abused children had more frontotemporal and anterior region brain electrophysiologic abnormalities recorded on electroencephalography.

Dissociative identity disorder, formerly multiple personality disorder, often has been associated with child sexual abuse ([Ross, 1994](#)). Dissociative identity disorder has been found to be associated with optical functioning changes, variances in skin conductance, respiration, and skin temperature, and heart rate with changes in personality alters ([Putnam et al., 1990](#)). "Alters" have been found to be associated with different visual evoked potential and electroencephalographic patterns ([Putnam, 1990](#)).

Changes involving the hormones of the hypothalamic–pituitary–adrenal axis and the hypothalamic–pituitary–gonadal axis also have been associated with sexual abuse. [Putnam et al. \(1990\)](#) found higher morning cortisol levels in sexually abused compared with nonabused girls. In addition, [De Bellis et al. \(1994\)](#) found increased urinary secretion of the catecholamine metabolite homovanillic acid by sexually abused compared with nonabused girls.

Menarche also has been reported to have an earlier onset in sexually abused than in nonabused girls ([Herman-Giddens et al., 1988](#)), as well as an earlier onset in women who reported childhood sexual abuse than in women who did not report such abuse ([Kendall-Tackett and Simon, 1988](#)).

---

### CASE ILLUSTRATION

Ten-year-old Nancy cried during her fifth grade teacher's sex abuse prevention educational presentation. After this lesson, when approached by her teacher, Nancy revealed that her father often "touched her private parts." Nancy's teacher made a child abuse report to the state department of social services. Nancy stayed after school with her teacher and was interviewed by a representative from the county child protective service office.

Nancy spoke of her mother working as a nurse during night shifts and of her father caring for her and her 5-year-old brother while her mother worked. Her father worked days as a computer programmer. Each night after he tucked her brother into his bed in his own room, Nancy said that her father came into her bed. She said he took off his underpants, cuddled up to her, touched her private parts, and had her touch his. She said her father then rubbed up against her and that yellow toothpaste-like stuff came out his

privates. Nancy was taken by the child protective service worker to the nearby emergency department, where she was examined by a pediatrician and interviewed by a team that included a pediatric social worker and a child and adolescent psychiatry resident.

Nancy was found to have a dilated and scarred hymen and a vaginal discharge. She was examined using a pediatric colposcope and cultures were obtained of her vaginal discharge for possible venereal disease. During her interview regarding possible sexual abuse, she was able correctly to identify body parts with the aid of male and female anatomically detailed dolls. She was interviewed using nonleading questions and disclosed again that her father had genitally touched her and had orgasms while in bed with her while her mother worked. She further disclosed that her father had told her not to tell her mother because her mother would become upset and might divorce her father and call the police. He said that he would go to jail if the police came and that they would be poor if he could not work, because he would go to jail. Each month, he rewarded Nancy with a secret present to be known only to the two of them. Nancy said that her father began touching her when she was 8 years old and in the third grade. She said that when she began fifth grade, he began putting his private part inside her.

Psychiatric evaluation, at the time of the physical examination, revealed that Nancy was an anxious child who feared retribution by her mother and father because of having disclosed sexual abuse. She expressed fears that her mother would be angry with her and that her father would go to jail. She said it would be her fault if he goes to jail and if her parents get divorced. She said that she was "a bad girl." She spoke of trying to avoid her father, of being afraid of him, of having thoughts all day of him touching her private parts, and of feeling numb and like someone other than herself was being touched by her father. She said that she had recurrent nightmares of being chased by her father and of her mother not wanting to help her from being caught by her father. She said that she had had trouble concentrating in school during the fifth grade and that she was getting only "satisfactories" in reading and mathematics on her report card, even though since first grade, when grades began, she had gotten "excellents" in reading and in mathematics.

There was no evidence of sustained depressive symptoms or of a suicidal plan, attempt, or ideation. There also was no evidence of thought disorder and no history of cigarette or other substance use.

A diagnosis was made of PTSD and Nancy, her mother, and her brother were referred to the child abuse mental health treatment program located in the nearby teaching hospital. Nancy's father was arrested. He was released on bail and told not to return home at this time. He was referred by the child mental health program to a sexual offender treatment program.

Nancy was treated with cognitive-behavioral therapy in a group with other sexually abused girls. Her mother was individually evaluated, diagnosed as having a major depressive disorder, and was provided with individual psychotherapy and antidepressant medication. She also was provided with supportive group therapy together with the mothers of the girls in Nancy's psychotherapy group. Nancy's father was prosecuted, convicted, and released from prison after 1 year. He received cognitive-behavioral and group therapy and was allowed supervised visits with his children. After 2 years of treatment in an outpatient sex offender treatment program, as well as participating in marital therapy with his wife, he was permitted to join in psychotherapy sessions with his children. Three years after his arrest, he was permitted to return to his home. His wife, however, then only worked day shifts and he continued on parole.

---

## LEGAL RESPONSIBILITIES

All states have reporting laws mandating that professionals in the areas of health care, social service, law enforcement, and education report suspected cases of child sexual abuse. All child mental health clinicians have reporting responsibilities. It is essential for clinicians to know their particular state's child abuse reporting statute. In addition, child sex abuse may be prosecuted by the district attorney and investigated by the police. Child mental health clinicians may be called on for information by these agencies.

## PROFESSIONAL ORGANIZATIONAL ASSESSMENT GUIDELINES

The following professional organizations relevant to child and adolescent psychiatric practice have issued guidelines for the evaluation of children and adolescents suspected of being physically and sexually abused: the American Academy of Child and Adolescent Psychiatry ( [Bernet, 1997](#)); the [American Professional Society on the Abuse of Children \(1990, 1995\)](#); the [American Psychological Association \(1994\)](#), the [American Academy of Pediatrics \(1991\)](#), and the [American Medical Association \(1994\)](#).

## INTERVIEWING ALLEGEDLY ABUSED CHILDREN: ISSUES

Anatomically detailed dolls have been used to facilitate children's identification of body parts. Interview guidelines for use with these dolls, including those of [Boat and Everson \(1988\)](#) and [White \(1991\)](#), have been developed. A general consensus has emerged that because there is no known behavior with anatomically correct dolls that provides definitive evidence that a child has been abused, these dolls should not be used in isolation as a diagnostic test for child sexual abuse ( [American Professional Society on the Abuse of Children, 1995](#) ). The research of [Bruck et al. \(1995\)](#) and others also has led to the recommendation that these dolls should be used with caution because they have been associated with false reports in preschoolers.

There is no evidence that anatomically correct dolls are superior as interview aids to anatomic drawings or regular dolls. However, some clinicians argue that there may be a place for these dolls in clinical settings, where they may serve as aids to labeling of body parts and demonstration, and as facilitators for children who are better able to "show" rather than "tell" what happened ( [American Professional Society on the Abuse of Children, 1995](#) ).

## MEMORIES OF ABUSE

Since the early 1990s, there has been increasing recognition that, under certain circumstances, false memories of abuse may develop in children ( [Ceci and Bruck, 1993](#) ). Preschoolers, in particular, have been found to be vulnerable to confusion and false memories because of faulty interview techniques ( [Ceci and Bruck, 1993](#) ). Recent studies inform clinical practice by suggesting that children are most likely to be misled during interviews if (a) they feel it is preferable to "guess" or "pretend" during interviews rather than to acknowledge "not knowing" ( [Saywitz and Moan-Hardie, 1994](#) ); (b) their memories are "weak" ( [Saywitz et al., 1991](#) ); (c) they are confused about "adult" language that does not take the child's developmental level into account ( [Saywitz et al., 1991](#) ); (d) the interviewer is seen as unfriendly, intimidating, or authoritarian ( [Goodman et al., 1992](#) ); or (e) the interviewer has a preconceived bias about the event ( [Ceci and Bruck, 1993](#) ).

There also is a general consensus that the use of open-ended questions when interviewing children suspected to have been sexually abused, although associated with lowest risk for confusion, also is associated with the generation of least information. In contrast, leading questions, which pressure a child to agree with the interviewer, can lead to a permanent distortion of memory for what happened. Focused questions, which fall between free recall and leading questions, have been found to be necessary by many clinicians when faced with a child reluctant to discuss abuse ( [Saywitz and Goodman, 1996](#) ). For example, specific nonleading questions, such as "tell me about your dad . . . what do you like about him?" may generate information that the child otherwise would not volunteer. To minimize suggestibility in forensic interviews of allegedly abused children, [Reed \(1996\)](#) has recommended that interviewers systematically clarify to children what is expected of them by specifically teaching children to state when they are "confused" or "do not know" answers to questions.

## TREATMENT

### Psychotherapies

Most clinicians would agree that victims of child abuse should be routinely assessed to determine the need to receive appropriate referrals for mental health treatments. Social service agencies and juvenile courts refer only a minority of victims for treatment ( [Chapman and Smith, 1987](#) ). Multiple reasons exist for this gap in mental health needs assessment and treatment referrals for these children. They include a lack of available child protective services personnel to do other than focus on the protection needs of children, and a lack of available and affordable child mental health services dedicated to serving maltreated children and their families.

Nevertheless, there has been a growing consensus that the most effective therapeutic approaches in dealing with victims of abuse are those that use structured and direct approaches focused on integrating feelings related to the abuse ( [Finkelhor and Berliner, 1995](#); [Friedrich, 1994](#); [James, 1994](#) ). These therapies emphasize helping children to organize and express their memories and feelings regarding trauma in a manner that facilitates their viewing abuse as something bad that happened to them, rather than as indicating stigmatization or destiny.

Most approaches include parallel treatment of the parents involving education regarding abuse effects and methods of helping their children deal with its aftermath. Diagnosis and treatment of psychiatric disorders in abusive parents as components of the treatment of maltreated children also are important because of their high risks for depression, antisocial personality disorder, and substance abuse ( [Kaplan et al., 1990](#) ).

[James \(1994\)](#) makes the important point that therapy of traumatized children requires a developmental approach. Even after termination of an initial course of treatment, it may be necessary to have the child return at later developmental stages to "work through" the meaning of trauma in light of a new stage of development. This is most evident in the case of sexual abuse where the traumatic sexualization, often is seen in victims of incest, may not become fully apparent until the abused child becomes sexually active as an adolescent or a young adult. These considerations need to be balanced with the potential use of long-term therapy with children who have permanent views of themselves as victims.

### Sexual Abuse and Psychotherapy

A major advance in the field of child abuse since the early 1990s has been the systematic evaluation of the effectiveness of a variety of treatments for child targets of sexual abuse ([Becker et al., 1995](#); [Finkelhor and Berliner, 1995](#)). Most of these use either cognitive-behavioral ([Cohen and Mannarino, 1993, 1998](#); [Deblinger et al., 1990, 1996](#)) or structured group psychotherapy approaches ([De Luca et al., 1993](#); [Larzelere, et al., 1993](#)). These studies report that sexually abused children show improvement in some symptoms after even a relatively brief course of treatment. [Finkelhor and Berliner \(1995\)](#), after an extensive review of the empirical literature on treatment of sexually abused children, conclude that although there remains a need for large-scale, randomized trials, research lends support to the effectiveness of abuse-focused directive therapies compared with less trauma-focused treatments.

Because sexually abused children may present with a wide variety of symptom patterns, further research is needed to determine the most effective treatment approaches for particular constellations of symptoms. There is evidence, for example, that aggressive and sexualized behaviors may be more resistant to change than "internalized" symptoms such as depression or anxiety ([Larzelere et al., 1993](#)). Use of specialized treatment strategies for sexualized behaviors therefore may be indicated ([Gil and Johnson, 1993](#); [Ryan, 1991](#)). Optimum therapeutic intervention strategies for the approximately 40% of sexually abused children who have no clearly demonstrable associated symptomatology ([Kendall-Tackett et al., 1993](#)) remain to be determined.

Parenting-focused therapies need to be components of child sexual abuse treatments. However, the high rates of depression and social isolation often seen in abusive parents ([Kaplan et al., 1990](#)) are two of the variables that have been associated with poor prognosis for parenting-focused interventions, unless parental disorders also are treated. In addition, although therapeutic efforts targeting abusive parents may be viewed as important components of treatment processes, interventions that do not include the abused child are, by definition, going to be limited in effectiveness.

### Pharmacotherapies

There have been few studies of the efficacy of psychopharmacologic treatments of PTSD or other mental disorders associated with abuse that have used abused children as subjects. Studies of the effectiveness of medication in adults with PTSD have relied most often on clinical reports or on open trials. These studies suggest that psychopharmacologic interventions may be helpful adjuncts to psychotherapy, but usually do not suffice as isolated treatment. Carbamazepine and the benzodiazepines have been found to be helpful in decreasing affective instability ([Friedman, 1988](#)). However, there is little evidence that either of these medications improves the full spectrum of PTSD symptoms. Two double-blind studies of tricyclic antidepressants ([Davidson et al., 1990](#); [Frank et al., 1988](#)) and one study of monoamine oxidase inhibitors ([Frank et al., 1988](#)) found these medications to be moderately helpful in treating PTSD. [Van der Kolk et al. \(1994\)](#) found that fluoxetine diminished the sense of numbing, the affect dysregulations, the impaired relationships with others, and the loss of sustaining beliefs reported by persons with PTSD. Sertraline has been reported to diminish symptoms of PTSD, depression, and the alcohol cravings of patients with PTSD in substance abuse treatment ([Brady et al., 1995](#)). Several double-blind studies that did not find antidepressants to be helpful in treating adults with PTSD have been criticized for measuring the effectiveness of the medication for only 4-week periods ([Reist et al., 1989](#)).

One of the few studies of the usefulness of psychotropic medication in the treatment of childhood PTSD ([Famularo et al., 1988](#)) found that propranolol, given at a dose of 2.5 mg/kg, was effective in lowering hyperarousal and hypervigilance in victims of physical or sexual abuse diagnosed with PTSD. [Terr \(1989\)](#) has suggested the use of propranolol or other beta-blockers for traumatized children as an adjunct to behaviorally based treatments ([Terr, 1991](#)).

[McCarthy et al. \(1994\)](#) reported that responses of depressive symptoms to fluoxetine were greater in bulimic patients with histories of physical or sexual abuse than in those with no abuse histories. Clonidine has been found to reduce symptoms of aggression, hyperarousal, and sleep problems in preschool children with severe PTSD ([Harmon and Riggs, 1996](#)).

### SEXUAL ABUSE PREVENTION

In contrast to physical abuse, where the focus typically has been on helping parents learn appropriate child-rearing practices, the focus in primary prevention of sexual abuse has been on child education. School-based programs typically aim to teach children to differentiate "good" from "bad" touch, to deal with abusers' efforts to keep abuse a secret, and what actions to take should sexual abuse be attempted. Children also are taught that abuse may be attempted by people they know, and that should abuse occur, the child is never at fault ([Wolfe et al., 1995](#)).

Although research has found that children's knowledge of how to deal with sexual abuse increases after these programs ([Berrick and Gilbert, 1991](#)), there has not been evidence that such knowledge translates into ability of children to take action when exposed to abuse experiences. [Pelcovitz et al. \(1992\)](#) described 22 young school-age children who were sexually abused by a school employee and did not disclose their abuse, despite having received prevention training before and during the abuse. The reasons the children gave for nondisclosure included confusion about what the prevention program told them to do in the case of abuse, fears of retaliation by the abuser, and concerns that they would be blamed by their parents for the sexual activities associated with the abuse. The adequacy of most prevention programs to teach preschoolers even basic concepts has been questioned ([Wolfe et al., 1995](#)). Preschoolers exposed to six sexual abuse prevention curricula often found the material in these programs to be confusing, suggesting their developmental inappropriateness for preschoolers ([Berrick and Gilbert, 1991](#)). However, sexual abuse prevention has been demonstrated to be adequately taught, even to preschoolers, when the curriculum is sensitive to the child's developmental level, is of sufficient length, and includes the active involvement of the child through role play and other participatory techniques ([Kraizer et al., 1989](#)).

There remains little evidence that sexual abuse prevention programs are effective in the primary prevention of child sexual abuse, but there is a general consensus that these programs can be effective in prompting sexually abused children to disclose, for the first time, that they were abused ([Finkelhor and Strapko, 1992](#)). There also now is a need to develop programs that more actively include parents because responsibility for child sexual abuse protection currently rests primarily with children.

### CONCLUSION

Child sexual abuse has been found to involve up to 5.7% of children in the United States ([Finkelhor et al., 1997](#)). It also has been found to be correlated with emotional and behavioral problems, including sexual behavioral problems, of victims. Suicidal behavior, substance abuse, and psychiatric disorders including PTSD also have been demonstrated to be correlates of sexual abuse exposure.

Despite the high prevalence and the mental health consequences of childhood sexual abuse for victims, insufficient efforts are being made to recognize these consequences and there are too few resources available to provide the needed mental health services to these victims and their families. Screening for victim mental health problems does not routinely occur during the abuse legal documentation investigative and case planning period by state child protective services. Victim mental health assessments also do not usually take place when a sexual abuse report is made. Children, as well as their families, are not routinely referred for mental health services after legal documentation of abuse. There also are few specialized treatment programs to which to refer sexually abused children and their families.

Exciting advances have taken place regarding care of sexual abuse victims. Clinical research has demonstrated the effectiveness of psychotherapies and suggested the efficacy of medications in ameliorating the behavioral and emotional consequences of child sexual abuse exposure. Specific clinician interviewing strategies have been developed to avoid suggestion and interference with sexual abuse-associated litigation. Psychiatry and allied mental health professionals have much to contribute in terms of advocacy for sexual abuse victims and an increased understanding of the need for provision of rehabilitation opportunities to these children.

## DEFINITION AND HISTORICAL NOTE

### Definition

Munchausen syndrome by proxy is a disorder in which a person persistently fabricates symptoms of illness on behalf of another, thereby causing that person to be regarded as ill ([Meadow, 1977](#)). In instances involving children, it is nearly always their mothers who are fabricating the illness. The severity of the disorder and extent of the fabrication are variable: In the least severe cases mothers only report false symptoms, and the physical harm to the children is only that resulting from the medical investigations carried out in attempting to diagnose the illnesses; at the other end of the spectrum are instances in which mothers have caused severe physical harm to their children or even the death of their children in the continued pursuit of making their children appear ill. Although a form of child abuse, there are characteristics of this syndrome that set it apart from other types of abuse.

### Historical Note

In 1951, Asher first used the eponym Munchausen syndrome to describe adults who consistently fabricate symptoms of illness for themselves, leading to numerous medical investigations and frequently to surgical operations. The syndrome was named after Baron von Munchausen of Hanover, who lived in the 18th century and was renowned for telling greatly embellished stories about his adventures in the wars against the Turks. His tales became even more fantastic when written by a friend, Rudolf Eric Raspe, who published a pamphlet ([1948](#)) retelling some of the stories. In [1976](#), Sneed and Bell used the term "the dauphin of Munchausen" to describe a case in which a 10-year-old boy presented with factitious recurrent urinary calculi and in which the mother was suspected of colluding with the child in fabricating the symptoms. The following year, [Meadow \(1977\)](#) coined the term Munchausen syndrome by proxy in his report of observations of two cases in which mothers repeatedly caused their children to be ill. Prior to this time, there had been reports in the literature of cases referred to as "nonaccidental poisoning" in which children repeatedly presented as diagnostic dilemmas and were found to have been poisoned by a parent ([Lansky and Erickson, 1974](#); [Rogers et al., 1976](#)); such cases are now considered to be variants of Munchausen syndrome by proxy. Subsequent to Meadow's initial report, there were other suggestions for a title for the syndrome; these included the names Meadow's syndrome or Polle syndrome, but these have now given way to the more commonly used Munchausen syndrome by proxy ([Lazoritz, 1987](#); [Meadow and Lennert, 1984](#); [Verity et al., 1979](#)). However, this name may eventually be replaced by the term factitious disorder by proxy, which is listed in Appendix B of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) as a category requiring further study ([American Psychiatric Association, 2000](#)).

## PREVALENCE AND EPIDEMIOLOGY

Although the true prevalence remains unknown, Munchausen syndrome by proxy is almost certainly a rare disorder. Active reporting of cases in a prospective study conducted over a 2-year period in the United Kingdom and Republic of Ireland established an annual incidence of 0.5/100,000 children aged under 16 years, and the peak incidence of 2.8/100,000 children in the first year of life ([McClure et al., 1996](#)).

The most comprehensive description of the presentation of cases is found in an article published in 1987 in which Rosenberg conducted a review of the existing literature and summarized all the published reports. These included 117 children in 97 families. In nearly all instances the perpetrator was the mother, although there have now been reports of other persons such as a baby sitter or other relative being involved. Fathers have only been rarely implicated as being the perpetrator or appearing to be complicit in the fabrication of illness ([Makar and Squier, 1990](#); [Meadow, 1984](#)), although recently Meadow has published a series of 15 such cases occurring over a 10-year period (1998).

The diagnosis has been made in children of all ages from the first month of life to 21 years. Rosenberg reported the mean age at time of diagnosis as 40 months, with the mean time interval between the onset of symptoms and time of diagnosis being 15 months. In the more recent epidemiologic study from Britain, the median age of diagnosis was 20 months, suggesting that the diagnosis is now being made earlier ([McClure et al., 1996](#)). There are reports of instances in which the condition started prior to birth with mothers inducing preterm delivery ([Goss and McDougall, 1992](#); [Porter et al., 1994](#)). There is an approximately equal prevalence among male and female children.

## CLINICAL DESCRIPTION

The variety of medical symptoms in children who present with Munchausen syndrome by proxy is extensive and includes practically all organ systems. Generally the illness appears to be multisystem, and the children may appear to have different types of illness at different times. Bleeding is the most common presentation and accounted for 44% of the 117 cases included in Rosenberg's review of the literature. The apparent bleeding may be from many different sites, including the gastrointestinal, genitourinary, and respiratory systems. Seizures accounted for 42% of the cases, central nervous system depression for 19% of the cases, and apnea was present in 15% of the cases. Diarrhea was a presenting symptom for 11%, vomiting for 10%, and fever for 10%. Altogether Rosenberg listed 68 different presentations or pathologic findings. The means by which the perpetrators caused the symptoms or abnormal findings are just as diverse and illustrate the severity and horrifying nature of the syndrome: One mother had put bleach in her child's eye, causing the appearance of a periorbital infection; others had repeatedly suffocated their children so as to simulate recurrent apnea or seizures. Other mothers caused sepsis by putting fecal material into their children's intravenous lines.

In approximately one-quarter of cases in Rosenberg's review, the mother had simulated an illness but had not actually done anything directly to the child to cause harm. These were instances where the mother had done something such as putting drops of her own blood in her child's urine or contaminating the specimen. In these instances, although the mother does not herself physically harm the child, she does continue to collaborate with the physicians as distressing and often painful investigations and procedures are carried out. Meadow also has reported cases in which false allegations of sexual abuse have occurred in the wider context of Munchausen syndrome by proxy with other factitious illnesses ([Meadow, 1993](#)).

[Bools and associates \(1992\)](#) have pointed out that there is a significant amount of comorbidity among cases of Munchausen syndrome by proxy: In a review of 56

cases, 29% had a history of failure to thrive and 25% had a history of either nonaccidental injury or neglect. Siblings also might have a history of such findings or might themselves have been the subjects of fabricated illnesses. This appears to be particularly true among cases that have presented as apnea and which, in fact, are owing to suffocation ([Alexander et al., 1990](#); [Light and Sheridan, 1990](#); [Meadow, 1990](#)). When children present with apnea, Munchausen syndrome by proxy should always be considered if there is a history of death of a sibling or if serious episodes of apnea have occurred only in the presence of one person.

### Description of the Mother

These mothers often have had prior extensive exposure to the health care system. This, in some instances, has been from past training and work experience as a nurse, medical receptionist, or other health care professional. In [Meadow's \(1982\)](#) description of 17 families, nine of the mothers had such a background, and [Rosenberg \(1987\)](#) reported that 27% of 97 mothers had a nursing background and another 3% had worked in medical offices. In other cases, the mother herself has had Munchausen syndrome and therefore has brought to her experience as a mother both her own psychopathology and often a vast knowledge of medicine, hospitals, and medical practice acquired from her experiences prior to her child's birth.

A striking characteristic of the mothers is that they are nearly always considered exemplary in all their interactions with medical staff. This is in contrast to adults with Munchausen syndrome and also parents who provoke sickness behavior in their children and refuse to accept psychological mechanisms ([Kaplan and Sadock, 1988](#); [McKinlay, 1986](#)). Both of these groups are often described as demanding and difficult. In Munchausen syndrome by proxy, the mothers often develop close relationships with the nurses and doctors with whom they come in frequent and continued contact. These relationships sometimes traverse the more usual boundaries between parent and medical staff and may include such things as helping the nurses in their duties, eating meals with the doctors, or maintaining social contact with the medical personnel outside of the hospital. However, these mothers tend to be unavailable for genuine interpersonal interactions, and hospital staff often report subjective feelings of uneasiness or feeling intrusive in the mother's presence ([Zitelli et al., 1987](#)).

The quality of the mother's care for her child is also notable. These mothers are often considered model parents who are extremely attentive to their children. They take over the care of their children to a greater degree than is usual in hospitals. They often live in the hospital and remain with the child constantly. It has been noted, however, that the care given to the child can be of an excessive nature; for example, the child may be dressed in inappropriately lavish clothing, or the hospital room may be stocked with an outrageous number of toys ([Zitelli et al., 1987](#)).

One striking quality of the mother that may be important in recognizing the syndrome is her inappropriate affect when given information about the severity of her child's illness or discussing invasive medical investigations. There is a bland acceptance, rather than obvious distress, and she appears to be relatively at ease with medical uncertainties ([Zitelli et al., 1987](#)). In one report, the mother was even described as appearing euphoric as her child became sicker ([McGuire and Feldman, 1989](#)).

Besides fabrication of symptoms of illness, these mothers often fabricate extensively about other parts of their lives. An example of this is a mother who reported that she had just completed a law degree and was working toward a master's degree in Russian history, both of which were false ([Guandolo, 1985](#)). Certainly an important element of the syndrome is the mother's ability to converse with the medical staff about her child's illness in a very knowledgeable and medically sophisticated manner. The other fabrications often serve to add to the mother's appearance as an intelligent person or as someone who has achieved despite adversity.

### Description of the Father

In contrast to the mother's constant presence, the father may have very little involvement in his child's care and sometimes does not even visit the hospital. This is particularly noteworthy considering the severity of the child's illness. In a review of 37 families, [Gray and Bentovim \(1996\)](#) described 70% of the fathers as peripheral or absent from the family system; often the fathers have jobs that keep them away from the family for prolonged periods of time ([Meadow, 1982](#)). The marital relationship between the parents is often poor, although in some instances the child's apparent illness serves to bring the parents closer together.

In those rare instances where fathers are the perpetrators of Munchausen syndrome by proxy, their interactions with medical personnel appear quite different than is the case with mothers. Like mothers, the fathers often stay with their children in hospital, but are considered by staff to be demanding, overbearing, and unreasonable, and are often quick to make formal complaints and seek legal redress ([Meadow, 1998](#)). It is notable that in Meadow's description of 15 fathers, none were actively employed and 11 had factitious disorders, including five that were considered to be Munchausen syndrome.

## ETIOLOGY AND PATHOGENESIS

Although reports of Munchausen syndrome by proxy are largely found in pediatric journals rather than the psychological or psychiatric literature, there is now an expanding literature that has contributed to a greater understanding of the disorder. Most have been individual case reports ([Chan et al., 1986](#); [Lansky and Erickson, 1974](#); [Nicol and Eccles, 1985](#); [Palmer and Yoshimura, 1984](#); [Waller, 1983](#)), but more recently [Bools and colleagues \(1994\)](#) have reported the systematic evaluation of a series of cases. Thus, there is now some understanding of the underlying psychopathology of the condition and knowledge of features that are common to most cases. However, the full extent to which some of the descriptions may be generalized and an understanding of the limits of the spectrum of the disorder remain undefined.

Three major etiologic factors appear to be important in the pathogenesis of the disorder. These include the mother's experience of abuse or rejection in her own childhood, her pathologic relationship with her child, and the rewarding effect of the medical care system on the mother. In addition, associated psychopathology often contributes to the development of the syndrome.

### Abuse or Rejection of the Mother

Perpetrators of Munchausen syndrome by proxy often have experienced abuse in their own childhoods or have felt rejected by one or both parents ([Krener and Adelman, 1988](#); [McGuire and Feldman, 1989](#); [Palmer and Yoshimura, 1984](#)). In the study conducted by [Bools and coworkers \(1994\)](#) of 47 cases, they were able to interview 19 mothers at variable intervals after the event. Of these 19, 15 (79%) were described as having suffered emotional neglect or abuse in childhood, four had experienced physical abuse, and five had experienced sexual abuse. The experience of rejection continues into adult life, and there is often a poor marital relationship ([Meadow, 1982](#)). The mothers often feel isolated and have a decreased sense of self-worth.

### Pathologic Relationship with Child

These mothers have an extremely close, symbiotic relationship with their children. The child is viewed as very precious but also as somehow damaged and susceptible to illness or harm. [Meadow \(1977\)](#), in his first description of the syndrome, described a child who had been a "long-awaited baby" and who was born after the mother had taken a fertility medication. The child described by [Nicol and Eccles \(1985\)](#) was born after a pregnancy in which there had been a threatened miscarriage at 12 weeks' gestation, an antepartum hemorrhage at 36 weeks, and termination of breast-feeding because of cracked nipples when the child was 5 weeks old. In this regard, cases of Munchausen syndrome by proxy are similar to those seen in the vulnerable child syndrome in which the mother develops an abnormally overprotective relationship with the child following a severe illness early in the child's life ([Green and Solnit, 1964](#)). Obviously, there is the important difference that in the vulnerable child syndrome the mother does not cause her child to be ill, although she views her child as abnormally susceptible to illness. In Munchausen syndrome by proxy there is the complicated and contradictory situation of a mother being excessively concerned about what may be minor complaints while actually causing illness herself.

The contradictory relationship between mother and child is extremely complex and not fully understood. In the case reported by [Nicol and Eccles \(1985\)](#), they describe the mother as experiencing the failure of breast-feeding as "a personal deprivation and attack on herself by the baby." This distorted perception is explained as a protective identification in a stressed person with an abnormal coping mechanism. In the case described by [Palmer and Yoshimura \(1984\)](#), the mother herself had Munchausen syndrome and incorporated her daughter as an integral part of herself. In this way the child experienced both the love and self-hate of the mother.

### Effect of the Medical Care System

Important components in the development of the syndrome are the behavior of the doctors, the hospital environment, and the effect that both have on the mother. In the report by [Nicol and Eccles \(1985\)](#), the mother reported that "she found, in her general practitioner, a source of support and kindness and this reinforced the pattern of very regular attendance at the surgery." [Guandolo \(1985\)](#) has commented that "illness is the ticket of admission to a place where understanding and caring

relieved the feelings of hopelessness and isolation." The interaction, however, is more complex than just the mothers' feelings of being supported. With the increasing severity of illness of their children, these mothers feel a sense of self-worth and importance that is otherwise lacking in their lives. One mother, after confessing to repeatedly suffocating her child, reported that whenever she did it, she experienced a similar feeling to that which she had felt on her graduation day. This mother, during one of the times her child was being resuscitated in the hospital, was overheard by a nurse calmly telling other mothers on the ward that she had already had a child die from a similar episode. This, in fact, was a fabrication but serves to illustrate the mother's need to make the situation even direr so as to gain greater sympathy and appear the more heroic. The hospital environment contributes to these feelings of importance. [Chan and associates \(1986\)](#) described a mother who would visit the intensive care unit just to talk to other mothers, and [Meadow \(1984\)](#) has described another mother who had some nursing training and who would help teach nursing students. There obviously becomes an increasing need for the mother to gain admission to the hospital through her child's illness.

Another factor is the pleasure gained from the contact with the doctors. In the case discussed by [Nicol and Eccles \(1985\)](#), the mother reported that she liked to feel that she "was being considered by intelligent people." There appears to be an additional element in which the mother gains pleasure from outwitting the doctors. It becomes a bizarre game in which the mother matches herself against the specialists, and as one problem is resolved, another one is created.

### Associated Psychopathology

As [Meadow \(1985\)](#) has stated, "Many mothers who have perpetrated Munchausen syndrome by proxy have been referred to psychiatrists, and many have had detailed psychological testing. Usually the tests are normal and no disorder is apparent to the psychiatrist." This likely speaks to the misdirected focus of these evaluations rather than to a true lack of psychopathology. In the follow-up study of 47 mothers conducted by [Bools and coworkers \(1994\)](#), 55% had a history of harming themselves, 21% had a history of abuse of alcohol or drugs (usually prescribed medications), and 72% had a history of somatoform or factitious disorders. For the 19 cases in which there were detailed interviews and completion of the Personality Assessment Schedule, 17 of the 19 were considered to have personality disorders. Many of these had multiple disorders, however; histrionic and borderline personality disorders were predominant. Other disorders included avoidant, dependent, narcissistic, schizotypal, and paranoid categories. However, the cases evaluated in this study likely represent a biased sample with more severe symptomatology, and it is often true that there is sometimes a surprising lack of associated psychiatric symptoms, considering the severity of the nature of the disorder.

Some of the case reports serve to demonstrate a spectrum of illness rather than a universal picture. [Chan and associates \(1986\)](#) described a mother who demonstrated several features consistent with both narcissistic and borderline personality disorders. She was explosive, constantly sought attention, displayed sadomasochistic tendencies, showed marked shifts in attitude and affect, and presented a sense of entitlement. Her primary defenses seemed to be denial and splitting. In the report by [Nicol and Eccles \(1985\)](#) of a mother's progress in psychotherapy, they describe an important part of the pathogenesis of the abuse as being the mother's affect, which included infantile rage as a central component together with devastatingly low self-esteem. In the report by Palmer and Yoshimura of a mother who herself had Munchausen syndrome, psychological testing

revealed a profoundly needy individual whose reality testing was impaired. She perceived the world as a malevolent place and people as attacking. Thought processes were distorted and interpersonal boundaries were blurred. Coping strategies included extreme forms of denial, projection and paranoid vigilance ([Palmer and Yoshimura, 1984](#), p. 506).

The fabrication of illness and often-continued denial do not have the fixed quality of a delusion, although the mother does not appear to be consciously lying ([Waller, 1983](#)). It has been described as "quasidelusional" and Waller has commented that

the disturbance in thought content and behavior may be a dissociative phenomenon or a form of pseudologia phantastica or pathological lying in which the parent comes to believe, at least intermittently, the fantasy that the child has a primary rather than a factitious illness ([Waller, 1983](#), p. 83).

Mothers who have confessed to the perpetration of injury on their children have been able to describe the incident but have little recollection for the details and describe themselves as committing the act in a disassociated-like state.

### PSYCHIATRIC DESCRIPTION OF THE CHILD

There is little in the literature describing the children in this disorder. The one striking comment, however, is that the children, particularly older children, collude with their mothers in the ongoing deception. In the original report of [Sneed and Bell \(1976\)](#), it was the 10-year-old boy who was presenting the pebbles as renal calculi. A 2½-year-old girl at our institution did not cry out when her mother, in what must have been a painful process, produced signs of gastrointestinal bleeding by excoriating her anal canal. Furthermore, these children, like children who have been repeatedly physically abused, quickly learn to passively tolerate medical procedures. Other symptoms that have been described include feeding disorders among infants and toddlers and withdrawn, hyperactive, or oppositional behavior among preschoolers ([McGuire and Feldman, 1989](#)).

### SPECTRUM OF THE DISORDER

[Meadow \(1985\)](#), in reporting on what he terms mild cases, raises questions regarding the limits of the definition of the disorder. He points out that, at times, parents often exaggerate their children's symptoms or may perceive that a problem is present when it is not apparent to the doctor. This is particularly true for some parents who consider their children allergic and limit their exposure to various foods and things in the environment. Certainly some of these parents share a number of the same characteristics as those more severe cases of parents who actually cause their children to be ill ([Warner and Hathaway, 1984](#)).

It is also important to ask the question of when Munchausen syndrome by proxy begins in an individual case, recognizing that some cases start with parental concerns surrounding a real illness and that these concerns, at some stage, overflow into fabricated illness. Also, is it only the lack of the medical knowledge that prevents others from developing Munchausen syndrome by proxy? In fact, the syndrome has been described as only one end of a spectrum of parental behaviors surrounding chronic and factitious illnesses of children ([Eminson and Postlethwaite, 1992](#); [Krener and Adelman, 1988](#); [Libow and Schreier, 1986](#)). It is important, however, that we recognize the significant differences in the psychopathology of the parent who injures her child or causes her child to appear ill and the parent who repeatedly presents as overly concerned about her child's illness. What appears to set Munchausen syndrome by proxy apart is the synergistic effect of the mother's prior experience of abuse or rejection, her pathologic symbiotic relationship with her child, and the powerful rewarding effects of her interaction with the medical environment. [McKinlay \(1986\)](#) describes the parent "who provokes sickness behavior in the child, refuses to accept psychological mechanism, seeks multiple opinions and insists on repeated investigations," and points out that this type of parent is often combative or has a contemptuous style, which is very different from the exemplary, ingratiating parental style seen in Munchausen syndrome by proxy. The former does not appear to experience the elevation of self-worth and feeling of importance that seem so much a part of Munchausen syndrome by proxy. There is, however, a striking similarity between these cases and Munchausen syndrome by proxy in the symbiotic relationship between mother and child and the way in which the child colludes with the mother in continuing the illness ([Woollcott et al., 1982](#)).

In DSM-IV, factitious disorder by proxy has been identified as requiring further study, with the following criteria suggested:

1. There is intentional production or feigning of physical or psychological signs or symptoms in another person who is under the individual's care.
2. The motivation for the perpetrator's behavior is to assume the sick role by proxy.
3. External incentives for the behavior (e.g., economic gain) are absent.
4. The behavior is not accounted for by another mental disorder.

Such criteria would limit the use of the term to cases in which the perpetrator's behavior is motivated by the need to assume the sick role by proxy, which would serve to exclude a number of situations in which the term Munchausen syndrome by proxy is presently inappropriately used, such as with parents who are overanxious or "doctor-shopping" or seek opinions from multiple doctors for other reasons ([Meadow, 1995](#)). However, at present, there continues to be some controversy regarding the spectrum of the disorder and the use of either of the terms Munchausen syndrome by proxy or factitious illness by proxy ([Bools, 1996](#); [Fisher and Mitchell, 1995](#)).

### TREATMENT

The management of Munchausen syndrome by proxy often is extremely difficult. There are a number of reasons why this is true: First, there is the difficulty of making the diagnosis—it often goes unsuspected for a long time, and then, even when suspected, it is often difficult to be sure that one's suspicions are in fact correct.

Second, the disbelief that the diagnosis engenders often serves to sabotage overall management. Last, psychotherapy is extremely difficult when the therapist is reliant on the patient telling the truth, which is something that rarely happens in these cases, at least initially.

## Medical Management

The warning signals that should alert a physician to the possibility of a factitious illness have previously been identified by [Meadow \(1982\)](#) and are shown in [Table 102.1](#). Once it is suspected that an illness may be fabricated, the physician needs to establish the diagnosis with certainty. This is often an arduous and time-consuming task. Obviously, the safety of the child and protection from further harm are of utmost importance during this time.

---

Persistent or recurrent illness that cannot be explained  
Discrepancies between the history, clinical findings, and general health of the child  
Wrong diagnosis is a rare disorder, or experienced clinicians have "never seen a case like it before"  
Symptoms and signs occur only in the mother's presence  
A mother who is extremely attentive and always in the hospital  
A child who is frequently intolerant to treatments  
A mother who appears less worried about her child's illness than is the medical staff  
Seizures that do not respond to appropriate therapy  
Families in which sudden unexplained infant death has occurred  
A mother with previous medical or nursing experience or who has an extensive history of illness

---

Adapted from Meadow R: Munchausen syndrome by proxy. *Arch Dis Child* 57:92-98, 1982.

**Table 102.1. Warning Signals of Munchausen Syndrome by Proxy**

The physician should review the medical history in detail and distinguish those complaints that may have been fabricated from those that are definitely real; complaints that occurred when only the mother was present need to be separated from those witnessed by others; details of the medical, psychiatric, personal, and social history, as presented by the mother, need to be verified. This may require careful and detailed histories from other family members.

Detailed descriptions of the mother's behavior and incidents that occurred while in the hospital may provide a profile consistent with Munchausen syndrome by proxy. A number of laboratory methods have been used to confirm fabricated symptoms. These include biochemical analyses of blood and urine samples, typing of blood to determine if it is the child's or the mother's, and analyzing recordings from apnea monitors. Continuous observation of the mother by nursing staff is extremely difficult and usually not possible. Also, it is often not possible to exclude the parents from the hospital for a long enough time to establish a temporal association between the symptoms and the presence of the mother. Video surveillance of the mother and child in the hospital has also been carried out. This, like searching a mother's personal belongings, creates ethical and legal problems. However, these need to be weighed against the risks to the child, and if there is no recourse, video surveillance may need to be carried out ([Meadow, 1987](#); [Williams and Bevan, 1988](#)).

Once the diagnosis has been established, the mother needs to be confronted and informed of the doctor's knowledge about what is going on and the course of action that needs to be taken to ensure the safety of the child. Other family members also need to be notified and the diagnosis explained to them. The protective services agency needs to be notified, and legal services need to be involved because in most instances the child has been abused and needs continued protection.

## The Role of the Psychiatrist

Although the early literature seldom commented on the role of the psychiatrist in the management of Munchausen syndrome by proxy, more recent reports of cases being successfully managed with psychiatric approaches suggest that child psychiatrists have a very important role to play in ensuring an optimal outcome for these children and parents. One difficulty is that, although it is a psychiatric disorder, the clinical presentation is medical, and often the apparent lack of psychiatric symptoms precludes a reason for the psychiatrist's involvement. Once the diagnosis is suspected, however, the child psychiatrist's contribution can be very important in a number of different ways.

### HELPING TO ESTABLISH THE DIAGNOSIS

Even though the mother may not herself request psychiatric help, once the diagnosis is suspected, a reason should be sought for the child psychiatrist to meet with the mother. Because care needs to be taken not to sabotage the overall management plan by giving the mother warning that she is under suspicion, the reason might be that the psychiatrist can often be helpful to families of children with chronic illnesses. The history taken at this time should include family, social, and psychiatric information, but the most important focus, and that likely to be most acceptable to the mother, is around the child's illness. In reviewing the details of the child's life and illness, the child psychiatrist may be able to obtain an understanding of the special meaning of this child to the mother and the symbiotic relationship between mother and child. An example of this is a mother's description of how much more worried she had been about her daughter (the child now presenting with illness) than she had been about her older child, a son, although both had been on home monitoring because of concern about apnea (see the [Case Illustration](#)). When the daughter, who was named after the mother, was 8 weeks old, the mother heard of another child who had died of sudden infant death syndrome. Since that time, she had feared that her daughter would die and was compulsively careful about the apnea monitor in a way that she described as being very different from when her son was on the monitor. With her son, she had often turned the monitor around so that she could not see all the flashing digital lights and alarms; with her daughter it was intolerable for her not to see these. It is the ability to elicit this quality of the relationship between the mother and child that might be most helpful in the interview. The child psychiatrist, with his or her training and experience in understanding the relationship between mother and child, is likely to be more helpful in assessing this quality of the relationship than would someone without training in child psychiatry ([Eminson and Postlethwaite, 1992](#); [Meadow, 1985](#)). During the assessment, the child psychiatrist also may be able to elicit other information that provides evidence of fabrication or is indicative of other psychiatric symptoms associated with Munchausen syndrome by proxy. The child psychiatrist also should be able to provide an assessment of the degree of psychological disturbance experienced by the child and should be key in planning how this should be addressed.

### DEVELOPING A THERAPEUTIC RELATIONSHIP

A potentially important part of the early assessment is to provide an opportunity for the mother to start to develop a therapeutic relationship with the psychiatrist. Because in most of the cases reported in the literature the psychiatrist has only been involved once the mother has been confronted, it is unclear whether an earlier meeting, prior to the confrontation, might be beneficial, or whether the mother's later realization that the psychiatrist was complicit in the suspicion of her might be detrimental to ongoing treatment. It seems likely, however, that the mother could accept reassurance that the psychiatrist is intent on helping her and that she could therefore maintain the trust necessary for ongoing therapy. Therefore, it may be important for the psychiatrist doing the early assessment to continue to provide ongoing treatment, although this is not always possible in some centers.

### CONFRONTATION

The aim of the confrontation is to explain to the mother that the clinicians know she is harming her child and the possible consequent effects. She should be informed of the steps that will be taken to protect her child and provide help for her and her family. [Meadow \(1985\)](#) has suggested that the pediatrician alone, without other professionals or family members present, best confronts the mother. Although this may be true for someone like Meadow, who has such a vast experience with this syndrome, it may not necessarily be true in instances where the pediatrician has had no prior experience of Munchausen syndrome by proxy. In these cases, it may be helpful to have a child psychiatrist present to help in the process. It is important, however, that the pediatrician be the one who confidently affirms what has been going on. The child psychiatrist then is able to speak of it as a psychiatric problem and outlines what is likely to happen, at the same time being supportive.

At this stage, only a few mothers will confess to what they have been doing, although at times there are remarks that serve as tacit admission of the activity. The majority of mothers continue to deny their activity, often in a very convincing way, although sometimes in a remarkably calm, flat manner. It is not helpful to try to prove to the mother that you are right and she is wrong, nor is it helpful to counter every explanation she provides.

Some mothers have become extremely agitated, acutely psychotic, or depressed and suicidal following the confrontation ( [Palmer and Yoshimura, 1984](#)). An assessment may need to be made regarding the need for psychiatric hospitalization. Needless to say, it is critically important that the child be protected from the mother at this time, because she may have a heightened need for the child to be truly sick.

#### ASSISTING STAFF IN UNDERSTANDING THE DYNAMICS OF THE CASE

This may be an extremely difficult problem to deal with for medical and social services staff, particularly if they have had no prior experience with or knowledge of the syndrome. The emotional responses of the staff are made more complicated by the fact that some might have known the family for a long time and developed close relationships with the mother and child. For some people, there is complete disbelief; for others, there is anger at the mother and feelings of guilt that they have participated in harming the child or have not been more astute in correctly identifying the problem at an earlier time. Group discussions are helpful in both informing staff about the syndrome and providing them an opportunity to express their feelings. It is also helpful to provide written material about the syndrome for staff to read.

The psychiatrist also may play an important role in providing protective services workers and lawyers with an understanding of the syndrome and may even appear as an expert witness in the courts. In this way, the psychiatrist can help to facilitate an appropriate legal course of action. The psychiatrist's role in this may have important ramifications in later treatment: The assertion of the severity of the disorder and the danger to the child, together with an uncritical view of this as a psychiatric disorder, may have therapeutic implications for the mother.

#### PSYCHOTHERAPY

As noted, there is limited information available in the literature concerning psychotherapy of mothers and children with Munchausen syndrome by proxy. Palmer and Yoshimura have emphasized that the following are important determinants of how a case should be managed:

the degree and duration of abuse; the parent's psychological state; whether the reaction to the confrontation is denial or acknowledgment of behavior; resistance or willingness to engage in treatment; and whether the child is perceived as part of herself or as a separate entity ( [Palmer and Yoshimura, 1984](#), p. 507).

Obviously, each of these factors might be an important indicator of the accessibility of the individual to psychotherapeutic intervention, but an adverse factor should not necessarily be considered a contraindication to therapy.

Nicol and Eccles have provided details of their case in which the mother initially denied the allegations but later confessed when faced with the possibility that her children might be placed in foster care. The mother, in this case, continued in therapy on a weekly basis for 6 months and then biweekly for a further 6 months. From early on it was "clear that the mother had a strong wish to understand herself, that she was intelligent, and that she had a capacity to bring active and painful feelings to therapy sessions." General themes of therapy included the complex reasons for the abuse, where a full realization of the danger she had put her child in gradually emerged. Other important themes were her relationship with her parents and fears about her child's health that first originated during her pregnancy.

In a report describing outcomes for 13 cases receiving psychiatric intervention, Berg and Jones described an inpatient treatment approach provided in the family unit of a children's hospital by a multidisciplinary psychiatric team experienced in management of child maltreatment. "The theoretical orientation of the team is founded on principles of infant-parent attachment theory" and treatment included

psychological interventions targeted at: the parent-child relationship, the quality of the child's attachment to each parent, the abuser's own childhood experiences, and the current social network and family dynamics, together with work with the parental couple ( [Berg and Jones, 1999](#), p. 466).

The length of stay in the family unit varied between 3 days and 4 months with the average duration being 7½ weeks.

#### OUTCOME

The final outcome for children with Munchausen syndrome by proxy is very variable and dependent both on the severity of the disorder and treatment provided. The mother who has other psychiatric disorders in addition to Munchausen syndrome by proxy and the child who has been involved in the fabrication of symptoms for many years are more difficult to treat than those with a simpler presentation. This is likely true for those mothers who have Munchausen syndrome themselves, which is often very difficult to treat successfully ( [Mayo and Haggerty, 1984](#)). The child whose symptom of illness has been caused by a more dangerous activity (e.g., suffocation) is obviously more at risk of dying than the child whose symptom was owing to less dangerous methods (e.g., a mother's putting blood in her child's urine). In [Rosenberg's \(1987\)](#) review of the 117 cases reported in the literature, 9% died and 8% of the survivors had permanent disfigurement or impairment of physical function. The leading causes of death were suffocation and poisoning. Children have died even after the diagnosis was made and their mothers confronted, and younger siblings have been abused after older siblings died.

The psychiatric sequelae have been less well described both for the mother and child. Certainly, some of these children have continued to fabricate illness for themselves, and the child with Munchausen syndrome by proxy has grown up to be the adolescent or adult with Munchausen syndrome ( [Bools et al., 1993](#); [Meadow, 1985](#)). Of the 12 children described by [McGuire and Feldman \(1989\)](#), 11 were described as having adverse effects that included immaturity, abnormal relationships with their mothers, separation problems, and aggressive behavior. Some children have expressed fears of poisoning and death, and at least two children have required psychiatric hospitalization ( [Rogers et al., 1976](#)).

In the most comprehensive follow-up study reported to date, [Bools and colleagues \(1993\)](#) described 54 children for whom they obtained information an average of 5.6 years after the event. Thirty of these children continued to live with their biologic mothers, whereas 24 children were with other family members or in substitute care. For 10 of the 30 children living with their mothers there was evidence of further fabrications, and for another eight there were "other concerns," either about the relationship between the mothers and their children, or about other aspects of the mothers' behaviors. Of these 18 children for whom there were continuing concerns about the family, 12 exhibited psychological symptoms, including somatic complaints, emotional disorders, conduct disorder, and poor functioning at school. Among the 24 children who were no longer living with their biologic mothers, eight had persistent psychological symptoms, and another six children had disorders that had shown signs of gradual improvement. Altogether, the authors of the study concluded that half of the children had outcomes that they considered to be unacceptable, but, because of the variability in cases, it was not possible to comment on whether better outcomes were obtained when children remained with their mothers or were separated. However, the authors did conclude that when children remained with their mothers, the outcome appeared improved when there had been a temporary placement in foster care.

In reporting on the follow-up of cases enrolled in the intensive, inpatient treatment program described above, [Berg and Jones \(1999\)](#) reported greater success. When 16 families were reevaluated an average of 27 months after treatment, there were no ongoing concerns for nine of the families; the mothers had no mental health problems and had insight into their original condition, and the children had no psychological disorders. There continued to be mild concerns for five families in which the mothers continued to have mild to moderate mental health problems, although these did not impact on their relationship with their children or on the children's development. In only two families were there more serious concerns about the mother's mental health, although they were not overtly abusive. However, the authors stressed that these cases had been selected for treatment on their likelihood of achieving success and that cases considered unsuitable for psychiatric treatment were excluded, usually because of persistent parental denial or the severity of the parent's personality disorder.

#### CONCLUSION

In this condition, perhaps more so than any other, there needs to be extensive collaboration between the child psychiatrist and pediatrician, as well as with the other services involved ( [Bentovim, 1985](#); [Eminson and Postlethwaite, 1992](#); [Meadow, 1985](#)). The role of the psychiatrist may be very different from that with other psychiatric diagnoses, particularly when a case is first diagnosed, and although it is recognized as a psychiatric disorder, it needs also to be remembered that it is a serious form of child abuse. It is hoped that with our increased understanding of this syndrome and an appropriate psychiatric approach to management, there will be an improvement in outcome for both the children and their mothers.

---

## CASE ILLUSTRATION

A 10-month-old girl was admitted to the hospital for the fourth time over a 3-month period. Each admission was for treatment of unilateral periorbital swelling and inflammation. The presumed diagnosis was recurrent periorbital cellulitis, and on each admission she was treated with intravenous antibiotics. While on treatment, her eye would sometimes improve, and then inexplicably become worse. Numerous consultations and diagnostic studies were carried out. Corneal ulcers were noted on the final admission. Suspicions had already been aroused, and at this time the pH of the conjunctival fluid was tested and found to be more alkaline than that of the other eye. A diagnosis of Munchausen syndrome by proxy was made.

This child was the younger sibling of a 3-year-old boy who had had bacterial meningitis in the neonatal period and had developed apnea when 8 weeks old. He was started on apnea monitoring at home and then, at the age of 11 months, started having seizures. The index child was also reported to have apnea starting at 8 weeks of age. She was monitored at home and had a number of significant apneic episodes. Three of these episodes occurred in the hospital: At the start of each occasion the mother was alone with the child, and when called, the medical staff found the child cyanosed and with gasping respirations. Later, once the correct diagnosis was realized, a recording stored in memory in the apnea monitor was reviewed and showed that prior to the last episode of apnea, the monitor had been switched off for 2 minutes and that when it was switched on again, the child was apneic. The mother had been the only one present during this interval, and there was no reasonable explanation for why the monitor had been switched off.

A child psychiatrist experienced in Munchausen syndrome by proxy was consulted, and the mother was confronted with both the pediatrician and psychiatrist present. She appeared extremely upset and denied all allegations. Her husband and other family members were disbelieving but agreed to the plan of management "in case it were true." The management included referral for ongoing psychotherapy and initiation of plans with the protective service agency to ensure continued protection of the children. Because placement of the children with members of the extended family was a consideration, a family meeting was called to ensure that everyone believed what had happened and understood the seriousness of the disorder. The mother confessed to what she had done prior to this meeting. She sought help from her psychiatrist and, at the meeting, was able to talk about her problem and ask for help from her family. It was decided at the court hearing that the children should be placed in the custody of their father and paternal grandparents, with the mother to have supervised visitation and to continue in psychotherapy.

### Comment

In this instance, the mother shared many characteristics described in cases of Munchausen syndrome by proxy. She had been abused as a child, her parents were divorced, and she had little contact with her father. Her relationship with her husband was described as good, but he had three jobs and was seldom at home. She herself had not had frequent illnesses, nor did she have nursing training, but she had become acquainted with medical care and technology with her first child. She considered her second child to be very special and was particularly concerned that she might die. She was extremely attentive to her child, stayed in the hospital constantly, and was very friendly with the medical staff.

In this case, the mother developed a trusting relationship with the child psychiatrist right from the time when she was most distressed, following the confrontation. The family meeting was extremely helpful in ensuring the family's continued attention to the safety of the children and support for the mother. It should be noted, however, that in some respects this case was less complex than many and less difficult to manage.

More than 3 million children in the United States are estimated to suffer from some type of chronic illness ( [Schoenborn and Marano, 1988](#)). Given the scope and pervasiveness of pediatric problems, the occurrence of a serious physical illness is increasingly understood to represent a major early risk factor for subsequent emotional disturbance ( [Table 103.1](#)). However, it has been difficult to develop a national intervention strategy. One factor that may have impeded progress in this area has been the wide variability in the results of outcome studies designed to demonstrate the association between the occurrence of early illnesses and subsequent problems in emotional development. The range of adaptation to physical illness is broad. Some children seem to thrive heroically despite long periods of difficult symptoms, prolonged and painful treatments, and interruptions in school and peer experiences. This developmental variability in response to early stressors is actually typical of children's response to many risk factors and is well demonstrated by the substantial range of responses that children demonstrate to major life events such as the divorce of their parents ( [Hetherington and Stanley-Hagan, 1999](#)).

---

Onset	Particularly difficult developmental periods include early childhood (6 mo-5 yr) and early adolescence.
Etiology	Illness that are the result of some environmental exposure (trauma or infection) or inherited genes provide specific stressors on the family.
Diagnosis	Prolonged delay in diagnosis or misdiagnosis has a negative impact on the family-doctor relationship.
Deformity	Physical deformity and disability negatively influence both the development of self-image and availability of support.
Prognosis	The more negative the prognosis, the greater is the risk posed to adaptive emotional development.

---

**Table 103.1. Illness-Related Risk Factors**

Two contrasting approaches can be used to develop a conceptual understanding of the emotional impact of medical illnesses on children. The first strategy is to look for typical responses that occur in children with a range of different types of medical diseases. Using this approach, investigators have described a set of characteristics typical of most children with persistent severe illnesses. Two commonly discussed concerns are problems with self-esteem and the maintenance of supportive peer relationships. However, these difficulties are also present in physically healthy children who grow up in highly stressful environments. Such problems in the formation of identity and relationships are probably better considered to be generic sequelae of early adversity rather than the consequence of a specific risk factor. This approach provides a unifying conceptual model that can be useful politically to advocate for all children at risk. However, it does not provide guidance for the clinician who is faced with the challenge of helping a particular child with a specific chronic disease.

The second approach is to define the unique characteristics of each chronic severe illness. The goal is to identify a specific set of physical symptoms associated with the illness that places children at risk for problems in adaptation. Such a perspective is best organized by considering children within their family and social contexts. This can be conceptualized as defining the mediating variables that modify the child's development. This approach requires an analysis of the interactions of illness-related risk factors, familial risk and protective factors, and other environmental risk and protective factors. This approach also emphasizes strengthening protective influences as an essential aspect of the treatment of the child, to maximize the potential therapeutic impact of the child's family and community. Risk and protective factor analysis has long been used to understand the factors relevant for the development of psychopathology in physically well children ( [Rutter and Garmezy, 1983](#)). This chapter focuses primarily on chronic illness-related risk and chronic illness-related protective factors within the broader context of the family and the community.

## ILLNESS-RELATED RISK FACTORS

Illness-related risk factors are the characteristics of specific chronic diseases that place children at increased risk of emotional disturbance. Physically ill children are not immune to the negative effects of poverty, poor parenting, parental divorce, or overt neglect and abuse. In addition to these and other risk factors, they must cope with hardships imposed on them by their physical symptoms, limitations of function, and disruptive and painful treatments. On a more positive note, they may benefit from illness-related protective factors, such as the support provided by sensitive physicians and nursing staff. These beneficial influences can be further potentiated by protective influences that are not related to illness, such as secure parental attachments and strong family cohesiveness. Many of the more recent innovations in pediatric treatment represent institutionalization of illness-related protective factors. Familiar examples include the systematic preparation of children for difficult medical procedures and the encouragement of parental support and presence throughout the hospitalization of their children.

When a family learns that a child has a serious chronic illness, it does not mean that the child will inevitably become depressed, lonely, or feel socially rejected. Chronic illness should be viewed as a condition characterized by a set of serious challenges that can either be overcome or lead to a sense of emotional defeat. Every pediatrician can provide an anecdote of a particularly competent child who faced dreadful illnesses with great courage. Similarly, pediatricians can describe the sense of accomplishment that some families achieve when they successfully manage the symptoms of their seriously ill child. These stories of victories are retold with pride, because the success of these patients also reflects the skill and support of their committed doctors. It is more difficult to remember the family that falls apart or the child who stops trying. Helping children who cannot overcome the emotional traumas associated with a serious medical illness often becomes the central role of the child psychiatrist in a pediatric setting. The need for psychiatric consultation becomes even more evident when illness-related risk factors begin to contribute to the development of overt psychopathology in either the child or the parents.

### Impact of Time of Onset

The point at which an illness begins has a differential impact on the effect of a chronic illness. A guiding therapeutic principle has been that the painful and frightening symptoms of chronic illnesses are most difficult for young children to manage. This is, in part, because young children lack both the ability to understand the concept

of illness fully and the rationale for required treatments. The exception to this principle is the experience of very young infants. During the first months of life, immature central nervous system organization may contribute to actual amnesia of the traumatic aspects of the illness. A review of the cognitive appraisal of illness supports the general principle by demonstrating a link between cognitive development and the capacity to cope with medical procedures ( [Brewster, 1982](#)).

However, the onset of a serious illness during adolescence can have stressful consequences as a result of quite different developmental considerations. Body image, personal identity formation, and peer acceptance are major issues for the young teenager, and the onset of a chronic illness during these years can dramatically disrupt the normal process of self-development. For example, a child may be able to deal with aspects of an illness quite well in the elementary school years, but with the onset of puberty and a strong desire to establish a sexual relationship, an adolescent may find rejection in early romantic explorations very upsetting. Depressive symptoms clearly increase with the onset of adolescence, and management of suicidal ideation and actual suicide risk must become a more central concern in the care of teenage patients.

### **Nature of the Etiology of the Illness**

It is critical to develop an appreciation of how a particular child understands his or her illness. Similarly, the belief system of the child's parents must be appreciated. Both rational and irrational elements are important to understand. Genetic illnesses provide a special challenge, because there is an element of rational responsibility that must be considered. In many cases, an illness is inherited from one parent. Although passing a problematic polymorphism onto a child may occur with no appreciation of the risk, it is common to feel remorse when a recognized family illness appears in the next generation. As it becomes more common for parents to have a far greater understanding of the negative polymorphisms that they carry, the issue of dealing with parental responsibility will become a more critical aspect of helping families to cope with the consequences of decisions. Such interactions will be particularly challenging when there has not been full disclosure of probable genetic risk between the two parents.

When an illness is caused by an infection, there is an even clearer link between potential parental behavior and outcome. If the illness could have been prevented by recommended immunizations, the parents have clearly made a decision that placed their child at increased risk. The occurrence of traumatic injury is perhaps the most difficult, particularly with young children. If an element of neglect is associated with an injury, particularly in a child who is already compromised by being chronically ill, the negative impact on the parental relationship with the child can be very serious.

In contrast, diseases that are believed to be "an act of God" provide much less direct interpersonal stress for the patient and family. In these cases, there is no one to blame, and the "reason" for the illness is accepted to be beyond the understanding of the family. However, even in the presence of superficial acceptance of the illness, a period of grief and depression often emerges as the family begins to try to understand how such a dreadful outcome as a life-threatening illness could actually be part of a larger plan. Allowing families to work through the loss of their hopes for the future of a healthy child is a critical component of adjusting to the many illness-related stressors that complicate the treatment of severe illnesses.

Regardless of the cause of the illness, the therapeutic task ultimately requires a shift away from a preoccupation with concern about *why* the illness has emerged. It must move forward to a determination of *what* treatment should be initiated and *how* the family can adapt to the changes that the illness will inevitably bring to their lives. A special consideration occurs when the origin of the illness is clearly genetic and there is a quantifiable risk for future children in the family. First the pediatrician or a genetic counselor working as part of a treatment team must explain to the parents the risk for future children. Once the family can appreciate this risk, a child psychiatrist can play an important role in helping families to integrate the meaning of this information realistically and to make well-informed decisions based on the risks involved in having additional children.

### **Certainty of Diagnosis**

Once the diagnosis is established with certainty, the child and family can begin the process of coming to grips with whatever life changes are required to manage the illness. When a long period of uncertainty follows the onset of physical symptoms, various negative processes emerge that can disrupt the doctor-family relationship. Among the most difficult is the situation that arises when the diagnosis is unnecessarily delayed as a result of error or confusion in communication. If it is eventually determined that a specific treatment could have been provided earlier in the course of the illness that would have had a positive impact on the patient's long-term prognosis, the possibility of malpractice suit should not be minimized.

As a general rule, dealing with a defined problem is less difficult than coping with the unknown. This principle often provides guidance to the medical team members, who may be overtly uncomfortable with the painful news of the diagnosis of a chronic illness and may be tempted to delay the actual naming of the disease for months. This avoidance is most common in the case of a terminal illness. In many cases, both the parents and the pediatrician may collude to avoid sharing the grim prognosis with a young child. In such cases, it is not unusual to make the suggestion that the child psychiatrist should be consulted with the explicit expectation that he or she be the one to explain to the child that recovery is unlikely. The consultation is usually prompted by the rationale that the psychiatrist is particularly skillful in speaking directly with children and is trained to understand the nature of their emotional responses. This may ultimately be the only possible way to proceed, and such a strategy is clearly superior to a prolonged pretense during which time the child must try to make sense of the disparity between what he or she is told about the illness and the manner in which the people most important to the child are responding to him or her. Whenever possible, it is more productive for the child psychiatrist to play the role of the facilitator in a session that includes the family and the pediatrician. The goal of this effort is to establish an openness about the prognosis of the child so the child can begin to understand the emotional communications of those around him or her. Ultimately, the objective is to ensure that the parents and pediatrician will be able to be aware of the wishes of the child as they make difficult treatment decisions.

### **Degree of Deformity and Disability**

The presence of physical deformity and functional disability will clearly increase the negative impact of chronic illness. These illnesses are usually associated with some degree of limitation. The first principle of the treatment team is to determine how to help the pediatric patient to address these issues, to minimize negative effects on emotional development. Cumulative evidence suggests that the degree of impairment is directly associated with increased psychopathology.

A different set of considerations is raised when a major deformity in body image is the result of the treatment rather than the disease. Although a major physical deformity is a difficult issue throughout development, the time of greatest vulnerability occurs during early and middle adolescence. The treatment goal should not be to deny the impact of the deformity, but rather to provide critical emotional reassurance that, despite disfigurement, the child is still a valued part of the family and community. In this circumstance, actions are clearly more important than verbal remedies. The child must feel that he or she is included in the life of the family in a substantive way if reassurances are to be at all effective. A particularly useful strategy to normalize the child's experience is to encourage a peer group experience with children with similar deformities who have made an adequate adjustment. One of the therapeutic aspects of these experiences is that peers with similar deformities are highly credible in that they are dealing with similar struggles.

### **Prognosis and Course of the Illness**

A child must learn to live with a chronic illness. When a reasonable hope exists that the illness will either remit completely or eventually provide little disability, an optimistic stance by the medical team and family is highly adaptive. A similar approach is indicated when the illness falls in the category described as the *Damocles syndrome* ([Koocher and O'Malley, 1981](#)). In these cases, a dreadful outcome is possible, but the best strategy is still to assume an optimistic stance, because remission is a realistic possibility. In contrast, terminal illnesses provide a set of specific challenges to both the family and the treatment team. After achieving the first therapeutic challenge, open acknowledgment of the impending death of the child, the treatment team must begin a long process of helping the child and family to come to grips with stages of the illness. Denial is a common defense and must be dealt with sensitively. There are few tragedies more difficult for a family than the impending death of a child. Parents always need time to find ways to mobilize family supports and to reorganize their future hopes and expectations. Staying with them through the process is the central goal of the final stages of support.

## **SEVERE CHRONIC ILLNESSES**

Although many chronic illnesses exist, the most common serious diseases and their estimated prevalence are listed in [Table 103.2](#). Less serious illnesses occur frequently during childhood, but these are for the most part self-limiting problems that are rarely associated with severe emotional sequelae that require child psychiatric intervention. Five quite distinct chronic illnesses are reviewed in this chapter to serve as models of the clinical issues presented by this wide range of pediatric disease. (Further information on some of the illnesses selected may be found in [Chapter 61](#) and [Chapter 95](#).)

Disease	Children Per 1,000
Asthma	62.0
Migraine	15.2
Epilepsy	4.9
Arthritis	1.9
Diabetes	1.2
Cystic fibrosis	0.5
Leukemia	0.15 <sup>a</sup>

**Table 103.2. Prevalence of Serious Chronic Conditions in Children in the United States: 1996.<sup>R</sup>**

## Asthma

Asthma continues to affect more than one in 20 American children and is the most prevalent chronic illness of childhood ( [Myers, 2000](#)). Prevalence rates over a 1-year evaluation in the United States have been reported to be 5.8% of children younger than 5 years of age and 7.4% of children between 5 and 14 years of age ( [Mannino et al., 1998](#)). Incidence estimates in other countries vary widely, reaching a maximum rate of one in 10 in New Zealand. In many ways, asthma is the prototypic psychosomatic illness. Although there is no question that asthma has a demonstrable physical component, both acute and chronic stressors directly affect the management of the illness ( [Mrazek et al., 1999](#)).

*Asthma* is defined as a reversible reactive airway disease triggered by both immunologic and nonimmunologic factors. It is familial, with a significantly increased risk of the disease occurring in first- and second-degree family members. Whereas serum immunoglobulin E may play a role in the expression of symptoms in many patients with asthma ( [Burrows et al., 1989](#)), the disease is heterogeneous in presentation, a finding suggesting that different mechanisms may be prominent in different patients.

The onset of asthma usually occurs quite early in life; approximately 75% of children who ever develop the illness experience it within their first 3 years ( [Falliers, 1970](#)). However, asthma can begin for the first time at any age. This presents an important clinical issue. The panic associated with the rapid onset of intense chest tightness and respiratory distress can be a particularly frightening problem for children younger than 3 years of age. Earlier onset is more difficult to manage, whereas onset during adolescence, relatively unusual, it is easier to adapt to than other chronic illnesses arising during the teenage years. Reasons include the availability of increasingly effective pharmacologic agents to control symptoms and the absence of visible physical symptoms. It has long been recognized that severely asthmatic children have a greater likelihood of anxiety and depressive disorders. In one study of children with persistent asthma who had moderate or severe symptoms, 42% were found to have an Axis I psychiatric illness, with anxiety disorders particularly common ( [Vila et al. 2000](#)).

The origin of asthma is complex and still not completely understood. Despite clear evidence of increased familial risk of developing the illness, twin studies unequivocally demonstrate that environmental factors are necessary for the expression of the disease. Environmental factors that have been considered to be salient include early respiratory infection, difficulties in parenting ( [Mrazek et al., 1995](#)), and excessive exposure to a highly antigenic environment in infants with elevated levels of immunoglobulin E ( [Mrazek et al., 1999](#)). Exposure to cigarette smoke is a nonspecific irritant that may affect the onset of asthma. The wide range of potential factors involved in the expression of the disease complicates the process of attributing causality to specific experiences that have been hypothesized to be associated with its onset. Like all illnesses with a genetic basis, the alleles that a child has at specific gene sites determine the likelihood of disease expression. However, potential therapeutic strategies targeted at familial behavior may well delay or prevent the onset of the symptoms ( [Mrazek, 1999](#)). Evidence examining the links between the quality of parent-child relationships and the occurrence of depressive symptoms in asthmatic children suggests that an ongoing secure relationship may be a protective factor in mediating problems with depressed affect ( [Bleil et al., 2000](#)).

The establishment of the diagnosis can be difficult in the first months of life. In addition, it has been a common practice among some pediatricians consciously to avoid making the diagnosis in the first years of life to avoid "stigmatizing" the child. The rationale for this strategy has included the avoidance of implying that disease may be self-limited. One strategy has been to diagnose wheezing in infancy as "bronchiolitis," even though the attacks may be occurring without a clear concurrent infection. Although it is true that this practice avoids an early confrontation with the potential long-standing nature of the problem, it also may postpone early intensive management of the illness. In short, overly optimistic reassurance that a child may well "grow out of asthma" may inadvertently lead to inadequate treatment of the illness and a worse long-term outcome.

Asthma rarely has any visible stigmata. However, in the 5% to 10% of asthmatic children who become dependent on steroids, striking changes in appearance can occur. These children often suffer from chronic respiratory insufficiency. This may result in the development of a *barrel chest*. In extreme cases, systemic use of steroids can cause cushingoid stigmata and permanent short stature.

The issue of limitation of activity is important for children. A natural parental tendency is to shelter asthmatic children from the rigors of intense exercise. This is clearly inadvisable. [Strunk et al. \(1989\)](#) demonstrate the beneficial impact of improved fitness on the adaptation of asthmatic children. For most children with asthma, an active program of normalization of their activities is the appropriate clinical approach.

The prognosis of asthma is complex. Most children with mild asthma have little risk of a fatal attack and good reason to expect, with proper management, a high probability of remission of symptoms. Consequently, appropriate treatment, which includes pharmacologic, environmental, and psychological interventions, usually results in the control of symptoms. A permanent "cure" or remission is less likely.

The prognosis is less clear for children with steroid-dependent asthma. In these children, the risk of a fatal episode may approach 5%, although more recent evidence suggests that the mortality rates associated with this form of the illness have stabilized ( [Sly and O'Donnell, 1997](#)). These severely asthmatic children must learn to pay close attention to their physiologic state because responding to early warning signs of respiratory distress is often critical, to reach help in time to reverse bronchoconstriction and to avert a respiratory arrest. Prescription of steroids is a complicated issue. Although steroid control is essential in these children, the side effects of prednisone can be disturbing. Negative reactions to steroid treatment are particularly common in young adolescents, who are most self-conscious. Unfortunately, this is the precise developmental period when children seem to be at risk of a fatal episode ( [Strunk et al., 1985](#)). A set of risk factors associated with fatal episodes has been established and essentially creates a profile of children at increased risk. The three most prominent features of this profile are a history of seizures, documented affective disturbance, and demonstrated conflict between the child's family and the medical caregivers.

---

### CASE ILLUSTRATION

Sybil was a 12-year-old chronically asthmatic girl with a lifelong history of unremitting asthma. Her symptoms were complicated by serious steroid side effects. She was admitted to an academic medical center to review the management of her symptoms comprehensively. Before this comprehensive evaluation, Sybil experienced little improvement in her symptoms despite more than 40 previous hospital admissions. She had received long-term steroid treatment to control her airway reactivity. This had resulted in severe cushingoid stigmata and retardation of growth, to the extent that her height was that of a 7-year-old child. Her steroid treatment had resulted in the development of scoliosis with respiratory compromise.

Sybil was an extremely intelligent child, with an intelligence quotient of 152. Despite her multiple hospitalizations and many school absences, she was able to score above grade level in basic academic skills. Although her nuclear family was intact, her father had developed chronic pancreatitis secondary to the heavy use of alcohol, and he had become increasingly depressed.

During a 4-month intensive rehabilitation effort, Sybil's steroid dose was dramatically reduced. She received intensive psychotherapy and developed a more realistic perspective on her range of abilities. Concretely, she made a readjustment in personal goals that involved giving up her fantasy of becoming a competitive ice skater. During this time, her depressive affect improved dramatically. Family communication was improved, and her parents were better able to understand her need to individuate from them.

However, Sybil's asthma was acutely sensitive to emotional factors. This was well illustrated after her 4-month rehabilitation, when she developed an episode of acute respiratory distress that was not relieved by oral medication or injections of epinephrine. A plan for an immediate transfer to an intensive care unit for an intravenous aminophylline infusion and the possibility of mechanical ventilation was instituted. While waiting for transfer to the intensive care unit, Sybil requested that her therapist hypnotize her to relieve her intense anxiety. She proved to be a good subject, and hypnosis resulted in a complete remission of her acute respiratory distress within 10 minutes. This remission was persistent, and no intensive care unit admission was required.

On returning to her home, Sybil's course deteriorated dramatically. She became resistant to medical treatment and acutely depressed. Her father's emotional problems became more severe, resulting in intense family conflict. Despite antidepressant medication, Sybil developed intense suicidal ideation. She announced to the psychiatrist at a regular session that she would not see him again because she was going to die before their next meeting. Three days later, she had an acute episode of asthma and died in the back seat of the family car on the way to the emergency room.

---

---

## Epilepsy

Many quite heterogeneous central nervous system disorders can be broadly classified as chronic epilepsy. *Epilepsy* can be defined as a condition characterized by persistent major motor seizures. It affects approximately five children per 1,000. Onset of the seizures can occur throughout childhood, with onset in the first years of life being particularly common. Hereditary transmission is rarely the attributed causality. Unless seizures begin after physical injury, issues of parental responsibility and potential blame are not usually a central consideration. The level of anxiety associated with the diagnosis of epilepsy is clearly linked to how a given family understands the prognosis and cause. Although a single febrile seizure is rarely a cause of persistent concern, focal seizures that suggest central nervous system disease have a major impact on both the child and the family. [Harrison and Taylor \(1976\)](#) examined the long-term outcome of a sample of children with seizures and found a mortality rate of 10.1%. In this sample, 24.2% of the children developed chronic epilepsy. As with many physical illnesses, chronicity and severity of symptoms are among the key factors influencing subsequent deviations in emotional development. Similarly, many different psychosocial stressors have been reported to be associated with the onset or recurrence of seizures. These may include quite discrete events such as the occurrence of sexual abuse ([Greig and Betts, 1992](#)).

The onset of epilepsy in adolescence can be particularly disturbing. A teenager's natural strivings for greater independence can be dramatically interrupted by the uncertainty created by episodic seizures. It has long been demonstrated that children with seizures are at increased risk of emotional disturbance. In the classic Isle of Wight study, nearly 30% of children with uncomplicated epilepsy and almost 60% of children with documented lesions above the brain stem suffered from emotional disturbance ([Rutter et al., 1970](#)). More recent studies report similar rates of psychopathology ([Hoare and Kerley, 1991](#)). These rates have been consistently found to be higher than rates of psychopathology in children with other chronic physical illnesses. The clear inference is that central nervous system damage may often be directly responsible for the onset of behavioral and emotional disturbances ([Howe et al., 1993](#)).

The differential diagnosis of epilepsy can be complex. An initial seizure is often difficult to differentiate from an episode of loss of consciousness that may result from cardiac or functional factors. Confusion in establishing the nature of the episodes can result in both loss of confidence in the medical team and considerable anxiety about the nature of the underlying disorder.

Although epilepsy does not result in persistent physical deformity, the emotional stigmata of an epileptic attack have been well documented. [Taylor \(1987\)](#) suggests that prejudice against persons with epilepsy is in part the result of a publicly perceived association between epilepsy and madness and mental deterioration. There are often real limitations in the ability of an epileptic child to participate in team sports or wilderness activities fully. The subsequent negative impact on self-esteem is frequently compounded by the repeated experience of loss of control. Parents and medical teams need to work together to construct an appropriate strategic plan designed to maximize the opportunities that a child has to develop an appropriate sense of autonomy and independence.

[Hermann et al. \(1990\)](#) adopted a risk factor strategy for predicting the occurrence of psychopathology in persons with epilepsy. More than 100 adults were studied. For most, their disease began during childhood and adolescence. The mean duration of their illness was more than 16 years. Illness-related risk factors included an early onset of symptoms and the perception of being stigmatized. Additionally, experience of embarrassment, disturbances of self-esteem, and the perceived sense of personal rejection were associated with the development of psychiatric symptoms. Other risk factors associated with disturbance were more frequent adverse life events, financial stress, and vocational difficulties. Successful surgical intervention has been reported to be associated with better long-term outcomes ([Seidman-Ripley et al., 1993](#)).

## Cystic Fibrosis

*Cystic fibrosis* is an autosomal recessive illness affecting only about 0.05% of white children and fewer black and Asian children. In white populations, about 5% of adults are carriers of the gene for the disease. The expression of the symptoms of cystic fibrosis occurs almost universally during infancy and involves multiple organ systems. Chronic bronchial airway obstruction often leads to infection. Maldigestion subsequent to pancreatic defects results in unpleasant gastrointestinal symptoms. An alternative name for this illness is mucoviscidosis, which describes the increased viscosity of the secretions that represent the common origin of many of the symptoms. Affected organs include lung, pancreas, liver, intestine, and genitals. The initial presentation of the illness can involve either pulmonary or gastrointestinal symptoms, which can delay the determination of the diagnosis. There has been a dramatic increase in the life span of children with cystic fibrosis. Although previously it had been unusual for children to live to adulthood, the median survival rate has increased beyond 20 years. Sexual development is usually delayed, and 98% of male patients are sterile ([Tausig et al., 1976](#)). Pregnancy is associated with increased risk of deterioration in respiratory function. However, successful pregnancies have been managed within the context of intensive medical support.

Because the diagnosis of cystic fibrosis usually occurs in infancy or early childhood, the child and family must learn early to cope with the related symptoms. Caring for a child with cystic fibrosis requires a major time commitment because of the need for frequent physical therapy to decrease the occurrence of pulmonary complications. [Burke et al. \(1989\)](#) examine the occurrence of obsessive-compulsive symptoms in children with cystic fibrosis and find modestly elevated scores but no overt obsessive-compulsive disorder. Given the demands of cystic fibrosis, obsessive attention to self-care may well be a good coping strategy and may serve a protective function in minimizing disease sequelae.

Adolescents with cystic fibrosis often experience their physical symptoms as intrusive and having a negative impact on peer activities. Problems that typically become more acute during the teenage years include unpleasant flatus, which is associated with maldigestion, anxiety regarding sexual potency, and an increased awareness of coping with a compromised life span. Despite these difficulties, some patients do marry and have reported that their sexual relationships are satisfactory ([Levine and Stern, 1982](#)).

Given that the disease results from a well-described homozygous occurrence of a single gene, genetic counseling is a standard component of a comprehensive plan for supporting these families. Because of the high level of phenotypic expression of the disease in infants, one in four subsequent children born to parents of a child with cystic fibrosis will also develop the illness. Given that the genotype of the fetus can be determined *in utero*, uncertainty concerning future pregnancies is no longer an issue. Both parents must be carriers of the illness for their children to develop the disease. The decision to have a child with cystic fibrosis now includes the awareness that each parent has contributed a dysfunctional gene to the child and both have agreed to proceed with the pregnancy. Because of the need for early intensive treatment, the establishment of the initial diagnosis is an important factor and usually supports the development of a strong and supportive doctor-family relationship.

Studies have suggested variable frequencies of comorbidity of emotional disturbance with cystic fibrosis. Some studies have reported that children with cystic fibrosis have no increased incidence of psychiatric disturbance ([Blair et al., 1994](#)) and that they have normal intellectual and academic abilities ([Thompson et al., 1992](#)). However, a comparison of four chronic pediatric illnesses suggested that methodologic issues of ascertainment of psychopathology in physically ill children may result in lower estimates of psychopathology. Twenty-five percent of the school-age children with cystic fibrosis within this sample were diagnosed with a psychiatric disorder ([Canning, 1994](#)).

Illness-related risk factors have been hypothesized to be minimized by protective factors such as positive familial involvement and high-quality medical support. [Steinhausen et al. \(1983\)](#) examined a set of hypothesized risk factors thought to be associated with psychological disturbance. Only in children with cystic fibrosis was severity of illness an illness-related risk factor. The other risk factors included parental pathology, disturbed parenting, and socioeconomic difficulties. The entire set of risk factors, including severity of illness, was responsible for nearly 37% of the variance in the occurrence of psychiatric disturbance in this sample. Approximately one-third of the children were diagnosed as having severe emotional disturbance. Another 22% of the children had less severe emotional difficulties.

The occurrence of maternal depression has been examined in the mothers of children with cystic fibrosis, based on both the guarded prognosis of their children and the large burden of care that is required as part of the treatment. Mothers of children with cystic fibrosis report higher levels of depression and greater levels of emotional strain than do the fathers of these children ([Quittner et al., 1992](#)). Other studies have linked maternal distress with higher levels of adjustment problems ([Thompson et al., 1994](#)).

[Venters \(1981\)](#) show an association between competent family functioning and the child's adjustment. Two characteristics, seeking out social support during stressful periods and the ability of the family to understand the illness within a broader religious or philosophic frame of reference, are shown to be associated with better outcome. Although a broad range of problems has been reported to occur in families with a child with cystic fibrosis, [Petzel et al. \(1984\)](#) identify concerns about

treatment and premature death as the most salient issues for both the children and their parents.

### Insulin-Dependent Diabetes Mellitus

Juvenile-onset *insulin-dependent diabetes mellitus* (IDDM) is a disease of the islet cells of the pancreas characterized by a deficiency in the production of insulin. It is a rare illness in very young children, but it does occur in about 0.1% of school-age children and adolescents. Reports have suggested that exclusive breast-feeding may be protective and that frequent early infections may be a risk factor for onset ([McKinney et al., 1999](#)). Because of its delay in onset, IDDM presents an interesting contrast to the problems associated with lifelong chronic physical illness. It has been suggested that less evidence of psychopathology has been demonstrated in children with IDDM when compared with children with other serious physical illnesses that begin in infancy. Possible factors that contribute to a better outcome would include the following: (a) the later onset, with less negative impact on early emotional development; (b) a more effective mode of treatment; and (c) minimal early central nervous system involvement.

Questions have arisen related to the role of stress in the initial onset of diabetes. [Barglow et al. \(1986\)](#) report no significant association between psychopathology in mothers with diabetes and the subsequent development of "developmental deficits" in their children when obstetric and perinatal factors other than diabetes are well controlled. [Chase and Jackson \(1981\)](#) report an association between stressor scores and serum glucose and triglyceride concentrations in an adolescent sample. [Gustafsson et al. \(1987\)](#) document an association between disturbed family interaction and diabetic control in adolescents, as measured by elevated glycosylated hemoglobin concentrations 5 years after the initial assessment.

Although associations between poor emotional adjustment and difficulty in control of diabetic symptoms have been repeatedly observed, the nature of the relationship is not clear. It is often suggested that poor emotional regulation subsequently interferes with medical compliance. However, the alternative view, that poor chemical control causes emotional disturbance, remains a viable hypothesis.

Although there is a strong familial propensity for the development of diabetes, the genetic risk is less clear than for illnesses with a better established pattern of inheritance. Diagnostic issues are for the most part less of an issue than the therapeutic issues associated with management of the illness. [Wilkinson \(1987\)](#) identifies two of the characteristics of IDDM that result in later disturbance. The first is that it affects a wide range of aspects of everyday living. The second is that it requires a high degree of personal responsibility to manage the illness medically. In his study of adults with diabetes, as many as 18% of the sample patients were diagnosed with a psychiatric disorder. Depression and anxiety were the most frequently reported conditions.

Little physical deformity is initially associated with IDDM. However, children may experience anxiety related to fears of hypoglycemic or hyperglycemic coma and later vascular complications ([Moran, 1984](#)). Some interference with normal function is a key problem in adolescence, when restrictions in activity and dietary compliance can be particularly problematic. [White et al. \(1984\)](#) studied the association between potential stressors and poor diabetic control in children with very labile IDDM. Ketoacidosis was sometimes associated with "intercurrent illness" (15% to 30%) and insulin mismanagement (5% to 10%). However, most of these children came from families with multiple problems that were believed to be highly associated with their poor medical control.

IDDM has a relatively uncertain outcome. Although most children survive well into adulthood, the fear of diabetic sequelae and the occurrence of severe ketoacidotic episodes can be very upsetting. [Gath et al. \(1980\)](#) demonstrated certain cognitive difficulties in children with IDDM who were between the ages of 9 and 10 years. The duration of the illness was about 3.5 years. A correlation was shown between poor diabetic control and (a) the presence of a psychiatric disorder, (b) problems in reading, and (c) adverse psychosocial factors in the family background. Neuropsychological studies of children who had onset of the disease before 5 years of age have found impairment in the abstract/visual reasoning subscales of the Stanford-Binet Intelligence Scale. These lower scores were noted in some children with only mild hypoglycemia ([Golden et al., 1989](#)). Another study found delays in information processing speed and conceptual reasoning that developed over the course of 2 years after diagnosis in the IDDM cohort ([Northam et al., 1999](#)).

[Kovacs et al. \(1985\)](#) studied a group of school-age children with IDDM and found no evidence of increased life stress or psychiatric disturbance preceding the diagnosis. She described two patterns of coping in these children. Some social withdrawal and sadness were noted in about two-thirds of the children. The remaining one-third met criteria for psychiatric disorder, with depressive syndromes most prominent. Ninety-three percent of the children recovered from these reactions to the diagnosis within the first year of their illness. In a study of the rehospitalization of children with IDDM, externalizing symptoms were shown to be correlated with readmission, a finding prompting the recommendation of appropriate intervention for these problems as a preventive measure ([Kovacs et al., 1994](#)).

[Fonagy et al. \(1987\)](#) conducted a well-controlled study to examine psychological factors that influence the management of children with IDDM. Psychological disturbance in both the children and the parents predicted low glycosylated hemoglobin concentration in the children and accounted for 44% of the variance in blood glucose control. These findings suggest that as many as one-third of the children with IDDM have appreciable emotional and behavioral problems. However, children perceived as having problems were less often responsible for the care of the illness. The authors conclude that children younger than 12 years of age are often unable to manage the self-care regimens prescribed to treat their illness. The importance of parental involvement in maintaining optimal diabetes management has been clearly demonstrated and well accepted ([Weist et al., 1993](#)). A report focusing specifically on adolescent response to both hypoglycemia and hyperglycemia suggests surprisingly inappropriate reactions that were not substantially improved by involving parents ([Johnson et al., 2000](#)).

### Pediatric Malignancies

*Pediatric malignancies* are rare and can begin throughout childhood. The leukemias are the most common, although they still occur in only 15 children per 100,000. They are commonly diagnosed between 2 and 4 years of age. Prior to 1970, childhood malignancies were considered fatal illnesses. Today, because of the dramatic improvements in chemotherapy and radiation treatment, leukemia is now more appropriately considered a chronic illness, given that the current 5-year survival rate is well in excess of 50%.

The causes of most malignancies remain unclear. Evidence of increased genetic risk for some subtypes of leukemia has been determined, but many cases appear to occur sporadically. Although various hypotheses have been developed suggesting that both infectious and immunologic mechanisms are involved in the onset of leukemia, the diagnosis usually comes as a shock, with little sense of parental responsibility.

Malignancies vary in how difficult they are to diagnose. For example, leukemias can be asymptomatic for months. However, once the suspicion of leukemia is raised, the definitive diagnosis can be quickly and reliably confirmed through simple laboratory examination. Given the importance of aggressive early treatment, any delay in establishing the diagnosis presents an important psychological issue in the care of the family.

For the most part, leukemias result in only minimal physical deformity. However, bruising and wasting can be a problem in the later stages of the illness. In contrast, solid tumors that require surgical intervention may result in radical and abrupt changes in the child's body image. In many ways, adolescence is a particularly difficult time for the onset of these illnesses and the often quite extensive treatment that is required. One study examining identity formation in survivors of childhood cancer suggests that these children may have a "foreclosed" or premature formation of identity, which diminishes their exploration of some positive options for the future ([Madan-Swain et al., 2000](#)).

Considerable controversy exists regarding the frequency of emotional disturbance in children with malignancies. Some studies ([Eiser, 1979](#); [Greenberg et al., 1989](#); [Kupst et al., 1984](#)) suggest relatively low levels of either emotional or behavioral disturbance. [Sawyer et al. \(1986\)](#) report significant differences in behavioral and emotional problems between affected children with leukemia and their siblings in the 2-year period after the diagnosis. A longer-term follow-up some 4 years after the initial evaluation ([Sawyer et al., 1989](#)) shows considerable normalization of the functioning of leukemic patients; the only remaining difference between the patients and their siblings is in regard to problems in school performance as noted by both teachers and parents. Three possible explanations for these persistent findings are (a) the direct effect of central nervous system irradiation on neuropsychological functioning, (b) the documented large number of school days missed, and (c) the lasting impact of documented earlier emotional and behavioral problems that had occurred primarily in school-related areas. The treatment of the illness should be considered an illness-related risk factor to the degree that repeated, painful bone marrow biopsies and other invasive procedures are required. This can be particularly difficult for children with early onset of disease.

The cranial irradiation literature suggests that aggressive treatment can result in neuropsychological damage ([Stehbens and Kisker, 1984](#)), particularly if treatment is administered before 8 years of age ([Moehle and Berg, 1985](#)). [Pavlovsky et al. \(1983\)](#) report that children with cranial irradiation and intrathecal methotrexate treatment have the greatest number of psychological sequelae and associated abnormal computed tomography scans. [Brouwers et al. \(1984\)](#) again note associations with computed tomography scans. Specifically, greater neuropsychological deficits and attention deficit problems are noted in patients with evidence of atrophy. In the

relatively few patients who show calcification, the greatest deficits are noted. Long-term follow-up of survivors of acute lymphoblastic leukemia reveals a greater likelihood that the children will be placed in special education programs. However, they generally have reasonably good outcomes. Other studies have suggested that academic problems may be more persistent (Raymond–Speden et al., 2000). Dosage of cranioradiotherapy and earlier age at diagnosis are found to be important education-related risk factors (Eiser, 1991; Haupt et al., 1994; Leung et al., 2000).

The effect of chronic illness should not be considered in isolation from other concurrent stresses. This is illustrated by Kalins et al. (1980), who document the occurrence of non-illness-related stressors in the families of physically ill children. A higher frequency of other serious life events is noted to have occurred in those families with sick children. However, independent studies have noted an association between “family cohesion and adaptation” and better psychological outcome in adolescent cancer survivors across a wide range of stressful experiences (Rait et al., 1992).

Mulhern et al. (1981) describe the differences in the perception of prognosis for recovery in physicians, parents, and children. Physicians have the most negative view of prognosis. Parents hold an intermediate view. Children are the most optimistic about the future. Although it is probably therapeutic to support an optimistic outcome, the authors point out that the somewhat unrealistic expectation may provide an explanation for studies that find few affective and emotional symptoms in children with serious disease. This denial may be an adaptive form of coping with the seriousness of their medical prognosis as long as it does not interfere with maintaining good compliance with treatment recommendations by children and their families.

---

#### CASE ILLUSTRATION

An example of an adaptive response to an overwhelming disability was demonstrated by George. At the time of diagnosis, George was 17 years old and was the second of four children in a middle-class, upwardly mobile suburban family. George was not chronically ill as a young child. In fact, throughout high school, he was an outstanding athlete who played three sports and qualified for state finals in track and field. During his senior year in high school, he suddenly developed intense pain in his right leg. The diagnosis of osteosarcoma in his right tibia was made within 2 days of the onset of his first symptom. An immediate amputation was recommended, and the serious nature of his prognosis was openly discussed with George and his family in a sensitive and thorough manner. Surgical intervention was performed without delay.

For George, the impact of the loss of his leg was enormous. His appearance and athletic ability were central components of his identity. Considerable concern that he could become depressed was expressed. Instead, George responded to his surgical treatment in an extremely positive and forward-looking manner. His adaptive and spirited recovery was strongly supported by his family, who could both acknowledge the severity of the illness and at the same time remain emotionally supportive. A very aggressive postoperative rehabilitation program was planned that included visits by teenage amputees to the hospital before George was discharged. By the time he was ready to return home, George had heard from dozens of his classmates, and his courage was widely recognized at his school. This community support was coupled with the unshakable conviction of his family that he would persevere. On follow-up, no depressive symptoms had developed, and George continued to be an outstanding student. The following year, he went onto a prestigious university and established himself as a campus leader.

---

## EFFECTS OF MULTIPLE HOSPITALIZATIONS

A pediatric hospitalization should be considered as an experience during which a child will be exposed to a set of illness-related risk factors that are likely to have a negative impact on subsequent adaptation (Mrzcek, 1986). Substantial evidence suggests that a single hospitalization, particularly if managed sensitively, will have relatively minimal impact on the long-term development of the child (Quinton and Rutter, 1976). However, as is true with many risk factors, multiple exposures increase the potentially negative impact of the experiences. At least five sets of variables influence the impact of hospitalizations. These include (a) the nature of the disease, (b) the nature of the hospital experience, (c) the sociocultural context of the hospitalization, (d) the adaptive abilities of the parents, and (e) the child's capacity to cope with the illness. Developmental considerations are particularly important. Early hospitalization, occurring within the first 6 months of life, has not been associated with later difficulty. However, some early studies show that children between 1 and 4 years of age may be particularly sensitive to prolonged hospitalizations (Mrzcek et al., 1984; Prugh et al., 1953). During this period, the parent is perceived as the primary attachment figure. Unfortunately, parents may be unable to modulate the experience of a preschool child during difficult procedures that are part of the hospitalization. This results in the parent's being unable reliably to provide a secure haven for the child and in more persistent perturbations in the quality of the primary caregiving relationship. Preschool children would normally be developing a sense of independence and autonomy, which is essentially incompatible with the passive, dependent behaviors that are required during the hospitalization. Yet another issue is that preschool children have preoperational cognitive abilities. As a consequence, it is not possible to rely on concrete operational thinking. This means that therapeutic strategies that require the understanding that specific causes will have predictable effects cannot be used to help these children anticipate likely positive or negative outcomes that will result from necessary but uncomfortable aspects of their treatment.

Ensuring that parents become a part of the treatment team during hospitalizations is critical. The basic objective during acute hospitalizations is to provide a sense of emotional security for the child. To the degree that the parents are unable to cope with their own anxieties about the illness of their child, they will have difficulties in modulating stressful experiences. It is critical for parents to take an active role in providing emotional support. This includes the realization that their physical presence is important. However, they can also be involved in helping their child make sense of what can sometimes be a series of bewildering experiences. As stressed earlier, this is particularly true for the preschool child. It is usually best to assume a proactive stance. Even in a maximally sensitive hospital, the emotional needs of a child in a medical crisis cease to be a primary focus. At such moments, the pediatric team is appropriately exclusively concerned with preserving the life of the child. In this climate, the parent is often the critical link between the pediatric treatment team and the child. If the parents are able to assume this role, it is often advisable for the medical team to encourage parents to become a partner in the provision of their child's care. The child psychiatrist can play a role of supporting the parents in this difficult position and then can help them to understand retrospectively what has happened after the crisis has passed. Although this is demanding for all involved, the successful accomplishment of helping a child through a critical episode provides a strong basis for all subsequent consultative efforts.

It is essential to help children proactively to cope with the most difficult aspects of hospitalization. The evolution of Child Life programs is a good example of the development of many proactive strategies. The alliance between the medical team and the family is of central importance. A trusting and communicative relationship with the pediatrician can be extremely important in managing the anxiety level of the parents and the child. This primary relationship can be either enhanced or threatened by the nursing staff. Nurses have become increasingly sophisticated in the identification of parents who are having difficulties with coping. They are now able to organize nursing care to maximize potential parental emotional support.

The child psychiatrist who provides pediatric liaison is a critical part of the treatment team. In addition to the classic role of diagnostician and therapist able to intervene at moments of family crisis, child psychiatrists have increasingly taken proactive roles in the development of systems designed to help families to deal with the experience of hospitalization. One specific aspect of this role is taking the responsibility to ensure that both cognitive and emotional understandings of the implications of medical procedures are considered. All too often, misunderstandings about medical care can arise that lead to major disruptions in the emotional well-being of the child. Ensuring that both the family and the child have a good understanding of the need for medical procedures and of the implications of proceeding in a particular clinical direction is a cornerstone of appropriate care for ill children.

In analyzing the impact of hospitalization on an individual child, two variables should always be considered. The first is an assessment of the severity of illness. The second is the duration of the discomfort associated with required therapeutic procedures. Minde et al. (1982, 1983) developed a morbidity scale to monitor these variables in infants. This approach highlights the specific needs of some families, who may cope well during early phases of an illness but do less well when the stressors associated with hospitalization continue for prolonged periods.

During the prolonged hospitalization of young children, the single most important aspect of treatment is to ensure that the primary attachment figures are available for the children. For older children who must remain in the hospital for prolonged periods, other issues are important. First, it is helpful to provide opportunities for educational and tutorial experiences to ensure that these children do not fall behind in their learning objectives. Furthermore, the maintenance of close contact between friends and classmates can support the coping strategies of most teenagers. However, it is helpful to consider a hospitalization as a new opportunity during which new peers can be identified. In some cases, this can lead to the creation of a new peer support group consisting of children with similar physical challenges. Such groups can be particularly helpful during very extended hospitalizations.

## SUMMARY

In conceptualizing the impact of chronic medical conditions on child development, it is helpful to integrate the stressful aspects of an illness into a broader systems perspective that considers the entire spectrum of early childhood adaptation. Both illness-related and more generally appreciated protective factors should also be considered in developing a treatment plan for a particular child. This approach represents an appreciation that whereas all chronic illnesses have some similar negative impacts on development, illness-related stressors are associated with each individual disease. Illnesses that have a long, unremitting course share characteristics, as do illnesses with uncertain prognoses, with early onset, and with similar causes. To the degree that the illness-related characteristics of various diseases are similar, their emotional sequelae will also be similar (Table 103.2).

## RESEARCH DIRECTIONS

The need to have ongoing prospective longitudinal studies is overwhelmingly apparent in a review of the multiple cross-sectional studies of physically ill children. When one is considering problems with a genetic origin, the optimal plan is to recruit a sample of children before the onset of illness and to follow them longitudinally. When illnesses have more spontaneous onsets, the best approach is a study that is designed to follow-up children after the initial diagnosis. Any prospective longitudinal study should include the documentation of not only the key characteristics of the illness itself but also of the familial risk and protective factors that simultaneously influence development. Through the judicious examination of the interaction of these factors, primary prevention strategies can probably be developed to minimize the emotional sequelae of physical illness. Given the prevalent nature of these problems, the implications of early intervention for physically ill children are of substantial public health importance.

Dying is a transitional state during which the child and the family may look to the physician for understanding, support, and direction. However, a physician may experience anxiety in the presence of a dying child because of (a) the feelings of impotence, failure, and anxiety that are aroused in a physician when confronted with his or her own limitations and mortality; (b) the regressive pull the child's loneliness, abandonment, neediness, and insecurity evokes in the physician; and (c) the difficulty of dealing with the parents' anxiety, depression, anger, resentment, and denial.

Yet there is probably almost nothing that the child or parent fears, imagines, feels, or experiences that cannot be discussed with the child in an honest way. The basis for the discussion is a trusting relationship. Children in particular soon learn whom they can trust and hence to whom they can open up. Indeed, the child often senses more accurately what the adult can tolerate than the adult senses how much the child can assimilate, and the child acts accordingly.

## CHILDREN'S CONCEPTS OF DEATH

The child's reaction to his or her own dying or the death of others is related in part to his or her concept of death ( [Schonfeld, 1993](#)), which in turn is related to the child's developmental stage ( [Table 104.1](#)).

Age	Concepts of Death	Implications for Adjustment to Loss
0-2	Death is seen as a permanent phenomenon from which there is no return.	Failure to comprehend this concept prevents the child from engaging in the process of mourning from the deceased, a necessary step toward successful mourning.
2-4	Death is seen as a state in which all the functions cease completely.	Examples of incomplete understanding: The child worries about a fourth relative being cast or in pain; the child wishes to bury both with the deceased.
4-7	Death is seen as a mixture phenomenon that no living being can escape eventually.	Examples of incomplete understanding: The child views significant individuals (i.e., self, parents) as immortal; if the child does not view death as inevitable, he or she is likely to view death as a punishment rather than a choice or thought of the cause of the deceased leading to excessive guilt and shame.
7-10	The child develops a realistic understanding of the causes of death.	Examples of incomplete understanding: The child who relies on magical thinking is apt to assume responsibility for deaths of a loved one by desiring food thoughts or unrealistic actions toward cause of death.
10-12	Death is seen as a punishment rather than a choice or thought of the cause of the deceased leading to excessive guilt and shame.	Implication: Tends to lead to excessive guilt that is difficult for the child to resolve.

Table 104.1. Death and Childhood

The stages in the child's understanding of the concepts of death have been well studied ( [Hostler, 1978](#); [Kastenbaum, 1967](#); [Smilansky, 1987](#); [Speece and Brent, 1984](#); [Wass, 1984](#)). Four major concepts related to death have been noted consistently: irreversibility, finality (also termed *nonfunctionality*), causality, and inevitability (also termed *universality*). Failure to comprehend each of these concepts impairs the child's ability to mourn successfully ( [Table 104.2](#)). [Speece and Brent \(1984\)](#), in a review of the literature, concluded that most studies found the age of acquisition of the three concepts they reviewed (irreversibility, nonfunctionality, and universality) to occur between 5 and 7 years; earlier studies citing an older age of acquisition typically were noted to have significant procedural flaws.

Concept	Example of Incomplete Understanding	Implication	Adjustment to Loss
1. Irreversibility	Death is seen as a permanent phenomenon from which there is no return.	Failure to comprehend this concept prevents the child from engaging in the process of mourning from the deceased, a necessary step toward successful mourning.	
2. Finality (nonfunctionality)	Death is seen as a state in which all the functions cease completely.	Examples of incomplete understanding: The child worries about a fourth relative being cast or in pain; the child wishes to bury both with the deceased.	
3. Inevitability (universality)	Death is seen as a mixture phenomenon that no living being can escape eventually.	Examples of incomplete understanding: The child views significant individuals (i.e., self, parents) as immortal; if the child does not view death as inevitable, he or she is likely to view death as a punishment rather than a choice or thought of the cause of the deceased leading to excessive guilt and shame.	
4. Causality	The child develops a realistic understanding of the causes of death.	Examples of incomplete understanding: The child who relies on magical thinking is apt to assume responsibility for deaths of a loved one by desiring food thoughts or unrealistic actions toward cause of death.	Implication: Tends to lead to excessive guilt that is difficult for the child to resolve.

Table 104.2. Concepts of Death and Implications of Incomplete Understanding for Adjustment to Loss

During the first few years, the child ordinarily has virtually no concept of death other than that of a disappearance. However, when faced with traumatic events, such as the death of a parent, children younger than 5 years of age may develop what seems to be a precocious understanding of death. In general, the role of personal exposure to death of others has been controversial; although several studies have shown that such personal experience may promote the acquisition of the concepts of death ( [Kane, 1979](#); [Reilly et al., 1983](#)), other studies have failed to support this conclusion ( [Jenkins and Cavanaugh, 1986](#); [Townley and Thornburg, 1980](#)). Cross-cultural comparisons ( [Florian and Kravetz, 1985](#); [Schonfeld and Smilansky, 1989](#); [Wass et al., 1979](#)) also have illustrated significant cultural variations and important cross-cultural consistencies, suggesting that although the underlying developmental framework is likely to be robust across cultures, various sociocultural variables may have a significant and profound impact on the rate of acquisition of important individual concepts.

Children between 5 and 10 years of age (approximately) continue to clarify their concepts of death but still are confused at times. For example, a child may say, "When I die, my heart stops, I can't see, and I can't hear. But if I'm buried, how will I breathe?" Some of the child's difficulty in thinking clearly about death is

developmental, but some of the difficulty is emotional. If the child of this age has a heightened concern about a part of his or her body and its functioning, the child may tend to think of death in terms of the harm to that part of his or her body and its functioning, especially because the child also tends to think in concrete terms at this stage. Children in this age group with a terminal illness have been shown to have a marked awareness of the seriousness of their illness, even if never told that their illness is fatal, and a precocious understanding of personal mortality ( [Clunies-Ross and Lansdown, 1988](#); [Spinetta, 1974](#)).

Somewhere between 10 and 15 years of age, the average child acquires a grasp of the meaning of mortality ( [Kastenbaum, 1959](#)). The child's reaction to death at this time is influenced more by his or her emotional struggles than by the child's intellectual capacities. Thus, a young adolescent who is concerned with, among other things, sexual performance, control of impulses, physical intactness, and separation from parents may react with anxiety if any one of these sensitive conflict areas is involved in the fatal illness.

## THE CHILD'S REACTION TO HIS OR HER OWN DYING

The very young child mostly is preoccupied with the discomfort of the illness, whether acute or chronic, and the separation and withdrawal that occur when hospitalization is necessary. A somewhat older child, although also troubled by pain and separation, interprets his or her illness according to his or her level of cognitive development and emotional conflicts. Thus he or she may interpret the illness as an act of "immanent justice" for the guilt he or she feels about some real or imagined misdeed. Usually the child shows regressive behavior in the face of the illness, hospitalization, and its treatment, and a fear of mutilation. Occasionally the child shows a denial of discomfort or dread ( [Solnit, 1965](#); [Solnit and Green, 1959](#)). An older child who is aware of the irreversibility of death may deny his or her own anxiety but may exhibit a depression, occasionally mixed with outbursts of anger and anxiety. This reaction is especially common in adolescents. On the other hand, some children are astoundingly courageous and steadfast in the face of death.

The range of reactions is great. In a sense, all that has gone before contributes to the child's understanding of death and his or her reaction to it. Each child is an individual, and a myriad of variables influence the behavior of the child, the family, and the helping persons around the child.

## REACTIONS OF OTHERS TO THE DEATH OF A CHILD

An important determinant of children's reaction to death is the reaction of those around them to death. Those others may be parents, siblings, or hospital staff members.

### Reaction of Parents

#### GENERAL REACTIONS

The general reactions of parents have a chronologic sequence, starting before and continuing during and after the moment of death. Initial shock and denial of the diagnosis may last from a few seconds to a few months. This stage may be followed by anger ("Why my child?") or guilt ("If only I had..."). Sooner or later, the parent starts to bargain ("If he could only live to..."). This stage is followed by normal grieving and mourning over the impending loss and by the beginning of separation. Finally, a stage of resignation or acceptance can be reached.

#### SPECIFIC REACTIONS

##### *Reactions to a Rapid Death*

When the death has occurred relatively rapidly (e.g., perhaps as a consequence of a brief illness), the period before death is filled with anxiety and concern. (For a discussion of sudden infant death syndrome, see [Chapter 95](#).) The parents may be desperately hopeful, but they also may have feelings of guilt and a need to deny the possibility of death as an eventual outcome. After a rapid death of their child, the parents may again feel some diffuse anger, which may be displaced onto the physician. This reaction may occur regardless of whether the physician has been diligent, but it is more likely to fester and be prolonged if the physician fails (out of his or her own discomfort) to show consideration at the time and to provide the opportunity for a follow-up interview. Over time, the parents will then go through their own characteristic mourning process. Their mourning may include some identification with the lost person and, occasionally, an overidealizing of the lost person (particularly in cases in which the parent also experiences the loss of what they had expected for the lost child). Further possible normal reactions (within limits) may include (a) a displacement of attitudes toward the dead child onto one or more of the surviving children, (b) attempts to fill the loss by another pregnancy, or (c) withdrawal for a time. These and other normal reactions, in general, should be respected and left alone. Extreme forms of defenses may be dysfunctional and are an indication for therapy ( [Krell and Rabkin, 1979](#)).

##### *Reactions to Prolonged Dying*

Occasionally, premature mourning may occur, with anticipatory grief and withdrawal of interest in the dying child, perhaps accompanied by the displacement of warm feelings onto an infant child in the family. Often, unacceptable thoughts arise. For example, a parent may find himself or herself wishing that the child would finally die and relieve everyone of the emotional and financial burden and suffering. Such a wish may horrify a parent and lead to the immediate mobilization of certain defense mechanisms. A common defense mechanism is that of reaction formation: The parent becomes extra protective in caring for the dying child. The parent also may feel guilty and express his or her guilt (and anxiety) by asking repetitive questions that require tactful answers.

As a chronically ill child nears death, the parents may be filled with remorse and may experience a resurgence of love. Rarely, a denial that death is imminent may remain in force. After the death of a chronically ill child, parents may feel a mixture of relief and guilt, perhaps with feelings of remorse being uppermost.

### Reactions of Siblings

Siblings who are very young, especially those younger than 5 years of age, feel the withdrawal of the parent intensely and consequently feel a loss of love. Young siblings may view the death as an abandonment, as punishment, as the realization of unacceptable wishes, or as all three. Children between approximately 5 and 10 years of age in general are somewhat more concerned for the dying child and also may be fearful for themselves. Although it is expected that older children usually can muster a supportive attitude and temporarily assume parental roles for the younger siblings at home, even teenagers feel and react to parental withdrawal and may "act up" during such a trying time. They too require special attention ( [Adams and Deveau, 1987](#)). Children as well as adults may experience survivor guilt after the death of a child ( [Lifton, 1967](#)). Some surviving children suffer serious symptoms and subsequent distortions of character structure ( [Cain et al., 1964](#)). Through identification with the deceased, thought to be more common and dramatic in children than in adults, surviving children also may manifest conversion symptoms. In one series of conversion disorders in children, 58% were associated with unresolved grief reactions ( [Maloney, 1980](#)).

### Reactions of the Hospital Staff

Hospital staff members also experience anxiety in the presence of a dying child or a grieving parent ( [Solnit and Green, 1959](#)), and they tend sometimes to deal with that anxiety by withdrawal and a conspiracy of silence. These reactions may hamper them from giving the dying child and his or her family the best care possible and may prevent the staff members from carrying out certain essential psychological tasks. Besides comforting the parents, such tasks include helping the child feel as active as possible in his or her attempts to cope with anxiety and allowing the child some hope. Furthermore, the privacy and dignity of the child require protection. Last, certain distortions require correction. The child, for example, may show his or her concern by asking such questions as "Am I safe?" "Will someone be with me when I need them?" "Will I be helped to feel better?" The need for tact carries through into the period of care for the survivors.

Survivors outside of the family also will need assistance in dealing with their grief. Psychiatrists not infrequently are consulted to provide crisis intervention for bereavement support in settings outside of the hospital, such as in the schools. Different techniques often are required to provide this type of intervention service and are described elsewhere ( [Newgass and Schonfeld, 2000](#); [Schonfeld, 1989](#); [Schonfeld et al., 1994](#)).

## CLINICAL CARE OF THE DYING CHILD

## Talking with the Parents About Fatal Illness

The hardest task for the physician is to tell the parents that their child is fatally ill. The physician should take the parents into a private office and allow at the very least half an hour, uninterrupted by telephone calls or other tasks. He or she can begin by telling the parents the diagnosis and the nature of the illness. He or she might then go on to describe the treatment that is available to offer some relief for the child's symptoms. At some point, the physician will have to tell the parents that there is no treatment that can cure the child of the illness. Throughout this interview, the physician should pause and give the parents every opportunity to express their feelings and ask questions. The physician must resist an understandable impulse to "shut off" the parents' grief. If the parents ask whether the child will die from the illness, the physician will have to say that the child will. If they do not ask, the physician should at some point attempt to clarify that the illness is progressive and that the child will die. At the same time, the physician must remember that the parents will not necessarily understand or accept what they have been told.

The physician should not end the interview then but should stay with the parents as they experience their shock (and perhaps anger) and grief. The physician might then tell the parents how he or she plans to treat the child and help the parents feel some measure of participation in and control of the treatment.
