---

## CONTENTS

---

---

[Editor](#)

[Dedication](#)

[Foreword to the First Edition](#)

[Preface to the Third Edition](#)

[Preface to the First Edition](#)

[Contributors](#)

[Color Plates](#)

### SECTION I. NORMAL DEVELOPMENT

---

#### A/ Developmental Aspects of Biological Growth

[1 GENES AND DEVELOPMENTAL NEUROBIOLOGY](#)

*James F. Leckman, Flora M. Vaccarino, and Paul J. Lombroso*

[2 MOLECULAR BASIS OF CHILDHOOD PSYCHIATRIC DISORDERS](#)

*Paul J. Lombroso and James F. Leckman*

[3 GENESIS OF NEOCORTEX IN HUMAN AND NONHUMAN PRIMATES](#)

*Pasko Rakic*

[4 NEUROCHEMISTRY OF CHILDHOOD PSYCHIATRIC DISORDERS](#)

*George M. Anderson and Donald J. Cohen*

[5 DEVELOPMENTAL ASPECTS OF NEUROPHYSIOLOGY](#)

*Edward M. Ornitz*

[6 DEVELOPMENTAL ASPECTS OF PSYCHONEUROIMMUNOLOGY](#)

*Jacqueline A. Bartlett and Michael Irwin*

[7 DEVELOPMENTAL PSYCHONEUROENDOCRINOLOGY](#)

*Thomas K. Cummins, K.J.S. Anand, and Charles B. Nemeroff*

[8 BRAIN AND BEHAVIOR](#)

*John Scott Werry, Alan Zemetkin, and Monique Ernst*

[9 PEDIATRIC NEUROIMAGING](#)

*Robert Schultz, David Rosenberg, Ken Pugh, Daniel Pine, Bradley Peterson, Joan Kaufman, Wendy Kates, Leslie Jacobsen, Jay Giedd, Xavier Castellanos, and Adam Anderson*

#### B/ Major General Theories of Child and Adolescent Development

[10 COGNITIVE-BEHAVIORAL APPROACHES](#)

*Philip C. Kendall, Muniya Choudhury, He Len Chung, and Joanna A. Robin*

[11 ATTACHMENT THEORY AND RESEARCH](#)

*Ross A. Thompson*

[12 THEORIES OF COGNITIVE DEVELOPMENT](#)

*Timothy Yates*

[13 CHILD PSYCHOANALYTIC THEORIES OF DEVELOPMENT](#)

*Steve Marans and Donald J. Cohen*

[14 THE CONTRIBUTION OF TEMPERAMENT TO DEVELOPMENTAL PROFILES](#)

*Jerome Kagan*

[15 TEMPERAMENT AND ITS CLINICAL APPLICATIONS](#)

*Stella Chess and Alexander Thomas*

#### C/ Developmental Pathways

[16 DEVELOPMENT OF ATTENTION, PERCEPTION, AND MEMORY](#)

*Daniel J. Siegel and Barry Nurcombe*

[17 DEVELOPMENT OF COMMUNICATION](#)

*Rhea Paul and Stephanie Miles*

[18 COGNITIVE AND AFFECTIVE IMPLICATIONS OF IMAGINATIVE PLAY IN CHILDHOOD](#)

*Jerome L. Singer*

[19 MORAL DEVELOPMENT](#)

*Sula Wolff*

[20 CHILDHOOD SEXUALITY](#)

*Alayne Yates*

[21 FAMILY DEVELOPMENT AND THE ROLES OF MOTHERS AND FATHERS IN CHILD REARING](#)

*Kyle D. Pruett*

#### D/ Developmental Phases

[22 INFANCY](#)

*Michael E. Lamb, Douglas M. Teti, Marc H. Bornstein, and Alison Nash*

[23 DEVELOPMENT OF SCHOOL-AGE CHILDREN](#)

*Lee Combrinck-Graham and Geri Fox*

[24 ADOLESCENCE](#)

## SECTION II. DEVELOPMENT OF SYMPTOMS

---

### [25 DEVELOPMENT OF THE SYMPTOM OF ANXIETY](#)

*Daniel S. Pine*

### [26 SYMPTOMS OF DEPRESSION](#)

*Ian M. Goodyer*

### [27 DEVELOPMENT OF PSYCHOTIC THINKING IN CHILDREN](#)

*Rochelle Caplan and Peter Tanguay*

### [28 DEVELOPMENTAL, NEUROBIOLOGICAL, AND PSYCHOSOCIAL ASPECTS OF HYPERACTIVITY, IMPULSIVITY, AND ATTENTION](#)

*Lily Hechtman*

### [29 DEVELOPMENT OF THE SYMPTOMS OF VIOLENCE](#)

*Dorothy Otnow Lewis*

### [30 NEUROPSYCHIATRIC SIGNS, SYMPTOMS, AND SYNDROMES](#)

*Daniel T. Williams*

### [31 THE DEVELOPMENT OF PAIN PERCEPTION AND PRINCIPLE OF PAIN CONTROL](#)

*Neil L. Schechter*

## SECTION III. OVERVIEW OF ETIOLOGICAL INFLUENCES

---

### [32 GENETIC INFLUENCES ON CHILD PSYCHIATRIC CONDITIONS](#)

*John P. Alsobrook, Elena Grigorenko, and David L. Pauls*

### [33 TRAUMATIC AND INFECTIOUS BRAIN INJURY IN CHILDREN: PSYCHIATRIC SEQUELAE](#)

*Agnes H. Whitaker, Boris Birmaher, and Daniel Williams*

### [34 TERATOLOGIC AND DEVELOPMENTAL EFFECTS OF PRENATAL DRUG EXPOSURE: ALCOHOL, HEROIN, MARIJUANA, AND COCAINE](#)

*Linda C. Mayes, Karen Meteyer, and Richard H. Granger*

### [35 SEPARATION AND DEPRIVATION](#)

*Adriana Molitor and Linda C. Mayes*

### [36 GRIEF](#)

*Elizabeth B. Weller, Ronald A. Weller, Tami Benton, and Julie J. Wiltsie Pugh*

### [37 EFFECT OF DISORDERED PARENTING ON THE DEVELOPMENT OF CHILDREN](#)

*Klaus Minde and Regina Minde*

### [38 EFFECTS OF CULTURE AND ETHNICITY ON CHILD AND ADOLESCENT DEVELOPMENT](#)

*John F. McDermott*

## SECTION IV. NOSOLOGY AND CLASSIFICATION

---

### [39 CLASSIFICATION IN CHILD AND ADOLESCENT PSYCHIATRY: PRINCIPLES AND ISSUES](#)

*Fred R. Volkmar, Mary Schwab-Stone, and Michael First*

## SECTION V. DIAGNOSTIC ASSESSMENT

---

### [40 CLINICAL ASSESSMENT OF INFANTS AND TODDLERS](#)

*Walter S. Gilliam and Linda C. Mayes*

### [41 PSYCHIATRIC ASSESSMENT OF INFANTS, CHILDREN, AND ADOLESCENTS](#)

*Melvin Lewis and Robert A. King*

### [42 STRUCTURED INTERVIEWING](#)

*Adrian Angold and E. Jane Costello*

### [43 PSYCHOLOGICAL ASSESSMENT OF CHILDREN AND ADOLESCENTS](#)

*Nancy E. Moss and Gary R. Racusin*

### [44 NEUROLOGICAL MEANING OF SOFT SIGNS](#)

*Jonathan H. Pincus*

### [45 PSYCHOEDUCATIONAL EVALUATION IN THE SCHOOLS](#)

*Lynne Doran Zimmerman, Robert M. Casey, Jr., and Robert P. Franks*

## SECTION VI. SYNDROMES

---

### [46 AUTISM AND THE PERVASIVE DEVELOPMENTAL DISORDERS](#)

*Fred R. Volkmar, Catherine Lord, Ami Klin, and Ed Cook, Jr.*

### [47 REACTIVE ATTACHMENT DISORDERS OF INFANCY AND CHILDHOOD](#)

*Margot Moser Richters and Fred R. Volkmar*

### [48 MENTAL RETARDATION](#)

*Fred R. Volkmar and Elisabeth Dykens*

### [49 DISORDERS OF COMMUNICATION](#)

*Rhea Paul*

### [50 DEVELOPMENTAL LEARNING DISORDERS](#)

*Larry B. Silver*

### [51 PSYCHIATRIC EVALUATION OF PERCEPTUALLY IMPAIRED CHILDREN: HEARING AND VISUAL IMPAIRMENTS](#)

*Mayu P.B. Gonzales and Stella Chess*

### [52 ATTENTION DEFICIT HYPERACTIVITY DISORDER](#)

*Margaret Weiss and Gabrielle Weiss*

### [53 CONDUCT DISORDER](#)

*Dorothy Otnow Lewis and Catherine A. Yeager*

### [54 EATING AND GROWTH DISORDERS IN INFANTS AND CHILDREN](#)

*Joseph L. Woolston*

### [55 ANOREXIA NERVOSA AND BULIMIA NERVOSA](#)

*Katherine A. Halmi*

[56 MODERN APPROACHES TO ENURESIS AND ENCOPRESIS](#)

*Edwin J. Mikkelsen*

[57 FIRESETTING](#)

*Jessica Gaynor*

[58 GENDER IDENTITY DISORDERS](#)

*Kenneth J. Zucker*

[59 TIC DISORDERS](#)

*James F. Leckman, Bradley S. Peterson, and Donald J. Cohen*

[60 CHILDHOOD SCHIZOPHRENIA](#)

*Fred R. Volkmar and Katherine D. Tsatsanis*

[61 NEUROLOGICAL DISORDERS](#)

*Daniel T. Williams, Richard R. Pleak, and Helen Hanesian*

[62 DEPRESSIVE DISORDERS IN CHILDREN AND ADOLESCENTS](#)

*Elizabeth B. Weller, Ronald A. Weller, Amy B. Rowan, and Hrach Svadjian*

[63 BIPOLAR DISORDER IN CHILDREN AND ADOLESCENTS](#)

*Elizabeth B. Weller, Ronald A. Weller, and Laura E. Sanchez*

[64 SEASONAL AFFECTIVE DISORDER IN CHILDREN AND ADOLESCENTS](#)

*Javad H. Kashani and Joseph M. Pastor*

[65 SUICIDAL BEHAVIOR IN CHILDREN AND ADOLESCENTS: CAUSES AND MANAGEMENT](#)

*Cynthia R. Pfeffer*

[66 PREVENTION OF DEPRESSION AND SUICIDE IN CHILDREN AND ADOLESCENTS](#)

*Judy Garber and Elizabeth McCauley*

[67 ANXIETY DISORDERS](#)

*Jennifer B. Freeman, Abbe M. Garcia, and Henrietta L. Leonard*

[68 OBSESSIVE-COMPULSIVE DISORDER](#)

*Kenneth E. Towbin and Mark A. Riddle*

[69 SOMATOFORM DISORDER](#)

*Gregory K. Fritz and John V. Campo*

[70 DISSOCIATIVE IDENTITY DISORDER](#)

*Catherine A. Yeager and Dorothy Otnow Lewis*

[71 SLEEP DISTURBANCES AND DISORDERS](#)

*H. Allen Handford and Alexandros N. Vgontzas*

[72 BORDERLINE DISORDERS IN CHILDREN AND ADOLESCENTS](#)

*Melvin Lewis and Fred R. Volkmar*

[73 ALCOHOL AND DRUG ABUSE IN CHILDREN AND ADOLESCENTS](#)

*Steven L. Jaffe and Deborah R. Simkin*

[74 POSTTRAUMATIC STRESS DISORDER](#)

*Betty Pfefferbaum*

[75 CHILDREN EXPOSED TO DISASTER: THE ROLE OF THE MENTAL HEALTH PROFESSIONAL](#)

*Nathaniel Laor and Leo Wolmer*

## SECTION VII. TREATMENT

---

[76 PEDIATRIC PSYCHOPHARMACOLOGY I: PHARMACOKINETIC AND PHARMACODYNAMIC PRINCIPLES](#)

*Andrés Martin, Jessica Oesterheld, Christine Konradi, Paul Klein, Stephan Heckers*

[77 PEDIATRIC PSYCHOPHARMACOLOGY II: GENERAL PRINCIPLES, SPECIFIC DRUG TREATMENTS, AND CLINICAL PRACTICE](#)

*Lawrence Scahill and Andrés Martin*

[78 PSYCHODYNAMIC PSYCHOTHERAPY](#)

*Rachel Z. Ritvo and Samuel Ritvo*

[79 INTENSIVE INDIVIDUAL PSYCHODYNAMIC PSYCHOTHERAPY: THE THERAPEUTIC RELATIONSHIP AND THE TECHNIQUE OF INTERPRETATION: THE USE OF PLAY IN PSYCHODYNAMIC THERAPY](#)

*Melvin Lewis*

[80 USE OF PLAY IN PSYCHODYNAMIC PSYCHOTHERAPY](#)

*Henry P. Coppolillo*

[81 CHILD AND ADOLESCENT BEHAVIOR THERAPY](#)

*Lawrence A. Vitulano and Jacob Kraemer Tebes*

[82 COGNITIVE THERAPIES](#)

*Theodore A. Petti and William G. Kronenberger*

[83 GROUP PSYCHOTHERAPY FOR CHILDREN AND ADOLESCENTS](#)

*Fern J. Cramer-Azima*

[84 FAMILY THERAPY](#)

*Allan M. Josephson*

[85 PARENT WORK](#)

*Paula Armbruster, Ursula Chock, Emily Tanner, and Samantha Holmes*

[86 PSYCHODYNAMIC PARENT PSYCHOTHERAPY: TREATING DISORDERS IN PARENTING AND IN THE PARENT-CHILD RELATIONSHIP](#)

*Julian B. Ferholt*

[87 PSYCHOTHERAPIES: A CRITICAL OVERVIEW](#)

*John Scott Werry and Leah K. Andrews*

[88 CHILD AND ADOLESCENT PARTIAL HOSPITALIZATION AND AMBULATORY BEHAVIORAL HEALTH SERVICES](#)

*Laurel J. Kiser, Jerry D. Heston, and David B. Pruitt*

[89 PSYCHIATRIC INPATIENT SERVICES](#)

*Joseph L. Woolston*

[90 RESIDENTIAL TREATMENT](#)

*Melvin Lewis, Jeffrey W. Summerville, and Paul N. Graffagnino*

[91 CHILD AND ADOLESCENT PSYCHIATRIC EMERGENCIES](#)

*Lynelle E. Thomas and Robert A. King*

## SECTION VIII. CHILD PSYCHIATRY AND ALLIED PROFESSIONS

---

### A/ Child Psychiatry and Pediatrics

[92 CONSULTATION PROCESS IN CHILD AND ADOLESCENT PSYCHIATRIC CONSULTATION-LIAISON IN PEDIATRICS](#)  
Melvin Lewis

[93 COLLABORATION BETWEEN CHILD PSYCHIATRISTS AND PEDIATRICIANS IN PRACTICE](#)  
Richard H. Granger and Elsa L. Stone

[94 CHILD'S COGNITIVE UNDERSTANDING OF ILLNESS](#)  
David J. Schonfeld

[95 PREMATURE BIRTH, BIRTH DEFECTS, AND EARLY DEATH: IMPACT ON THE FAMILY](#)  
Linda C. Mayes, H. Paul Gabriel, and Richard Oberfield

[96 PSYCHIATRIC ASPECTS OF CANCER IN CHILDHOOD AND ADOLESCENCE](#)  
Jonathan A. Slater

[97 PSYCHIATRIC ISSUES IN PEDIATRIC BONE MARROW, STEM CELL, AND SOLID ORGAN TRANSPLANTATION](#)  
Jonathan A. Slater

[98 NEUROBIOLOGICAL AND PSYCHOSOCIAL SEQUELAE OF HIV DISEASE IN CHILDREN AND ADOLESCENTS](#)  
Robert A. Murphy, Brian W.C. Forsyth, and Jean Adnopoz

[99 CARE OF INFANTS, CHILDREN, AND ADOLESCENTS WITH BURN INJURIES](#)  
Frederick J. Stoddard

[100 CHILD PHYSICAL ABUSE AND NEGLECT](#)  
Sandra J. Kaplan

[101 CHILD AND ADOLESCENT SEXUAL ABUSE](#)  
Sandra J. Kaplan

[102 MUNCHAUSEN SYNDROME BY PROXY](#)  
Brian W.C. Forsyth

[103 CHRONIC PEDIATRIC ILLNESS AND MULTIPLE HOSPITALIZATIONS](#)  
David A. Mrazek

[104 DYING AND DEATH IN CHILDHOOD AND ADOLESCENCE](#)  
Melvin Lewis and David J. Schonfeld

### B/ Child Psychiatry and Education

[105 EARLY CHILDHOOD EDUCATION](#)  
David Elkind

[106 IMPROVING PSYCHOEDUCATIONAL OUTCOMES FOR AFRICAN-AMERICAN CHILDREN](#)  
James P. Comer, Norris M. Haynes, and Lynelle Thomas

[107 SCHOOL AVOIDANCE, SCHOOL PHOBIA, AND TRUANCY](#)  
Ian Berg

### C/ Child Psychiatry and Law

[108 ADOPTION](#)  
Andre P. Derdeyn and Christopher A. Lamps

[109 THE CHILD AND THE VICISSITUDES OF DIVORCE](#)  
Judith S. Wallerstein and Shauna B. Corbin

[110 LEGAL CONSIDERATIONS IN THE PSYCHIATRIC HOSPITALIZATION OF CHILDREN AND ADOLESCENTS](#)  
Stephen Wizner

[111 THE MENTAL HEALTH PROFESSIONAL IN THE JUVENILE JUSTICE SYSTEM](#)  
Stephen Wizner

[112 MALPRACTICE](#)  
Barry Nurcombe

[113 LEGAL ISSUES IN PROFESSIONAL LIABILITY](#)  
Angela Holder

[114 TESTIFYING IN COURT: A TRIAL LAWYER'S PERSPECTIVE](#)  
David N. Rosen

[115 ROLE OF THE CHILD EXPERT IN COURT-REQUESTED EVALUATIONS](#)  
Barbara Nordhaus and Albert J. Solnit

### D/ Child and Adolescent Psychiatry and Public Health

[116 EPIDEMIOLOGY AND PREVENTION](#)  
David R. Offord and Kathryn J. Bennett

[117 MENTAL HEALTH DELIVERY SERVICES FOR CHILDREN AND ADOLESCENTS](#)  
Jerry M. Wiener

[118 NATIONAL POLICIES FOR CHILDREN, ADOLESCENTS, AND FAMILIES](#)  
Edward F. Zigler, Matia Finn-Stevenson, and Emily M. Tanner

[119 INTERNATIONAL CHILD AND ADOLESCENT MENTAL HEALTH REVIEW](#)  
Myron L. Beller

## SECTION IX. CHILD PSYCHIATRY AND THE COMMUNITY

---

[120 SCHOOL CONSULTATION](#)  
Mary E. Schwab-Stone, Christopher Henrich, and Paula Armbruster

[121 SCHOOL CONSULTATION: THE INDIVIDUALS WITH DISABILITIES ACT](#)  
Mary E. Schwab-Stone, Christa M. Helms, Joshua M. Barenbaum, Carroll L. Lucht

[122 HIGH-RISK CHILDREN, ADOLESCENTS, AND FAMILIES: ORGANIZING PRINCIPLES FOR MENTAL HEALTH PREVENTION AND INTERVENTION](#)  
Jean Adnopoz and R. Kevin Grigsby

[123 THE RUNAWAY ADOLESCENT](#)

David A. Tomb

[124 HOME-BASED CHILD AND FAMILY TREATMENT](#)

Jean Adnopoz

[125 CONSULTATION WITH FOSTER CARE HOMES, GROUP HOMES, YOUTH SHELTERS, DOMESTIC VIOLENCE SHELTERS, AND BIG BROTHERS AND BIG SISTERS PROGRAMS](#)

R. Kevin Grigsby

[126 PSYCHIATRY AND THE PRIMARY CARE PHYSICIAN](#)

Bina P. Patel and Michael S. Jellinek

[127 POLICE—MENTAL HEALTH RESPONSES TO CHILDREN EXPOSED TO VIOLENCE: THE CHILD DEVELOPMENT—COMMUNITY POLICING PROGRAM](#)

Steven Marans, Robert A. Murphy, and Steven J. Berkowitz

[128 CHILD PSYCHIATRY AND THE JUVENILE COURT](#)

Hans Steiner and Allison D. Redlich

[129 TELEPSYCHIATRY: AN EMERGING SERVICE DELIVERY MODEL IN CHILD AND ADOLESCENT PSYCHIATRY](#)

R. Kevin Grigsby and Maureen T. McSwiggan-Hardin

## SECTION X. TRAINING, ETHICS IN RESEARCH AND PRACTICE, AND HISTORY

---

[130 RECRUITMENT, TRAINING, AND CERTIFICATION IN CHILD AND ADOLESCENT PSYCHIATRY IN THE UNITED STATES](#)

John E. Schowalter

[131 RESPECT FOR CHILDREN AS RESEARCH SUBJECTS](#)

Robert J. Levine

[132 ETHICS IN THE PRACTICE OF CHILD AND ADOLESCENT PSYCHIATRY](#)

Diane H. Schetky

[133 HISTORY OF CHILD PSYCHIATRY](#)

David F. Musto

## CONTRIBUTORS

---

---

**Jean Adnopoz, M.P.H.**

*Associate Clinical Professor, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**John P. Alsobrook II, Ph.D**

*Research Affiliate, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**K.J.S. Anand, M.B.B.S., D.Phil.**

*Department of Pediatrics, University of Arkansas College of Medicine, Little Rock, Arkansas*

**Adam Anderson, Ph.D.**

*Department of Biomedical Engineering, Vanderbilt University, Nashville, Tennessee*

**George M. Anderson, Ph.D.**

*Research Scientist, Director, Laboratory of Developmental Neurochemistry, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Leah K. Andrews, M.B., Ch.B., F.R.A.N.Z.C.P.**

*Clinical Director, Child and Family Unit, Auckland Children's Hospital; Clinical Lecturer, Department of Psychiatry and Behavioural Science, University of Auckland School of Medicine, Auckland, New Zealand*

**Adrian Angold, MRCPsych.**

*Associate Professor, Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, North Carolina*

**Paula Armbruster, M.A., M.S.W.**

*Assistant Clinical Professor of Social Work, Director, Outpatient Services, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Joshua Barenbaum, B.A.**

*Harris Predoctoral Fellow in Urban Child Development, Yale University School of Medicine, New Haven, CT*

**Jaqueline A. Bartlett, M.D.**

*Associate Professor, University of Medicine and Dentistry, New Jersey Medical School, Newark, New Jersey*

**Myron L. Belfer, M.D., M.P.A.**

*Professor of Psychiatry, Department of Social Medicine, Harvard Medical School, Boston, Massachusetts, and Consultant, Mental and Brain Disorders, World Health Organization, Geneva, Switzerland*

**Kathryn J. Bennett, M.D.**

*Associate Professor, Department of Clinical Epidemiology and Biostatistics, McMaster University, West Hamilton, Ontario, Canada*

**Tami Benton, MD**

*Assistant Professor, University of Pennsylvania, Director of Clinical Services, Director of Education, The Children's Hospital of Philadelphia, Department of Child and Adolescent Psychiatry, Philadelphia, Pennsylvania*

**Ian Berg, M.D., FRCPsych, FRCP(Edin)**

*Senior Clinical Lecturer, Department of Child and Adolescent Mental Health, University of Leeds, Leeds, England*

**Steven J. Berkowitz, M.D.**

*Assistant Professor, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Boris Birmaher, M.D.**

*Associate Professor of Child Psychiatry, Western Psychiatric Institute and Clinic, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania*

**Marc H. Bornstein, Ph.D.**

*Senior Research Scientist and Head, Child and Family Research, National Institute of Child Health and Human Development, Bethesda, Maryland*

**John V. Campo, M.D.**

*Assistant Professor of Psychiatry and Pediatrics, University of Pittsburgh School of Medicine, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania*

**Rochelle Caplan, M.D.**

*Professor in Residence, Department of Psychiatry and Biobehavioral Science, University of California, Los Angeles, School of Medicine, Los Angeles, California*

**Robert M. Casey, Jr., Ph.D.**

*Associate Research Scientist, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**F. Xavier Castellanos, M.D.**

*Child Psychiatry Branch, National Institute of Mental Health, Bethesda, Maryland*

**Stella Chess, M.D.**

*Professor of Child Psychiatry, New York University Medical Center, New York, New York*

**Ursula Chock, M.S.W.**

*Clinical Instructor in Social Work, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Muniya Choudhury, M.A.**

*Graduate Student, Temple University, Philadelphia, Pennsylvania*

**He Len Chung, M.A.**

*Graduate Student, Temple University, Philadelphia, Pennsylvania*

**Paul D. Clein, M.D.**

*Clinical Fellow, Division of Child and Adolescent Psychiatry, Johns Hopkins Medical Institutions, Baltimore, Maryland*

**Donald J. Cohen, M.D.**

(deceased)

**Lee Combrinck-Graham, M.D.**

*Medical Director, Waterbury Child Guidance Clinic, Waterbury, Connecticut*

**James P. Comer, M.D.**

*Maurice Falk Professor of Child Psychiatry, Yale Child Study Center, Associate Dean, Yale University School of Medicine, New Haven, Connecticut*

**Ed Cook, Jr., M.D.**

*Professor, Department of Psychiatry and Pediatrics, University of Chicago, Chicago, Illinois*

**Henry P. Coppolillo, M.D.**

*Clinical Professor of Psychiatry, University of Colorado School of Medicine, Denver, Colorado*

**Shauna B. Corbin, Ph.D.**

*Private practice, Topeka, Kansas.*

**E. Jane Costello, M.D.**

*Professor, Department of Psychiatry and Behavioral Science, Durham, North Carolina*

**Fern J. Cramer-Azima, Ph.D.**

*Associate Professor, Department of Psychiatry, McGill University, Montreal, Quebec, Canada*

**Thomas K. Cummins, M.D.**

*Assistant Professor, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia*

**Andre P. Derdyn, M.D.**

*Wohdan Professor of Psychiatry, Professor of Pediatrics, and Director, Division of Pediatric Psychiatry, University of Arkansas, Chief of Psychiatry, Arkansas Children's Hospital, Little Rock, Arkansas*

**Elizabeth M. Dykens, Ph.D.**

*Professor, Neuropsychiatric Institute, University of California, Los Angeles*

**David Elkind, M.D.**

*Professor, Department of Child Study, Tufts University, Medford, Massachusetts*

**Monique Ernst, M.D., Ph.D.**

*Head of Neurodevelopment of Reward Systems, Mood and Anxiety Disorders Program, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland.*

**Julian B. Ferholt, M.D.**

*Associate Clinical Professor of Psychiatry and Pediatrics, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Matia Fin-Stevenson, Ph.D.**

*Associate Director, Yale Bush Center, Associate Research Scientist, New Haven, Connecticut*

**Michael First, M.D.**

*Research Psychiatrist, New York State Psychiatric Institute, Associate Professor of Clinical Psychiatry, Department of Psychiatry, Columbia University, New York, New York.*

**Brian W. C. Forsythe, M.B., Ch.B. F.R.C.P. (C.)**

*Associate Professor of Pediatrics, Yale Child Study Center, Yale University School of Medicine, Attending Physician, Department of Pediatrics, Yale-New Haven Hospital, New Haven, Connecticut*

**Jennifer B. Freeman, Ph.D.**

*Assistant Professor (Research), Brown University School of Medicine, Staff Psychologist, Department of Child and Family Psychiatry, Rhode Island Hospital, Providence, Rhode Island*

**Elliot M. Friedman, Ph.D.**

*Postdoctoral Fellow, Department of Psychiatry, University of California, San Diego, San Diego, California*

**Gregory K. Fritz, M.D.**

*Professor and Director of Child & Adolescent Psychiatry, Brown Medical School, Medical Director, Bradley Hospital, Director of Child and Family Psychiatry, Rhode Island Hospital, Providence, Rhode Island*

**Geri Fox, M.D.**

*Associate Professor of Clinical Psychiatry, Director of Graduate Medical Education Programming, Special Assistant to the Senior Associate Dean, Department of Psychiatry, University of Illinois at Chicago/Institute for Juvenile Research, Chicago, Illinois*

**H. Paul Gabriel, M.D.**

*Clinical Professor of Psychiatry, New York University Medical Center, New York, New York*

**Judy Garber, Ph.D.**

*Professor, Department of Psychology and Human Development, Vanderbilt University, Nashville, Tennessee*

**Abbe M. Garcia, Ph.D.**

*Postdoctoral Fellow, Brown University School of Medicine, Child and Family Psychiatry, Rhode Island Hospital, Providence, Rhode Island*

**Jessica Gaynor, Ph.D.**

*Assistant Clinical Professor, Department of Psychiatry, University of California at San Francisco, San Francisco, California*

**Jay N. Giedd, M.D.**

*Chief, Brain Imaging, Child Psychiatry Branch, National Institute of Mental Health, Bethesda, Maryland*

**Walter S. Gilliam, Ph.D.**

*Associate Research Scientist, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Mayu P.B. Gonzales, M.D.**

*Clinical Assistant Professor, Department of Psychiatry and Behavioral Sciences, New York Medical College, Valhalla, New York, and Director and Chief Psychiatrist,*

*Mental Health Services, New York Foundling Hospital, New York, New York*

**Ian M. Goodyer, M.D., F.R.C.Psych.F.Med.Sci.**

*Professor of Child and Adolescent Psychiatry, University of Cambridge, Cambridge, England*

**Paul N. Graffagnino, M.D.**

*Clinical Professor of Psychiatry, University of Connecticut School of Medicine, Farmington, Connecticut*

**Richard H. Granger, M.D.**

*(deceased)*

**Elena Grigorenko, Ph.D.**

*Research Scientist, The PACE Center and Child Study Center, Yale University, New Haven, Connecticut*

**R. Kevin Grigsby, M.D.**

*Vice-Dean for Faculty and Administrative Affairs, Professor of Behavioral Science, Penn State College of Medicine, Milton S. Hershey Medical Center, Hershey, Pennsylvania*

**Katherine A. Halmi, M.D.**

*Professor of Psychiatry, Cornell University, New York, New York, and Director, Eating Disorder Program, New York Presbyterian Hospital, White Plains, New York*

**H. Allen Handford, M.D.**

*Emeritus Associate Professor, Division of Child and Adolescent Psychiatry, Pennsylvania State University College of Medicine, M.S. Hershey Medical Center, Hershey, Pennsylvania*

**Helen Hanesian, Ed.D.**

*Assistant Professor of Clinical Psychology, Columbia University College of Physicians and Surgeons; Psychologist, Pediatric Neuropsychiatry Service, Columbia-Presbyterian Medical Center, New York, New York*

**Norris M. Haynes, Ph.D.**

*Associate Clinical Professor of Psychiatry, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Lily Hechtman, M.D., C.M., F.R.C.P.(C.)**

*Professor, Department of Psychiatry and Pediatrics, Director of Research, Division of Child Psychiatry, McGill University, Director of ADHD Services and Adolescent Services, Department of Child Psychiatry, Montreal Children's Hospital, Montreal, Quebec, Canada*

**Stephan Heckers, M.D.**

*Assistant Professor, Department of Psychiatry, Harvard Medical School, Assistant Director, Psychiatric Neuroimaging, Massachusetts General Hospital, Boston, Massachusetts*

**Christa M. Helms, B.A.**

*Graduate Student in Behavioral Neuroscience, Oregon Health and Science University, Portland, Oregon*

**Jerry D. Heston, M.D.**

*Associate Professor of Psychiatry, Division of Child and Adolescent Psychiatry, Medical Director, Child and Adolescent Day Treatment Program, University of Tennessee College of Medicine, Memphis, Tennessee*

**Angela R. Holder, LL.M.**

*Professor of the Practice of Medical Ethics, Center for the Study of Medical Ethics and Humanities, Duke University School of Medicine and Duke University School of Law, Durham, North Carolina*

**Samantha Holmes**

*Graduate Fellow, Yale Child Study Center, Yale University, New Haven, Connecticut*

**Michael Irwin, M.D.**

*Professor of Psychiatry, University of California, San Diego; Veterans Affairs Medical Center, San Diego, California*

**Leslie Jacobson**

*Assistant Professor of Psychiatry and Pediatrics, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Steven L. Jaffe, M.D.**

*Professor of Psychiatry, Emory University School of Medicine, Clinical Professor of Psychiatry, Morehouse School of Medicine, Atlanta, Georgia*

**Michael S. Jellinek, M.D.**

*Chief, Child Psychiatry Service, Massachusetts General Hospital, Professor of Psychiatry and of Pediatrics, Harvard Medical School, Boston, Massachusetts*

**Allan M. Josephson, M.D.**

*Professor, Department of Psychiatry and Health Behavior, Medical College of Georgia, Chief, Section of Child, Adolescent and Family Psychiatry, Children's Medical Center, Augusta, Georgia*

**Jerome Kagan, Ph.D.**

*Professor, Department of Psychology, Harvard University, Cambridge, Massachusetts*

**Sandra J. Kaplan, M.D.**

*Vice Chairman, Department of Psychiatry, North Shore University Hospital-New York University School of Medicine, Professor of Clinical Psychiatry, New York University School of Medicine, Manhasset, New York*

**Javad H. Kashani, M.D.**

*Professor of Psychiatry, Case Western Reserve University, Cleveland, Ohio, Director of Child and Adolescent Services, Laurelwood Hospital, Willoughby, Ohio*

**Wendy Kates, M.D.**

*Assistant Professor, Department of Psychiatry-Brain Imaging, Kennedy Krieger, Johns Hopkins University, Baltimore, Maryland*

**Joan Kaufman, M.D.**

*Assistant Professor of Psychiatry, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Philip C. Kendall, Ph.D., A.B.P.P.**

*Laura H. Carnell Professor, Head, Division of Clinical Psychology, Child and Adolescent Anxiety Disorders Clinic, Temple University, Philadelphia, Pennsylvania*

**Robert A. King, M.D.**

*Professor of Child Psychiatry and Psychiatry, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Laurel J. Kiser, Ph.D., M.B.A.**

*Associate Professor, Center for Mental Health Services Research, University of Maryland at Baltimore, Baltimore, Maryland*

**Ami Klin, Ph.D.**

*Harris Associate Professor of Child Psychology and Psychiatry, Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**Christine Konradi, Ph.D.**

*Director, Laboratory of Neuroplasticity, Psychiatry Department, McLean Hospital, Harvard Medical School, Belmont, Massachusetts*

**William G. Kronenberger, Ph.D.**

*Associate Professor, Department of Psychiatry, Indiana University School of Medicine, Indianapolis, Indiana*

**Michael E. Lamb, Ph.D.**

*Head, Section on Social and Emotional Development, National Institute of Child Health and Human Development, Bethesda, Maryland*

**Christopher A. Lamps, M.D.**

*Instructor, Division of Pediatric Psychiatry, University of Arkansas for Medical Sciences, Arkansas Children's Hospital, Little Rock, Arkansas*

**Nathan Laor, M.D., Ph.D.**

*Tel Aviv Community Mental Health Center and Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel, and Yale Child Study Center, Yale University School of Medicine, New Haven, Connecticut*

**James F. Leckman, M.D.**

*Neison Harris Professor of Child Psychiatry and Pediatrics, Yale Child Study Center, Yale University School of Medicine, Yale-New Haven Medical Center, New Haven, Connecticut*

**Henrietta L. Leonard, M.D.**

*Professor, Department of Psychiatry and Human Behavior, Brown University, Director of Training, Department of Child and Family Psychiatry, Rhode Island Hospital, Providence, Rhode Island*

**Robert J. Levine, M.D.**

*Professor of Medicine, Lecturer in Pharmacology, Yale University School of Medicine, New Haven, Connecticut*

**Melvin Lewis, M.B., B.S., F.R.C.Psych., D.C.H.**

## FOREWORD TO THE FIRST EDITION

---

---

On two previous occasions, including my Presidential Address to the American Psychiatric Association (1984), I delineated the requirements for a field of medical practice to be identified as an independent specialty. Among a number of requirements, I emphasized the need for a scientific base that is specific to the specialty, even though substantial reliance might be placed on the basic sciences of other specialties. I went on to point to the importance for clinicians in the specialty to have a unique set of knowledge and skills. I also stated that both the scientific base and the specific skills must have a degree of conceptual clarity to form the framework of a required educational curriculum. Child and adolescent psychiatry now has such an educational curriculum.

A specialty such as child and adolescent psychiatry also needs its own comprehensive textbook that conceptualizes the whole field for the reader. Such a textbook should combine information on the scientific bases and the techniques into an amalgam that enables the reader to acquire the up-to-date knowledge necessary for state-of-the-art practice. No easy task!

Approaching Lewis' volume precisely in the context of the above concepts, readers will acquire equal knowledge about what to do, when to do it, and, most importantly, why to do it. They will also become better practitioners whose actions will be based not on empiricism alone but on scientific evidence as well. Best of all, *Child and Adolescent Psychiatry* has the content and conceptual clarity needed for the education of new generations of students.

In addition to students of child and adolescent psychiatry, others concerned with the mental health of children and adolescents will find the text of great value. *Child and Adolescent Psychiatry* will be useful for experienced practitioners, pediatricians, psychologists, and neurologists, as well as allied professionals such as educators, nurses, social workers, lawyers, and policy planners. Some will find the scientific expositions of greater interest, others will focus on the practical clinical issues. All will gain a new opportunity for enlarging their knowledge and rounding out their clinical expertise through reading this intellectually satisfying and clinically informative book.

*Child and Adolescent Psychiatry* is more than a detailed primer for students of child and adolescent psychiatry. It is, in fact, a truly comprehensive reference manual for those who labor for the advancement of mental health for children and adolescents. Conceptually, scientifically, clinically, and pedagogically this book fills an important need in child and adolescent psychiatry. This was the goal for which Mel Lewis and the contributors strive for with the hope of contributing to the greater achievements and happiness of new generations of our young. They have succeeded admirably in this goal.

George Tarjan, M.D.  
Professor Emeritus of Psychiatry  
University of California, Los Angeles

## PREFACE TO THE THIRD EDITION

---

---

This is a big book, bigger than its first and second editions. Its growth reflects that of the field of child and adolescent psychiatry. Our understanding of normal child development and of the roots of psychopathology has advanced from a primarily psychodynamic paradigm to a sophisticated appreciation of the ways in which genetic, neurophysiological and environmental variables interact to influence adaptation. Advances in neuroimaging, psychoneuroendocrinology and psychoneuroimmunology are beginning to shed light on the different ways in which human development can go awry. As we literally and figuratively unravel the human genome and compare ourselves to the other denizens of our planet, we begin to appreciate those characteristics we share and those that distinguish us from more primitive species.

Our increasing recognition of the differences between the neuroanatomy, neurophysiology and psychoneuroendocrinology of males and females from infancy through adulthood has moved us beyond simplistic social explanations for behavioral differences. Scientific advances in the understanding of gender identity and behavior have encouraged not only a reexamination of the differences between the ways that boys and girls think and feel, but also a reassessment of the ways that we measure intelligence and even morality.

In tandem with our increasing knowledge regarding the ways that genetic and neurophysiological variables affect behavior has come an increasing appreciation of the numerous ways in which social and cultural variables influence adaptation. Mental illness is understood and expressed in different ways in different settings. We are just beginning to recognize our own prejudices and the ways that they, and the availability or lack of treatment resources influence the diagnoses and dispositions we make. Most important, the devastating effects of poverty, grinding poverty, on the growth, development, mental health and adaptation of children of every race and culture has been well documented. We can now identify its effects at the biochemical, neurophysiological, neuroanatomical and behavioral levels. Unfortunately we are less skilled at preventing and reversing these consequences.

This big purple book contains an account of where we stand clinically and scientifically. It confronts us with the chasm that separates what we know about the causes and treatments of children's psychiatric disorders and what we as a society actually provide. It reminds us that the current constraints imposed on caregivers, the extreme criteria for admission to hospital, and the absurdly limited lengths of stay permitted under our current delivery systems, deprive the majority of mentally ill children in our country of the optimal care we know how to provide. At this point in our own development as a society our social values and priorities have a long way to go to catch up with our scientific understanding and our sophisticated technology. We must keep in mind that in the face of all that we know about human development and the ongoing myelination of the frontal lobes into the third decade of life and beyond, we nevertheless allow our children to be tried as adults and executed for crimes committed before their eighteenth birthdays. Let us hope that before the fourth edition of this book appears, our ethical values will have caught up with our scientific knowledge.

This purple book contains the knowledge and wisdom of 200 experts in their respective clinical and research disciplines. To thank them individually would add enormously to the length of this volume. Therefore I must thank them together for their enthusiasm, dedication and especially for the time spent sharing their expertise with the rest of us in clear, readable, plain English. I am grateful too to the members of the advisory committee for their suggestions and wisdom.

Lippincott, Williams & Wilkins have collaborated with me to make what at first seemed an insurmountable task into an exhilarating challenge to be met. I particularly want to thank Joyce Murphy, managing editor, and Charley Mitchell, executive editor, for their warmth, common sense and ongoing encouragement and Allison Risko, project editor, for her untiring striving for perfection in correcting the page proofs.

I am especially grateful to Ann Chieppo who has assisted me through all three editions of the purple book and who, unfazed by 133 chapters and 200 authors, helped bring it all together.

Finally, I thank my family, Dorothy, Gillian, and Eric, for rejoicing with me when chapters were flowing in, commiserating with me when authors requested "just one more week" in order to include their newest data, and for being there to share the frustration and exhilaration of putting together this big purple book.

Melvin Lewis M.B., B.S., F.R.C.Psych, D.C.H.  
Professor of Child Psychiatry and Pediatrics  
Yale Child Study Center  
Yale University School of Medicine  
New Haven, Connecticut

## PREFACE TO THE FIRST EDITION

---

---

*Child and Adolescent Psychiatry* presents an up-to-date, comprehensive, and useful account of child and adolescent psychiatry today. The book covers the field completely, from the migration of cells in the embryonic cortex to issues of world mental health. The book encompasses normal development, psychopathology, diagnosis, and treatment. International authorities have contributed scholarly chapters on virtually the complete syllabus for the modern child and adolescent psychiatrist.

The book contains nine sections: Normal Development; Development of Symptoms; Overview of Etiological Influences; Nosology and Classification; Diagnostic Assessment; Syndromes; Treatment; Child Psychiatry and Allied Professions (pediatrics, education, law, and public health); and Training and Research.

A unique feature is Section II, Development of Symptoms. Here, authorities were invited to describe their understanding of the actual development of cardinal symptoms encountered in child and adolescent psychiatry. Symptoms such as anxiety, depression, psychotic thinking, and violence, seen in a variety of different kinds of disorders, are explored in a manner similar to the way internal medicine would approach symptoms such as fever and pain. Another unusual feature of the book is its emphasis on the relevance of research findings to clinical experience. Clinical case illustrations highlight important aspects of the syndrome being described. The book also draws on many theories of development, which are discussed in terms of their clinical relevance. The book will be useful to all specialists who try to help children and their families. There are subsections on child psychiatry and pediatrics, child psychiatry and education, child psychiatry and law, and child and adolescent psychiatry and public health. For the child psychiatry trainee and the young researcher, there are specific chapters on training and certification in child and adolescent psychiatry, new research techniques, and the ethics of research involving children.

The enthusiasm of the authors and their commitment to excellence is a source of great pleasure and pride to me. I am indebted to each of them. I wish to express special appreciation and gratitude to Doctors Dennis Cantwell, Stella Chess, James Leckman, Dorothy Otnow Lewis, David Tomb, Elizabeth Weller, and Gabrielle Weiss who comprised the Advisory Committee and whose advice was invaluable. I wish to thank the staff at Williams & Wilkins, including Nancy Collins, Carol Eckhart, Michael Fisher, John Gardner, Rebecca Marnhout, Anne Stewart Seitz, Steve Siegforth, Deborah Tourtlotte, and Chuck Zeller for their special combination of competence and enthusiasm. I also thank my secretary, Ann Chieppo, for her steadfast support and assistance in this immense task. Finally, I wish to thank my wife Dorothy for her clarity of thought and loving support.

Melvin Lewis

Human beings are complex living organisms that can be characterized by their appearance and behavior at each point in the life cycle. Many of these characteristics are uniquely human, such as the array of languages that facilitate interpersonal communication and permit a meaningful interplay of ideas and emotions. Other characteristics, such as affection and aggression, are less distinctive and place our species as one among many that populate the earth. Scientific advances over the past 150 years clearly indicate that hereditary factors are transmitted from generation to generation and account for much of the observed variation among and within species. Although the complexities of human existence cannot be reduced simply to the effects of genes, it is inescapable that genetic factors provide the biological basis for many of our potentialities and vulnerabilities as human beings ([Leckman and Mayes, 1998](#)).

Our genetic endowment, as a species, is a unique collection of discrete units of heredity (genes) that for the most part are linearly arranged on 46 chromosomes (22 pairs of homologous chromosomes and two sex chromosomes) ([Fig. 1.1](#)). This collection of genes makes us both alike and different from other organisms. Although the precise genetic determinants of our interspecies similarities and differences are largely obscure, it is probable that many of the responsible genetic factors will be identified. For example, investigators are in the midst of discovering the cascade of genes that have contributed to the remarkable neuroanatomic and functional evolution of the cerebral neocortex across different mammalian species over the past 50 million years ([Northcutt and Kaas, 1995](#)).

**Figure 1.1.** Depiction of high-resolution banded human chromosomes. (Adapted from Yale-HHMI Human Gene Mapping Library Chromosome Plots, Number 5. New Haven, CT, Howard Hughes Medical Institute, 1989.)

Genetic factors also contribute to variations within species. A large number of physical and psychological traits, including gender, height, and intelligence, have been shown to be under at least partial genetic control. One need only examine the striking physical and psychological similarities between monozygotic (genetically identical) twins reared apart to recognize the powerful influence of genes in determining who we are ([Juel-Nielsen, 1980](#); [Shields, 1962](#)). Some of these intraspecies differences, such as gender, are owing to actual differences in the number and type of genes present in the individual. For example, any gene on the Y chromosome is present only in males and is transmitted exclusively from father to son. Other intraspecies differences are owing to there being multiple forms (polymorphic alleles) of specific genes that are distributed within the population. Some of these allelic variants contribute to traits such as blood type, height, or eye color. In others, the changes within the genes are more subtle and make the individual more susceptible to additional factors, genetic or environmental, that lead to phenotypic expression of clinical significance.

Some allelic variations are so significant that we use the term "mutation" to signify that the changes will usually lead to disease states such as Rett's syndrome, Huntington's disease, Marfan's syndrome, or sickle cell anemia, disorders in which other ameliorating factors will have little effect. Finally, some intraspecies differences may depend on the sex of which parent passed on a particular piece of genetic material through the process of genetic imprinting ([Moore and Haig, 1991](#)). Briefly, imprinting is an epigenetic process that effects the shape of the DNA molecule and its accessibility to proteins that regulate gene expression, such that the genes within an imprinted chromosomal region from one parent are effectively silenced. The most dramatic example of imprinting concerns two distinctively different developmental disorders, Prader-Willi and Angelman's syndrome, that are caused by alterations of DNA in the same general chromosomal region on chromosome 15 ([Knoll et al., 1993](#)) ([Chapter 2](#)).

Apart from interspecies and intraspecies variations, it is also important to recognize that maturational differences within an individual member of a species can also result from genetic factors. Simply put, this means that not all genes are active at the same time. For example, the hemoglobin genes active during fetal life are different from those active in adults. As the temporal patterns of gene expression during human development become known, we may come to be able to better predict each individual's genetic potential.

The next two sections, Genes, and Regulation of Gene Function, present a condensed summary of some of the fundamental aspects of the structure and function of genes and gene products. Several excellent general references cover this material in greater depth ([Alberts et al., 1995](#); [Watson et al., 1988](#)).

## GENES

The existence of discrete hereditary factors or genes was initially postulated by Mendel in 1865 ([Mendel, 1965](#)), but their importance was not appreciated until the early 1900s. Genes are linearly arranged on chromosomes found in the nuclei of cells ([Fig. 1.2](#)). They are composed of deoxyribonucleic acid (DNA). DNA consists of a string of nucleotides (complex molecules that contain a sugar moiety, a phosphate group, and either a purine or pyrimidine base) that are linked end to end. These linkages involve connecting the carbon atom of one sugar moiety to the carbon atom of the next nucleotide through a phosphate group. Every nucleic acid chain has a direction determined by the orientation of its sugar phosphate backbone. The two ends are designated 5' and 3' to indicate this orientation. Four separate nucleotides are found in DNA. Two contain purine bases (adenine and guanine), and two contain pyrimidine bases (thymine and cytosine) ([Fig. 1.3](#)).

**Figure 1.2.** The structure of chromosomes. Chromosomes are thread-like packages of DNA in the nucleus of a cell. This drawing also depicts a diagram of the DNA double helix in its common form showing the antiparallel orientation of the complementary strands and the wrapping of DNA around histone cores. (Adapted from the Glossary of Genetic Terms and associated illustrations found on the web site of the National Genome Research Institute, 2000.)

**Figure 1.3.** Chemical structure of DNA, showing the 3'-5' phosphodiester linkages that connect the nucleotides. (Adapted from Watson JD, Hopkins NH, Roberts JW, et al.: *Molecular Biology of the Cell*. Menlo Park, CA, Benjamin/Cummings, 1987.)

Genetic information is conveyed by the specific nucleotide sequence of a particular DNA molecule. Most DNA molecules exist in a double helical structure composed of two polynucleotide chains held together by a series of hydrogen bonds between complementary base pairs (adenine is bonded to thymine and guanine to cytosine) (Fig. 1.3). This structure confers stability on the molecule and provides the basis for replication. Knowing the sequence of one strand immediately provides precise knowledge of the sequence of the other because each strand of DNA in the double helix is exactly complementary to the other.

The sequence of nucleotides on a DNA molecule determines the order of the 20 different amino acids in proteins. As a consequence, the information contained in DNA provides the instructions that direct cells to grow and divide, set in motion developmental sequences that lead to orderly differentiation of cell types, and provide for the maintenance of a diversified population of cells necessary for the successful functioning of complex organisms.

The nucleotide sequence, however, does not provide a direct template for protein synthesis. Instead, there is a series of intervening steps that requires the DNA to be transcribed into messenger ribonucleic acid (mRNA). Messenger RNA molecules are very similar in composition to DNA and can hybridize with complementary DNA sequences. All mRNA chains grow in a 5' to 3' direction and are single stranded. Mature mRNA molecules are rapidly transported out of the nucleus and into the cytoplasm where they serve as the template for protein synthesis.

The translation of a part of the genetic code into a specific amino acid sequence occurs at ribosomes located in either the cytoplasm or attached to the endoplasmic reticulum. The genetic code is determined by the sequence of bases, with sets of three bases constituting one coding unit, or codon. At the ribosome, codons of an mRNA molecule bind to complementary anticodons of transfer RNA (tRNA), which then transfer specific amino acids to a growing protein chain. The basic elements of this "central dogma" of protein production were first proposed by Crick in 1956 and remain fundamental to our understanding of these basic molecular events (Crick et al., 1961).

Genes are normally extremely stable and are precisely copied during the chromosomal duplications that precede cell divisions (mitosis). Obviously, any mistakes that occur have the potential of disturbing the normal sequence of amino acids in a protein. There are a number of proteins within the nucleus whose functions are to recognize and repair any errors within the DNA sequence. Very rarely, mistakes go uncorrected and result in mutations. The majority of such changes have no effects as they occur in regions on the DNA molecule that do not encode for protein; however, when mutations occur within the sequence that encodes for protein, they may have several effects. First, they may have no effect or slightly change the function of the protein, leading to the allelic variations discussed in the preceding. Second, they may be deleterious to the function of the encoded protein and, ultimately, to the organism. Finally, this capacity for change can, in rare instances, lead to positive consequences that serve as the basis for evolution.

## REGULATION OF GENE FUNCTION

According to some estimates, only about 1% of the genome is being expressed at a given time in higher eukaryotic cells (Mendel, 1965). During the course of development and in any particular tissue, different but overlapping sets of genes are active. Some genes are constitutively expressed, whereas others are highly responsive to environmental changes. Regulation of gene function can occur at any one of the many steps required for gene expression (Fig. 1.4).

**Figure 1.4.** Sequence of events leading to gene expression. A protein-coding gene comprises a stretch of genomic DNA that contains an open reading frame. This region contains instructions for making the protein, as well as adjacent control regions—promoters and enhancers—where the gene's transcriptional mechanism is switched on or off. The promoter region is the site at which RNA polymerase binds and starts transcribing. The enhancer regions may be thousands of base pairs distant from the promoter. Transcription of the gene into mRNA may be either stimulated or inhibited by transcription factors that bind to promoter and enhancer regions. The mRNA formed by transcription is spliced to remove introns and processed within the cell nucleus to produce mRNAs that are exported to the cytoplasm for translation into protein at the ribosomes. Some proteins go through posttranslational modification to become biologically active. The four examples depicted include: cleavage of precursor proteins, conformational change through covalent cysteine-cysteine (C-C) bonds, phosphorylation of serine (S) or tyrosine (Y) (black squares), and glycosylation of asparagines (N, branching motif).

## Transcriptional Factors

Transcription depends on a complex series of events that lead to the formation of mRNA. A central event is the binding of RNA polymerase II in combination with other general transcription factors to specific region of the DNA, termed core promoter sites ( [Gumucio et al., 1996](#)). These core regions are usually found immediately upstream of the transcriptional start site, the most common being the “TATA” box. This is a sequence of highly conserved nucleotides within the promoter that serves as a signal and allows the active RNA polymerase II complex to bind tightly to the double-stranded DNA. A series of steps is initiated that unravels the sense strand and makes it more accessible to DNA polymerase II, which is able to initiate transcription. In addition to these factors, other highly conserved DNA sequences have been identified that either enhance or repress the transcription of target genes. These sequences are usually found within the promoter region and are capable of forming a wide variety of unusual DNA structures with simple and complex loop folding patterns. Enhancers function by interacting with transcription factors to form complexes of proteins that allow the transcription machinery to bind more efficiently to the underlying gene. By way of contrast, repression factors function by making it even more difficult for DNA polymerase II to gain access to the gene in question. In this way, genes are expressed or repressed depending on the precise mixture of enhancers, repressors, and transcription factors present in the cell. Hence, the configuration of transcriptional elements and their interplay confer on each gene a unique spatial and temporal transcription program.

Some of these highly conserved repetitive DNA sequences in the promoter regions of genes serve as “phylogenetic footprints,” reliable guides to important regulatory regions ( [Mitchell and Tjian, 1989](#)). As such, their presence is being used as one element of algorithms to identify putative novel genes within the vast sequence data bases generated by the Human Genome Project and related commercial efforts ( [Hardison et al., 1997](#)).

Several classes of DNA-binding proteins exist that regulate the transcription of most genes. The best characterized of these transcription factors contain conserved amino acid regions that in turn bind to specific DNA sequences. For example, homeodomain-containing genes have a highly conserved DNA sequence of 180 nucleotides that encode a polypeptide with a helix-turn-helix structure. This structure contains two a helices that bind in the major groove of the double helix of DNA ( [McGinnis et al., 1984](#)). Other transcriptional factors have different tertiary structures known as *zinc fingers* and *leucine zippers* that also bind to DNA regulatory sequences within the promoter and facilitate the initiation of transcription ( [Landschultz et al., 1988](#); [Miller, 1985](#)).

Another major issue concerns the mechanisms by which genes remain quiescent in some cell lineages or in a repressed configuration after a period of activity ( [Davidson, 1986](#)). This is a critical issue during the complex cascade in time and space of the genes necessary for the formation of the brain. During specific points in development, different genes are sequestered within heritable forms of chromatin complex that preclude transcription. Developmental repression of adult somatic cell genes is remarkably efficient. Ratios of 1:10,000,000 or more have been estimated for the level of globin and growth hormone transcripts in cells not expressing these genes compared with those that are ( [Groudine and Weintraub, 1975](#); [Ivarie et al., 1983](#)).

One way to achieve gene repression is for transcription factors to act on the acetylation of histones. In normal transcription, histone acetylation causes an unwinding of the DNA allowing the transcriptional machinery to bind. Consequently, factors that activate histone acetylases act as gene promoters. Another important mechanism of repression is achieved through “CpG islands” that are present within the 5' control regions of most genes. “CpG islands” refer simply to the presence of regions rich in C+G nucleotides. Intriguingly, the methylation status of these islands has emerged as being an important factor in two neurodevelopmental disorders, Rett's and fragile X syndrome, as well as the molecular events leading to various cancers. (See [Chapter 2](#) for a more detailed examination of these two syndromes.) DNA in somatic tissue is characterized by a bimodal pattern of methylation, which is established through a series of developmental events ( [Greally and State, 2000](#)). Very early in development, most DNA is unmethylated, but after implantation, a wave of *de novo* methylation modifies most of the genome, excluding the majority of CpG islands, which are mainly associated with housekeeping genes. These genomic methylation patterns are broadly maintained during the life of the organism by maintenance methylation and generally correlate with gene expression.

Beyond the complete silencing of genes, “gene dosage” is another crucial issue. Under normal circumstances in adults, there are large classes of genes where only one of the two inherited copies is active. Two prominent examples include X-inactivation and genomic imprinting. X-inactivation is the early coordinated silencing of nearly all genes on one of the two X chromosomes in females. Typically, imprinting also involves the coordinated silencing of contiguous genes in certain chromosomal regions coming either from the father or mother. Although the mechanisms that underlie such events are poorly understood, significant progress is being made to understand these processes at the molecular level ( [Marahrens, 1999](#); [Sleutels et al., 2000](#)).

It is evident from this description that a complex combination of regulatory proteins exists. A different pattern of gene expression emerges depending on which nucleotide sequences are present within a promoter region, as well as which transcription factors, enhancers, or repressor proteins are present within the cell. Moreover, this interplay of regulatory factors determines whether and how much of a specific protein is transcribed.

A species' genetic program unfolds in a largely predictable fashion despite its formidable complexity from the earliest gene expression in the zygote through the entire morphogenesis of the organism. This uniformity may depend, in part, on the presence of redundant pathways and in part from the fact that development proceeds largely in the direction of increasing complexity, but lesser potential. We return to these concepts in the following when we describe exactly how certain growth factors, as well as environmental factors, interplay with transcription factors to either initiate or repress expression of genes within the brain.

## Posttranscriptional Events

Transcribed RNA typically goes through a number of modifications before it is ready for export from the nucleus. These steps include the excision of intervening regions of the message, termed introns, that do not encode for protein. This processing of immature RNA molecules occurs through a mechanism called splicing. The end result is a mature mRNA that contains an uninterrupted sequence of nucleotides that encode the amino acid sequence for the protein. In addition, long stretches of adenine nucleotides, the poly(A) tail, are added to the mRNA message prior to its being shuttled out of the nucleus and into the cytoplasm.

Several splice sites might be present within a gene and allow for different portions of the gene to be brought together. This flexibility in mRNA formation has several important functions. A single gene may produce several nearly identical proteins that differ in certain critical amino acid sequences. The resulting proteins may have different enzymatic functions or unique binding affinities for novel proteins. Alternatively spliced messages are particularly enriched within the central nervous system (CNS), where they are often expressed at different developmental periods.

## Translational Factors

The process of translating mature mRNA molecules into proteins occurs in the cytoplasm. Ribosomes bind to the mRNA messages and initiate a complex series of events, many of which are themselves under regulatory control. Although regulatory mechanisms at this level may seem unnecessary, they do provide a means of rapidly controlling synthesis of gene products by cells.

The stability of a mature mRNA that has entered the cytosol is a critical determinant of how many copies of a protein will be synthesized by the ribosomal apparatus. Certain base sequences in the 3' untranslated region, as well as the poly(A) tail, are thought to influence the stability of many mRNA molecules and their rate of degradation.

## Posttranslational Processing

Once a protein has been formed, it often undergoes further modification. For example, sulfhydryl groups in two cysteine residues may form a covalent bond with each other; this provides stability for the protein, as well as helping to fold it into its final tertiary structure. Several other chemical modifications can occur also, such as the phosphorylation of serine, tyrosine, and threonine residues; glycosylation of the amino acid asparagine; acetylation of the NH<sub>2</sub> terminal amino acids; or hydroxylation of proline and lysine residues. Glycoproteins are formed by the addition of various sugar moieties to the free hydroxyl group of serine or threonine ( [Freifelder, 1987](#)).

The removal of certain amino acid stretches from a protein is another posttranslational process that occurs. One example is the formation of polypeptide hormones and neuropeptides that often involves the cleavage of precursor proteins at specific sites. For example, the processing of prodynorphin molecules leads to a variety of dynorphin moieties and leu-enkephalin. Intriguingly, differential processing of prodynorphin, as well as other precursor proteins, in different tissues is commonplace, so that the form of dynorphin found in the anterior lobe of the pituitary is different from the form of dynorphin found in the neurointermediate lobe ( [Molineaux et al.,](#)

## ENVIRONMENTAL EFFECTS ON GENE TRANSCRIPTION

### Growth Factors

Growth factors have been implicated in a broad range of developmental processes in which cell specification, growth, and survival have to be coordinated across tissues or germ layers. For example, members of the transforming growth factor family, such as the polypeptide, nodal, are necessary for the initial specification of mesoderm within the developing embryo. In contrast, members of the fibroblast growth factor (FGF) family are required for the proliferation of tissues that form the primordia of the placenta and connect the mammalian embryo with its mother. Members of the FGF family are also required during the earliest phases of anterior-posterior patterning of the embryo, possibly through the regulation of downstream homeodomain-containing genes. More recently, basic fibroblast growth factor (Fgf2) has been determined to be necessary for cell proliferation and neurogenesis in the developing cerebral cortex ( [Raballo et al., 2000](#); [Vaccarino et al., 1999](#)). Later, in brain development, growth factors are thought to play a critical role during periods of development when external events and environmental factors influence axonal connectivity, and the development and pruning of synapses, as well as apoptosis (cell death) ( [Klintsova and Greenough, 1999](#)). Thus growth factors are required for multiple steps during development ( [Vaccarino et al., 1999](#)).

Although many different growth factors are produced within the CNS, only minute amounts of these molecules are secreted. The end result is that neurons compete for the small amounts of trophic factors present. The receptors for the various growth factors lie on the outer membrane and bind their specific growth factor. Once bound, a cascade of signals is initiated that promotes their growth and differentiation, as well as the development of synaptic connections and their long-term survival.

Most receptors have two functional domains: an extracellular portion that binds to the signaling molecule, and an intracellular domain that passes along the signal. The binding of a growth factor to its receptor often results in two ligand–receptor complexes coming together on the membrane and association with each other to form dimers ( [Fig. 1.5](#)). The catalytic domains of the receptors are protein kinases, and the dimerization leads to the phosphorylation of each.

**Figure 1.5.** Signal transduction and the action of growth factors. Growth factors generate signals in a cell by binding to specific receptors on the plasma surface and initiating transcription of needed proteins. Two molecules of a growth factor are shown binding to their receptor. The receptors are transmembrane tyrosine kinase receptors that associate with each other after ligand binding and become phosphorylated. In their phosphorylated state, the receptors attract other signaling proteins, including the adapter protein SOS and the enzyme, Ras. The newly formed complex of proteins activates several kinase pathways, one of which is shown here (MAPKs). In this pathway, transcription factors (Elk-1, Jun) are activated by phosphorylation within the nucleus and initiate the transcription of genes that are themselves transcription factors (immediate early, or IE, genes). The IE transcription factors initiate transcription of additional genes, and their mRNA messages are transported back into the cytoplasm and translated into proteins, such as the ion channels shown. In this example, an ion channel is being synthesized and leads to an increased level of the second messenger,  $\text{Ca}^{2+}$ . (Adapted from Vaccarino FM, Lombroso PJ. Growth factors. *J Am Acad Child Adol Psychiatry* 37:789–790, 1998.) (See [color plate](#).)

Several events then occur in rapid succession. A number of proteins are recruited from the cytoplasm to form complexes of signaling proteins at the plasma membrane. These associated proteins are often themselves phosphorylated and thereby activated by the receptors. For example, one of the best studied signaling pathways leads through a series of successive phosphorylations to the activation of a protein called “mitogen activated protein kinase” (MAPK). MAPK is transported to the nucleus where it phosphorylates specific transcription factors and initiates expression of genes important for cell proliferation or differentiation.

In summary, the binding of growth factors to their receptors on the cell surface leads to the rapid transmission of the signal into the neuron. It is not surprising that gain-of-function mutations in some of these receptor proteins disrupt the normal transmission of intracellular signaling, leading to a number of developmental disorders affecting the structure and function of the CNS ( [Passos-Bueno et al., 1999](#)).

### Hormones

Hormones use a related mechanism to transmit signals into cells ( [Evans, 1988](#)). There are many different types of hormones within our bodies. We review one of these that has an important role within the CNS. Hydrocortisone is a glucocorticoid hormone secreted in response to stressful events. Although stress responses are critical for our survival as a species, too much stress has adverse effects on our physiology and may damage neuronal structure and function ( [Post et al., 1998](#)).

Hydrocortisone is synthesized in the cortex of the adrenal gland where it is released into the blood stream. Similar to most steroid hormones, hydrocortisone is a water-insoluble molecule. This fact leads to several important differences between this family of signaling proteins and the growth factors.

Growth factor receptors lie on the plasma membrane where they are able to directly bind their ligand. In contrast, the receptors for most hormones are concentrated in the cytosol or nucleus. Hormones are able to pass directly across the membrane because they are water-soluble molecules and bind to their receptors to initiate specific cascades of signals.

A second difference lies in the fact that hormone receptors can act directly as transcription factors. Prior to binding their respective hormones, the receptors are in an inactive state because they are tightly associated with an inhibitory protein. The inhibitory protein is released when the hormone binds to the receptor and a DNA-binding domain on the receptor–hormone complex becomes unmasked. The complex is now able to interact with specific DNA sequences within the promoter region of genes. In this way, hormone receptors initiate the transcription of genes required by the cell at that moment.

Most hormones exert their effects in two stages. Initially, the hormone receptor induces the transcription of a small number of genes. This effect usually occurs within 30 minutes and is known as the primary hormonal response. Because many of these genes are themselves transcription factors, a cascade of transcription is begun. Steroid hormones thus are able to exert much longer-lasting responses than growth factors. Typically, the immediate effects of growth factors disappear within seconds or milliseconds, although their action can be prolonged by the activation of downstream signaling. In contrast, hormones such as hydrocortisone persist in the blood for hours, whereas the thyroid hormones last even longer and their actions persist for days. The newly synthesized transcription factors activate additional genes in a delayed or secondary hormonal response. A single hormone, therefore, can initiate complex patterns of gene expression.

## GENE AND THE CREATION AND MAINTENANCE OF THE NERVOUS SYSTEM

Although the precise number of genes that regulate the growth and development of the CNS is unknown, some investigators have estimated that at least one-third of the mammalian genome is devoted exclusively to this task ( [Hahn et al., 1982](#)). Recent estimates that there are over 80,000 genes in the human genome come from the human genome sequencing project. Approximately 30,000 of these are specifically expressed within the human CNS. This figure does not include constitutively expressed genes that maintain the basic functions of cellular life, including the regulation of the cell cycle, production of subcellular organelles, and maintenance of

the cellular structure.

The process of development is a heritable feature of all organisms. Genetic factors must contain virtually all of the information necessary to guide the orderly succession of events that will transform portions of the fertilized egg into a fully developed CNS. The morphogenesis of the nervous system involves at least five major processes that are regulated in part by genetic factors: the birth of specific cell types, their migration to their final destination, their growth, the development of neural connections, and cell death (Jacobson, 1970; Vaccarino and Leckman, 1998). A fundamental understanding of these processes would require precise knowledge of: (a) the developmental information relevant to the CNS that is encoded in the human genome, (b) how this information is regulated and utilized in (morphogenetic" time and space, and (c) how the products of these genes endow the differentiating and differentiated cells of the embryonic CNS with their functional characteristics (Davidson, 1986). Although we remain largely ignorant of the critical determinants of these processes, remarkable progress toward understanding them has been made during the past decade (Rubenstein and Rakic, 1999). Genetic studies of the development of the CNS in flies, worms, and other model systems have led the way to many of our most fundamental discoveries.

### Spatial Differentiation and Determination of Specific Cell Lineages

Interestingly, RNA synthesized by the mother during oogenesis provides the basis for most of the biosynthetic capacity of early embryos. By the time of fertilization, the egg has already been programmed to ensure the development of spatially distinct embryonic cell lineages. Literally, thousands of mRNAs are formed during oogenesis and remain dormant within the egg until fertilization occurs. One of the reasons for this is that much of the machinery required for the proper transcription, translation, and processing of mature proteins is not yet available in the very early embryo. In some species, the set of maternal genes constitutes the majority of all genomic loci active during ontogeny (Davidson, 1986).

The maternal mRNAs persist until the blastula stage, when they are replaced by transcripts produced by the developing organism. Many of these transcripts are homologous with the maternal transcripts, but some are novel genes not included in the maternal set. An instructive example of this transition from maternal to zygotic transcription concerns several evolutionarily conserved proteins that act as a trigger for cell divisions. In this case, studies have shown that the accumulation of the maternally derived protein cyclin serves as the mitotic trigger for early cellular divisions, whereas later cell divisions depend on the production of a different trigger protein produced by the developing zygote (O'Farrell et al., 1989).

Two other important classes of genes active at this point in development are segmentation and homeotic genes. These genes have been best characterized in *Drosophila*, where they determine the number and polarity of body segments and the identity and sequence of body segments (Gehring, 1987). Many of these genes are evolutionarily conserved and present in the human genome.

Although the precise functions of these genes in mammalian development have not been fully established, they are known to be differentially expressed in the central and peripheral nervous systems, as well as in mesodermal derivatives (Graham et al., 1989). Intriguingly, some of these genes exist in multigene clusters related by duplication and divergence. In some instances, the relative chromosomal position of the gene in a cluster corresponds to the domain of expression in the developing embryo (Fig. 1.6). Many of these genes code for transcription factors. As a consequence, attention has focused on their roles in organizing the differential expression of other genes that are ultimately responsible for establishing distinctive cellular phenotypes. Indeed, their expression patterns provided new evidence for the segmental organization of the rostral CNS (Puelles and Rubenstein, 1993; Rubenstein et al., 1994).

**Figure 1.6.** Homeodomain-containing genes and their expression in the neural axis. Hox gene expression in the mouse embryo. The three panels show lateral views of 9.5 day old mouse embryos stained with antibodies specific for the protein products of *Hoxb1*, *Hoxb4*, and *Hoxb9* genes. (Adapted from Wolpert L, Beddington J, Brockes J, et al.: *Principles of Development*. Oxford, Oxford University Press, 1998, p. 103.) (See [color plate](#).)

Dozens of regulator genes have been identified during the past decade that appear to play crucial roles in the development of the vertebrate CNS. These include the vertebrate homologs of *Drosophila* segment polarity genes *engrailed* and *wingless* (Joyner, 1996). The first forebrain-specific homeodomain-containing genes including the *distalless*, *gastrulation and brain specific gene*, *orthodenticle*, and *emptyspiracle* gene families were isolated and characterized by the early 1990s (Boncinelli et al., 1993; Murtha et al., 1991; Rubenstein and Puelles, 1994; Simeone et al., 1992). Subsequently, vertebrate genes encoding for secreted morphogens such as sonic hedgehog were found to be expressed in stripes along the entire neural axis (Tanabe and Jessell, 1996). The intricate cascade of genetic and molecular events that lead to the development of the mammalian CNS is one of the most exciting stories in the developmental neurosciences.

Not surprisingly, defects in genes controlling neuronal proliferation are being recognized with increasing frequency as a cause of cortical malformations (Raymond et al., 1995). Examples of this phenomenon include tuberous sclerosis (Vinters et al., 1998) and schizencephaly (Brunelli et al., 1996).

Finally, it has also become clear that neurogenesis occurs in adults as well as in the prenatal period. New neurons have been identified that originate in the subventricular zone and then migrate through the white matter to the neocortex, where they extend axons, and become functionally active (Gould et al., 1999).

### Migration of Neurons

The early embryonic development of the nervous system is characterized in part by the migration of populations of neurons. Examples of this phenomenon include the migration of neural crest cells to form elements of the peripheral nervous system (autonomic and sensory ganglia, glial cells, and adrenomedullary cells) and the migration of neurons born within the ventricular zone to their final destination within the cortical laminae. A range of factors mediate these events, and some have been identified, including proteins that contribute to inherent directional preferences, chemotaxis, and differential adhesion of cells as they migrate (Purves and Lichtman, 1985).

In the case of corticogenesis, it has been established that the newly formed glutaminergic projection neurons migrate along radial glial guides that stretch between the ventricular surface and outer cortical surface (Rakic, 1988a) (Chapter 3). It is likely that certain recognition and adhesion molecules are necessary for this migratory process to occur (Hatten and Mason, 1986; Rakic, 1981; Rakic, 1988b). The differential expression for some of these molecules has been established, and genetically mediated defects in their structure and function are now known to result in aberrant migratory patterns (as is seen in the "reeler" and "weaver" mouse mutants) (Rakic and Sidman, 1973a,b). Intriguingly, GABAergic interneurons in the cerebral cortex arise in the primordia of the basal ganglia and migrate tangentially into the cerebral cortex (Ware et al., 1999).

Genetically based abnormalities in the genes that govern neuronal migration have been implicated in a number of human disorders, including X-linked lissencephaly, focal pachypolymicrogyria, and the "double-cortex" syndrome (Gleeson et al., 1998) (Chapter 2). In some instances, the genes responsible for the abnormal migration have not yet been identified (Yoshimura et al., 1998).

### Neural Connectivity and Survival

Developing nerve cells have the remarkable characteristic of being able to maintain contact with literally thousands of other nerve cells by extending cellular

processes over substantial distances. These contacts are of crucial importance in establishing and maintaining the functional integrity of the nervous system. These processes initially develop by way of local extension and retraction of specialized areas on the surface of the neurons called growth cones. A variety of external signals regulate the formation, maintenance, and/or degradation of these neuronal connections, including mechanical guides, differential adhesiveness, the influence of electrical fields, and interaction with gradients of trophic substances ( [Kalil et al., 1986](#); [Purves and Lichtman, 1985](#)).

Once neuronal processes reach their target field, the neurons acquire obligatory trophic dependencies. Target fields contain growth factors such as nerve growth factor that bind to the axons projecting to that field and are retrogradely transported to the afferent cell body. A given target field, however, is able to support only a limited number of neurons, and the “extra” neurons are lost. For example, although nerve growth factor (NGF) does not attract sensory nerve fibers to their target-fields, it is intimately involved in the target-mediated survival of neurons. Indeed, from the first appearance of the neuronal processes in the target-field, there is a marked increase in the rate of transcription of the NGF gene and the amount of NGF in the target-field. There is also a rapid appearance of cell surface receptors for NGF on the sensory neurons (mediated by the transcription of the NGF receptor gene) ( [Davies et al., 1987](#) ). We discuss in the following how these growth factors send their signals from the neuronal surface to the inside of the cell to effect changes in the transcription of specific genes that are required at that moment.

Genetic factors are likely to play an important facilitatory role in neurite outgrowth and synaptogenesis throughout life. The dynamic equilibrium between neurite outgrowth and synaptogenesis versus neurite pruning and synapse withdrawal may well be a crucial mechanism that allows organisms to modify their behavior or “learn” as a result of experience. Although the precise genetic mechanisms that underlie these complex processes are not well understood, one mechanism may involve those genes that regulate the expression of molecules involved in neuronal communication. For example, *in vitro* and *in vivo* studies have indicated that many neurotransmitters and neuromodulators, in addition to their communicative function in mature neural systems, play important roles in the development and maintenance of these systems by promoting or inhibiting the growth of neural processes ( [Lipton and Kater, 1989](#) ).

Recently, a carboxypeptidase A inhibitor, latexin, has been identified that appears to play a role in cortical projection neurons that are fated to establish links between the primary sensory motor cortex and secondary association areas ( [Arimatsu et al., 1999](#) ). A number of mouse mutants are also providing valuable insights into the genes, molecules, and mechanisms that mediate the connection of cortical neurons to cortical and subcortical targets ( [O'Leary et al., 1999](#) ).

## THE ROLE OF EARLY LIFE EXPERIENCE

The development of the nervous system depends on epigenetic and environmental factors, as well as genetic influences. At each level and stage of development, the microenvironments and macroenvironments of the organism play a crucial role. The unfolding of the genetic program, with its complex sequences and patterns of gene expression, depends in large measure on the presence of transcriptional factors in the microenvironment of the nucleus. This means that our ability to separate out the relative contributions of genetic and epigenetic influences is difficult because the genes influence the environment through the production of various proteins and the environment, in turn, alters the expression of genes ( [Fig. 1.7](#) ).

**Figure 1.7.** Gene-environment interactions. (Adapted from Purves D, Lichtman JW. *Principles of Neural Development*. Sunderland, MA, Sinauer, 1985.)

This reciprocal relationship between genes and the environment is played out over the entire course of development. Developmental biologists have long been interested in characterizing the sequence of microenvironmental changes occurring within the CNS that allow for the normal unfolding of these processes. In fact, a great deal has been learned regarding the orderly turning on of various transcription factors that organize the body plan, including the brain ( [Fig. 1.5](#) ). In addition to transcription, a growing list of growth factors and cell surface molecules plays a critical role in the early growth and differentiation of neurons, migration, and survival of neurons by activating signaling pathways that were discussed in the preceding.

This is not to say that external environmental factors can not influence some of these early developmental events. It is well established that drugs, alcohol, altered nutrition (including a lack of oxygen, or hypoxia), and certain viral illnesses disrupt the orderly progression of neuronal growth during critical periods of brain development. However, the brain of a healthy fetus in a “normal” environment will develop because of the directions contained in its genetic code.

The situation changes significantly during the latter part of gestation onward as the CNS becomes functionally active. In humans as well as other mammals, there is a tremendous growth in the number of synaptic connections ( [Bourgeois and Rakic, 1993](#) ). Moreover, as neuronal connections form, the proper ones are strengthened throughout early infancy by the expansion of functioning synaptic contacts. Although neuronal connections can be made throughout life, it is during the early childhood years and again during puberty that the greatest explosion occurs in synapses throughout the nervous system.

A great deal of experimental evidence has indicated that neuronal activity is required for the proliferation of these connections, as well as their later refinement ( [Edelman, 1987](#); [Shatz, 1990](#) ). Neuronal activity is triggered by interactions of the developing organism with its intrauterine and postnatal environments. Ultimately, genes within the brain must be activated while others must be repressed to permit the normal development of axonal growth cones and the elaboration of synapses, as well as the pruning back of unwanted or unnecessary connections. Much of what developmental neurobiologists have learned regarding these processes began with the seminal work of Hubel and Wiesel over 30 years ago. These investigators were interested in determining how the visual cortex develops and organizes itself. The visual cortex is a region of the brain that encompasses approximately 30% of the cortex when its associated regions are included. Their work clearly established that the connectivity of the adult visual cortex is critically dependent on early synaptic input ( [Hubel, 1988](#); [Wiesel, 1982](#) ). Visual experiences are required for the development in the primary visual cortex of what are termed ocular dominance columns. In order to function properly, visual input from the right or left eye must be separated into alternating columns within layer IV. Prior to and immediately following birth, inputs from the eyes are not separated but, rather, make overlapping synaptic contact with neurons in the visual cortex. Once visual activity is initiated after birth, there is a progressive segregation of the visual inputs into orderly columns. This reshaping of the axonal connections within the cortex by visual experiences is referred to as activity-dependent development ( [Purves, 1994](#) ).

What was perhaps unexpected from the work of Hubel and Wiesel was the discovery that the orderly segregation requires visual experience during a critical period of time. Normal ocular dominance columns will not develop if an animal, such as a kitten, is raised for the first 6 weeks with vision permitted only through one eye because the occluded eye will become fundamentally disconnected from the cortex. Consequently, if vision is then restored to the deprived eye, a “catch-up” does not occur, and the failure to develop proper segregated columns becomes permanent. The visual cortex remains abnormally organized throughout the animal's life ( [Katz and Shatz, 1996](#) ).

Similar deficits are seen in humans who do not experience normal visual inputs during their first years of life. The clinical examples most commonly described are the abnormalities that occur occasionally in an infant born with either unilateral or bilateral cataracts. If the cataract is not diagnosed and surgically removed early in life, the child will never develop vision in the affected eye(s). Moreover, there appears to be a critical period in human infants when proper synaptic connections within the visual cortex must be formed. This is in contrast to the situation in adulthood, where cataracts are sometimes present for years; however, once removed, the individual regains visual acuity.

The preceding discussion raises several related issues. One is whether other regions of the brain show a similar reliance on environmental input for their growth and development. The visual system remains the best studied cortical area that has addressed this issue. However, it is clear that other regions of the cortex involved in sensory perception must have neuronal activity to develop proper synaptic outgrowth ( [Katz and Shatz, 1996](#) ). One example comes from the work of investigators interested in what happens to cortical regions after amputation of a finger ( [Merzenich et al., 1983](#) ). The earlier this occurs, the more plastic is the cortex in remodeling. Regions that used to subserve the amputated finger regress and nearby digits expand their representations into the region.

An extreme example of neural plasticity and the capacity for the brain to reorganize connections involves the rewiring of visual projections to the auditory cortex early in life that allows the animal to “see” using its auditory cortex ( [von Melchner and Pallas, 2000](#) ).

Another example relates to how much easier it is to learn a second language early in life. Recent work in this area suggest that other regions of the brain are profoundly influenced by early neuronal activity. Functional magnetic resonance imaging was used to determine the areas of the brain that are metabolically activated during language acquisition in individuals who learn both native and second languages. When a child learns two languages, both languages are

represented in a single language center; however, when an adult attempts to learn a second language, a new language center is established that is clearly distinguishable from the primary language center ( [Kim et al., 1997](#)).

At the macroenvironmental level, manipulation of sensory input can alter the structure and function of cytoarchitectonic areas of the cortex ( [Kalil et al., 1986](#); [Rakic, 1988b](#)). Although these external events are unquestionably translated into internal events that alter the microenvironment and disturb the balance of factors that permit neuronal outgrowth and survival, they underline the exquisite sensitivity of the developing nervous system to its external environment.

The sphere of influences acting on the nervous system continually enlarges during development ( [Purves and Lichtman, 1985](#)). Assuming a “good enough” environment to support development, the cytoplasm of the egg, with its maternally derived biosynthetic apparatus, provides the initial milieu. Later local cellular interactions between neurons and glia and the reciprocal activity of more distant neurons influence the multiple microenvironments of the discrete cell lineages and regulate morphogenesis. Finally, the nervous system is also shaped by wholly external events in the prenatal and postnatal world.

Consistent with this view, evidence for a critical period in the establishment of stress responsivity and maternal behavior has recently been presented ( [Francis et al., 1999](#)). In these animal studies, the level of maternal care as measured by licking and grooming by the mothers profoundly influenced the quality of maternal care offered by the female adult offspring. It also established an enduring pattern of stress response in the pups as they matured. The pups raised by the attentive dams were more likely to show less stress in response to novel environments. These findings are also consistent with other studies of the enduring impact of maternal stress in the perinatal period ( [Ladd et al., 2000](#); [Vallee et al., 1999](#)). Importantly, many of these effects appear to result from environmental and not genetic effects in large measure. It is also likely that alterations in these neurobiological systems may alter an individual's vulnerability to latter psychopathology, including mood and affective disorders ( [Heim and Nemeroff, 1999](#)).

Finally, it is likely that events in early family life, interactions with peers, and educational opportunities shape the course of development just as surely as the developing individual profoundly influences his or her environment. The developmental perspectives of child psychiatry echo in the study of developmental neurobiology.

## FUTURE PROSPECTS

Genetics and the developmental neurosciences are on the threshold of a new era in which the sequence of the human genome will be known and widely available, and the intricate cascade of molecular events that govern brain development will be established. “DNA chips” containing fragments of virtually all the mRNAs coded for by the human genome will also rapidly become available to investigators in commercial, as well as academic settings. Using these tools, animal models of even complex human diseases are likely to be successfully developed.

Although the scientific, information management, and logistical challenges to understanding the complexity of the human genome vis á vis brain development are daunting, they are likely to pale in comparison to the ethical dilemmas to be faced as information about our vulnerability genes becomes accessible. The ethical problems will multiply as commercial firms develop even more potent pharmacologic tools to influence these developing neurobiological systems. We also predict that this new knowledge will emphasize the importance of early life events in shaping the CNS and will point the way to the profound and enduring importance of selective early interventions for families at high risk ( [Harris, 1996](#); [Olds et al., 1998](#)).

[Williams Syndrome](#)  
[Common Child Psychiatric Disorders](#)  
[Conclusion](#)  
[Chapter References](#)

The past decade has seen remarkable progress in the application of molecular genetic strategies to the study of neurologic and neuropsychiatric disorders ( [Martin, 1989](#)). The approximate chromosomal location for a number of autosomal-dominant, autosomal-recessive, and X-linked recessive disorders has been accomplished ( [Table 2.1](#)). The genes that are actually mutated in many of these illnesses have been identified, and determining the function of both the normal and mutated proteins has begun. This chapter reviews some of the important accomplishments in this area and closes with a brief consideration of the molecular basis of more common child psychiatric disorders.

**Table 2.1. Chromosomal Localization and Gene Abnormalities in Selected Psychiatric and Neurologic Disorders**

### RETT SYNDROME

Rett syndrome is a disorder within the autism spectrum ( [Rett, 1966](#)). It has a prevalence of 1 in 10,000. Affected children develop normally and reach developmental milestones within the first year of life; parents are unaware of any abnormalities. One of the first clinical symptoms is the loss of purposeful hand movements. Other clinical findings soon emerge, including loss of speech, growth retardation with microcephaly, ataxia, and a severe disruption of normal cognitive functioning. Clinical symptoms stabilize for the next several decades of life after this initial rapid regression ( [Naidu, 1997](#)).

One unusual feature of the disorder is that females are almost exclusively affected. An early explanation for the preponderance of affected females is that the mutated gene is located on the X chromosome. There are many examples of X-linked disorders in which males die *in utero* because males only have one X chromosome and only a single copy of the gene in question. Females have a second copy of the gene on their other X chromosome, and it appears that transcription of this gene in a significant subset of cells provides some degree of protection during fetal development and early postnatal life. However, symptoms may eventually emerge because haploinsufficiency, a single functional copy of a gene, is unable to confer lasting protection.

The chromosomal location for the gene was facilitated by analysis of affected sisters, and its approximate position was identified at Xq28 ( [Webb et al., 1998](#)). Candidate genes known to be present in this region were carefully studied. A number were systematically excluded as analyses of their nucleotide sequences revealed no mutations compared to the identical sequences from normal individuals; however, a gene was recently discovered that is mutated in several affected individuals ( [Amir et al., 1999](#)). The protein encoded by this gene is methyl CpG-binding protein 2 (MeCP2), and mutations in two of its functional domains have now been characterized ( [Fig. 2.1](#)).

**Figure 2.1.** Rett syndrome. *A:* The *MeCP2* gene consists of three exons separated by two introns. The exons are spliced together to produce a mature RNA message that is translated into MeCP2 protein. The gene has been implicated in Rett syndrome after several mutations were found within the coding regions in a number of patients. These are indicated by asterisks (\*) in the nucleotide sequence and protein. Mutations to date have been found to change the amino acid sequence within two functional domains of the protein. *B:* MeCP2 protein, through one of its functional domains, binds to methylated cytosine nucleotides present in CpG islands that are enriched within regulatory regions of many genes. After binding to DNA, the second functional domain is activated and recruits a deacetylase complex that chemically modifies nearby histone molecules. The chemical modification of histones leads to a further compacting of the DNA into chromatin. The transcriptional machinery, including DNA polymerase II, no longer has easy access to the underlying DNA and is unable to initiate transcription. (Adapted with permission from Lombroso PJ: Rett syndrome *J Am Acad Child Adol Psychiatry* 2000.)

How are mutations in this gene related to clinical symptoms? As discussed in the previous chapter, many genes are specifically expressed in certain tissues and not in others. Of the approximately 45,000 to 100,000 genes on the human genome, only about one-third are expressed exclusively within the central nervous system (CNS). Some of these genes and their protein products are important for normal development during critical periods of brain development. Others are needed only after birth, whereas others must be expressed at all times because they are involved in normal housekeeping functions required of the cell. This illustrates how carefully gene expression must be regulated for normal development and maintenance of tissues to proceed.

The previous chapter reviewed how transcription factors and other regulatory proteins such as enhancers and repressors bind to promoter regions of genes and either initiate transcription of specific subsets of genes or maintain their stable repression. The proteins involved in these regulatory events bind to specific deoxyribonucleic

acid (DNA) sequences within the promoter regions that control gene expression.

The protein that is mutated in Rett syndrome plays a critical role in regulating gene expression. The accessibility of DNA sequences depends to a large extent on the degree of methylation present within the regulatory regions ( [Kass et al., 1997](#)). Methylation is a chemical modification to DNA that occurs when methyl groups are added to cytosine nucleotides. It is particularly prevalent in regions of DNA that contain a high content of cytosine and guanine pairs, so-called CpG islands. Although CpG islands are present throughout the genome, they are most enriched within the promoter regions of genes. In fact, one approach to identifying transcriptional start sites is to look for CpG islands because they are often found immediately upstream of the transcriptional start site.

It was thought that DNA methylation alone was capable of repressing gene expression. DNA polymerase II is the enzyme that transcribes most DNA into RNA. Methylation of CpG islands within promoter regions was initially believed to be sufficient to prevent the enzyme from gaining access to these regions and initiating transcription; however, what actually occurs is somewhat more complicated.

The protein implicated in Rett syndrome, MeCP2, has two functional domains. One end of the protein recognizes methylated cytosines and binds tightly to them. The second domain is then activated and functions by recruiting another set of proteins, the histone deacetylase complex, to the immediate vicinity. Histones are a family of proteins present within the nuclei of all cells. Their role in modifying the secondary structure of DNA has been recognized for some time because they provide a core of protein around which the chromosomal DNA is wrapped ( [Nan et al., 1997](#)). The histone deacetylase complex that has been recruited by MeCP2 chemically modifies histones. The result is a compaction of the DNA surrounding the promoter region such that the transcriptional machinery of the nucleus is no longer able to gain efficient access to the gene. This effectively silences it.

The initial report on Rett syndrome found six distinct mutations among the patients who had a mutation of their *MeCP2* gene ( [Amir et al., 1999](#)). Several of these are missense mutations that replace critical amino acids within the protein. Mutations of this type are located within the methyl-binding domain and disrupt its ability to recognize and interact with methyl groups. The remaining mutations are found in the second functional region, the domain that recruits the deacetylation complex. Two types of mutations are present in this second domain. One is the insertion of a single nucleotide that leads to a shift in the downstream codons. A shift such as this results in the translation of a new amino acid sequence downstream of the point of mutation. The second mutation results in a novel stop codon. This type of mutation leads to the production of a shortened or truncated protein. Each of the mutations results in an impaired or nonfunctional protein ( [Amir et al., 1999](#)).

So far, mutations of the *MeCP2* gene were found in only a minority of Rett syndrome patients. There are several possible explanations for this. Only certain regions of the *MeCP2* gene were actually sequenced in the initial study. The regions sequenced were those that contain the open reading frame or that portion of the DNA that encodes for protein. These regions are often analyzed first because they require far fewer nucleotides to be sequenced compared to an analysis of the entire gene with its multiple introns and regulatory regions. Mutations in open reading frame, therefore, are the first to be detected, although regulatory regions of a gene also may be disrupted by mutations. For example, mutations at a promoter area may interfere with the proper initiation of transcription, whereas mutations in introns may interfere with the proper splicing together of exons by disrupting a splice site regulatory sequence.

*Allelic heterogeneity* refers to the presence of different mutations within a single gene. In the majority of disease-causing mutations studied so far, the same or a very similar clinical phenotype is seen when different functional domains of a single gene are mutated. This type of allelic heterogeneity was demonstrated in the initial study on Rett syndrome ( [Amir et al., 1999](#)). Six distinct mutations were found in different regions of the same gene, and all the patients had the same disorder. It is likely that additional mutations will be found within regulatory sequences of *MeCP2* that result in a similar phenotype. On the other hand, mutations to a single gene occasionally cause very different clinical presentations. For example, several mutations within the receptor for the fibroblast growth factor are responsible for a number of distinctly different skeletal and growth abnormalities ( [Park et al., 1995](#)).

By way of contrast, *locus heterogeneity* refers to mutations in different genes that result in a similar clinical presentation among affected individuals. This can happen, for example, when several proteins are involved in a series of related enzymatic reactions. For example, *MeCP2* encodes for one member of a larger family of proteins. At least two other members have been discovered that also bind to DNA and are involved in the recruitment of the histone deacetylation complex. Each of these proteins is now being examined to determine whether mutations in their genes also cause Rett syndrome. Moreover, as discussed, a number of proteins besides MeCP2 are required to properly repress target genes. Mutations of any of these other genes may result in a related clinical phenotype.

The recent findings with Rett syndrome raise a number of interesting questions. One relates to the predominance of neurologic symptoms in the clinical examination. *MeCP2* is not uniquely expressed in the brain but is found in many other tissues. Nevertheless, symptoms outside of the brain are not a predominant part of the disorder. It appears that the CNS is particularly vulnerable to disruptions of this gene. A similar situation occurs in Huntington's chorea, where neurologic symptoms are also the central part of an illness, although the mutated gene is expressed in many tissues.

A second related question concerns the normal developmental trajectory early in life that precedes the development of symptoms. Much longer delays are seen with a number of neurodegenerative disorders where symptoms are not detected until the fourth or fifth decade of life. One explanation put forward is that toxic compounds are slowly produced over time and must accumulate before neuronal damage occurs. Free radicals are examples of toxic compounds implicated in a number of neurodegenerative disorders, including Huntington's chorea. Normally, enzymes are present that detoxify free radicals within cells. If these enzymes lose their full functional activity through a mutation or are expressed in smaller amounts, then the toxins will accumulate over time and eventually interfere with normal neuronal function.

This may be what happens in the brains of Rett syndrome patients. As discussed, the normal function of the MeCP2 protein is to repress transcription of several additional genes. These downstream target genes are not yet known, but it is reasonable to assume that mutations to *MeCP2* lead to the inappropriate expression of these genes. It is possible that the products of these genes are themselves toxic, or interfere with the normal signaling pathways that function during this developmental period. Neuroanatomic studies might clarify this hypothesis. The literature contains a single autopsy report ( [Belichenko et al., 1994](#)), and abnormalities were detected in pyramidal neurons in layers II–III of the cerebral cortex. They had fewer dendrites than normal and many fewer dendritic arborizations. Additional neuroanatomic studies are necessary to help clarify the neuropathologic process that occurs in Rett syndrome.

## FRAGILE X SYNDROME

The application of molecular biology to child psychiatric disorders has also advanced our knowledge of fragile X syndrome ( [Nelson, 1995](#)). This disorder is the second most common cause of mental retardation and affects as many as 1 in 750 to 1,000 males and 1 in 500 to 750 females ( [Dykens et al., 1993](#)) ( [Chapter 48](#)).

Children with fragile X syndrome are born with mild to severe mental retardation. Additional clinical symptoms include facial, testicular, and connective tissue abnormalities ( [Baumgardner et al., 1995](#); [Martin and Bell, 1943](#)). Abnormal speech patterns are present in the majority of cases and include echolalia and high-pitched speech, as well as poor articulation, dysfluency, and dyspraxia. There is often gaze aversion among these children, as well as stereotypic behaviors, hyperactivity, and attentional difficulties. Aggressive and self-injurious behaviors are prominent features in some cases ( [Bregman et al., 1987](#)). Although there has been some interest in identifying specific linguistic, cognitive, or behavioral deficits among affected individuals, these have not been found and a wide variation exists in neuropsychiatric results ( [Dykens et al., 1993](#); [Freund et al., 1992](#); [Fryns, 1986](#); [Hodapp et al., 1992](#)).

Fragile X syndrome is transmitted from one generation to the next as an X-linked disorder. It has been known for many years that the phenotype of fragile X syndrome often co-segregates with what appears to be a "fragile" site on the X chromosome. In a certain proportion of cells grown in the absence of the nutrient, folic acid, a break point becomes visible on one of the X chromosomes ( [Fig. 2.2](#)) ( [Lubs, 1969](#)). These findings suggest that the gene or gene(s) involved in the disorder might lie near the disrupted site.

**Figure 2.2.** Fragile X site. The fragile site is shown on an affected chromosome of an individual with fragile X syndrome. (Adapted with permission from Lubs H: A marker X chromosome. *Am J Hum Gen* 21:231–244, 1969.)

Several unusual aspects of the disorder also were noted before the gene was actually cloned. Approximately 20% of the males who carry the abnormal gene are not mentally impaired. If the gene lay on the X chromosome, then why were these individuals not affected? They have no normal copy of the gene to compensate for the mutated gene. These men, called “normal transmitting males,” pass the abnormal gene to their daughters, who typically are also not affected. However, their grandsons are at high risk for the full syndrome. This progression in severity over several generations is known as *anticipation*.

The molecular basis for anticipation is now understood, and relates to the molecular defect found in the affected *FMR-1* gene (Fu et al., 1991). A novel type of mutation has been identified with the isolation of this gene. Triplet repeats refer to any three bases in the normal nucleotide sequence that is repeated several times one after the other. In the case of fragile X syndrome, the three repeated nucleotides are cytosine-guanine-guanine (CGG). Normal individuals have between six to 50 repeats of these bases in their *FMR-1* gene, with 29 repeats being the most frequent number seen (Fu et al., 1991). Affected individuals, however, have a dramatic increase in the number of repeated sequences, with 200 to 1,000 repeats typically. The extreme amplification of this CGG repeat sequence is responsible for the fragile X mutation site in the great majority of cases. Mothers of affected probands often have numbers of CGG repeats that fall in between those seen in normal individuals and those affected with the full fragile X syndrome. They typically have between 50 and 200 CGG repeats (Fu et al., 1991); repeats in this range are called *premutations* (Fig. 2.3).

**Figure 2.3.** Anticipation. Anticipation refers to the increase in severity for a disorder over several generations. In myotonic dystrophy, for example, the increase in symptoms ranges from cataracts late in life, to mild and then more severe muscle disorder, to fatal congenital illness. A corresponding increase is found in the triplet repeat expansion for cytosine-thymidine-guanine (CTG).

Some individuals who carry the premutation of the *FMR-1* gene often have mild cognitive and behavioral symptoms (Hagerman et al., 1996). Heterozygotic fragile X females perform poorly on visuospatial and/or memory subtests (de von Flindt et al., 1991; Kemper et al., 1986). Moreover, magnetic resonance imaging (MRI) and positron emission tomography (PET) analysis have shown premutation female carriers to have significant decreases in total brain volumes, as well as metabolic increases in the hippocampus and cerebellum (Murphy et al., 1999). These cognitive and behavioral symptoms are thought to result from the intermediate length of their CGG triplet repeat. Mothers who have the premutation are at a much higher risk of expanding the triplet repeat in the next generation to produce affected children with the full mutation. Although why it happens remains unclear, the expansion change from premutation to the full mutation is the molecular basis for the phenomenon of anticipation.

In addition to the 200 to 1,000 CGG repeats in affected individuals, other abnormalities in the DNA have been noted. As described, CpG islands are normally modified chemically through a process known as methylation. The triplet repeat expansion produces a large increase in the number of CpG islands. It is not surprising that abnormal methylation patterns are often found in patients with fragile X who have thousands of CGG repeats (Oberle et al., 1991), and these regions become highly methylated. In addition, the extent of methylation correlates directly with the loss of functional protein (Pieretti et al., 1991). The variations in the CGG repeat sequence induce abnormal methylation patterns adjacent to the promoter region of the *FMR-1* gene. The normal transcription of the gene is interfered with, ultimately leading to the absence of functional protein seen in most affected individuals.

What is the normal function of the FMR-1 protein and how does its absence lead to clinical symptoms? Soon after the gene was isolated in 1991, researchers noticed that the protein contained two domains with a highly conserved amino acid pattern. These domains are homologous to a motif found in other proteins known to bind tightly to ribonucleic acid (RNA) molecules. These proteins are called RNA-binding proteins and are often involved either in processing messenger ribonucleic acid (mRNA) transcripts or translating these transcripts into proteins (Eichler et al., 1993; Siomi et al., 1993, 1994). A mutation in an RNA-binding protein would seriously impair the ability of cells to produce mature messages or translate those messages into protein.

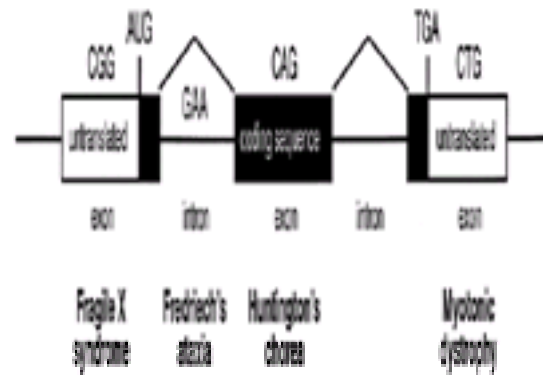

Knowledge of the intracellular location of the FMR-1 protein has extended our understanding of its normal function. The fragile X protein binds to ribosomes, the organelles within cells that are made from ribosomal RNA and various RNA-binding proteins and function as factories that translate mRNA transcripts into proteins (Khandijian et al., 1996). The fragile X protein is normally found in cells that produce large volumes of protein for export, such as neurotransmitter-producing neurons and androgen-producing testicular cells.

In the majority of cases, fragile X syndrome is caused by a triplet repeat expansion; however, any mutation that disrupts the functional activity of the FMR-1 protein could reasonably lead to a similar clinical syndrome. This was in fact described in a fragile X patient who did not have the expected triplet repeat expansion, but instead had a point mutation that changed a single highly conserved amino acid normally present within one of its functional domains, the RNA-binding motif (De Boulle et al., 1993; Musco et al., 1996; Siomi et al., 1994). The domain is critical for the proper function of FMR-1 protein, and mutations in this domain interfere with its ability to bind RNA molecules and to process them correctly. It is another example of allelic heterogeneity, where mutations in different parts of a single gene lead to the identical phenotype.

Studies of the pattern of expression of the *FMR-1* gene during development show the areas of the brain that normally have the highest level of expression. These include the basal forebrain and hippocampus (Abitbol et al., 1993). Both are involved in short-term memory and sequential processing of information, and are affected in some neurodegenerative disorders, such as Alzheimer's disease. The results of these developmental expression studies are consistent with both clinical and phenomenologic investigations that have demonstrated the cognitive, speech, and language strengths and weaknesses seen in fragile X syndrome. In addition, clinical neuroimaging studies have detected age-related volumetric changes in fragile X individuals in the cerebellar vermis, fourth ventricle, and hippocampus (Mostofsky et al., 1998a,b; Riess et al., 1994). Finally, animal models, such as knockout mice, have been developed by disrupting the normal expression of *FMR-1*. Some of the clinical features seen in fragile X syndrome are present in these knockout mice, setting the stage for even more detailed examination of the

neurobiological consequences of the abnormal *FMR-1* gene ([Dutch-Belgian Fragile X Consortium, 1994](#)).

Expansion of the *FMR-1* gene through triplet repeats was originally thought to be a genetic anomaly unique to fragile X syndrome. More than a dozen other triplet repeat disorders have now been identified ([Fig. 2.4](#)), including Huntington's chorea, Friedreich's ataxia, and myotonic dystrophy ([Caskey et al., 1992](#); [Nelson and Warren, 1993](#); [Warren, 1996](#)). The phenomenon of anticipation was apparent in most of these disorders but early investigators dismissed it as the result of ascertainment bias. The discovery of triplet repeat expansions, however, provides the molecular explanation for this phenomenon.

**Figure 2.4.** Triplet repeat disorders. A hypothetical gene is shown prior to the splicing together of exons and the removal of introns to produce a mature RNA message. Triplet repeat expansions have been discovered in all regions of a gene. In fragile X syndrome, the cytosine-guanine-guanine (CGG) repeat lies in the 58 untranslated region immediately adjacent to the promoter region. The expansion to 1,000 to 2,000 repeats leads to abnormal methylation patterns and disrupts normal transcription of the gene. In myotonic dystrophy, the cytosine-adenine-guanine (CAG) repeat is found at the other end of the gene within the 38 untranslated region. It is believed that the expansion there results in an unstable mRNA prone to degradation, as well as perhaps affecting the transcription of a second nearby homeobox gene. In Huntington's chorea, the triplet repeat expansion occurs in the open reading frame of the gene and leads to the inappropriate incorporation of an amino acid, in this case glutamine, within the protein sequence. Triplet repeat expansions have also been found in introns, where they presumably interfere with the proper splicing of the message. Friedreich's ataxia is an example of this type of expansion.

The degree of anticipation can be quite remarkable ([Fig. 2.3](#)). In myotonic dystrophy, for example, expansions that are just above the threshold for disease may only result in individuals who develop cataracts late in life. Several generations later, descendants have the full expansion with long repeats and fatal congenital illness ([Furuta et al., 1992](#)). Interestingly, anticipation has been described in families with schizophrenia and bipolar disorder, and some investigators believe triplet repeat expansions may account for a subset of affected patients ([McInnis et al., 1993](#); [Morris et al., 1995](#); [O'Donovan et al., 1995](#)).

## LISSENCEPHALY

The cerebral cortex is formed of billion of cells that are born during just a few months of embryonic life by a small population of progenitor cells. The cells that are born must differentiate and migrate to reach their final resting place in the appropriate layer of the cortex. These events are discussed at greater length in the following chapter.

However, a number of disorders are caused by mutations in genes whose proteins are required for the orderly progression of events from birth, differentiation into appropriate neuronal subtypes, migration, and eventual elaboration of synaptic connections.

Neurogenesis occurs in a region called the ventricular zone, which lies adjacent to the lumen of the neural tube. Although neurogenesis primarily occurs during the development of the brain *in utero*, some degree of neurogenesis occurs throughout life ([Gould and Tanapat, 1999](#)). In the cerebral cortex, neurons must travel through layers of earlier born cells to reach their final destinations. Those born at later periods have more complex migratory routes. Many employ a guidance system composed of radial glial cells ([Rakic, 1972](#)). The radial glial cells are thought to send a process that spans the developing cortex and serves as scaffolding along which certain neurons migrate. We believe that chemotactic signals are produced that keep the neurons moving along the radial glial process. When it reaches its final destination, other signaling molecules are produced that instruct the neuron to stop migrating, enter the proper lamina, and begin to elaborate its processes ([Rakic et al., 1994](#)).

Disruption of the normal migration of neurons causes several human disorders. The most common of these are the lissencephalies that consist of several syndromes: isolated lissencephaly (ILS), Miller-Dieker syndrome (MDS), and X-linked lissencephaly ([Dobyns and Truwit, 1995](#)). In each, the disruption to the normal neuronal migration is reflected in a smooth cortical surface that lacks the normal pattern of gyri and sulci. In addition, although the cerebral cortex normally has six layers, cortices of affected individuals have only four ([Fig. 2.5](#)).

**Figure 2.5.** Lissencephaly. The normal cerebral cortex is a highly organized structure, and its six layers are shown on the left (1–6). In contrast, the lissencephalic brain lacks the normal pattern of sulci and gyri, and there are only four layers. (Adapted with permission from Reiner O, Lombroso PJ: Lissencephaly. *J Am Acad Child Adol Psychiatry* 37:231–232, 1998.)

In 1993, a large deletion on chromosome 17 was found in two patients with MDS. The search then began to clone the gene responsible for the disorder, and it was soon isolated and termed *LIS-1* ([Reiner et al., 1993](#)). This gene and genes on either side of it were absent owing to the deletion and is another example of a contiguous gene syndrome. The absence of several genes is believed to be responsible for the more severe MDS phenotype, which also has numerous congenital abnormalities. Point mutations in the same *LIS-1* gene were soon found in other affected individuals. These individuals had the milder form of lissencephaly (ILS).

How does a mutation in *LIS-1* cause the observed cortical abnormalities? *LIS-1* encodes for a regulatory protein that controls the activity of a second protein, termed platelet activating factor (PAF)-acetyl hydrolase ([Hattori et al., 1994, 1995](#)). PAF acts as a signaling protein that binds to the surface of neurons. A cascade of signals is initiated required for the normal migration of neurons ([Reiner et al., 1995](#)). *LIS-1* is expressed at its highest levels in the developing cortex, consistent with the protein's putative role signaling. Exactly how mutations in *LIS-1* interfere with normal migration is not well understood, although one model suggests that a disruption occurs to cytoskeletal proteins that need to rearrange themselves at the growing tip of the migrating neuron ([Sapir et al., 1999](#)).

A second disorder that affects neuronal migration is termed subcortical band heterotopia ([Walsh, 1999](#)). This disorder, also known as X-linked lissencephaly or double cortex, is associated with mental retardation and epilepsy. The histologic findings are made of bilateral bands of gray matter consisting of disorganized neurons present in the central white matter between the cortex and ventricular wall. The degree of mental retardation is directly related to the thickness of the extra

neuronal tissue.

The gene that causes double cortex was recently cloned ([des Portes et al., 1998](#); [Gleeson et al., 1998](#)). The gene encodes for the protein double cortin (*DCX*). Structurally, this protein is highly homologous to a family of kinases, called calcium calmodulin-dependent kinases. Although its exact role in neuronal migration remains to be clarified, recent studies indicate that it binds to and appears to stabilize cytoskeletal proteins required for the normal movement of neurons ([Francis et al., 1999](#); [Gleeson et al., 1999](#)).

It is interesting to note that 20% of individuals with lissencephaly have no detectable mutation in *LIS-1*, whereas a similar number of individuals with subcortical band heterotopia have no detectable mutation of *DCX*. It is possible that additional studies will detect novel mutations within these genes; however, it is likely that different genes are mutated and lead to similar cortical abnormalities—another example of locus heterogeneity.

## PRADER-WILLI AND ANGELMAN SYNDROMES

Half of our 46 chromosomes derive from our mothers and the other half from our fathers. For years, it had been assumed that genes that lay on either chromosomal pair were equivalent and that each produced the same amount of functional protein. Mutations that lay in one gene often could be overcome through the actions of the normal protein derived from the homologous gene.

This is an accurate description of the molecular events for the majority of genes; however, recent studies over the past decade have demonstrated that some gene pairs are not functionally equivalent. Instead, the production of functional proteins depends on whether the gene that encodes it lies on the chromosome derived from the mother or the one from the father. In some cases, the maternal gene is expressed; in others, the paternal gene. This phenomenon is termed *genomic imprinting*.

For the majority of disorders, mutations within a gene change the specific nucleotide sequence and thereby disrupt protein expression. For a smaller group of disorders, factors other than the underlying nucleotide sequence determine whether the DNA produces useful patterns of gene expression. These factors are known as *epigenetic* phenomena to distinguish them from events that have an effect on the actual nucleotide sequences. We have discussed some epigenetic factors earlier in our discussions of Rett syndrome and fragile X syndrome. In these disorders, the extent of chromatin packaging or DNA methylation influences gene expression.

Approximately 30 genes have been discovered to date that are imprinted. Many of them play a key role in the growth and differentiation of various tissues. Disruption of these genes is implicated in a number of cancers and developmental disorders. These advances are reviewed in the following with an emphasis on two developmental disorders caused by defects in the imprinting mechanism—Prader-Willi and Angelman syndromes.

Prader-Willi syndrome (PWS) is a rare disorder with a prevalence of 1 in 10,000 births. A constellation of symptoms arises shortly after birth ([Prader et al., 1956](#)). Infants are often hypotonic and fail to thrive; however, their dietary habits change within the first year or two of life, and these individuals typically become hyperphagic and obese ([Holm et al., 1993](#)). They are often mildly to moderately mentally retarded and have a number of additional behavioral problems that include temper tantrums, aggressive behaviors, and obsessive-compulsive symptoms outside of the compulsive food-related behaviors ([Dykens et al., 1996](#); [Dykens and Cassidy, 1995](#); [State et al., 1999](#)).

Angelman syndrome is also a relatively rare disorder with a prevalence of 1 in 10,000 births. Individuals with the disorder are often hypotonic as infants and then develop motor delays and moderate to severe mental retardation. They have a characteristic facies with a large mandible with an open-mouth expression, abnormal gait, and puppet-like limb movements; they rarely develop speech. Epilepsy develops soon after birth and affected individuals have an abnormal electroencephalogram ([Angelman, 1965](#)).

By the mid-1980s, it was known that both disorders are caused by a deletion on chromosome 15 (15q11–q13). Cytogenetic and molecular techniques show that the same region is deleted in individuals with each syndrome. This result was somewhat puzzling because the disorders are very different, yet the identical deletion seemed to cause PWS in some cases and Angelman syndrome in others ([Ledbetter et al., 1981](#); [Magenis et al., 1987](#)).

It was then discovered that the clinical symptoms depend on which parent donates the deleted chromosome ([Cassidy and Schwartz, 1998](#)). The deletion derives from the father in most cases of PWS. In contrast, most individuals with Angelman syndrome have a deletion on the chromosome that derives from the mother.

A further clarification of the underlying mechanism came when the region for each disorder was pinpointed on chromosome 15. The section of DNA responsible for PWS is distinct but very close to the area responsible for Angelman syndrome. Part of the puzzle was, thus, clarified. A large deletion may occur that spans both regions. The child will develop PWS only if the deletion occurs on the paternal chromosome, and Angelman syndrome if the deletion occurs on the maternal copy.

Chromosome 15 contains two nearby regions that are differentially imprinted. Among unaffected individuals, genes within the PWS region are expressed on chromosomes that derive from the father. Immediately downstream is a second set of genes within the Angelman-critical region. These genes are imprinted and not expressed on the paternal chromosome. The opposite expression pattern is found on the maternal chromosome. Genes within the Angelman region are expressed, whereas genes within the PWS region are imprinted ([Cassidy, 1997](#)) ([Fig. 2.6](#)).

**Figure 2.6.** Imprinting in Prader-Willi and Angelman syndromes. Imprinting refers to the silencing of certain genes. It is a stable and reversible event that depends on the parental origin of the chromosome on which the gene lies and results in repression of a gene. For some genes, the paternal gene is silenced, whereas for other genes, it is the maternal gene. On chromosome 15, two adjacent regions are imprinted. In the normal situation (shown in the left, top panel), genes in the Prader-Willi syndrome (PWS) region are expressed on the paternal chromosome, whereas genes in the Angelman region are imprinted. The opposite situation exists on the maternal chromosome: Genes in the PWS region are repressed, whereas genes in the Angelman region are expressed. Three mechanisms for developing PWS are shown, whereas four mechanisms have been discovered for Angelman syndrome (AS). The key at the bottom indicates genes, imprinting patterns, and mutations in both disorders. The relative proportion of each type of genetic abnormality in each syndrome is also shown. UPD, uniparental disomy. (Adapted with permission from Everman D, Cassidy S: Genomic imprinting: Breaking the rules. *J Am Acad Child Adol Psychiatry* 39:386–389, 2000.) (See [color plate](#).)

Deletions are responsible for approximately 70% of cases of both PWS and Angelman syndrome. A second mechanism exists and provides further insight into disorders caused by disruptions of the normal imprinting mechanism. Both illnesses also may be caused when children receive two copies of this region of chromosome 15 from one of their parents. This unusual mechanism is called uniparental disomy (UPD). It occurs after an initial trisomy event in which two chromosomes from one parent are inappropriately passed along with one copy of the chromosome from the other parent, resulting in a total of three (rather than two) chromosomes. One chromosome is lost during gamete formation. If the initial trisomy involves two maternal and one paternal chromosome, then loss of the extra paternal copy would result in two maternal chromosomes, or maternal UPD. If the initial trisomy involves two paternal and one maternal chromosome, then loss of the extra maternal copy would result in paternal UPD.

Maternal UPD is a second mechanism by which PWS occurs ([Nicholls et al., 1989](#)). In this situation, the genes that lie within the PWS region are present but on two maternal chromosomes. In this case, all the genes within the critical region are imprinted and no functional proteins are produced. Paternal UPD represents the

opposite situation. PWS genes are present on both chromosomes and both are expressed. However, the genes that lie immediately adjacent and within the Angelman region are imprinted; therefore, even though there are two copies, both are repressed and no protein is expressed.

A third mechanism that leads to these disorders involves a region of DNA called the imprinting center. This center controls imprinting by regulating the extent of methylation and chromatin compaction for hundreds of kilobases of DNA on either side. It appears that one center determines the state of imprinting within both the PWS- and Angelman-critical regions. Mutations within the imprinting center have been discovered that lead to inappropriate imprinting or a lack of imprinting where it should normally occur. These types of mutations cause PWS or Angelman syndrome in about 2% to 3% of affected individuals ( [Ohta et al., 1999](#)).

Finally, a fourth mechanism exists that causes Angelman syndrome in approximately 25% of the cases. This is a mutation within a single gene lying within the Angelman-critical region called *UBE3A* ([Kishino et al., 1997](#); [Matsuura et al., 1997](#)). The protein encoded by this gene normally regulates the life span of other proteins within the cell by regulating their degradation or proteolysis ( [Fig. 2.7](#)).

**Figure 2.7.** Angelman syndrome. It is critical to remove unwanted proteins from within cells before they disrupt cellular metabolism. Several steps are involved in this process and lead to the addition of one or more ubiquitin molecules to proteins targeted for degradation. The addition of ubiquitin to the protein serves as a signal to the proteasome, an organelle that breaks down proteins and serves as the cellular equivalent of a garbage disposal for a cell's unwanted proteins. (Adapted with permission from Lombroso PJ: Genetics of childhood disorders: XVI Angelman syndrome. *J Am Acad Child Adol Psychiatry* 2000.)

Certain proteins must be quickly degraded and removed from the intracellular environment to ensure proper cell function. These include signaling proteins (such as neurotransmitters) in which rapid turnover permits repeated signaling. It is also critical to remove certain enzymes that have become damaged before they interfere with normal intracellular signaling pathways. A small molecule is added to many proteins destined for degradation. This molecule, ubiquitin, acts as a flag to target the protein for degradation by other chemicals. The *UBE3A* gene is required in this process. It is one of several proteins that are needed in sequential order to attach ubiquitin molecules to the target proteins. Intracellular organelles called proteasomes recognize ubiquitinated proteins, bind to them, and activate proteases that cut the protein into its constitutive amino acids. When this protein is mutated and unable to function properly, it is thought that an inappropriate accumulation of proteins occurs within CNS neurons.

Several enzymes in addition to *UBE3A* are required in the series of enzymatic reactions that ends with the addition of ubiquitin molecules to proteins targeted for destruction. It is possible that mutations in these other genes will be found and lead to similar clinical problems. These mutations would represent other examples of locus heterogeneity in which mutations in distinctly different genes produce the same phenotype. A number of laboratories are actively investigating this possibility. On the other hand, no single gene mutation has yet been found in patients with PWS, and it remains likely that deletions of several genes within the critical PWS region are necessary for the disorder.

One final note should be made regarding Angelman syndrome. One of the genes within the Angelman region encodes for a subunit of the GABA<sub>A</sub> receptor ([DeLorey et al., 1998](#)). The absence of this gene and a related disturbance in GABA transmission is believed to be responsible for the seizure disorders present in individuals with the full deletion syndrome. As expected, individuals with a point mutation within only the *UBE3A* gene do not have epilepsy.

## WILLIAMS SYNDROME

Deletions that span a number of genes and cause a constellation of symptoms are called *contiguous gene syndromes*. Williams syndrome is one such disorder caused by a deletion on chromosome 7. This developmental disorder is characterized by distinct facial features, a variable degree of mental retardation, cardiovascular disease, and a very distinctive cognitive profile ( [Pober and Dykens, 1996](#)). The cognitive problems consist of visual-spatial deficits, which are difficulties in visualizing a complete picture. Affected children are unable to integrate the parts of a picture into a whole pattern ( [Ewart et al., 1993](#)). Interestingly, these children frequently exhibit strengths in other cognitive areas, including verbal skills. Indeed, some elements of their speech are normal, such as the quality of their vocabulary, auditory memory, and social use of language. Moreover, many patients sing or play musical instruments with considerable talent. The disorder, first described by Williams in 1961, has a rather low prevalence of 1 per 20,000 live births, but remains a topic of considerable interest because of the striking disparity in cognitive strengths and weaknesses ( [Bellugi et al., 1990](#); [Wang et al., 1995](#)).

This disparity raises the possibility that the gene(s) responsible for Williams syndrome influences the development of specific cortical regions and related cognitive abilities. This is in contrast to other forms of mental retardation, such as fragile X syndrome, where a more uniform depression is seen across many cognitive skills. As such, Williams syndrome has the potential to help identify factors that are important for acquisition of cognitive abilities during normal development.

Imaging and neuropathologic studies have helped clarify some of the underlying neuropathologic mechanisms in Williams syndrome. [Jernigan and Bellugi \(1990\)](#) conducted MRIs on IQ- and age-matched subjects with Williams and Down syndromes. The cerebral cortices of both groups showed an overall decrease in volume. Cerebellar size, on the other hand, differentiated the two conditions. It was normal among the Williams syndrome subjects but significantly hypoplastic among the Down subjects.

Jernigan and coworkers extended this study by focusing in greater detail on the morphologic abnormalities in the cortices of Williams subjects ( [Jernigan et al., 1993](#)). The overall volume of the cerebral cortex was once reduced compared to normal subjects, but there was a relative sparing of the frontal areas and limbic structures, as well as a greater degree of hypoplasia in more posterior cortical structures. Different cortical regions are apparently affected to different degrees in Williams subjects.

Additional morphologic data comes from the autopsy of a Williams subject. Galaburda and colleagues found abnormal organization among the neurons in posterior cortical regions (area 17), an increase in cell packing density throughout cortical regions, and abnormal neuronal clustering ( [Galaburda et al., 1994](#)). It is a single autopsy case, however; additional work is necessary to clarify the underlying pathologic process.

Taken together, these findings suggest that abnormal, nonuniform development of the cerebral cortex may be responsible for the nonuniform cognitive findings that characterize these patients. The relatively intact cognitive skills related to affective recognition, face processing, and linguistic skills may be a consequence of the relatively normal development of limbic and frontal cortices and perhaps the relatively normal cerebellar structures. Poor functioning in visuospatial skills may be owing, at least in part, to the abnormalities in the posterior cortical structures, such as the parietal and occipital cortices known to be involved in visual processing. It is reasonable to suggest that the gene or genes affected in Williams syndrome may have their greatest impact on the development or normal functioning of more posterior regions of the cerebral cortex.

Nearly all patients with Williams syndrome have a large deletion of a segment of chromosome 7 ( [Lowery et al., 1995](#); [Nickerson et al., 1995](#)). A number of researchers note that the cardiovascular symptoms seen in many patients co-segregate with a gene in the deleted region called elastin. Elastin is a major component of skin, blood vessels, and lung tissues. The haplodeficiency caused by the deletion of elastin is likely to cause the vascular abnormalities and characteristic facies in these patients ( [Lowery et al., 1995](#)). Elastin, however, is not detectable in fetal or adult nervous tissue and probably does not contribute to the cognitive abnormalities

(Frangiskakis et al., 1996).

Tassabehji and colleagues (1996) were the first to report the deletion of a second gene in 20 out of 20 Williams syndrome patients. The sequence of this gene is nearly identical to a previously characterized gene called *LIM kinase 1*. Because it is expressed in high concentrations in the brain (Mizuno et al., 1994; Proschel et al., 1995), mutations in this gene are being searched for and are possible candidates responsible for the cognitive deficits seen in Williams syndrome patients.

For a brief period, it was thought that elastin and LIM kinase 1 were the only genes within the deleted region. It is now known, however, that at least 16 genes are present within the Williams syndrome critical region (Fig. 2.8). In addition to elastin (Ewart et al., 1993; Nickerson et al., 1995) and the LIM kinase 1 (Frangiskakis et al., 1996; Tassabehji et al., 1996), other genes include syntaxin 1A (Osborne et al., 1997), CLIP-115 (Osborne et al., 1996), and Frizzled 9, a receptor for Wnt signaling (Wang et al., 1997), the replication factor C subunit (Peoples et al., 1996), and the general transcription factor 2I (Perez Jurado et al., 1998). Several laboratories are currently investigating the function of numerous other genes.

**Figure 2.8.** Williams syndrome. The deletion at 7q11.23 in patients with Williams syndrome contains at least 16 genes. Several of these genes are expressed within the central nervous system. These are candidate genes for contributing to the neuropsychiatric symptoms observed in Williams subjects. When several genes contribute to the expression of a disorder through their deletion, the illness is termed a contiguous gene syndrome.

## COMMON CHILD PSYCHIATRIC DISORDERS

Child psychiatry has yet to establish the molecular basis of many of the most common child and adolescent mental disorders. The reasons for this failure lie beyond the scope of this chapter, but genetic complexity is one culprit. Many of the disorders described in the preceding exhibit mendelian patterns of inheritance, such as the X-linked transmission of Rett and fragile X syndrome; however, pedigree studies of most common child and adolescent mental disorders fail to show such a pattern of vertical transmission across generations. The presence of non-mendelian patterns of transmission does not necessarily imply that genetic factors are unimportant, only that their role in the transmission and expression of disease phenotypes is complex. Examples include polygenetic transmission in which a multiplicity of genetic and environmental factors is causative. Height and intelligence are good examples of polygenetic traits and it may be that some forms of childhood-onset anxiety disorders and attention deficit hyperactive disorder will fall into this category similarly. Interestingly, the alleles that contribute to the vulnerability to develop these disorders may be common in the population and be seen as normal variants when they act in concert with other vulnerability alleles or adverse environments that they produce the syndrome in question.

Understanding the genetics of complex disorders is relevant to other fields of medicine and significant progress has been made in areas such as breast cancer and hypertension (Lifton, 1996; Miki et al., 1994) and our field is poised to take advantage of their success. If child psychiatric disorders follow in a similar course, we can expect that in rare instances single gene mutations will be responsible for common disease phenotype. Such observations will then set the stage for animal studies that will serve a valuable heuristic role in elucidating additional genes and relevant neurobiological pathways.

One example is resistance to thyroid hormone (RTH) and attention deficit hyperactivity disorder (ADHD). RTH is a heritable condition defined by normal or elevated levels of thyroid-stimulating hormone (TSH) in the presence of high levels of serum triiodothyronine and thyroxine, and resistance of tissues to the actions of thyroid hormone (Refetoff et al., 1993). RTH is caused by mutations in exons 9 and 10 of the *thyroid hormone B receptor gene (TRB)*, which codes proteins in the T3-binding domain of the thyroid hormone receptor (Parilla et al., 1991). ADHD is a common symptom of RTH (Hauser et al., 1993). Further, transgenic studies of mice bearing the human mutant *TRB* gene show that they have similar phenotypic features as children with ADHD, including motoric hyperactivity and impaired learning (McDonald et al., 1998). More extensive studies of the role of the thyroid hormone receptor in mediating attentional mechanisms over the course of development are needed and may lead to more profound insights into the molecular basis of ADHD.

## CONCLUSION

Advances in genomics, molecular genetics, and developmental neuroscience provide an impressive array of accomplishments that are laying the foundation for a deeper understanding of the biological basis of some childhood onset neuropsychiatric disorders. Success in these areas will likely herald success in other rare diseases, such as autism and other pervasive developmental disorders. Therapeutic advances also can be anticipated as therapeutic agents are developed that specifically target the molecular and cellular consequences of specific genetic mutations. Perhaps even the promise of gene therapy can be realized for some of the single gene conditions. Nevertheless, the road ahead, particularly for common disorders, will not be an easy one given the complexities involved and the crucial role of the environment in shaping and reshaping the CNS within the constraints of our genetic endowment.

The human cerebral cortex comprises about two-thirds of the neuronal mass of the brain and contains almost three-quarters of all our synapses. It is also the structure that most distinctively sets us apart from other species. Therefore, the principles governing the development of the cerebral cortex may provide the key to explaining our cognitive capacity, as well as the evolution of human intelligence and creativity. Modern developmental neurobiology provides insight into how this complex structure may have evolved, how it develops, and how this finely tuned process may go astray in various neuropsychiatric disorders.

One of the most prominent features of the cerebral cortex in all species, particularly primates, is its parcellation into distinct laminar, radial, and areal domains ([Eccles, 1984](#); [Goldman-Rakic, 1987a](#); [Mountcastle, 1997](#); [Rakic and Singer, 1988](#); [Szentagothai, 1978](#)). However, although the surface of the neocortex has expanded enormously during phylogeny, its thickness and basic cellular organization have undergone relatively minor change ([Rakic, 1995b](#)). Comparison of the cytoarchitectonic cortical maps in the three mammalian species in [Fig. 3.1](#) illustrates some differences among species that have profound functional significance. First, the surface of the neocortex has expanded enormously during our common ancestral evolution (e.g., the human neocortex surface is 10 times larger than that of a macaque monkey and 1,000 times larger than that of a rat). Second, during evolution, cytoarchitectonic areas do not expand uniformly (e.g., the primary visual cortex occupies one-fifth of the neocortical surface in monkeys and only one-thirtieth that of humans). Third, new functional and anatomic areas are introduced during evolution (e.g., Broca's language areas in humans). Fourth, there are large variations in the size of cortical areas among individuals of the same species and between both hemispheres in the same individual (e.g., the planum temporale is larger on the left side in most right-handed humans). However, despite these enormous differences in size of cortical surfaces and pattern of cytoarchitectonic maps, the thickness of the cortex relatively has not changed in phylogeny.

**Figure 3.1.** Lateral (*upper figures*) and medial (*lower figures*) views of the cerebral hemisphere in human (*right*), macaque monkey (*left top*), and rat (*left bottom*), with schematic designation of individual cytoarchitectonic areas. (Reproduced to approximate scale from Brodmann K: *Vergleichende Localisationslehre der Grosshirn-hinde*. Leipzig, Barth, [1909](#).)

Understanding the development of the cerebral cortex and its expansion in size and complexity critically depends on the answer to some fundamental questions: When and where are cortical neurons generated? How is their number determined in each species and individual? When and how are cell phenotypes determined that constitute the cortex? How do postmitotic cells attain their proper laminar and areal position within the cortex? Why does the surface of the cortex expand so enormously during evolution, whereas its thickness remains relatively constant? How are interspecies and intraspecies differences in cortical parcellation generated? To what extent is the size of cytoarchitectonic areas determined innately and can this size be changed by external stimulation? What are the mechanisms for the formation of complex connections between areas and with various subcortical structures? What is the role of various environmental factors, including functional activity and experience, in this process? How is the number and proportion of various classes of synapses in the cerebral cortex established? When does the critical period for structural and functional modifiability of cortical connections and cytoarchitectonic cortical maps end? Are there additions and/or turnover of neurons in the adult neocortex? Elucidation of these issues is an essential prerequisite for understanding the etiology of genetic and acquired developmental disorders of the cerebral cortex.

This chapter is based mainly on experimental studies of neocortical development in the macaque monkey. The large size of the cerebrum and presence of visible landmarks on the convoluted surface in this primate species allow precise delineation of cortical areas, whereas its protracted development enables accurate timing of cellular events. Furthermore, the macaques, similar to the human, belong to a group of Old World primates who share many aspects of cortical organization and developmental mechanisms. Therefore, the data on the basic cellular and molecular events in these two primate species are reviewed whenever available.

### TIME OF NEURON ORIGIN

The cerebral cortex in the newborn child has well-delineated cortical layers. Based on studies using classical methods, it has been suspected that most cortical neurons in the human cerebrum were generated before birth ([Poliakov, 1949](#), 1959, [1965](#)). The <sup>3</sup>H-thymidine autoradiography, which denotes the time of final deoxyribonucleic acid (DNA) replication, that is, the "birthday of a neuron" ([Angevine, 1965](#); [Sidman and Rakic, 1973](#)), provides an opportunity to obtain precise data on the onset and termination of specific neuronal subclasses during corticogenesis in primates. The examination of a series of adult macaque monkeys exposed to <sup>3</sup>H-thymidine during prenatal and postnatal ages revealed that genesis of cortical neurons occurs during the middle of the 165th day gestation in this species ([Rakic, 1974](#), [1988a](#)). Neurogenesis of cortical neurons starts around the 40th embryonic day (E40) and lasts between 1 and 2 months, depending on the cytoarchitectonic area. For example, in the anterior cingulate cortex (Brodmann's area 24), neurogenesis stops at E70, whereas in the primary visual cortex (area 17), it stops at E100 ([Fig. 3.2](#)). Analysis of DNA labeling with <sup>3</sup>H-thymidine in brain sections of animals exposed to <sup>3</sup>H-thymidine after birth revealed no radiolabeled cells with clear neuronal morphology, suggesting that neocortical neurons in macaque monkeys are not produced during the 30-year life span of this species ([Rakic, 1985](#)).

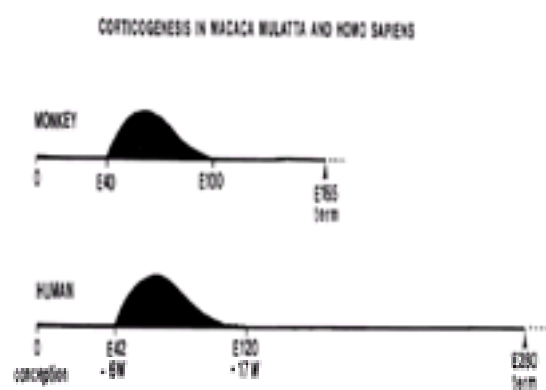

**Figure 3.2.** Diagrammatic representation of the positions of heavily labeled neurons in the cortex of juvenile monkeys, each of which had been injected with  $^3\text{H}$ -thymidine at selected embryonic days. *Top*: area 17; *bottom*: area 24 of Brodmann. On the left side of each diagram is a drawing of the cortex from cresyl violet-stained sections, in which subdivisions into cortical layers are indicated by roman numerals. Embryonic days ( $E$ ) are represented on the horizontal line, starting on the left with the end of the first fetal month ( $E27$ ) and ending on the right at term ( $E165$ ). Positions of vertical lines (*left to right*) indicate the embryonic day on which one animal received a pulse of  $^3\text{H}$ -thymidine. On each vertical line, short horizontal markers indicate positions of all heavily labeled neurons encountered in one 2.5-mm long strip of cortex. WM, white matter. (From Rakic P: Neurons in the monkey visual cortex: Systematic relation between time of origin and eventual disposition. *Science* 183:425–427, 1974 (*top*); Rakic P: Prenatal genesis of connections subserving ocular dominance in the rhesus monkey. *Nature* 261:467–471, 1976a (*bottom*).

The claim that the primate neocortex continues daily to acquire a large number of new neurons throughout the entire adult life (Gould et al., 1999) has been met with skepticism (Nowakowski and Hayes, 2000; Rakic, 2001). These data were obtained by more sensitive, but less reliable methods for detection. The Gould and associates data contradicts previous studies conducted in species ranging from rodents to carnivores and primates, all indicating that cortical neurons originate during the prenatal and/or early perinatal period (Angevine and Sidman, 1961; Luskin and Shatz, 1985b; Rakic, 1974). These data were obtained by more sensitive, but less reliable methods for detection. Furthermore, the suggestion that “new cortical neurons” are transient and die within a few weeks after their genesis was not supported by the finding of pyknotic cells that is commensurate with the massive apoptosis suggested to occur. Thus, until credible evidence is provided, neurons of the primate neocortex all appear to be generated prenatally.

Autoradiographic data cannot be obtained for the human fetal brain, but comparative cytological analysis indicates that production of cortical neurons starts around E45 (6.5 gestational weeks), proceeds in two large waves until about E125 or 17 GA weeks (Fig. 3.3) and then continues on a much smaller scale for another 2 months (Judas et al., 1999; Rakic, 1978, 1988a; Sidman and Rakic, 1973). At the time of birth, the proliferative ventricular and subventricular zones that generate the cortical neurons are exhausted, and the subependymal layer begins to produce a massive number of nonneuronal cells such as the astrocytes and oligodendrocytes that populate the large white matter of the human cerebrum (Yakovlev and Lecours, 1967). In the human, these nonneuronal cells outnumber neurons by severalfold and are responsible, in part, for the postnatal growth of the cerebrum. The claim of a large addition and fluctuation in the number of cortical neurons during infancy, based on the old Conel (1939) photographs and data, has been considered unfounded (Korr and Schmitz, 1999). Thus, like most mammalian species that have been examined so far by using stringent criteria and appropriate methods (see the preceding), the neocortex in primates, including humans, also acquires its cortical neurons before birth, mostly during the middle third of gestation (Fig. 3.3).

**Figure 3.3.** Diagrammatic representation of the time of neuron origin in rhesus monkey (*top*) and humans (*bottom*). The data for monkeys are obtained by  $^3\text{H}$ -thymidine autoradiography, whereas the data for humans are based on the number of mitotic figures in the ventricular zone, supravital DNA synthesis, and the presence and density of migrating neurons in the intermediate zone of the fetal cerebrum. (From Rakic P: Neurons in the monkey visual cortex: Systematic relation between time of origin and eventual disposition. *Science* 183:425–427, 1974; Rakic P: Neuronal migration and contact interaction in primate telencephalon. *Postgrad Med J* 54:25–40, 1978; Rakic P, Sidman RL: Supravital DNA synthesis in the developing human and mouse brain. *J Neuropathol Exp Neurol* 27:246–276, 1968; Sidman RL, Rakic P: Development of the human central nervous system. In: Haymaker W, Adams RD (eds): *Histology and Histopathology of the Nervous System*. Springfield, IL, Charles C Thomas, 1982, pp. 3–145.)

Considering the existence of adult neurogenesis in many central nervous system (CNS) structures of lower vertebrates, the extent and capacity for adult neurogenesis has evidently diminished in mammalian evolution (Rakic, 1985). In the adult primate, brain neurogenesis has conclusively been shown only for the small interneurons of the olfactory bulb and dentate gyrus, where it is less prominent than in rodents (Kornack and Rakic, 1999; Rakic 2001). Cerebellar granule cells also continue to be generated during the first few postnatal years (Rakic and Sidman, 1977; Zecevic and Rakic, 1976). It has been proposed that this stable population of cortical neurons during adulthood may be a biological necessity, so that individual cognitive experience can be preserved in the synaptic assemblies through decades of the primate life span (Rakic, 1985; Rakic and Kornack, 1993). The resistance of mature neurons to cell division seems to be so powerful that no malignancy of the neurons has been recorded on the adult human cerebrum, although neuroblastoma in children and gliomas are frequent in the adult cortex (Russell and Rubenstein, 1963).

## SITE OF NEURON ORIGIN

It has been suspected, based on the high density of mitotic figures observed near the ventricular surface in the human fetal cerebrum, that most cortical neurons might be produced there, rather than in the cortex itself (His, 1904). However, again, the direct evidence for this hypothesis comes from  $^3\text{H}$ -thymidine autoradiographic analysis. Examination of a series of macaque monkey embryos killed shortly after injection of the DNA precursor revealed that all neurons destined for the neocortex are produced in the layer of germinal cells situated near the cerebral ventricle (Rakic, 1975). This layer, initially consisting of asynchronously dividing precursor cells, was named the ventricular zone (Fig. 3.4) (Boulder Committee, 1970). The nuclei of the precursor cells move away from the ventricular surface to synthesize DNA and then return back to the surface to undergo mitotic division (Sidman and Rakic, 1973). Golgi, electron microscopic, and immunocytochemical analyses reveal that neuronal and glial cell lines coexist in the ventricular zone from the onset of corticogenesis (Levitt et al., 1981; Rakic, 1971, 1972). The early divergence of these two basic cell types has been confirmed using retroviral gene transfer, which labels separate lineages of the precursor cells in the developing telencephalon (Cameron and Rakic, 1991; Luskin et al., 1988; Nakatsuji, et al., 1991; Tan et al., 1998). Furthermore, as illustrated in Fig. 3.5, the ventricular zone in primates is divided by glial septa into columns of precursor or stem cells, termed “proliferative units” that generate generations of neurons destined to form corresponding radial units (Fig. 3.5B) (Rakic, 1978, 1988a). The use of the retroviral gene transfer method in the monkey fetus has confirmed this radial organization that is particularly prominent in primates (Kornack and Rakic, 1995; Rakic, 1995a). Initially, the number of stem cells in a proliferative unit is only three to five, but increases to more than 10 at later developmental stages (Rakic, 1988b).  $^3\text{H}$ -Thymidine autoradiographic analysis indicates that around E40 proliferative units start producing postmitotic neurons, which migrate to their prespecified areal and laminar positions in the cortex (Rakic, 1974). The same method of analysis cannot be applied to human embryonic material, but the use of various cytologic criteria (Sidman and Rakic, 1982) and the application of supravital DNA synthesis to slices of fetal brain tissue (Rakic and Sidman, 1968) indicate that the corresponding time point for the onset of corticogenesis in humans is 6 fetal weeks, or about E42. At later stages of cortical development, there is another proliferative zone, termed the subventricular zone, which mainly produces glial cells in rodents but also becomes a source of interneurons in both primates

and humans ([Rakic, 1975](#); [Sidman and Rakic, 1982](#)).

**Figure 3.4.** Cytologic organization of the primate cerebral wall during the first half of gestation. *A*: The cerebral vesicle of 60- to 65-day-old monkey fetuses is still smooth and lacks the characteristic convolutions that will emerge in the second half of gestation. *B*: Coronal section across the occipital lobe at the level indicated by a vertical dashed line in (*A*). The lateral cerebral ventricle at this age is still relatively large and only the incipient calcarine fissure (CF) marks the position of the prospective visual cortex. *C*: A block of the tissue dissected from the upper bank of the calcarine fissure. At this early stage, one can recognize six transient embryonic zones from the ventricular surface (*bottom*) to the pial surface (*top*): CP, cortical plate; I, intermediate zone; M, marginal zone; SP, subplate zone; SV, subventricular zone; V, ventricular zone. Note the presence of spindle-shaped migrating neurons moving along the elongated radial glial fibers, which span the full thickness of the cerebral wall. The early afferents originating from the brain stem, thalamus, and other cortical areas invade the cerebral wall and accumulate initially in the subplate zone where they make transient synapses before entering the overlying cortical plate. (From Rakic P: A small step for the cell—a giant leap for mankind: a hypothesis of neocortical expansion during evolution. *Trends Neurosci* 18:383–388, [1995b](#).)

**Figure 3.5.** The radial organization of both ventricular zone and fetal cortical plate is best visible in cresyl violet-stained sections. *A*: Photomicrograph of an array of proliferative units within the ventricular zone of the occipital lobe in a 91-day-old monkey embryo. Most mitotic figures are located directly at the ventricular surface (*arrow*), although at this age some can be found in the subventricular zone (*crossed arrow*). *B*: Cortical plate in the occipital lobe of the same animal, showing ontogenetic columns composed of neurons that have originated from the set of proliferative units illustrated in (*A*). Epon-embedded tissue, cut at 1  $\mu$ m, stained with cresyl violet. (From Rakic P: Specification of cerebral cortical areas. *Science* 241:170–176, [1988a](#).)

## DEVELOPMENT OF THE TRANSIENT EMBRYONIC ZONES

During embryonic and fetal development, the telencephalic wall consists of several cellular layers or zones that do not exist in the mature brain: ventricular zone, subventricular zone, intermediate zone, subplate zone, cortical plate, and marginal zone ([Fig. 3.4](#)). The role of ventricular and subventricular zones was described in previous sections, whereas the present section focuses on the marginal and subplate zones.

The marginal zone, appearing early beneath the pial surface of the cerebral vesicle, is transformed into layer I after arrival of large Cajal-Retzius neurons ([Cajal, 1911](#); [Retzius, 1893](#)). The cellular composition of layer I in primates is distinct in several respects, including presence of the transient subpial granular layer that is absent or minimal in other mammals ([Brünn, 1965](#)). In the macaque monkey, neurons of layer I are generated during the period of corticogenesis ([Zecevic and Rakic, 2001](#)). The classic Cajal-Retzius (C-R) cells are generated first and their processes form a broad, rectangular network oriented parallel to the pia. Genesis of smaller, GABAergic neurons of the primate layer I begins slightly later and continues until completion of corticogenesis ([Zecevic and Rakic, 2001](#)). These late generated cells are imported from outside sources, such as the olfactory primordium, subventricular zone, and ganglionic eminence, via a massive subpial granular layer ([Lavdas et al., 1999](#); [Meyer et al., 1999](#); [Wichertle and Alvarez-Buylla, 2001](#); [Zecevic and Rakic, 2001](#)).

The hypothesis that C-R cells control layering in the cortical plate has gained support through the finding that they produce reelin, a glycoprotein missing in reeler mice, which show defective lamination ([D'Arcangelo et al., 1995](#); [Ogawa et al., 1995](#); [Rakic and Caviness, 1995](#)). A suggestion that C-R cells hold positional information essential for development of initial cortical connections was based on a variety of approaches ([Hevner et al., 2001](#); [Marin-Padilla and Marin-Padilla, 1982](#); [Soria and Fairén, 2000](#)) and is in harmony with the existence of an early primordial protomap in the developing cerebral wall (see the following). The remarkable perpendicular orientation of C-R cell processes has been observed in other species, and the geometrically precise pattern is more pronounced in primates ([Zecevic and Rakic, 2001](#)), which may be related to sharper laminar and columnar organization in this species ([Mountcastle, 1997](#); [Rakic, 1995a](#)).

Although many C-R cells disappear after birth, some survive or change their morphology ([Edmunds and Parnavelas, 1982](#); [Marin-Padilla, 1978](#); [Meyer et al., 1999](#); [Parnavelas and Edmunds, 1982](#); [Poliakov, 1965, 1969](#)), suggesting a more protracted additional role. Identification of subpopulations of layer I cells may help in elucidating their role in congenital malformations of the human cerebral cortex such as lissencephaly ([Hong et al., 2000](#)).

The main embryonic zones were described in classical literature ([His, 1904](#)), but the subplate zone has been recognized as a separate entity much later ([Kostovic and Rakic, 1990](#)). This zone consists of early-generated subplate neurons scattered among numerous axons, dendrites, glial fibers, and migrating neurons ([Fig. 3.4](#)). Most of the subplate neurons eventually degenerate, but some persist in the adult cerebrum as a set of interstitial cells ([Kostovic and Rakic, 1980](#); [Luskin and Shatz, 1985a](#)). Migrating neurons traversing this zone remain attached to radial glia cell guides before entering the cortical plate to form radially oriented columns ([Fig. 3.5](#) and [Fig. 3.6](#)). Although the existence of the subplate zone may provide an opportunity for interaction between migrating neurons, incoming afferent fibers, and early-generated neurons, the significance of these transient contacts is not fully understood.

**Figure 3.6.** Model of a proposed cascade of molecular events that take place during the migration of postmitotic cells in the developing cerebral wall. After their last mitotic division in the ventricular zone, migrating cells extend a leading process (LP) that follows the contours of the radial glial fiber (RG) as it spans the expanding cerebral wall. The cytoskeleton within the LP and trailing process (TP) contain microtubules (MT) and actin-like contractile proteins (AC) that are involved in translocation of the cell nucleus (N) and the surrounding cytoplasm within the leading process until the cell enters the cortical plate. This system, maintained *in vitro* in slice preparations or imprint culture provides an opportunity to examine the role of the various molecules that are engaged in recognition, adhesion, transmembrane signaling, and motility that underlies directed neuronal migration. The voltage-gated (N-type) and ligand-gated (NMDA-type) receptors/channels are thought to control calcium influx, which serves as messengers for execution of this movement. Abbreviations: AM, homotypic adhesion molecule; EAA, excitatory amino acid; EF, end foot of the radial glial fiber; Gly, glycine; RM(g), glycophilic recognition molecule; TP, tyrosine phosphorylation. (Modified from Rakic, 1997)

One possibility, suggested soon after discovery of the subplate zone, was that it serves as a “waiting” compartment for afferents that are generated ahead of their neuronal targets and for cellular substrata competed for among cortical afferents (Rakic, 1977). Subsequent autoradiographic, electron microscopic, and histochemical studies in primates indicate that axons observed in the subplate zone originate sequentially from the brain stem, basal forebrain, thalamus, and the ipsilateral and contralateral cerebral hemispheres (Kostovic and Rakic, 1990). After a variable and partially overlapping period, these diverse fiber systems enter the cortical plate, whereas the subplate zone disappears, leaving only a vestige of cells scattered throughout the subcortical white matter that are known as interstitial neurons (Chun and Shatz, 1989; Kostovic and Rakic, 1980).

In various species, examination of the developing cerebrum reveals that the size and relative duration of the subplate zone increases during mammalian evolution and culminates in human fetuses concomitantly with enlargement of the cortico-cortical fiber systems (Kostovic and Rakic, 1990). The regional difference in size, pattern, and resolution of the subplate zone also correlates with the pattern and size of cerebral convolutions (Goldman-Rakic and Rakic, 1984; Rakic, 1988b). Studies in developing macaque monkeys indicate that the prevailing view of the subplate zone as a vestige of the phylogenetically old neural network should be modified (Marin-Padilla, 1978; Shatz et al., 1988). This transient embryonic zone actually expanded during evolution of the cerebral cortex, most likely as result of the increasing number of cortico-cortical connections and the elaboration of cerebral convolutions (Kostovic and Rakic, 1990). An abnormally large vestige of subplate neurons may form heterotopic masses in the form of a double cortex, and these are believed to be the source of intractable epileptic discharges in children (Palamini et al., 1991b). It was also suggested that migratory defects, which leave an abnormal cell population within the subplate zone, might be a source of abnormalities in some form of schizophrenia (Akbarian et al., 1993).

The concept that layer I and subplate neurons are remnants of the initially common “preplate” zone, bisected by the developing neocortex (Aboitiz, 1999; Marin-Padilla, 1978), needs modification in light of the findings in both human and monkey, where the majority of layer I neurons are generated long after the split of the preplate (Kostovic and Rakic, 1980).

## CONTROL OF CORTICAL SIZE

Based on data on the time of cell origin and cell proliferation kinetics in the ventricular zone, we proposed that the number of cortical cells in a given species depends on the timing of cell production, mode of mitotic division (symmetric versus asymmetric), duration of the cell cycle, and the degree of programmed cell death in the proliferative zones (Rakic, 1988a, 1995b). In the past few years, technological advances have allowed analysis of these cellular events in transgenic mice as well as in nonhuman primates using the retroviral gene transfer method (Kornack and Rakic, 1995, 1998; Kuida et al., 1996, 1998; Zhong et al., 1996). Because most genes and their products involved in cell production and fate determination seem to be preserved during evolution, one might expect that control of neuronal number and differentiation would be basically similar in all species (Williams and Herrup, 1988). For example, one mechanism that regulates the number of cells produced in the ventricular zone is programmed cell death (PCD) or apoptosis. Although PCD has been considered a major factor contributing to the formation of the vertebrate brain (Glucksmann, 1951), contemporary research has focused mainly on histogenetic cell death involved in the elimination of inappropriate axonal connections at later stages of development (Oppenheim, 1991; Rakic and Riley, 1983a,b). However, the discovery of several classes of genes involved in PCD, which were initially identified in invertebrates, created the opportunity to study this phenomenon in the mammalian cerebrum. For example, a family of enzymes, called caspases, has been shown to play an important role in PCD in a variety of organs and tissues (Ellis and Horvitz, 1991). We have recently demonstrated that in mouse embryos deficient in caspase 9 and 3, fewer cells are eliminated than in their littermates (Kuida et al., 1996, 1998). Reduction of apoptosis in the knockout mice results in the formation of supernumerary founder cells in the cerebral ventricular zone. As a consequence, these mice form ectopic cells in the intermediate zone, as well as a larger cortical plate with more radial units. Remarkably, the cerebral cortex in these transgenic mice has a larger surface and begins to form convolutions. These new approaches provide an example of how mutation of a few genes that control the reduction of cells could result in the expansion of the cortex during evolution (Rakic, 1995b).

## NEURONAL CELL MIGRATION

Because all cortical neurons originate near the ventricular surface of the cerebral vesicle, they must all move to their final positions in the cortex, which develops in the outer regions of the cerebral wall, just below the pia. Initially, although the cerebral wall is still thin, cells move only a short distance. However, the length of their pathway increases with the enlargement of the cerebral hemispheres, particularly in the large primate cerebrum in which, during midgestation, a massive migration of neurons occurs concomitantly with the rapid growth of the cerebral wall (Rakic, 1988a; Sidman and Rakic, 1982). This magnitude of cell movement is perhaps the reason that neuronal cell migration was first observed in human embryos (His, 1874). In the early 1970s, advances in methods enabled the discovery that postmitotic neurons find their way to the cortex by following the elongated shafts of radial glial cells (Fig. 3.4, Fig. 3.6, and Fig. 3.7) (Rakic, 1972). These elongated cells, which span the fetal cerebral wall from the beginning of corticogenesis, stop transiently to divide during midgestation at the peak of neuronal migration (Schmechel and Rakic, 1979). The radial glial cells are not only much longer, but also have different structural and biochemical properties than in small rodents (Cameron and Rakic, 1991; Levitt et al., 1981).

**Figure 3.7.** *Left:* Camera lucida drawing of the occipital cerebral wall of the monkey fetus at midgestation. The composite illustration is derived from a Golgi-impregnated section (*black profiles*) and an adjacent section counterstained with toluidine blue (*outline of small nuclei*). The middle 2,000  $\mu\text{m}$  of the intermediate zone, similar in structure to the sectors drawn, is omitted. The rectangle marked with an asterisk shows the approximate position of the cell reconstruction seen in (*B*). *C*, cortical plate; *I*, intermediate zone; *M*, molecular layer; *MN*, migrating neuron; *RF*, radial fiber; *SV*, subventricular zone; *V*, ventricular zone. *Right:* Three-dimensional reconstruction of migrating neurons, based on serial electron micrographs made at the level of the intermediate zone, indicated by the rectangle in (*A*). The lower portion of the diagram contains parallel fibers of the optic radiation (OR), and the remainder is occupied by a more disposed fiber system. Except at the lower portion of the figure, most of these fibers are deleted from the diagram to expose the radial fibers (*striped vertical shafts RF<sup>1-6</sup>*) and their relations to the migrating cells A, B, and C. The soma of migrating cell A, with its nucleus (N) and voluminous leading process (LP), is situated within the reconstructed space, except for the terminal part of the attenuated trailing process and the tip of the vertical ascending pseudopodium. Cross-sections of cell A in relation to the several vertical fibers in the fascicle are drawn at levels a to d at the right side of the figure. The perikaryon of cell B is cut off at the top of the reconstructed space, whereas the leading process of cell C is shown just penetrating between fibers of the optic radiation (OR) on its way across the intermediate zone. LE, lamellate expansions; PS, pseudopodia. (From Rakic P: Mode of cell migration to the superficial layers of fetal monkey neocortex. *J Comp Neurol* 145:61–84, 1972.)

While moving along the glial surface, migrating neurons remain preferentially attached to glial fibers, which suggests a “gliophilic” mode of migration ( [Rakic, 1990](#)) that is mediated by heterotypic adhesion molecules ( [Rakic et al., 1994b](#)). However, some postmitotic cells do not obey glial constraints and move along tangentially oriented axonal fascicles (e.g., black horizontally oriented cell aligned with TR in [Fig. 3.6](#)). We suggested the term “neurophilic” to characterize the mode of migration of this cell class ( [Rakic, 1990](#)). Although lateral dispersion of postmitotic neurons was initially observed in Golgi-stained preparations ( [Boulder Committee, 1970](#)), it has attracted renewed attention after the discovery that a specific, presumably neurophilic, cell class moves from the telencephalon to the olfactory bulb ( [Menezes and Luskin, 1994](#)) and after studies in rodents suggested more widespread dispersion of clonally related cortical cells ( [Rakic, 1995a](#); [Tan et al., 1998](#)). However, it should be underscored that application of the same methods in the convoluted primate cortex revealed that the majority of migrating cells obey the radial constraints imposed by the radial glial scaffolding ( [Kornack and Rakic, 1995](#); see also section on Radial Glial Hypothesis).

Considerable progress has been made in understanding the molecular mechanisms behind neuronal migration and the physical displacement of cell perikarya during translocation of the cell nucleus and soma across the densely packed tissue. Initially, based on an observation *in situ*, it was proposed that a single pair of binding, complementary molecules with glycophilic properties can account for the recognition of glial guides ( [Rakic, 1981a](#)). In the last decade, however, several candidates for recognition and adhesion molecules have been discovered and are being tested ( [Anton et al., 1996](#); [Cameron and Rakic, 1994](#); [Edelman, 1983](#); [Hatten and Mason, 1990](#); [Schachner et al., 1985](#)). Recently, it was also shown that voltage- and ligand-gated ion channels on the leading process and cell soma of migrating neurons regulate the influx of calcium ions into migrating neurons ( [Komuro and Rakic, 1992, 1993, 1996](#); [Rakic and Komuro, 1995](#)). Calcium fluctuations, in turn, may trigger polymerization of cytoskeletal and contractile proteins essential for cell motility and translocation of the nucleus and surrounding cytoplasm ( [Rakic et al., 1996](#)). These studies indicate that neuronal migration is a multifaceted developmental event, involving cell–cell recognition, differential adhesion, transmembrane signaling, and intracytoplasmic structural changes ( [Rakic et al., 1996](#)). A simple model of molecular components involved in cell migration is provided on the diagram in [Fig. 3.8](#). The discovery of the glial-guided radial migration led to the proposal of the *radial unit hypothesis* ( [Rakic, 1988a](#)), which has served as a useful working model for research on the cellular and molecular mechanisms involved in normal and abnormal cortical development.

**Figure 3.8.** The relation between a small patch of the proliferative ventricular zone (VZ) and its corresponding area within the cortical plate (CP) in the developing cerebrum. Although the cerebral surface in primates expands and shifts during prenatal development, ontogenetic columns (outlined by cylinders) remain attached to the corresponding proliferative units by the grid of radial glial fibers. Neurons produced between E40 and E100 by a given proliferative unit migrate in succession along the same radial glial guides (RG) and stack up in reverse order of arrival within the same ontogenetic column. Each migrating neuron first traverses the intermediate zone (IZ) and then the subplate (SP) that contains interstitial cells and “waiting” afferents from the basal forebrain (NB), monoamine subcortical centers (MN), thalamic radiation (TR), and ipsilateral and contralateral cortico-cortical connections (CC). After entering the cortical plate, each neuron bypasses earlier-generated neurons and settles at the interface between the CP and marginal zone (MZ). As a result, proliferative units 1 through 100 produce ontogenetic columns 1 through 100 in the same position relative to one another without a lateral mismatch. Thus, the specification of cytoarchitectonic areas and topographic maps depends on the spatial distribution of their ancestors in the proliferative units, whereas the laminar position and phenotype of neurons within ontogenetic columns depends on the time of their origin. (Modified from Rakic P: Specification of cerebral cortical areas. *Science* 241:170–176, [1988a](#).)

## DETERMINATION OF NEURONAL PHENOTYPES

Immunocytochemical analyses in fetal monkeys provided the initial evidence that proliferative cells in the embryonic ventricular zone simultaneously produce both neurons and glial cell clones ( [Levitt et al., 1981](#)). Furthermore, examination of the fate of <sup>3</sup>H-thymidine-labeled cells suggests that multiple neural phenotypes are simultaneously produced and terminate either in the single or adjacent cortical layers ( [Rakic, 1988a](#)). Therefore, after their last cell division, postmitotic neurons seem to become restricted in the repertoire of their possible fates. Several lines of evidence support this. For example, if neurons remain in ectopic positions near the cerebral ventricle (as a consequence of x-irradiation during embryonic stages), they, nevertheless, acquire the morphology and connections expected from the time of their origin ( [Jensen and Killackey, 1984](#)). Likewise, ventricular cells transplanted from the embryos into the telencephalic wall of a newborn ferret migrate to the host cortex and assume laminar cortical positions, morphologic characteristics, and a pattern of connections appropriate for the stage that they have achieved in the donor ( [McConnell, 1988](#)). Callosal neurons send their axons to the contralateral hemisphere before their soma have entered layer II of the cortical plate ( [Schwartz et al., 1991](#)). This early laminar commitment of cortical neurons is also evident in the mutant *reeler* mouse in which sequentially generated neurons assume position in the cortical layers that is reversed compared to the normal mouse, but, nevertheless, differentiates into phenotypes expected from the time of their origin, rather than from their ectopic location ( [Caviness and Rakic, 1978](#)). Recent analysis, in which ribonucleic acid (RNA) retrovirus-mediated gene transfer was used to mark the progeny of dividing cells, revealed that neurons of a different type originate from separate clones ( [Parnavelas et al., 1991](#)). Collectively, these findings indicate that the range of morphologies and patterns of synaptic contacts of cortical neurons may be specified, in considerable measure, before they reach their final positions.

A survey of the emergence of the various transmitters and their receptors in the embryonic monkey telencephalon showed that, contrary to our expectations, most of them appear very early, prior to the formation of synapses. For example,  $\alpha_1$ -adrenergic receptors are prominent in the ventricular and subventricular zones, up to midgestation, in conjunction with the intensive proliferation of cortical neurons, whereas, in contrast,  $\beta$  receptor subtypes emerge in these zones only after the proliferation subsides and corticogenesis is completed ( [Lidow and Rakic, 1994](#)). This sequence of developmental events suggests that  $\alpha_1$  sites may participate in promotion of cell proliferation, whereas the  $\beta$  sites may participate in suppression of cell proliferation within the germinal zones of the fetal cerebrum. This suggestion is in harmony with the finding that cell division *in vitro* can be stimulated and inhibited by these two adrenergic subtypes, respectively. Since both ventricular and subventricular zones produce a variety of neuronal subtypes ( [McConnell and Kasanowski, 1991](#); [Parnavelas et al., 1991](#); [Rakic, 1988a](#)), it is possible that noradrenaline, or other neurotransmitters, can regulate the proliferation of various types of neurons already in the germinative epithelium. Both  $\gamma$ -aminobutyric acid (GABA), as well as GABA<sub>A</sub> receptor subtypes, are expressed on migrating neurons before they reach their destination in the cortex ( [Schwartz and Meinecke, 1992](#)). *In vitro* studies indicate that these signaling molecules may play a role in differential cell death and, therefore, can influence the areal- and layer-specific density of GABA-containing local circuit neurons ( [Vaccarino et al., 1995](#)). Collectively, these findings demonstrate that the range of morphologies and patterns of connections of cortical neurons may be specified, in considerable degree, by various neuroactive molecules before postmitotic cells reach their final positions in the cerebral cortex.

## RADIAL UNIT HYPOTHESIS

The cellular mechanisms underlying expansion of the cerebral cortex during individual development and evolution can be explained in the context of the *radial unit hypothesis* ( [Rakic, 1988a, 1995b](#)). In all species, the neocortex consists of an array of iterative neuronal groups (called interchangeably, radial columns or modules) that share a common intrinsic and extrinsic connectivity and subserve the same function ( [Goldman-Rakic, 1987a](#); [Mountcastle, 1997](#); [Szentagothai, 1978](#)). The larger the cortex in a given species, the larger the number of participating columnar units ( [Rakic, 1978, 1995b](#)). The radial unit hypothesis of cortical development postulates that the embryonic cortical plate forms from vertically oriented cohorts of neurons generated at the same site in the proliferative ventricular zone of the cerebral vesicle ( [Fig. 3.3](#), [Fig. 3.7](#), and [Fig. 3.8](#)) ( [Rakic, 1978](#)). Each radial unit consists of several clones (polyclones) that migrate to the cortex following glial fascicles spanning the cerebral wall ( [Rakic, 1988a](#)). In the cortical plate, later generated cells bypass earlier generated ones and settle in an inside-out gradient of neurogenesis ( [Rakic, 1974](#)). Thus, the two-dimensional positional information of the proliferative units in the ventricular zone is transformed into a three-dimensional cortical architecture: the X- and Y-axis of the cells is provided by their site of origin, whereas the Z-axis is provided by their time of origin ( [Fig. 3.8](#)). The radial unit hypothesis provides the explanation for the large expansion of cortical surface that occurred without a concomitant significant increase in thickness during phylogenetic and ontogenetic development ( [Rakic, 1988a](#)). It also shows how the genes controlling the number of founder cells at the ventricular surface sets a limit

on the size of the cortical surface during individual development, as well as during the evolution of mammalian species ( [Rakic, 1995b](#)). Thus, a relatively small change in the timing of developmental cellular events could have large functional consequences. For example, a minor increase in the length of the cell cycle or the magnitude of cell death in the ventricular zone could result in a large increase in the number of founder cells that form proliferative units ( [Rakic, 1988a](#)). Because proliferation in the ventricular zone initially proceeds exponentially because of the prevalence of symmetric divisions, an additional round of mitotic cycles during this phase doubles the number of founder cells, and consequently, the number of radial columns ( [Fig. 3.9](#)) ( [Rakic, 1995b](#)). According to this model, before the onset of corticogenesis, fewer than four extra rounds of symmetric cell divisions in the ventricular zone can account for a 10-fold difference in the size of the cortical surface. Because the mode of cell division predominantly changes to asymmetric after the onset of corticogenesis, one can predict that by extending cell production in humans by about 2 weeks longer than in macaques should enlarge the cortical thickness by only 10% to 15%, which actually is observed ( [Rakic, 1995b](#)). Thus, as illustrated in [Fig. 3.9](#), even a small delay in the onset of the second phase of corticogenesis results in a proportionately larger cortical surface owing to the increasing number of founder cells at the ventricular zone.

**Figure 3.9. A:** Schematic model of symmetric cell divisions that predominate before the E40. At this early embryonic age, the cerebral wall consists of only the ventricular zone (VZ), where all the cells are proliferating, and the marginal zone (M), into which some cells extend radial processes. Symmetric division produces two progenitors (P) during each cycle and causes rapid horizontal lateral spread. **B:** Model of asymmetric or stem division which becomes predominant in the monkey embryo after E40. During each asymmetric division, a progenitor (P) produces one postmitotic neuron that leaves the ventricular zone and another progenitor that remains within the proliferative zone and continues to divide. Postmitotic neurons migrate rapidly across the intermediate zone (IZ) and become arranged vertically in the cortical plate (CP) in reverse order of their arrival (1,2,3,4). (Modified from Rakic P: A small step for the cell—a giant leap for mankind: A hypothesis of neocortical expansion during evolution. *Trends Neurosci* 18:383–388, [1995b](#)).

The proposal that neurons comprising a given radial column may be clonally related has been tested experimentally using the retroviral gene transfer method that allows *in vivo* analysis of cell lineages in the mammalian brain ( [Sanes, 1989](#)). Use of this approach suggests that most progenitors originating in the same site of the ventricular zone remain radially deployed in the cortex in rodents ( [Luskin et al., 1988](#); [Tan et al., 1998](#); [Ware et al., 1999](#)), as well as in primates ( [Kornack and Rakic, 1995](#)). Furthermore, a number of studies in chimeric and transgenic mice have provided further evidence that a majority of postmitotic, clonally related neurons move and remain radially distributed in the cortex ( [Nakatsuji et al., 1991](#); [Rakic, 1995a](#); [Soriano et al., 1995](#)). Using the retroviral gene transfer method in the embryonic primate brain showed that even in the large and highly convoluted cerebrum, radial deployment of many clones is remarkably well preserved ( [Kornack and Rakic, 1995](#)), and the similarly convoluted human cerebrum develops by using the same cellular mechanism.

## ACQUISITION OF LAMINAR AND RADIAL POSITIONS

Because genesis of cortical neurons in macaque monkeys does not start until E40 ( [Rakic, 1974](#)) and until a few days later in humans ( [Sidman and Rakic, 1982](#)) ( [Fig. 3.3](#)), neuronal progenitors in the ventricular zone prior to that time produce only other progenitors. This so-called symmetric mode of cell division has initially been implied from data on the kinetics of cell proliferation using  $^3\text{H}$ -thymidine labeling of DNA in short-term experiments ( [Rakic, 1975](#)). Thus, radioactivity uniformly became diluted in the ventricular zone 1 or 2 days following injection of the isotope. After E40, however, many progenitor cells begin to produce dissimilar daughters (by asymmetric division), one of which becomes a postmitotic neuron, whereas the other may remain a stem cell or die ( [Fig. 3.9](#)). Initially, evidence that many stem cells in the proliferative units begin to divide asymmetrically also came from  $^3\text{H}$ -thymidine autoradiographic analysis, but only after using longer intervals following injections of the isotope ( [Fig. 3.10](#)). Examination of adult monkeys exposed to  $^3\text{H}$ -thymidine between E40 and E100 revealed that the radioactivity of neurons, progressively situated more superficially in the cortex, diminished stepwise by halves ( [Rakic, 1988a](#)). This finding indicated that, in a majority of mitotic divisions, one daughter cell remains in the proliferative unit and dilutes its radioactivity by subsequent divisions. However, many divisions must continue in a symmetric mode, because a given proliferative unit, which might initially contain a single stem cell, contains several progenitor cells during later stages of corticogenesis. The concept of a gradual shift from a purely symmetric mode of division to a mixture of symmetric and asymmetric modes in the telencephalic ventricular zone is supported by use of double labeling methods, enabling study of proliferation kinetics with two independent S phase markers ( [Takahashi et al., 1992, 1993](#)). Therefore, proliferative units in the ventricular zone should be regarded as polyclones, and each ontogenetic column in the overlying cortical plate should receive neurons from more than one clone. This model is supported by distribution of  $^3\text{H}$ -thymidine-labeled cells in the macaque monkey, which shows that, within the same column, intensely labeled and lightly labeled neurons (presumably from the same progenitor) can be interspersed among unlabeled neurons originating from a different progenitor within the same proliferative unit prior to or after injection of  $^3\text{H}$ -thymidine ( [Fig. 3.10](#)).

**Figure 3.10.** Microphotograph of three autoradiograms, showing neurons in the cortex of an adult monkey that was exposed to  $^3\text{H}$ -thymidine at E70. **A:** The most intensely radioactive neuron (a) lies deeper in the cortex than the two progressively less labeled, more superficially situated neurons (b and c). **B:** and **C:** Unlabeled neurons (crossed arrows) may be interspersed among radioactive neurons within the same ontogenetic column. Further explanation is in the text. (From Rakic P: Specification of cerebral cortical areas. *Science* 241:170–176, [1988a](#).)

Eventually, all postmitotic cells generated in a given proliferative unit of the ventricular zone ( [Fig. 3.5](#)) morphologically form an identifiable stack of neurons in the cortical plate ( [Fig. 3.5](#)). These radially deployed neurons are easily distinguishable and variously termed ontogenetic or embryonic columns ( [Rakic, 1978, 1988b](#)). The number of neurons in an ontogenetic column of the macaque monkey in the second half of gestation ranges between 70 in the anterior cingulate cortex (area 24), where neurogenesis lasts about 1 month, to more than 120 in the primary visual cortex (area 17), where neurogenesis lasts almost 2 months ( [Rakic, 1974, 1988b](#)) ( [Fig. 3.2](#)). However, the number of cells in the column is about 50% larger during midgestation and is eventually reduced by differential cell death, which starts after completion of neurogenesis in primates ( [Williams et al., 1987](#)). Within each column, earlier generated neurons occupy deeper positions, whereas those arriving to the cortex later must pass older neurons to become situated more superficially ( [Fig. 3.2](#)). This relationship among cells with different birthdays, called the “inside-out” gradient of neurogenesis, was suspected by classical anatomists, but has been proven only after use of the  $^3\text{H}$ -thymidine autoradiographic method in a number of mammalian species ( [Sidman and Rakic, 1973](#)). The inside-out gradient of neurogenesis is particularly prominent in primates, in whom each daily injection of  $^3\text{H}$ -thymidine labels a more selective sample of cortical neurons than in rodents ( [Rakic, 1974](#)). It is not clear why newly generated neurons must pass the older ones

instead of piling up below each other, but one of several hypotheses is that this sequence enables feedback signals to pass from the older to the arriving cells.

## PROTOMAP HYPOTHESIS

A major challenge of the cerebral cortex to students is how individual and species-specific cytoarchitectonic areas have emerged from the initially seemingly uniform ventricular zone and cortical plate. Both intrinsic and extrinsic factors have been suggested. One attractive hypothesis is that all cortical neurons are equipotential and that laminar and areal differences are induced by extrinsic influences exerted via thalamic afferents ( [Creutzfeldt, 1977](#)). However, modern neurobiology has provided a considerable amount of new evidence that cells generated within the embryonic cerebral wall contain some intrinsic information about their prospective species-specific cortical organization. To reconcile existing descriptive and new experimental data, we formulated a *protomap hypothesis* ([Rakic, 1988a](#)). This hypothesis suggests that the basic pattern of cytoarchitectonic areas emerges through synergistic, interdependent interactions between developmental programs intrinsic to cortical neurons that can be modified by extrinsic signals supplied by specific inputs from various subcortical structures to a certain extent. According to the protomap hypothesis, neurons in the embryonic cortical plate—indeed even in the proliferative ventricular zone where they originate—set up a primordial map that preferentially attracts appropriate afferents and have the capacity to respond to this input in a specific manner. The prefix *proto* was introduced to emphasize the primordial, provisional, and essentially malleable character of the protomap that is subject to considerable modification by extrinsic influences exerted at later stages ([Rakic, 1988a](#)).

The initial indication that developmental events in the proliferative ventricular zone foreshadow prospective regional differences in the overlying cerebral mantle comes from the observation that neurogenesis of the primary visual cortex, which contains more neurons per radial unit than the adjacent areas, lasts longer ( [Rakic, 1976b](#)). Furthermore, it has also been demonstrated that the mitotic index in the ventricular region subjacent to this area is higher than in adjacent regions ( [Kennedy and DeHay, 1993](#)). Therefore, region-specific differences in production of the ventricular zone can be detected even before neurons arrive at the cortex ( [Algan and Rakic, 1997](#); [Kennedy and DeHay, 1993](#)). Several lines of evidence indicate that, during final cell division, one or both daughter cells start to express a variety of neuron, class-specific signaling molecules ( [Lidow and Rakic, 1994](#); [LoTurco et al., 1995](#)).

Postmitotic cells not only become committed to a neuronal fate but also become restricted in their repertoire of possible fates ( [McConnell, 1988](#)). Numerous studies in which the cytology of postmitotic cells have been examined ( [LoTurco et al., 1995](#); [Schwartz et al., 1991](#)) and/or manipulated by a variety of methods, such as spontaneous mutations ( [Caviness and Rakic, 1978](#); [Rakic, 1995b](#)), ionizing radiation ( [Algan and Rakic, 1997](#)), retroviral gene transfer labeling ( [Parnavelas et al., 1991](#)), transgenic mice ( [Kuida et al., 1996](#)), and heterochronic transplantations ( [McConnell, 1988](#); [McConnell and Kasanowski, 1991](#)) all indicate that certain cell, class-specific attributes are expressed before migrating neurons arrive at the cortical plate and become synaptically connected.

More recently, retroviral tracing experiments and some clonal analyses suggest that the ventricular zone is comprised of a heterogeneous population of cells and that cell lineage contributes substantially to cell fate determination of neurons ( [Acklin and van der Kooy, 1993](#); [Kornack and Rakic, 1995](#); [Kuan et al., 1997](#); [Parnavelas et al., 1991](#); [Williams and Price, 1995](#)). These findings raise the question of whether laminar and areal identities of cortical plate cells provide cues or chemotactic attractants for incoming afferent axons. Data from axonal tracing indicate that afferent connections from subcortical structures and other cortical regions find their way to the specific regions of the cortical plate either directly and/or via the subplate zone ( [Agmon et al., 1995](#); [Catalano et al., 1996](#); [Kostovic and Rakic, 1990](#); [McConnell et al., 1991](#); Richards et al., 1997), suggesting the existence of region-specific attractants for path finding and target recognition. In support of this idea, the development of correct topological connections in anophthalmic mice and in early-enucleated animals indicates that basic connections and chemoarchitectonic characteristics can form in the absence of information from the periphery ( [Kaiserman-Abramof et al., 1980](#); [Kennedy and DeHay, 1993](#); [Kuljis and Rakic, 1990](#); [Olivaria and Van Sluyters, 1984](#); [Rakic, 1988a](#); [Rakic and Lidow, 1995](#)).

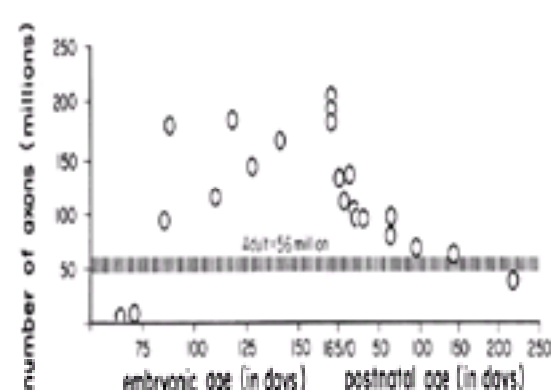

A large number of region-specific and layer-specific morphoregulatory molecules have been observed in the embryonic cerebral wall ( [Arimatsu et al., 1992](#); [Barbe and Levitt, 1992](#); [Buffone et al., 1993](#); [Cohen-Tannoudji et al., 1994](#); [Donoghue and Rakic, 1999a,b](#); Emerling and Lander, 1994; [Ferri and Levitt, 1993](#); [Gitton et al., 1999](#); Grove and Ragsdale, 2000; Levitt et al., 1997; [Porteus et al., 1992](#); [Rubenstein and Rakic, 1999](#)). Function of these molecules is not well understood, but a consensus seems to emerge that many of them contribute to the formation of specified axonal pathways. Thus, tangentially and radially distinct landmarks in the postmitotic cells may facilitate axonal path finding and target recognition that eventually leads to parcellation of the cerebral cortex. However, the initial species-specific protomap seems to be intrinsic to the cortex itself. Recently, it was shown that the cerebrum develops surprisingly well in knockout mice in which synaptic transmission is abolished ( [Verhage et al., 2000](#)) and that disturbance of thalamic input does not prevent formation of the basic cortical protomap ( [Bishop et al., 2000](#); [Miyashita-Lin et al., 1999](#)).

It should be underscored that although the embryonic cerebral wall exhibits gradients of several classes of morphoregulatory molecules, as well as other specific area-specific molecular differences, the protomap within the embryonic cerebrum only provides a set of species-specific genetic instructions and biological constraints. The precise position of interareal borders, the overall size of each cytoarchitectonic area, and the details of their cellular and synaptic characteristics in the adult cerebral cortex are achieved through a cascade of reciprocal interactions between cortical neurons and the cues they receive from afferents arriving from a variety of extracortical sources ( [Rakic, 1988a, 1988b](#)). Such afferents may serve to coordinate and adjust the ratio of various cell classes with the subcortical structures, as has been shown in the primary visual system ( [Kennedy and DeHay, 1993](#); [Meissirel et al., 1997](#); [Rakic et al., 1991](#); [Rakic and Lidow, 1995](#)). In summary, the concept of the cortical protomap includes the role of both intrinsic and extrinsic determinants in shaping the final pattern and relative sizes of the cytoarchitectonic areas.

## OVERPRODUCTION OF NEURONS AND THEIR PROJECTIONS

With few exceptions, most brain structures in vertebrates have a larger number of neurons and axonal connections during development than in adulthood ( [Hamburger and Oppenheim, 1982](#); [Williams and Herrup, 1988](#)). In all parts of the brain so far studied, neurons, as well as their axons and dendrites, were only found to be more numerous during a well-defined phase of development ( [Easter et al., 1985](#); [Purves, 1988](#); [Rakic et al., 1994a](#); [Rakic and Riley, 1983a](#)). The same basic phenomenon of initial exuberance has been observed during development of the cerebral cortex. Judging from the density of pyknotic (degenerating) cells, the visual cortex of fetal monkeys contains about 30% more neurons than that in adult monkeys ( [Williams et al., 1987](#)). The elimination of cells occurs mostly during the second half of gestation, when the superficial cortical layers may lose 35% to 40% of the initial number of neurons that arrived at the cortical plate. In contrast, the deep cortical layers, which are formed earlier, lose less than 25% of the original number. The reason for the lamina-specific difference in the magnitude of neuronal death is not clear, but it may be significant that local circuit cortico-cortical systems that are predominantly situated in the superficial layers (that are generated later) lose more cells than cortico-subcortical efferent systems, which originate from the deep layers (that are generated early).

The phase of massive neuronal elimination from the primate cerebral cortex precedes the phase of axonal elimination in the large cortico-cortical fiber tracts. For example, the newborn monkey has about 190 million callosal axons, compared to less than 50 million in the adult ( [LaMantia and Rakic, 1990](#)). A majority of these axons are eliminated during the first three postnatal weeks at the rate of 8 million per day or 50 per second. Therefore, callosal axons are lost at an estimated average rate of half a million per day or five per second, until the adult value is reached around puberty ( [Fig. 3.11](#)). This enormous loss of callosal axons is not accompanied by a significant change in the number of cortical neurons during the same period. This apparent paradox can be explained, at least in part, by the fact that callosal neurons represent less than 1% of the total cortical cells. However, it should be noted that many collateral branches or secondary axons of callosal cells might be eliminated from neurons that survive to adulthood. Other classes of interhemispheric connections, such as the anterior and hippocampal commissures, are also lost at a similar rate during approximately the same time ( [LaMantia and Rakic, 1994, 1995](#)). As discussed in the following, the number, pattern of distribution, or type of surviving neurons and axons can be modified at critical stages by the deletion of the neurons with which they have a direct synaptic relationship or more distant trophic dependence.

**Figure 3.11.** The estimated total number of axons in corpus callosum as a function of prenatal and postnatal ages in postconceptual days. Each point represents a single animal. Error values (<14%) are smaller than or equal to the size of the dots used to represent each data point. The hatched line indicates the average total number of callosal axons in eight adult monkeys. (From LaMantia AS, Rakic P: Axon overproduction and elimination in the corpus callosum of the developing rhesus monkey. *J Neurosci* 10:2156–2175, 1990.)

The biphasic development of cortical connections, which proceeds from initially diffuse to more sharply defined terminal fields, has been first and, perhaps, best documented in the primate visual area (Hubel et al., 1977; Rakic, 1976a). Subsequently, a similar developmental scenario also has been shown in diverse structures in a variety of species (Easter et al., 1985; Innocenti, 1981; O'Leary, 1989; Purves, 1988). In primates, for example, terminals of the corticostriatal projections in the caudate nucleus are initially distributed in a diffuse manner, across wide territories, before synapses retract from the sites that eventually become occupied by later-arriving afferent systems (Goldman, 1978; Goldman-Rakic, 1981b). These two examples, one afferent (geniculocortical) and the other efferent (corticostriatal), reveal that the formation of both input and output to the cortex may be achieved through dynamic competitive cellular interactions that occur prenatally and involve at least two well-defined steps. In the first step, several input systems project to the target structure in a diffuse and overlapping manner, without regard to its specific target area, the individual nerve cell, or its part. In the second phase, connections sort out and form more selective contacts with specific sets of neurons or their dendrites. However, unlike in cats, in primates, this rearrangement mostly occurs before birth and, thus, does not involve visual experience (Hocking and Horton, 1998; Rakic, 1976a, 1977). The finding that the ocular dominance columns can develop even in the absence of input from both eyes (Crowley and Katz, 1999, 2000) supports the hypothesis that the basic pattern of connectivity is innate, rather than experience dependent.

The functional significance of the large loss of axons in the cerebral cortex is not fully understood. In primates, it occurs after topographic and columnar organization has been achieved (LaMantia and Rakic, 1990; Schwartz and Goldman-Rakic, 1991) and therefore is not involved in establishing a basic pattern of connections. Likewise, in the adult rhesus monkey, area 17 does not have callosal connections, and unlike the developing cat, this region is never interconnected (Kennedy and Dehay, 1993). Callosal axons in the prefrontal cortex are interconnected with appropriate areas already in the middle of gestation, well in advance of the axonal loss phase that in this species occurs mostly postnatally (Schwartz and Goldman-Rakic, 1991). Therefore, axonal elimination in the cerebral cortex is probably involved in synaptic remodeling at the local rather than global level (LaMantia and Rakic, 1990). Indeed, as discussed in the following, loss of interhemispheric axons coincides with the period of rapid synaptic production rather than synaptic elimination.

### OVERPRODUCTION OF CORTICAL SYNAPSES

In most structures of the vertebrate brain, where quantitative data has been obtained with reasonable accuracy, both the density of synapses and their total number are higher during one stage of development than in the adult state (Easter et al., 1985; Purves, 1988). The cerebral cortex is not an exception to that rule, and the magnitude of the overproduction in this structure is even more pronounced. A bewildering number of growing axons eventually must establish synaptic junctions with a specific neuron class in each cortical area or, even more precisely, with only a part of their body and dendritic tree. In the primate cerebral cortex this precise pattern of synaptic connectivity in the target structure is achieved through a marked overproduction and subsequent elimination. For example, the cerebral cortex in both human and macaque monkeys contains more synapses during infancy than in adulthood (Bourgeois and Rakic, 1993; Huttenlocher and de Courten, 1987; O'Kusky and Colonnier, 1982; Rakic et al., 1986; Zielinski and Hendrickson, 1992). In the newborn monkey, the density of synapses per unit volume of neuropil and their total number is approximately equal to the adult values. However, during the first 2 to 3 months of life, synaptic density continues to increase until it reaches about 40% more than in an adult (Fig. 3.12). The phase of high synaptic density lasts throughout adolescence and decreases significantly during sexual maturation, which in this species occurs during the third year of life (Rakic et al., 1986, 1994a). The decline in number of synapses owes primarily to the elimination of asymmetric junctions located on dendritic spines, whereas synapses on dendritic shafts and cell bodies remain relatively constant. The course of decline in density and absolute number of synapses is perhaps best documented for the macaque monkey primary visual cortex. The number of synapses lost in area 17 of a single cerebral hemisphere is about  $1.8 \times 10^{11}$  (Bourgeois and Rakic, 1993). The magnitude of this loss is stunning when expressed as a loss of about 2,500 synapses per second in the striate area of each hemisphere during a period of about 2 to 3 years.

**Figure 3.12.** Histograms of the density of synapses per  $100 \mu\text{m}^3$  of neuropil in the primary visual (area 17), prefrontal association (area 46), primary motor (area 4), and primary somatosensory (area 1) at various ages. Each black circle represents the value obtained from a single electron microscopic probe, and data are corrected and transferred into N per volume according to the Anker and Cragg formula. The time is represented on a semilogarithmic scale. B, birth; DAC, days after conception; MAB, months after birth; P, days after puberty. (Data compiled from Bourgeois J-P, Rakic P: Changing of synaptic density in the primary visual cortex of the rhesus monkey from fetal to adult stage. *J Neurosci* 13:2801–2820, 1993; Bourgeois J-P, Goldman-Rakic PS, Rakic P: Synaptogenesis in the prefrontal cortex of rhesus monkey. *Cereb Cortex* 4:78–79, 1994; Zecevic and Rakic, 1991; Zecevic et al., 1989.)

Quantitative analysis of synaptogenesis in the motor (Zecevic et al., 1989), somatosensory (Zecevic and Rakic, 1991), visual (Bourgeois and Rakic, 1993), prefrontal (Bourgeois et al., 1994), and limbic (Granger et al., 1995) cortex in the macaque monkey indicates that a basic course of synaptogenesis, and, in particular, the ascending phase, occurs concomitantly (Fig. 3.12). Thus, contrary to the prevailing views, the entire population of synaptic junctions in the association Brodmann's area 46 matures concurrently with, rather than after, the primary sensory and motor areas. Although during this exponential phase there is a sequential accretion of some classes of synapses from diverse origins, overall the course of synaptogenesis is framed within a "window of time" centered on the exponential phase, which is common for all areas of the neocortex (Bourgeois et al., 1999).

The cortical synapses in humans also seem to form synchronously in diverse cortical areas, although the available data initially suggested a delay in the rapid phase of synaptogenesis in the prefrontal, as compared to that in the visual striate area (Huttenlocher, 1979; Huttenlocher and de Courten, 1987). However, if one eliminates the technical and procedural differences, the course of synaptogenesis in human and monkey is remarkably similar across the entire cortex. For example, when the data on synaptogenesis obtained from the human prefrontal (Huttenlocher, 1979) and human visual cortex (Huttenlocher and de Courten, 1987) were normalized and replotted to the maximum value of the curve on a semilogarithmic scale (Bourgeois et al., 1999; Rakic et al., 1994a), both curves overlap, as they do in the monkey (Fig. 3.13). Moreover, by means of linear regression analysis, the two sets of values were fitted to a straight line, and statistical comparison between the two regression lines failed to reveal a significant difference in their slopes. Therefore, it appears that synaptogenesis both in humans and nonhuman primates proceeds synchronously in the sensory and association cortex (Rakic et al., 1994a).

**Figure 3.13.** Synaptogenesis in human cerebral cortex. Synaptic density in the human striate area (open, large circles) and prefrontal cortex (black, small circles) based on the studies of [Huttenlocher and de Courten \(1987\)](#) and [Huttenlocher \(1979\)](#), respectively. We replotted each point from their published data on a semilogarithmic scale as a function of conceptual age and normalized to the maximum value of the curve. Under these conditions, both curves overlap as they do in monkeys. For further explanation see text. (From Huttenlocher PR, de Courten C: The development of synapses in striate cortex of man. *Hum Neurobiol* 6:1–9, 1987; Huttenlocher PR: Synaptic density in human frontal cortex—developmental changes and effects of aging. *Brain Res* 163:195–205, 1979; Rakic P, Bourgeois J-P, Goldman-Rakic PS: Synaptic development of the cerebral cortex: Implication for learning, memory, and mental illness. *Prog Brain Res* 102:219–235, 1994a.)

The time course of synaptogenesis in different cortical areas corresponds well with changes occurring simultaneously in cerebral metabolism during development of both the human and macaque cerebral cortex ([Chugani et al., 1987](#)). In humans, the use of fluorodeoxyglucose, which indicates the level of metabolic activity in positron emission tomography, reveals that, after birth, metabolic activity also increases concurrently in the prefrontal, motor, somatosensory, and visual cortex ([Chugani et al., 1987](#)). These studies lend support to the idea that maturation of diverse cortical areas in both monkey and human occurs simultaneously rather than in a pronounced sequential order. Further, the synchrony in synaptogenesis observed in the nonhuman primate is in harmony with biochemical and functional data on cortical maturation in the same species. Biochemical studies ([Goldman-Rakic and Brown, 1982](#)) suggest that concentrations of dopamine, noradrenaline, and serotonin increase rapidly in the cortex of the macaque monkey over the first 2 months and approach adult levels by the fifth month after birth. Recent studies of the accumulation of major neurotransmitter receptor sites in different cortical areas show that their maximum density is also reached between 2 and 4 months after birth in this species ([Lidow et al., 1991](#); [Lidow and Rakic, 1992](#)). The curves of the increase in receptor density are very similar to those of synaptogenesis in all areas examined irrespective of level of activity ([Bourgeois et al., 1989](#)) (Fig. 3.14). However, the phase of decline of receptor density appears to slightly precede the phase of synaptic decline. These observations from divergent cortical areas suggest that initial formation and maintenance of synapses, as well as their biochemical maturation, may be determined by intrinsic signals, which are common to the entire cortical mantle.

**Figure 3.14.** Developmental changes in the overall changes (across all layers) in density of the synapses and specific binding of radioligands labeling a representative selection of neurotransmitter receptor subtypes in the prefrontal, primary, motor, somatosensory, and primary visual cortical regions of the developing rhesus monkey. For receptor densities, the lines were obtained by locally weighted least square fit with 50% smoothing (KALEIDA GRAPH, Synergy Software, Reading, PA) based on mean  $B_{max}$  values obtained from the measurements of the entire cortical thickness in at least two animals at birth, 1, 2, 4, 8, 12, 36, and 60 months of age. Age is presented in postnatal days on a logarithmic scale. (The primary data are from Lidow MS, Goldman-Rakic PS, Rakic P: Synchronized overproduction of neurotransmitter receptors in diverse regions of the primate cerebral cortex. *Proc Natl Acad Sci USA* 88:10218–10221, 1991; Lidow MS, Rakic P: Postnatal development of monoaminergic neurotransmitter receptors with primate neocortex. *Cereb Cortex* 2:401–415, 1992; Rakic P, Bourgeois J-P, Eckenhoff ME: Concurrent overproduction of synapses in diverse regions of the primate cerebral cortex. *Science* 232:232–235, 1986.)

The concurrent course of synaptogenesis and formation of neurotransmitter receptors in functionally different areas of the cerebrum is at variance with the tacit assumption, widespread in the literature, that development of the cerebral cortex follows an hierarchical sequence of structural and functional development from sensory to motor and, finally, to the association cortex ([Filimonov, 1949](#); [Flechsig, 1920](#); [Greenfield, 1991](#); [Yakovlev and LeCourse, 1968](#)). We argue that myelination of large axonal tracts is not a very useful criterion of functional maturation of a given cortical area and, furthermore, that hematoxylin staining of sections used to measure the amount of myelin is not a reliable quantitative method. There are clear exceptions to the hierarchical rule of cortical maturation even in these studies. For example, the corticospinal motor system is among the last to myelinate and becomes stained by hematoxylin only during the second year of life, well after association pathways are myelinated ([Yakovlev and LeCours, 1978](#)). On the other hand, concurrent structural (synaptic) and biochemical (neurotransmitters, receptors) maturation of the cortical mantle appears reasonable when one takes into account that integration of sensory, motor, limbic, and associative components are essential for even the simplest cortical functions ([Goldman-Rakic, 1987a, 1988](#)). This concept of concurrency becomes even more compelling when one considers the coupling between early maturation of the neuronal circuits of the cortex and the first expression of cognitive capacity that requires coordination of sensory and associational cortical areas ([Spelke et al., 1994](#)).

Isochronic development of anatomically and functionally diverse regions indicates that establishment of cell-to-cell communication in this structure may be orchestrated by a single genetic or humoral signal. This phase of primate life may provide a long period of unparalleled opportunity for competitive, activity-driven stabilization among various initially overproduced intercortical and intracortical connections, which comprise the largest fraction of cortical synapses ([Goldman-Rakic, 1987a](#)). This period of supernumerary synapses in the cerebral cortex can be considered as a stage in life with maximal opportunity and minimal commitments, thus providing an enormous window of opportunity for the generation of cortical diversity beyond genes.

## SYNAPTIC ELIMINATION AND FUNCTIONAL VALIDATION

Studies of the cerebral cortex in a variety of mammalian species support the hypothesis of competitive interactions as a mechanism of attaining point-to-point connectivity during segregation of initially more numerous and diffuse projections ([Easter et al., 1985](#); [Edelman, 1987](#)). The balance between overproduction and elimination of neurons and axons and competition between them determines the size and site of territories devoted to a given terminal field. The first, and perhaps the best-documented example of developmental processes, which proceeds from diffuse to sharply defined terminal fields, is the primate binocular visual system ([Hubel et al., 1977](#); [Rakic, 1976a, 1977, 1991b](#)). This basic principle has since been shown in a variety of cortical areas ([Easter et al., 1985](#); [Innocenti, 1981](#); [O'Leary, 1989](#); [Shatz, 1983](#)). Perhaps the most prominent cellular mechanism for selective elimination of inappropriate and less used synapses is the process of sorting out connections through competition. When it occurs during postnatal development and is associated with sensory stimulation, it is also known as the Hebbian mechanism or synaptic stabilization ([Changeux, 1993](#); [Hebb, 1949](#)). However, in either case, this pruning involves elimination of already formed synapses, rather than creation of new connections.

After the number and density of synapses in the cerebral cortex reach adult levels, they remain relatively stable throughout the life span in both humans and nonhuman primates ([Bourgeois et al., 1999](#); [Huttenlocher and de Courten, 1987](#); [Rakic et al., 1986, 1994a](#)). Obviously, even though we learn and acquire an enormous amount of information during adulthood, the number of synapses in the cerebral cortex during this period remains basically the same. From crude

quantitative analysis of the overall density and number of synapses, one cannot exclude the possibility that certain classes of synapses are constantly being produced, whereas others are being eliminated in the same proportion (Rakic et al., 1986). However, the absence of profiles of immature synapses or their early forms, as well as the lack of hard ultrastructural evidence for their degeneration under normal conditions, suggests that the turnover of the synaptic population in primates must be either absent or negligible. Based on these findings, we argue that during infancy, childhood, and adolescence, learning basic skills and formation of intellectual capabilities may be associated with considerable changes in the population of synapses by both formation and elimination of selected synaptic junctions, as well as strengthening of their efficacy. In contrast, after puberty, learning and memory probably depend primarily on changes in the strength of already existing synapses. It should be pointed out that this concept does not negate the capacity for functional plasticity that remains in the adult cerebral cortex (Merzenich, 1988), nor does it contradict the existence of competitive interactions based on strengthening of the selected connections in response to stimulation (Edelman, 1987; Shatz, 1990). However, this hypothesis could explain the substantial qualitative and quantitative differences in learning capability before and after sexual maturity. This mode of learning may be particularly important in primates, who depend on retention of acquired knowledge by a permanent set of neurons and their connections during a prolonged life span (Rakic, 1985).

The theory of competitive elimination of synapses during development of the cerebral cortex was initially obtained from studies of monocular eye deprivation, which resulted in a decrease in the size of ocular dominance columns subserving the occluded eye and enlargement of the functional eye (Hubel et al., 1977). This was the first clear anatomic evidence that the pattern of neuronal connectivity can be visibly changed by a brief deprivation of function during the critical postnatal period of development. Even more dramatic changes are observed when the eye in a monkey fetus is enucleated before geniculocortical fibers have entered the cortical plate (Rakic, 1981a, 1983). In such cases, there is no trace of ocular dominance columns in the visual cortex; therefore, neurons that normally receive input from, and subserve the left eye now receive input from the right eye (Fig. 3.15). Retino-geniculo-cortical connections fail to withdraw to appropriate territories even after the blockade of electrical activity in one eye by tetrodotoxin (Dubin et al., 1986; Stryker and Harris, 1986). Some additional experiments performed on the developing cerebral cortex are reviewed in the following to illustrate the extent of changes in neuronal organization that can be induced by interference with the course of normal development.

**Figure 3.15.** Dark-field illumination photomicrograph of autoradiograms, showing distribution of transneuronally transported radioactive tracers in the primary visual cortex of normal adult monkeys (A and C) and in adult monkeys in whom one eye was enucleated during the first third of pregnancy (B and D). Note the lack of alternating ocular dominance columns in the cortex of experimental animals. The distribution of silver grains over sublayers of layer IV remains similar to that in the control. (From Rakic P: Genuculo-cortical connections in primates: Normal and experimentally altered development. *Prog Brain Res* 58:393–404, 1983.)

## EXPERIMENTAL MANIPULATION OF THE CORTICAL PROTOMAP

The cerebral cortex is basically an analyzer that associates diverse inputs originating from various sensory receptors communicated to its neurons via precisely and systematically organized thalamocortical connections. Although information essential for developing a basic species-specific pattern of these connections must be imprinted in our genome (see the preceding), interference with normal interaction with information derived from the periphery, where stimulation arises, can have a devastating effect. The role of afferents in the development of cortical parcellation can be examined by altering the number of axons comprising specific thalamocortical systems at early embryonic stages and determining the size and cytoarchitectonic pattern in corresponding target areas of the cortex in adult animals. For example, binocular enucleation performed in the monkey embryo around E60 reduces the number of geniculate neurons to less than one-half the number in age-matched controls without altering any other component in the thalamocortical system (Rakic, 1988a; Rakic et al., 1991). Furthermore, the occipital lobe in early enucleates displays dramatic and remarkably reproducible changes in convolutions of the occipital operculum. These changes are milder in later-operated cases and cannot be induced by downsizing geniculocortical input during the second half of gestation. Use of anterograde and retrograde transport of axonal tracers in early enucleates reveals the presence of topographically well-defined reciprocal connections of the occipital lobe with a vestige of the lateral geniculate nucleus (Rakic, 1988a).

In specimens with an experimentally produced smaller lateral geniculate, area 17 is well differentiated from adjacent area 18, and its thickness and characteristic laminar pattern are surprisingly normal. However, the surface area and the total number of neurons in area 17 in the early-enucleated subjects are less than half those in age-matched controls (Rakic et al., 1991). Despite the drastically reduced number of geniculocortical afferents, area 17 contained the normal number of neurons per unit volume of each layer and per each radial column. The distribution of major neurotransmitter receptors in early enucleates, in spite of some modification, retained the basic laminar pattern characteristic of area 17 (Rakic and Lidow, 1995). Furthermore, cytochrome oxidase blobs in layers II and III, which are thought to subserve color and form vision (Livingstone and Hubel, 1984), were segregated and maintained in the visual cortex of early binocular enucleates (Kuljis and Rakic, 1990). Finally, synaptic density per unit of neuropil, as revealed by quantitative electron microscopy, achieved normal range in all layers (Bourgeois and Rakic, 1996). These results indicate that the basic cytologic, synaptic, and biochemical characteristics of area 17 can develop in the absence of stimulation from the retina. However, the number of ontogenetic columns and therefore the size of the surface of area 17 is reduced to match the number of geniculocortical axons in the enucleated animals (Rakic, 1988a).

The reduction in size of area 17 in animals enucleated at early embryonic ages could result from either creation of fewer radial columns or from an increase in their elimination (Fig. 3.16). However, neither possibility seems likely because enucleation was performed after all proliferative units in the ventricular zone should have been formed, and cell death restricted to entire columns of cells has never been observed. It is possible, therefore, that the total number of ontogenetic columns in the cortices of animals that were operated on remained the same and that the adjacent cytoarchitectonic area, which normally receives input mainly from the adjacent thalamic nucleus (pulvinar), expanded (Fig. 3.16). Such changes would require respecification of neurons genetically programmed to become part of area 17 to accommodate input characteristic to area 18. This mismatch may create a “hybrid” cortex (Fig. 3.16) that retains some characteristics of area 17, but takes on some features of area 18 as a result of receiving a different set of afferents (Rakic, 1988a). These findings may provide a hint about how a new type of cytoarchitectonic area can be introduced by input-target mismatching during evolution (Rakic et al., 1991).

**Figure 3.16.** Schematic representation of the possible modes of decrease in the size of area 17 caused by experimental reduction of thalamic input. A: Relation between areas 17 and 18 in a normal animal. B: Differential cell death. C: Encroachment of adjacent area 18 into the territory of area 17. D: Formation of an abnormal cytoarchitectonic area (X) consisting of neurons genetically destined for area 17 that receive input characteristic for area 18. Further explanation is in the text. (From

Regulation by thalamic input to the developing cortical plate is probably only one part of a complex interactive process that occurs during parcellation of the neocortex. For example, prenatal resection of the fetal cortex, which eliminates or decreases the amount of cortico-cortical input to the subplate zone at early stages, also affects the pattern of cortical convolutions in some unoperated areas on both sides ( [Goldman-Rakic, 1980](#); [Goldman-Rakic and Rakic, 1984](#)).

## TIMING OF CORTICAL HISTOGENESIS IN HUMANS

Because our ultimate goal is to learn more about human neocortical development, it is important to determine whether the development of the human cortex proceeds according to time schedules relative to birth and shares the same cellular and molecular mechanisms uncovered in nonhuman primates. A comparison of some of the morphologic features of the cortex in human fetuses of different ages ( [Kostovic and Rakic, 1980, 1990](#); [Poliakov, 1949, 1959, 1965](#); [Rakic and Sidman, 1968](#); [Sidman and Rakic, 1973](#)) with those of the monkey may help to determine the corresponding time and sequence in these two species. Poliakov's comprehensive histologic studies of cortical development in humans have been reviewed in more detail elsewhere ( [Sidman and Rakic, 1982](#)) and are briefly summarized here and illustrated in [Fig. 3.17](#).

**Figure 3.17.** Semidiagrammatic drawings of the human cerebral wall at various gestational ages, listed in fetal weeks below each column. The stages refer specifically to an arbitrarily chosen area midway along the lateral surface of the hemisphere. (Detailed in Sidman RL, Rakic P: Development of the human central nervous system. In: Haymaker W, Adams RD (eds): *Histology and Histopathology of the Nervous System*. Springfield, IL, Charles C Thomas, 1982, pp. 3–145.) In addition, the subplate zone, situated below the cortical plate, appears in the last three stages. (Kostovic I, Rakic P: Developmental history of transient subplate zone in the visual and somatosensory cortex of the macaque monkey and human brain. *J Comp Neurol* 297:441–470, 1990.) Because there is a gradient of maturation, as many as three of five stages of cortical development may be observed in different regions of the neocortex in the same fetal brain. In the three columns on the right, the intermediate zone is not drawn in full because the thickness of the cerebral wall has increased markedly compared with earlier stages and cannot fit into the drawing. The curve below the drawing schematically indicates waves of cell migration to the neocortex assessed by the density of migrating neurons in the intermediate zone. CP, cortical plate; Im, intermediate zone; I.Im and O.Im, inner and outer intermediate zones, respectively; Mg, marginal zone; PL, plexiform layer; SGL, subpial granular layer; SP, subplate zone; SV, subventricular zone; V, ventricular zone; wks, age in fetal weeks. (From Rakic P: Defects of neuronal migration and pathogenesis of cortical malformations. *Prog Brain Res* 73:15–37, 1988b, with permission.)

### Stage I. Initial Formation of the Cortical Plate (Sixth to Tenth Fetal Week)

During the seventh fetal week, postmitotic cells begin to migrate from the ventricular zone outward to form a new accumulation of cells at the junction of the intermediate and marginal zones. Already, by the middle of this period, synapses of unknown origin are present above and below the cortical plate ( [Molliver et al., 1973](#)). This stage corresponds approximately to the level of cortical development found in the monkey fetus between E40 and E54, depending on the region.

### Stage II. Primary Condensation of the Cortical Plate (Tenth and Eleventh Fetal Weeks)

At this stage, the cortical plate increases in thickness, becomes more compact, and is clearly demarcated from the fiber-rich part of the intermediate zone, which seems to have fewer cells per unit volume, indicating that the first major wave of migration is almost spent ( [Fig. 3.17](#)). The end of this stage corresponds approximately to the E55–E59 period in the monkey when the majority of efferent neurons of layers 6 and 5 are generated in most regions of the cortex.

### Stage III. Bilaminate Cortical Plate (Eleventh to Thirteenth Fetal Week)

The uniform and compact cortical plate of the second stage becomes subdivided into an inner zone occupied mainly by cells with relatively large, somewhat widely spaced oval nuclei and an outer zone of cells with densely packed, darker, bipolar nuclei ( [Fig. 3.17](#)). This heterogeneity results from the more advanced maturation of the deep-lying neurons that arrived at the cortical plate during earlier developmental stages, plus the addition of a new wave of somas of immature neurons that take up more superficial positions. This period is also characterized by the appearance of the cell-sparse, fiber-rich subplate zone situated below the cortical plate. This transient embryonic zone in the human fetus is particularly wide in the regions subjacent to the association areas ( [Kostovic and Rakic, 1990](#)). Stage III roughly corresponds to the level of development achieved in the monkey between E59 and E64.

### Stage IV. Secondary Condensation (Thirteenth to Fifteenth Fetal Week)

During this period of gestation, the ventricular zone becomes progressively thinner, whereas the subventricular zone remains relatively wide ( [Fig. 3.17](#)). The cortical plate again becomes homogeneous in appearance and resembles, in a sense, a thickened version of Stage II. The reason for this change may be that, in Stage IV, most of the young neurons in the cortex become considerably larger as they differentiate, whereas relatively few new immature neurons enter the cortical plate. The result is a more uniform appearance. At the end of this stage, an accumulation of large cells appears below the cortical plate and the subplate zone enlarges further ( [Kostovic and Rakic, 1990](#)). Depending on the cortical region, this stage appears in the monkey between E64 and E75.

### Stage V. Sixteenth Fetal Week into the Postnatal Period

Morphologic data are inadequate in determining the length of time and the quantity of neurons that continue migrating to the human neocortex after 16 weeks; hence, the line at the right side of the curve is dotted in [Fig. 3.17](#). By the fifth lunar month, relatively few neuron precursors seem to be proliferating in the reduced ventricular zone of the human cerebral hemispheres, although many neurons generated prior to the 16th week have yet to reach the cortical plate. Comparison of the <sup>3</sup>H-thymidine autoradiographic results in the monkey ( [Rakic, 1974, 1977](#)) with comparable stages in humans ( [Kostovic and Rakic, 1990](#)) indicate that probably all neurons of the human neocortex are generated before the middle of gestation. Toward term, the subplate zone dissolves, and, as the intermediate zone becomes myelinated and transforms into white matter, only a vestige of the subplate neurons remain as interstitial neurons ( [Kostovic and Rakic, 1980](#)). After all cortical neurons have been generated and attained their final position, their differentiation, including formation of synapses, continues to proceed until reaching a peak during the second postnatal year. The subject of synaptogenesis in the cerebral cortex of both monkey and humans has been described in the preceding sections.

## RELEVANCE TO MENTAL ILLNESS

It is generally agreed that many psychiatric and neurologic disorders that become expressed in childhood and adolescence have a genetic and developmental background, but the exact time and place of the onset of a defective process has been difficult to place. Advances made in understanding normal cortical development provide insight into the pathogenesis of some inherited and acquired cortical malformations observed in animals and humans. However, the biological

bases of many psychiatric disorders, such as schizophrenia, obsessive-compulsive disorders, or various forms of congenital mental retardation have been more elusive. In such cases, methodologic limitations allow even relatively large changes in the relative size of cortical areas or in the synaptic number to remain undetected. In other cases, the defect may be biochemical, but only quantitative analysis of the distribution of the involved molecules could reveal the effects. A few examples are provided here of the visible and relatively well-defined disorders that are explicable in light of the present knowledge of corticogenesis that was reviewed on the preceding pages. These examples are selected because they also elucidate the main principles governing the development of the cerebral cortex.

One rare condition that is highly relevant for understanding development of the cerebral cortex is the formation of the cortex in the absence of sensory input from early stages of development. For example, it is surprising but well established that, when a child is born without both retinas, area 17 has a normal thickness and lamination but a greatly reduced surface ([Bolton, 1900](#); [Brunquell et al., 1984](#)). Although the cause of most cases of congenital anophthalmia is unknown, the result is wholly explicable by findings from bilateral enucleation experiments ([Rakic, 1988b](#); [Rakic et al., 1991](#)), which indicate that this cortical abnormality is caused by a defect in eye formation during the first third of gestation. The resection of retinas during the first third of gestation, provide a useful model system to study the pathogenesis of secondary anophthalmia. So far, it has been learned that the visual cortex in these animals develops a normal density of synapses and normal distribution and binding intensity of the major neurotransmitter receptors ([Bourgeois and Rakic, 1996](#); [Rakic and Lidow, 1995](#)). Other pertinent examples of cortical malformation are focal malformations found in both humans and mice, in which only a segment of the cortex confined to several radial units is highly disturbed and sharply delineated from adjacent areas ([Nowakowski, 1984](#); [Sherman et al., 1985](#)), indicating that only cells originating from a small part of the ventricular zone have been affected.

The classification of most cortical malformations in humans is traditionally based on the appearance of the cerebral cortex at autopsy. However, advances made in developmental neurobiology in the past decade allow some new interpretations. For example, according to the radial unit hypothesis, the pathogenesis of some cortical malformations can be classified into two major categories ([Rakic, 1988a,b](#)). The first category comprises malformations in which the number of radial units in the cortex is reduced, whereas the number of neurons within each ontogenetic column remains relatively normal. It can be expected that defects in this category result from an early-occurring event that alters the number of proliferative units at the time they are being formed in humans within the first 6 weeks of gestation. Once the number of proliferative units in the ventricular zone is established, albeit in fewer numbers, each unit can produce a normal or even greater number of neurons, which become crowded in the diminished cerebral vesicle. It could be expected that the cortex would have a smaller surface area in spite of a normal or enlarged thickness and the presence of massive neuronal ectopias in the white matter. These features are actually observed in some human malformations, such as lissencephaly and pachygyria ([Hong et al., 2000](#); [Volpe, 1987](#)).

The second category consists of malformations in which the initial formation of radial units is not affected, whereas the number of neurons within ontogenetic columns is reduced. The defect in this category should begin after the sixth fetal week, when the normal complement of proliferative units has already been established. Such malformations can be caused by interference with cell proliferation via intrinsic (genetic) or extrinsic (irradiation or viral infection) factors. Diminished production of neurons in the proliferative units results in fewer neurons within ontogenetic columns; therefore, the cortex is thinner. The number of neurons in ontogenetic columns could also be affected by cell death or by a failure of their migration. In the latter case, some neurons may survive in ectopic positions within the white matter. All of this can be observed in the so-called polymicrogyria brain ([Volpe, 1987](#)).

It should be recognized that only few cortical malformations have features of only one or the other general category described in the preceding, but in practice, most show a mixture of both. The proposed classification suggests possible developmental mechanisms by separating defects of unit formation from defects of ontogenetic column formation. In support of the radial unit hypothesis and the concept of a cortical protomap, experimental and neuropathologic data reveal that each step (formation of proliferative units, formation of ontogenetic columns, and formation of cytoarchitectonic areas) can be separately affected by genetic defects or by extrinsic factors ([Haydar et al., 1996](#); [Rakic, 1988b](#); [Sidman and Rakic, 1982](#)). It can, therefore, be predicted that genetic alteration as well as mechanical, chemical, or viral lesions of distant but synaptically related structures that result in reduced input to the cortex would affect subsequent developmental events and provide the setting for new cell relationships, the net outcome of which could be the emergence of a unique cytoarchitectonic map.

Of particular relevance to the psychiatric disorders of adolescence may be abnormalities that are associated with phases of synaptic overproduction and elimination. It is well established that many major psychoses, including schizophrenia, become manifest at the end of adolescence and in early adulthood. In addition, a growing number of studies of postmortem tissue samples from schizophrenics and of magnetic resonance images of the brains of living patients have provided a solid factual basis for morphological signs, such as enlarged ventricles, which predate the illness ([Weinberger, 1987](#)). The evidence for a genetic predisposition to schizophrenia ([Kety et al., 1968](#)) has naturally led investigators to consider the developmental antecedents of this major psychosis, and several hypotheses have invoked events related to synaptogenesis ([Bloom, 1993](#)). For example, it was proposed that schizophrenia might be caused by a fault in programs of synaptic elimination during adolescence ([Feinberg, 1982](#)). More recently, this concept has gained support by the finding that cortical neurons in schizophrenics have fewer synaptic contacts as judged by the reduction in neuropil ([Goldman-Rakic and Selemon, 1997](#); [Selemon et al., 1997](#)) by a computational model, which tests predictions relevant to particular symptoms in schizophrenia ([Hoffman and McGlashan, 1993](#)).

More direct evidence for the possibility of excessive pruning comes from recent studies of noninvasive methods in living patients ([Pettegrew et al., 1993](#); [Williamson et al., 1991](#)). In these studies, the structural integrity of the prefrontal cortex in drug naive schizophrenics shows excessive elimination of dendrites and axons. Complementing the *in vivo* studies ([Selemon et al., 1997](#)) found that there is a higher density of neurons per unit volume in prefrontal areas of schizophrenics compared with that in controls—a finding compatible with the loss of synaptic neuropil in schizophrenia. [Glanz \(1993\)](#) have reported preliminary evidence of reduced synaptophysin labeling in the prefrontal cortex of schizophrenics. The suggestion that Notch signaling pathway may be involved in regulation of synaptic pruning ([Sestan et al., 1999](#)) opens the possibility to test this hypothesis. These studies indicate a pathologic process at work in the various cortical regions of patients—findings that are compatible with a neurodevelopmental perspective. Although these changes occur at inflection points in the synaptogenesis curve, there is no direct evidence that they are causative in nature. It is likely, however, that knowledge of the normal course and mechanisms of synapse formation and the influence of various exogenous and endogenous events on synapse stability and turnover are essential prerequisites to determining the locus and timing of etiologic factors in diseases that affect the cortex and alter cognitive function. This is the ultimate justification for studies in nonhuman primates, where conditions are experimentally controlled and monitored.

[Conclusion and Future Research](#)

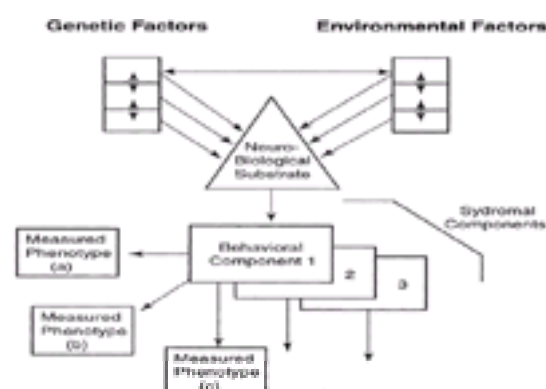

[Chapter References](#)

Accelerating advances in basic neuroscience have led to a much improved understanding of brain development and functioning and hold the tantalizing promise of understanding the alterations that may exist in childhood psychiatric disorders ( [Andreasen, 1997](#); [Kandel and Squire, 2000](#)). Research on the molecular control of developmental neurobiology ( [Chapter 1](#)) is particularly relevant. The recent elucidation of the genetic bases of a number of single-gene childhood psychiatric disorders ( [Chapter 2](#)) provides additional hope, and to some extent paradigms, for tackling the more complex molecular and biological influences in autism, attention deficit/hyperactivity, Tourette syndrome, anxiety, posttraumatic stress disorder (PTSD), depression, and suicide. Identification of causative factors in Parkinson's disease, Huntington's disease, Alzheimer's disease, and other adult neurologic and psychiatric disorders further encourages the notion that the biological bases of childhood psychiatric disorders can be ascertained.

Along with the successes in identifying the genetic and etiologic bases for syndromes like fragile X and Rett, there is accumulating evidence that genetics plays a large role in all of the common childhood psychiatric disorders. Thus, family and twin studies of adults and children have left no doubt that genetics and biology often can be even more important than environmental factors in influencing normal and abnormal behavior; however, the last decade has been one of disappointment in trying to find single gene or loci explanations for the more common syndromes and symptoms of child psychiatry. This research has made it increasingly clear that the genetics and biology of the common disorders are complex, in that multiple genes appear to contribute to the syndromes ( [Benjamin and Gershon, 1996](#); [State et al., 2000](#)). This is not surprising given the complex and diffuse nature of the neural systems that subserve the relevant brain processes ( [Abercrombie and Zigmond, 1995](#); [Heninger, 1999](#)). The genetic complexity is further multiplied by the wealth of variation arising from gene-environment interactions: illuminating the complexity will require the application of new and appropriate genetic methods ( [Burmeister, 1999](#); [Collier et al., 2000](#); [Pauls, 2000](#); [Petronis and Gottesman, 2000](#); [Weiss and Terwilliger, 2000](#)).

Recognition of the importance of genetics and complexity of the disorders is changing in fundamental ways how the disorders or behaviors are viewed; thus, the field of biological psychiatry is changing in its approach. Whether the field is termed "molecular psychiatry," "biological psychiatry," or "clinical neuroscience" is of little consequence; fundamental changes are being prompted by a better appreciation of the scope of the endeavor. An emerging overarching theme is that all biological, neuropharmacologic, and behavioral investigation needs to be performed in a genetic context. There is also a greater focus on components or domains of behavior and a greater interest in quantifying the traits or variables of interest. This move toward examining components is an understandable attempt to simplify the situation, and it has long been offered as an alternative to the more usual approach oriented toward diagnostic categories. The rationale for examining what have been referred to as "elementary units of psychological dysfunction" ( [van Praag, 1997](#)), "core or candidate symptoms" ( [Leboyer et al., 1992](#)), quantitative phenotypes ( [Leckman et al., 2001](#)), endophenotypes ( [Almasy and Blangero, 2001](#)), or "core psychopathological processes" ( [Krueger, 1999](#); [Wittchen et al., 1999](#)) is becoming more and more compelling. Finally, there is a greater appreciation of the advantages of combining methodologies. It is now clear that all sources of potentially relevant phenotypic information need to be considered, and the interrelationships among the different phenotypes can be fruitfully examined.

One formulation of the interrelated aspects of biological psychiatry is presented in [Fig. 4.1](#). The mutual interacting influences of genetic and environmental factors are shown determining the neurobiological systems that, in combination, form the substrate of relevant behaviors. The behaviors can be assessed in a number of ways, providing a range of measured phenotypes (a-c). In most cases, syndromes and disorders consist of multiple behavioral components, depicted by the receding additional behavioral components (1-3).

**Figure 4.1.** Schematic of the interrelated factors underlying biological psychiatry. The mutual interacting influences of genetic and environmental factors are shown determining the neurobiological systems that combine to form the substrate of relevant behaviors. The behaviors can be assessed through a range of measured phenotypes (a-c). The multiple behavioral components of most syndromes and disorders are depicted by the receding additional behavioral components (1-3).

The field of biological psychiatry has traditionally emphasized neurochemical and neuroendocrinologic approaches ( [Chapter 7](#)). Other fields that are now proving critical to advancing an understanding of brain neural transmission in psychiatry include neurophysiology ( [Chapter 5](#)), neuropsychology, neuroimaging ( [Hendren et al., 2000](#)) ( [Chapter 9](#)), psychopharmacology ( [Chapter 76](#) and [Chapter 77](#)), and pharmacogenetics/pharmacogenomics ( [Anderson and Cook, 2000](#)). Elucidation of the bases of the childhood disorders can be expected to proceed through an iterative process involving mutually beneficial relationships among all of the perspectives ( [Bailey et al., 1996](#); [McBride et al., 1996](#)). Although advances in a particular area typically will be incremental, they usually will have multiple applications in other areas. The multiple reciprocal relationships among all methods of phenotypic analysis and the field of genetics will be especially important; it has been pointed out that the circular aspect of this undertaking means that genotypic information will help to clarify phenotypes ( [Hyman, 2000](#)). The evolving approach to studying brain and behavior is discussed at length by Werry and colleagues in [Chapter 8](#). The importance of being ever mindful of the developmental context when studying childhood psychiatric disorder is clear ( [Cohen and Young, 1977](#); [Dawson et al., 2000](#); [Leckman, 1999](#); [Skuse, 2000](#); [Young et al., 1984](#)). In a sense, the diagram of [Fig. 4.1](#) needs to be thought of as moving through the fourth dimension of time, affected by (and affecting) the developmental chronology.

### NEUROCHEMICAL RESEARCH: AIMS, SCOPE, AND METHODS

#### Aims of Clinical Neurochemical Research

Biological or molecular psychiatry has been concerned with investigating possible alterations in neural transmission, with most studies focusing on the monoamine neurotransmitters. The research has had three main aims: the identification of useful markers of disorders, explication and description of pathophysiology, and

determination of etiology. These goals are not mutually exclusive: In most cases, hypotheses concerning etiology serve to direct the search for markers. Markers can be sought that reflect either the state of an illness or the trait of being predisposed toward an illness. State markers are not necessarily genetically influenced and should revert to normal on recovery or remission. They are presumably not related to the most basic etiologic alteration but to some aspect of symptom mediation. Trait markers can be considered to be associated in some way with the genetic vulnerability; they are usually present before, during, and after illness; and they are often present in family members of probands with heritable illness. The association of a trait marker with illness could be coincidental, owing to genetic linkage. Although such a linked marker might be extremely useful for pedigree analysis and gene localization, it would in itself give little or no information as to etiology.

Trait markers may be dichotomous, discrete, or continuous. Much of the work of biological psychiatry has been directed, implicitly or explicitly, toward finding trait markers in continuous variables that have been hypothesized to be related to etiologic alterations. Preferably, a marker is easily and reliably measured, with little overlap existing between normal and affected groups. A trait marker would be expected to be useful in diagnosis, subtyping, family and genetic studies, establishing prognosis, and selecting therapy.

The goals of understanding pathophysiology and etiology hold the promise of cure. Studies of etiology have typically examined several variables related to a neurotransmitter system that has been postulated to be altered or dysfunctional. Increased knowledge of pathophysiology and etiology should lead directly to the development of more sensitive and specific marker and the use of new, rational interventions.

## Neurotransmitter Systems

A number of neurotransmitter systems have been hypothesized to be involved in childhood psychiatric disorders (Cohen and Young, 1977; Rasmussen et al., 1990; Rogness et al., 1992; Young et al., 1983, 1984). Most extensively studied have been the three monoamine transmitters, serotonin (5-hydroxytryptamine, or 5-HT), dopamine (DA), and norepinephrine (NE). Other systems studied include opioid peptides, g-aminobutyric acid (GABA), and acetylcholine (ACh). The emphasis on monoamines has been a result of both the importance of these systems in mediating behavioral phenomena and the marked effects of pharmacologic agents known to affect monoamine functioning.

The metabolism of serotonin (5-HT) is depicted in Fig. 4.2. Serotonin is produced after hydroxylation and decarboxylation of the essential amino acid tryptophan. Cell bodies of 5-HT-containing neurons are located in the raphe nuclei of the hindbrain and project to nearly all areas of the central nervous system (Green, 1988; Iverson and Iverson, 1981; Jacobs and Azmitia, 1992). Interest in central 5-HT functioning derives from 5-HT's important role in processes as diverse and important as sleep, mood, appetite, perception, and hormone secretion (Lucki, 1998), as well as its critical role in neurodevelopment (Lauder et al., 1995; Rubenstein, 1998). A schematic diagram of a serotonergic neuron is shown in Fig. 4.3. Serotonin produced from tryptophan (TRP), can be taken up by the vesicular monoamine transporter (VMAT2) and stored in vesicles for subsequent release or metabolized by the mitochondrial enzyme monoamine oxidase (MAO). Once released, 5-HT can interact with presynaptic or postsynaptic receptors, diffuse to extrasynaptic sites, or be taken up by neuronal or glial membrane 5-HT transporters (5-HTTs). Blockade of the 5-HTT by selective serotonin reuptake inhibitors, such as fluoxetine (Prozac), results in higher levels of synaptic and extracellular fluid 5-HT and leads to greater 5-HT receptor stimulation.

Figure 4.2. Synthesis and catabolism of the indoleamine neurotransmitter serotonin (5-HT).

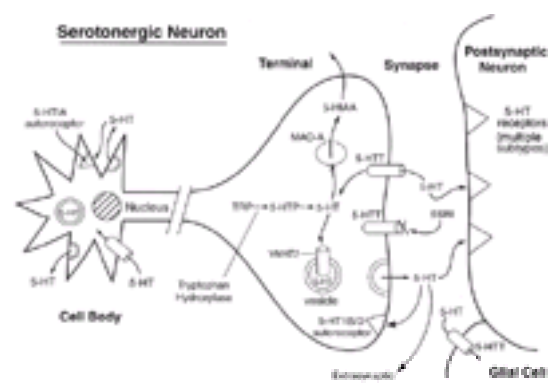

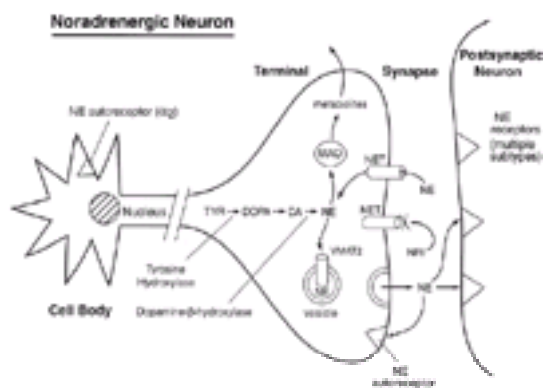

Figure 4.3. Diagrammatic illustration of a serotonergic neuron. Serotonin (5-HT) synthesized from tryptophan (TRP) by the rate-limiting enzyme tryptophan hydroxylase, can be taken up by the vesicular monoamine transporter (VMAT2) and stored in vesicles for subsequent release or metabolized by the mitochondrial enzyme monoamine oxidase. Released 5-HT can interact with presynaptic or postsynaptic receptors, diffuse to extrasynaptic sites, or be taken up by neuronal or glial membrane 5-HT transporters (5-HTTs). Inhibition of the 5-HTT by selective serotonin reuptake inhibitors (SSRIs) results in higher levels of synaptic and extracellular fluid 5-HT, leading to greater 5-HT receptor stimulation.

The metabolism of the catecholamines NE and DA is shown in Fig. 4.4. DA is synthesized from tyrosine, after hydroxylation and decarboxylation, and is found in highest concentration in the midbrain, although extensive cortical projections also occur. DA has been shown to be critical in reward, modulating movement, and cognition (Iverson and Alpert, 1982; Moore and Bloom, 1978; Randrup and Munkvad, 1974). NE is produced from DA by the action of the enzyme dopamine- $\beta$ -hydroxylase (DBH). Nearly all NE-containing neurons project from the locus ceruleus and innervate midbrain and cortical areas. A noradrenergic neuron is depicted in Fig. 4.5. The vesicular and membrane uptake, metabolic, and release processes present in serotonergic neurons have direct counterparts in noradrenergic and dopaminergic neurons. Major differences concern the membrane transporters (norepinephrine transporter, NET; dopamine transporter; or the 5-HTT) and types of presynaptic and postsynaptic receptors present. The three monoamine systems are highly functionally interrelated, making direct connections with one another; often, also, simultaneously modulating other transmitter systems.

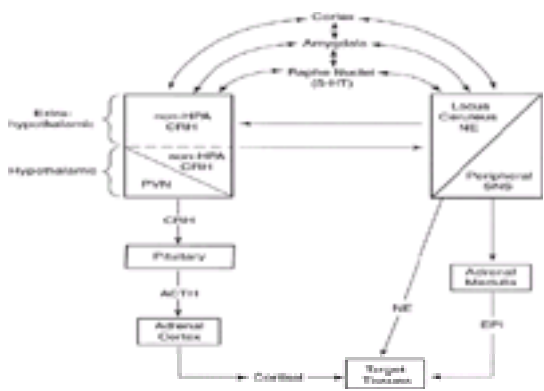

**Figure 4.4.** Synthesis and catabolism of the catecholamine neurotransmitters dopamine, norepinephrine, and epinephrine.

**Figure 4.5.** Diagrammatic illustration of a noradrenergic neuron. Norepinephrine (NE) synthesized from tyrosine by the rate limiting enzyme tyrosine hydroxylase, can be taken up by the vesicular monoamine transporter (VMAT2) and stored in vesicles for subsequent release or metabolized by the mitochondrial enzyme monoamine oxidase. Released NE can interact with presynaptic or postsynaptic receptor. Inhibition of the norepinephrine transporter (NET) by NE reuptake inhibitors (NRI) results in higher levels of synaptic and extracellular fluid of NE and leads to greater NE receptor stimulation.

Stress responses, central and peripheral arousal, and learning and memory are all critically modulated by noradrenergic neurons ( [Amaral and Sinnamon, 1977](#); [Arnsten, 1997](#); [Aston-Jones et al., 1991](#); [Iverson and Iverson, 1981](#)). The critical role of the noradrenergic system in the stress response is shown in [Fig. 4.6](#). The extensive interaction of the central/peripheral NE system with the hypothalamic-pituitary-adrenal (HPA) axis is evident and is summarized in the review of [Chrousos and Gold \(1992\)](#).

**Figure 4.6.** Diagram of the two major components of the stress response system: the central noradrenergic/sympathoadrenomedullary system and the hypothalamic-pituitary-adrenal (HPA) axis. The extensive interaction of the central/peripheral norepinephrine systems with the HPA axis is evident. Not shown are the extensive hormonal and neuronal inputs and feedback occurring from the periphery to the central nervous system.

## Methodologies of Neurochemical Research

The strategies employed in neurochemical research can be grouped into three areas: (a) measurement of neurotransmitters and their metabolites; (b) measurement of neurotransmitter-related enzymes; and (c) measurement of neurotransmitter receptors (number, affinity, and functioning). The neurotransmitters and their metabolites have been measured in postmortem (PM) brain tissue, cerebrospinal fluid (CSF), plasma and blood elements, and urine. Enzymes have been determined in the brain, CSF, and blood, whereas receptor measurements have been carried out with brain and blood specimens. Other biological research has included neuroendocrine studies, typically measuring blood hormone concentrations after administration of challenge agents, as well as brain-imaging studies employing computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and single-photon emission computed tomography (SPECT) to examine neuroanatomic structure, blood flow, and receptor binding. With all approaches, a critical issue is to what extent the measure provides information about the central neurotransmitter system of interest. Even when measurements are made on brain tissue itself, the relationship to neuronal functioning can be tenuous. This issue becomes even more problematic when measurements are made in peripheral fluids and tissue. The degree of correlation between a particular measure and central neurotransmitter functioning is difficult to judge and depends on the specific measure and system under study.

### POSTMORTEM BRAIN

Analysis of postmortem (PM) brain tissue allows the most direct access to the systems of interest. One can measure levels of neurotransmitters, their precursors and metabolites, associated enzymes (both synthetic and catabolic), reuptake sites, and presynaptic and postsynaptic receptor sites. This approach has been extensively employed in the study of neuropsychiatric disorders, including Alzheimer's disease, Parkinson's disease, Huntington's disease, schizophrenia, suicide, and depression ([Arai et al., 1984](#); [Bunney et al., 1997](#); [Gross-Isseroff et al., 1998](#); [Korpi et al., 1986](#); [Lee et al., 1978](#)). The anatomic resolution and the wide range of neurotransmitter-related analytes have made PM studies of paramount importance. Yet there are some disadvantages inherent in this approach, including PM degradation, subject recruitment, control matching, and the fundamental limitation arising from an inability to measure functionality ([Perry and Perry, 1983](#)).

### CEREBROSPINAL FLUID

Measurements of transmitters, metabolites, and enzymes in CSF have been considered to be the next best thing to PM analyses when attempting to assess central systems. Although a number of the compounds measured in CSF are derived predominantly from the brain, other analytes are thought to originate from spinal cord metabolism or to diffuse into the CSF from the blood ([Garelis et al., 1974](#)). Even when compounds are solely of brain origin, lumbar CSF concentrations are affected by clearance rates. The greatest limitation of CSF measures is their failure to provide information regarding anatomic localization. A resultant practical shortcoming is that only global or marked changes in brain neurochemistry are detected.

The DA metabolite homovanillic acid (HVA) has been extensively assayed in CSF and is probably substantially derived from the brain metabolism of DA ([Elchisak et al., 1978](#); [Elsworth et al., 1987](#); [Garelis et al., 1974](#); [Sourkes, 1973](#)). However, CSF levels of NE and the NE metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG) appear to primarily reflect NE metabolism in the spinal cord ([Kopin et al., 1983](#); [Ziegler et al., 1977](#)). Similarly, the 5-HT metabolite 5-hydroxyindoleacetic acid (5-HIAA) is apparently predominantly of spinal cord origin ([Bulat, 1977](#); [Moir et al., 1970](#); [Weir et al., 1973](#)). Recent studies of 5-HT in nonhuman primate cisternal CSF indicate that this measure may provide an alternative, improved route to assessing central 5-HT function. It is often unclear to what extent peptides and amino acids measured in lumbar CSF reflect brain, spinal cord, and peripheral metabolism.

### BLOOD AND URINE

Measurements of monoamine metabolites in blood and urine have been performed widely; however, the issue of peripheral versus central contribution is problematic. It is clear that the vast majority of plasma and urine 5-HIAA is of peripheral origin, arising from the catabolism of 5-HT produced in the enterochromaffin cells of the intestine ([Udenfriend et al., 1956](#)). This has limited the utility of measurements of blood and urine 5-HIAA levels to those situations where the rate of gut 5-HT

synthesis is of interest. Urine 5-HT has been rarely measured because it too probably reflects only gut synthesis of 5-HT. Blood levels of 5-HT have been more frequently studied because of 5-HT's localization in platelets. Similarities between platelet and neuronal uptake, storage, and release of 5-HT have made the platelet of special interest ([DePrada et al., 1988](#); [Pletscher, 1988](#); [Sneddon, 1973](#)). Findings in autism have further stimulated research in the area.

Plasma and urine HVA concentrations have been widely determined in an attempt to assess central DA functioning ([Bowers, 1991](#)). A number of studies have attempted to ascertain the central contribution to plasma (and urine) levels. Known sources of peripheral DA and HVA include the sympathetic nervous system, adrenal glands, and kidney. When peripheral DA synthesis and metabolism are inhibited with debrisoquin, a peripherally acting MAO inhibitor and neuronal blocker, plasma and urine HVA levels decrease to about 50% of baseline, indicating that at least half of the measured HVA originates in the periphery ([Maas et al., 1985](#); [Riddle et al., 1986](#)). Changes in the norepinephrine metabolite MHPG after debrisoquin administration are even more marked, indicating that less than 25% of plasma or urine MHPG is of central origin ([Kopin et al., 1988](#)). Investigators have also measured plasma and urine levels of the catecholamines themselves. It is clear that all plasma and urine NE arises from the adrenal glands and sympathetic nervous system. However, the tight coupling between the central norepinephrine neurons and the sympathetic nervous system suggests that plasma and urine NE might still be useful indices of central noradrenergic functioning. At the least, measurements of NE and related compounds appear to offer a useful index of sympathetic functioning. It is even clearer that measurement of epinephrine (EPI) in blood and urine offers an unambiguous reflection of adrenomedullary activity. Unfortunately, clearance and catabolism affect the measured levels of the monoamines and their metabolites. Urine measurements can actually offer advantages in that differences in clearance are less a problem than with plasma. Urine samples can be more easily obtained, although it is difficult to observe acute (<1- or 2-hour) changes.

Several monoamine-related enzymes have been measured in blood specimens. These include MAO B in platelets, catecholamine-O-methyltransferase in red blood cells, and dopamine-β-hydroxylase (DBH) in serum. Genetic influences on the enzymes have been recently described, making the measures of greater interest. This appears to be especially the case for DBH, with a recent report indicating that more than 50% of the population variance in serum DBH activity can be explained on the basis of a specific promoter polymorphism (-1021C>T). The virtual absence of serum DBH activity in individuals homozygous for the lower frequency -1021T allele is reflective of the highly functional nature of the polymorphism ([Zabetian et al., 2001](#)).

Neurochemical analyses of blood and urine have been made both in unperturbed (baseline) situations and after administration of centrally acting agents; the latter approach often bears a strong resemblance to neuroendocrine challenge studies. These neuroendocrine studies have attempted to assess central 5-HT, DA, NE, and opioid functioning by determining plasma levels of growth hormone, prolactin, cortisol, and other hormones. Hormone levels are determined after administration of challenge agents that are meant to selectively stimulate specific central neurotransmitter receptors. A number of factors tend to confound the neuroendocrine approach, including pulsatile and fluctuating release, poor specificity of the challenge agents, and the difficulty in relating findings in the hypothalamus, pituitary, or adrenal gland (or thyroid gland) to etiology.

The numbers and affinities of a range of neurotransmitter receptors have been measured in blood elements. Platelet serotonergic (5-HT<sub>2</sub>) and adrenergic (α<sub>2</sub>) receptors, platelet 5-HT uptake sites (imipramine-binding sites), and white blood cell adrenergic (β) receptor sites have been measured using radioactively labeled ligands. The measurement of receptor function has been less prevalent, although a host of studies have examined the platelet uptake of tritiated 5-HT and binding of reuptake inhibitors ([Owens and Nemeroff, 1994](#)).

## NEUROCHEMICAL RESEARCH IN CHILD PSYCHIATRY

In the following sections, neurochemical research on neurotransmitter ontogeny and the relatively common childhood psychiatric disorders of autism, Tourette syndrome (TS), and attention deficit hyperactivity disorder (ADHD) are considered in detail. The reader is also referred to the individual chapters on these disorders and to reviews of the substantial neurochemical and neuroendocrine research carried out in other childhood disorders. These latter areas include studies of childhood depression ([Ryan and Dahl, 1993](#)), anxiety ([Foote, 1999](#); [Pine, 1999](#)), and the effects of trauma ([Kaufman and Charney, 1999](#); [Pynoos et al., 1999](#)). Neurochemical research in these areas has been extensive and the recent studies demonstrate a movement toward a more symptom-based, multiperspective, and genetic approach. Although neuroendocrinology has been a large part of child biological psychiatry, this area is not a focus of our chapter.

### Neurochemistry of Normal Development

Many recent exciting advances have led to a better picture of neuronal development, both at the cellular level and in relation to cell-cell interactions and complex circuit assembly. Animal studies have examined the ontogeny of neurotransmitter synthesis, storage, release, and uptake, as well as receptor number, affinity, and coupling. Work on the developing primate brain has been most informative as to what changes may be occurring during different periods of childhood ([Kandel and Schwartz, 1981](#); [Purves and Litchman, 1986](#); [Rakic, 1988](#); [Shepherd, 1983](#)).

Studies of neurotransmitter ontogeny in psychiatrically normal children have predominantly dealt with the measurement of neurotransmitters, metabolites, and associated enzymes in CSF, blood, and urine. These studies have helped to establish normative ranges for contrasting with values seen in neuropsychiatric disorders and have also served to point out periods of change and allow the validity of animal models to be assessed.

A large study of CSF monoamine precursors and metabolites in children treated for leukemia found large decreases in HVA and 5-HIAA over childhood and adolescence. Mean values for HVA in subjects ages 2 to 5, 6 to 11, and 12 to 17 years decreased from 92 to 62 to 44 ng/mL, respectively, whereas 5-HIAA declined from 30 to 21 to 17 ng/mL, respectively. Changes in the precursors were substantially less. The multiple lumbar punctures performed allowed an estimation of mean intraindividual variation of 20% to 25% to be made ([Riddle et al., 1986](#)). The ontogenetic declines in HVA and 5-HIAA levels also have been observed in developing (12- to 42-day-old) rat pups. Changes in rat CSF metabolite levels tended to parallel declining brain metabolite levels, whereas levels of total brain monoamine levels (DA and 5-HT) increased ([Shaywitz et al., 1985](#)). Studies of CSF metabolite ontogeny in humans have been extended to the neonatal period, where even higher levels of 5-HIAA, HVA, tryptophan, and tyrosine are seen ([Anderson et al., 1985](#)). Mean levels of 5-HIAA and HVA in newborns were 143 and 184 ng/mL, respectively, substantially higher than in the 2- to 5-year-old period. Neonatal levels of MHPG were also significantly higher (27 ng/mL) than those seen in 2- to 5-year-olds, although unlike 5-HIAA and HVA, MHPG levels did not decline further after the period of 2 to 5 years of age. Another compound with an early, rapid maturational decline is the other acidic DA metabolite 3,4-dihydrophenylacetic acid (DOPAC) ([Anderson et al., 1988](#)). Although the causes of the maturational declines are not clear, the dissociation between the ontogenies of DOPAC (with its early, rapid decline) and HVA (with its more gradual decline) indicate that acid transport and clearance changes are not major determinants.

These studies of normal neurochemical ontogeny provide a context when examining levels seen in childhood disorders and after neonatal drug exposure. In studies of CSF levels of monoamine and metabolites in neonates exposed prenatally to cocaine, significantly lower levels of the dopamine metabolite HVA were seen in the exposed infants ([Needman et al., 1993](#)). Further studies are needed to see whether this decrease persists over the first months and years of life. A short-lasting decrease simply may be due to an acute pharmacologic effect; longer lasting reductions in HVA probably are a result of reductions in DA innervation.

Blood concentrations and urinary excretion rates of the catecholamines and their metabolites are generally observed to decline over childhood ([Dalmaz and Peyrin, 1982](#); [Gitlow et al., 1968](#)). This apparently is due both to decreasing synthesis and increasing activity of the catabolic enzymes MAO and catechol-O-methyltransferase (COMT) ([Young et al., 1984](#)). It is not clear whether the decreasing synthesis corresponds to decreasing functional release. Definite statements about relative central and peripheral contributions to plasma or urine catecholamine metabolite levels cannot be made, although the situation in childhood does not appear to be more favorable than in adulthood. Blood levels of 5-HT have been observed to decrease with age; however, most of this effect appears to occur at puberty ([McBride et al., 1998](#)). This suggests that platelet uptake and storage of 5-HT are fully developed in early childhood. In recent studies, platelet 5-HT levels in nursing infants have been used to index the extent of transporter blockade occurring after exposure to selective serotonin reuptake inhibitors (SSRIs) through breast milk ([Epperson et al., 1997](#)). The decline in levels seen after SSRI administration reflects the reduction in transporter activity because all 5-HT in the platelet is accumulated by uptake.

### Attention Deficit Hyperactivity Disorder

The symptomatology of attention deficit hyperactivity disorder (ADHD) includes inattention, distractibility, and impulsivity, with or without hyperactivity ([Carey, 1988](#); [Shaywitz and Shaywitz, 1982, 1992](#)) ([Chapter 52](#)). Early work focused on the presence of this behavioral pattern in children who had suffered from encephalitis or brain damage. Although the idea that there existed some sort of minimal brain damage (MBD) led to the use of MBD as a diagnostic category, no consistent or specific abnormality was demonstrated. The behavioral sequelae of encephalitis along with the remarkable effects of stimulants on ADHD children have led to a long-standing and continuing interest in the role of DA. Family and twin studies have strongly supported the idea that there are inherited components to the disorder

([Hewitt et al., 1997](#); [Levy et al., 1997](#); [Pauls et al., 1983](#); [Thapar et al., 1999](#)).

A great number of neurobiological studies have been carried out; the majority involves the measurement of neurotransmitter metabolites in blood and urine, either at baseline or after pharmacological perturbation ([Zametkin and Rapoport, 1987a](#)). Several neuroendocrine challenges have been performed, whereas there are only a limited number of studies involving receptor assessment ([Hunt et al., 1982](#); [Shekim et al., 1994](#)). An increasing number of brain-imaging studies have been reported ([Castellanos, 1996](#); [Hendren et al., 2000](#); [Schweitzer et al., 2000](#)) ([Chapter 9](#)). These studies have tended to focus attention on the frontal cortex and midbrain DA nuclei and their projection areas.

#### DOPAMINE

The simplest of the catecholamines has been extensively studied in ADHD; much of the work has been prompted by neuropharmacologic observations. Neuroimaging studies, the development of animal models ([Lipton et al., 1980](#); [Shaywitz et al., 1976](#)), and the recent replicated genetic investigations indicating an association with ADHD symptomatology and alleles of the dopamine transporter and D4 DA receptor genes ([Anderson and Cook, 2000](#)), have further increased interest in DA. Although the ameliorative effects of the stimulants methylphenidate, amphetamine, and pemoline have strongly implicated DA, the stimulants are known to also affect norepinephrine and epinephrine. The hypodopaminergic hypothesis also has been questioned because of the relatively benign or slightly beneficial effects of DA blockers.

Although the neurochemical evidence is extensive, it fails to conclusively support a role for DA involvement ([Zametkin and Rapoport, 1987a](#)). The limited CSF data suggest a possible lowering of HVA in ADHD. Baseline measurements of HVA in plasma and urine, and DA in urine have not revealed differences between ADHD and control subjects. Platelet levels of MAO activity are unchanged or decreased in ADHD, whereas serum DBH was similar in ADHD and control subjects. Urine or plasma levels of DA and HVA also have been measured after administration of stimulants or tricyclic antidepressants with no clear group differences emerging. Neuroendocrine studies in ADHD are limited and provide no definite information regarding possible group differences.

#### NOREPINEPHRINE AND EPINEPHRINE

Arousal mechanisms almost certainly play an important part in symptoms of hyperactivity, impulsivity, distractibility, and inattention ([Halperin et al., 1997](#); [McMahon, 1984](#); [Oades, 1987](#); [Ornitz et al., 1997](#); [Satterfield et al., 1974](#)). The crucial role of the central noradrenergic system and sympathetic nervous system (SNS) in regulating arousal, together with noradrenergic effects of stimulant medication, has led to hypotheses of noradrenergic involvement in ADHD ([Hunt et al., 1984](#); [Mefford and Potter, 1989](#); [Mikkelsen et al., 1981](#); [Pliszka et al., 1996](#); [Shekim et al., 1979](#); [Snyder and Meyerhoff, 1973](#)). Treatment studies employing the noradrenergic-specific agents clonidine and guanfacine, as well as an increasing appreciation of the role of central NE in attention and cognition ([Arnsten, 1997](#); [Arnsten et al., 1996](#); [Aston-Jones et al., 1991](#); [Williams and McGaugh, 1993](#)), have served to maintain interest in the role of NE in the symptoms of AD/HD.

Baseline measurements of NE in serum and MHPG in plasma have not revealed differences between ADHD and control subjects. The data with respect to MHPG and NE in urine are less consistent, with MHPG excretion, for instance, decreased, unchanged, or increased in ADHD ([Baker et al., 1993](#); [Zametkin and Rapoport, 1987a](#)). Platelet  $\alpha_2$ -adrenergic receptors are reported to be lower in ADHD ([Shekim et al., 1994](#)); as mentioned, serum levels of the NE synthetic enzyme DBH was similar in ADHD and control subjects. Urine or plasma levels of NE and MHPG also have been measured after administration of stimulants or tricyclic antidepressants. Although neurochemical changes are observed after the drug treatment (e.g., lowered MHPG with desipramine, increased NE with yohimbine), no conclusive differences in neurochemical response to the agents have been shown between ADHD and control subjects.

Research establishing a positive association between classroom performance and epinephrine (EPI) excretion ([Frankenhaeuser, 1971](#)), along with reports of stimulant-induced EPI release and long-standing observations of cognitive enhancing effects of systemically administered EPI ([Frankenhaeuser and Jarpe, 1963](#); [Williams and McGaugh, 1993](#)) suggest a possible role for EPI in attention. Several reviews have discussed how altered interaction of the adrenergic and noradrenergic systems might contribute to symptoms of ADHD ([McCracken, 1991](#); [Mefford and Potter, 1989](#); [Pliszka et al., 1996](#)). Although studies of baseline EPI excretion have not found differences between ADHD and control groups, three studies ([Anderson et al., 2000](#); [Hanna et al., 1996](#); [Pliszka et al., 1994](#)) have found substantially lower rates of EPI excretion during cognitive testing in ADHD patients compared to normal controls. In studies examining the effects of amphetamine or methylphenidate in patients with ADHD, both drugs increased EPI excretion, but relatively smaller adrenomedullary responses were seen in patients compared to controls following acute ([Rapoport et al., 1978](#)) or chronic ([Elia et al., 1990](#)) dosing. A similar reduced adrenomedullary response was observed in children with ADHD during hypoglycemic challenge when plasma levels of epinephrine were measured. Thus, the finding of a blunted epinephrine response in ADHD has been seen consistently across a number of situations. In the most recent study ([Anderson et al., 2000](#)), the blunted response appeared to be specific to the inattention component or domain of ADHD. Further work in this area appears warranted: It would not be surprising if genetically determined variations in the functioning of each of the catecholamines contributed some part to one or more of the component behaviors of ADHD.

#### SEROTONIN

Interest in a role for serotonin (5-HT) in ADHD was stimulated by early reports of decreased platelet 5-HT in affected children. Subsequent studies have not replicated this finding and have found normal levels of platelet and urine 5-HIAA ([Zametkin and Rapoport, 1987a](#)), as well as normal numbers and affinities of platelet imipramine-binding sites in ADHD subjects ([Weizman et al., 1988](#)). In addition, studies of CSF 5-HIAA have not found differences between ADHD and control subjects. On the whole, the neurochemical research and the minimal treatment response to serotonergic agents have made it seem less likely that a 5-HT alteration is etiologic. Even so, it appears that the role of 5-HT in disruptive behaviors, particularly with respect to impulse control, deserves further consideration ([Anderson, 1993](#); [Zubieta and Alessi, 1993](#)).

#### Autism

Autism is a pervasive developmental disorder with disturbances in social relations, language, and communication ([Cohen and Volkmar, 1997](#); [Waterhouse et al., 1996](#)). The three monoamine transmitters have been extensively studied in autistic children, and some work has also been carried out in relation to the opioid transmitters ([Anderson and Hoshino, 1997](#); [Cook et al., 1990](#); [Lotspeich and Ciaranello, 1993](#)).

#### NOREPINEPHRINE AND EPINEPHRINE

As one of the two major components of the stress response system ([Chrousos and Gold, 1992](#)), the sympathetic/adrenomedullary system has been of interest in autism owing to the hyperarousal, hyperactivity, and overreaction to novel situations often seen in autism. It should be mentioned that the HPA axis, the other major component of the stress response ([Fig. 4.6](#)), has also been well studied in autism. However, these neuroendocrinologic studies are reviewed elsewhere ([Tordjman et al., 1997](#)). The functioning of the sympathetic/adrenomedullary system has been assessed through measurements of norepinephrine (NE) and epinephrine (EPI) in plasma or urine. In addition, plasma and urine levels of the major NE metabolites, 3-methoxy-4-hydroxyphenylethylglycol (MHPG) and vanillylmandelic acid (VMA) have been determined. Serum levels of dopamine- $\beta$ -hydroxylase—the synthetic enzyme secreted along with NE from sympathetic neurons—also have been studied ([Anderson and Hoshino, 1997](#); [Minderaa et al., 1994](#)).

The results of the studies examining these neurochemical indices of sympathetic/adrenomedullary system functioning are summarized in [Table 4.1](#). The urine measures reflect basal functioning because of the absence of a stressful situation involved in the collection of the sample and owing to the long-term nature of the collection. Plasma levels of MHPG and VMA are basal indices because of their slow response to perturbation, a consequence of their long plasma half-lives. In contrast, plasma NE and the vascular measures respond very quickly to stressful situations. When considered in this fashion, it can be seen that the results are actually fairly consistent. Thus, in nearly all cases, indices that reflect basal functioning of the sympathetic/adrenomedullary system were found to be normal in patients with autism. On the other hand, most of the studies measuring indices of acute stress response have found elevations in patients with autism when they are exposed to the stress of a venipuncture or neuropsychological test. Taken together, the data support the idea that stress response systems are hyperresponsive when individuals with autism are stressed, but that autistic patients are not in a chronic state of hyperarousal. Findings from studies of HPA axis function are consistent with the sympathetic/adrenomedullary results, and support the same conclusions.

Measures of Basal Functioning		
Measure	Finding	Reference
Urine NE	Normal	Loucky et al., 1987; Marinneau et al., 1982; Minderaca et al., 1994
	Decreased	Young et al., 1978
	Increased	Batholomy et al., 1988
Urine EP	Normal	Minderaca et al., 1994
Urine MHPG	Normal	Loucky et al., 1987; Minderaca et al., 1994
	Decreased	Batholomy et al., 1988; Young et al., 1978
Urine VMA	Normal	Minderaca et al., 1994
Plasma MHPG	Normal	Minderaca et al., 1994; Young et al., 1981
Serum DHP	Normal	Lake et al., 1972; Young et al., 1980
CSF AHPA	Normal	Gilberg and Sorenstam, 1987; Young et al., 1981

Measures of Acute Response		
Measure	Finding	Reference
Plasma NE	Increased	Cook et al., 1990; Lake et al., 1977; Loboyer et al., 1992; Loventhal et al., 1990
BP/heart rate	Increased	Koolt and Cohen, 1981; Tordman, 1999

**Table 4.1. Sympathetic/Adrenomedullary Functioning in Autism**

The apparent increased response to stressors could result from a difference in the level of perceived stress, an over elicitation of the physiologic response, or an abnormality in the stress response systems themselves. It will be difficult to determine whether the individual with autism experiences a greater threat, if the response to the threat is less well regulated, or both. Despite the difficulties encountered in stress response research in autism, further research in this area is warranted, given the clinical relevance and possible etiologic nature of alterations in this area.

#### DOPAMINE

A case for altered DA functioning in autism can be made, based on its clear role in mediating motoric disturbances (e.g., stereotypies) and the observation that DA blockers are effective in treating some aspects of autism. The majority of relevant neurochemical studies have examined levels of HVA (Anderson and Hoshino, 1997). The concentration of HVA in CSF has been reported to be slightly decreased, apparently normal, or significantly (approximately 50%) increased in autism. The most recent study, using controls selected from patients undergoing myelography, did not find any difference between autistic and control subjects (Narayan t al., 1993). Measurements of HVA in urine have been in disagreement, with some groups reporting increased excretion and others reporting normal excretion in autism. The only study of plasma HVA reported similar levels in autistic and control subjects (Minderaca et al., 1989). Other relevant measures include urinary DA, reportedly normal in autism, and plasma prolactin, which also has been reported to be normal in autistic subjects (McBride et al., 1989; Minderaca et al., 1989). To summarize, the majority of studies report normal DA metabolism and normal baseline levels of prolactin, a hormone under strong inhibitory control by the tuberoinfundibular DA system. The bulk of the studies suggest that central dopaminergic functioning, to the extent it can be assessed by the measures employed, is normal in autism.

#### SEROTONIN

Initial interest in a role for 5-HT in autism stemmed in part from the powerful effects of serotonergic agents, such as lysergic acid diethylamide, on perception. Research in the area was further stimulated by, and has continued to evolve around, the early studies of Freedman of elevated 5-HT in blood of autistic children (Hanley et al., 1977; Schain and Freedman, 1961). Reports of the presence of 5-HT receptor antibodies in the CSF of autistic patients (Todd and Ciaranello, 1985), of beneficial effects of treatment with serotonin reuptake inhibitors (Cook et al., 1992; Gordon et al., 1993; McDougale et al., 1996a) and with the serotonergic agent fenfluramine (Campbell, 1988; Ritvo et al., 1986), and exacerbation observed after depletion (McDougale et al., 1996b) have also heightened interest in the role of 5-HT in autism. It should be pointed out that careful follow-up studies did not replicate either the autoantibody finding (Yuwiler et al., 1992) or the early reports of fenfluramine's benefits (Leventhal et al., 1993; Stern et al., 1990; Varley and Holm, 1990).

Although most of the 5-HT-related research has focused on the hyperserotonemia of autism, a number of studies of CSF 5-HIAA and several neuroendocrinologic studies of central 5-HT functioning have been reported (Anderson, 1987; Anderson and Hoshino, 1997). CSF studies are in general agreement that few or no differences exist between autistic and control groups' mean levels of 5-HIAA (Anderson, 1994). Neuroendocrine challenge studies have measured growth hormone and prolactin after administration of fenfluramine (McBride et al., 1989), the 5-HT<sub>1B/D</sub> receptor agonist sumatriptan (Novotny et al., 2000) or the 5-HT precursor 5-hydroxytryptophan (5-HTP) (Hoshino, personal communication). The fenfluramine and 5-HTP studies both observed a lowering or blunting of the prolactin response, whereas sumatriptan produced an elevated growth hormone response in autism. The data are not definitive, but they are consistent with decreased central presynaptic 5-HT<sub>2</sub> functioning in autism.

The bulk of the 5-HT-related studies deal with the characterization or elucidation of the hyperserotonemia of autism (Anderson et al., 1990). The basic finding of elevated platelet 5-HT is robust and well replicated. Increased levels are observed regardless of whether concentrations are expressed as amount per volume of blood (e.g., nanograms per milliliter) or as amount per number of platelets (nanograms per 10<sup>9</sup> platelets); in addition, platelet counts and size distribution have been reported to be normal in autism. Although the basic finding of a group mean increase in autistic subjects is well established, the magnitude of the increase is not clear. Recent research has indicated that substantial racial and pubertal effects exist; when these were accounted for a group mean increase of 25% was observed (McBride et al., 1998). The relationship of blood 5-HT to the behavioral aspects of autism and the distribution of the measure in the autistic group are also not clear. Serotonin levels have not been consistently correlated with degree of mental retardation (MR) or other symptomatology, and recent studies have not found an increase in the MR group. In groups of unmedicated autistic individuals, the distribution of blood 5-HT levels appears Gaussian, suggesting that the group mean increase was not caused by a subgroup of hyperserotonemic individuals; however, the possibility of a multimodal distribution cannot be ruled out, given the size of the groups examined.

The typical group mean increase observed in 5-HT is relatively robust (effect size ~1); however, the large degree of overlap with the normal population has prevented the use of blood 5-HT levels in screening or diagnosis of autism. Numerous investigators have been intrigued, nonetheless, by the possibility of discovering the cause(s) of the elevation (Anderson et al., 1990; Cook, 1990; Hanley et al., 1977; Young et al., 1982; Yuwiler et al., 1985). It has been hoped that understanding the mechanism of hyperserotonemia would lead to the development of more specific and useful markers, elucidation of the CNS abnormality, and useful approaches to the treatment of the condition.

Two main possibilities have been considered as potential causes of the hyperserotonemia: (a) increased exposure of the platelets to free 5-HT as a result of either decreased catabolism or increased synthesis of 5-HT and (b) altered platelet handling of 5-HT. The issue of decreased catabolism of 5-HT has been examined by measuring platelet MAO activity and monoamine substrates and metabolites. These studies have strongly suggested that MAO activity, and hence 5-HT catabolism, is not altered in autism (Anderson, 1990). The normal excretion rates observed for 5-HIAA in autistic subjects in most, but not all, studies also strongly indicate that 5-HT synthesis is not increased in autism.

Although these data strongly suggest that 5-HT metabolism is unaltered in autism, they do not definitely indicate whether or not the circulating platelet is exposed to increased levels of 5-HT. This issue can be addressed most directly by determining plasma free levels of 5-HT. When high-performance liquid chromatography (HPLC) was used to determine platelet-poor plasma 5-HT levels in autistic subjects, the levels were similar to those seen in normal controls (Cook et al., 1988). Urinary excretion rates for 5-HT in autistic subjects also have been measured, and the group mean was found to be similar to or slightly lower than that seen for normal subjects (Anderson et al., 1989). These measures of plasma and urine 5-HT levels, as well as the evidence regarding 5-HT metabolism, indicate that the platelet is not exposed to increased concentrations of 5-HT. This, in turn, strongly implies that the platelet's handling of 5-HT is altered in autism.

Accumulated evidence warrants focusing research on platelet uptake, storage, and release of 5-HT. Despite work in a number of laboratories, no consensus has been reached concerning relative rates of 5-HT uptake by platelets from autistic and normal subjects (Anderson et al., 1990). The studies have been more consistent in not finding differences in the affinities for uptake in the two groups. Group differences also were not seen when researchers examined the number ( $B_{max}$ ) and affinity ( $K_d$ ) of 5-HT transporter binding sites in autistic and normal individuals (Anderson et al., 1984; Weizman et al., 1987). The question of altered efflux has been studied in some detail after an initial report indicated that platelets from autistic subjects have a greater efflux of preloaded tritiated 5-HT during *in vitro* incubation. In a multicenter study, the consensus was that autistic and normal groups had similar mean efflux rates (Boullin et al., 1982). McBride and associates (1989) examined the 5-HT<sub>2</sub> receptor-mediated augmentation of adenosine diphosphate (ADP)-induced platelet aggregation and found lower 5-HT augmentation in the autistic group than in the normal subjects. In addition to the blunted augmentation response, the autistic group had lower numbers ( $B_{max}$ ) of 5-HT<sub>2</sub> receptors detected by iodinated-LSD binding. Recent investigations examining the possible role of the 5-HT transporter gene in affecting risk to, or expression of, autism have stimulated interest in the role of the transporter in the hyperserotonemia. It now appears that although the promoter polymorphism in the 5-HT transporter gene probably does not influence risk to

autism, it may affect severity in certain behavioral domains. It also seems unlikely to contribute substantially to the hyperserotonemia of autism given the allele frequencies and functional effects observed ([Cook et al., 1997](#); [Klauck et al., 1997](#); [Tordjman et al., 1998, 2001](#)).

#### OTHER STUDIES

Although there has been considerable speculation regarding a role for opioid peptides in autism and related behaviors ([Chamberlain and Herman, 1990](#); [Panksepp et al., 1980](#)), studies of plasma levels of the opioid peptide b-endorphin (BE) do not bear on the issue of central opioids ([Anderson and Hoshino, 1997](#); [Sandman, 1992](#)) and treatment studies with opioid antagonists are not conclusive. It should be pointed out that plasma BE is not centrally derived and the measure actually appears to be highly reflective of HPA axis activity ([Tordjman et al., 1997](#)). Two studies of CSF endorphins have found increased levels of the compounds in the CSF of autistic individuals ([Gillberg et al., 1985](#); [Ross et al., 1985](#)); however, this research has not been replicated to date.

Imaging studies have reported a number of intriguing findings in at least a portion of autistic subjects ([Chugani, 2000](#); [Chugani et al., 1999](#); [Hendren et al., 2000](#)), and neuropathologic studies have found changes in the limbic system and cerebellum ([Bauman and Kemper, 1984](#); [Ritvo et al., 1986](#)). These brain studies, along with the neurochemical research, will help to direct experiments using PM brain tissue. The recent availability of PM specimens from individuals with autism, made possible through the dedicated efforts of Margaret Bauman and colleagues, provides a tremendous new opportunity to study the neurochemistry of autism. Initial results, using the available brain tissue, have appeared ([Blatt et al., 1999](#); [Colantuoni et al., 1999](#)); many more reports are expected. Although we have discussed some of the difficulties inherent in PM brain research, this area has great promise in identifying central alterations in autism.

#### Tourette Syndrome

Tourette syndrome (TS) is a persistent familial neuropsychiatric disorder characterized by multiple motor and phonic tics that are stress-sensitive and that tend to wax and wane in severity ([Chappell et al., 1990](#); [Leckman et al., 1987](#); [Shapiro et al., 1988](#)) ([Chapter 59](#)). Knowledge of the disorder has grown dramatically in the past 10 to 20 years; a clearer picture of the clinical phenomena and an increased awareness of the disorder have allowed better diagnosis and more systematic neurobiological research. Neuroanatomic and neuropharmacologic considerations have prompted a number of neurochemical studies with a focus on the monoamines DA, 5-HT, and NE ([Anderson et al., 1999](#); [Cohen and Leckman, 1994](#); [Kurlan, 1992](#); [Singer and Wendlandt, 2001](#)).

#### DOPAMINE

A role for DA is suggested by the amelioration of tics by neuroleptics, exacerbation of symptomatology after administration of stimulants, and importance of DA pathways in modulating basal ganglia output. The basal ganglia play critical roles in motoric behavior, attention, and emotion and reward: areas of function that intersect in the symptoms of TS ([Leckman and Riddle, 2000](#)). The measurement of the DA metabolite HVA in CSF has not revealed consistent differences between mean levels in Tourette and control groups ([Leckman et al., 1995](#)). Only limited data are available comparing plasma or urine levels of HVA; however, group differences have not been apparent. Studies of PM brain from a small number of Tourette patients have given conflicting results. Singer and colleagues ([Singer et al., 1991](#); [Singer and Wendlandt, 2001](#)) have found increased densities of the DA transporter in basal ganglia regions and suggested that the increased densities are a reflection of increased DA innervation within the striatum; however, observations of the normal striatal levels of DA, homovanillic acid, and tyrosine hydroxylase do not support this idea ([Anderson et al., 1992a,b](#)). Although an initial imaging study reported higher striatal DA transporter binding in Tourette patients, subsequent studies have not confirmed this elevation ([Singer and Wendlandt, 2001](#)).

The notion that hypersensitive central DA receptors may be etiologic in TS has prompted attempts at receptor modulation by administration of dopaminergic agents ([Friedhoff, 1982](#)). Other than the observation of normal baseline plasma prolactin levels, little neuroendocrinologic assessment of central DA receptors has been performed. Interest in possible alterations in relative densities of brain D2 and D1 DA receptors has increased following a report of a relationship between density and tic severity in twins ([Wolf et al., 1996](#)).

#### NOREPINEPHRINE

The importance of noradrenergic projections from the locus ceruleus in controlling states of arousal, as well as reports of symptom amelioration after treatment with the  $\alpha_2$ -agonist clonidine ([Leckman et al., 1985, 1991](#)), are suggestive evidence for altered noradrenergic functioning in TS. There are several reports of lowered urinary excretion of MHPG in TS; however, this finding has not been consistently replicated. Measurements of plasma MHPG ([Leckman et al., 1986](#)), and platelet  $\alpha_2$ -adrenergic receptors and plasma NE ([Silverstein et al., 1984](#)), after clonidine administration or withdrawal have been relevant to the phenomena of rebound and modulation of receptor sensitivity; however, they do not provide definitive information concerning possible alterations in TS. Assessment of the sympathetic nervous system by measurement of autonomic cardiovascular measures has not revealed any substantial differences in the Tourette group ([van Dijk et al., 1992](#)). However, studies of plasma, urinary, and CSF stress hormones before and after a lumbar puncture clearly suggest that at least some Tourette patients have an increased stress response ([Chappell et al., 1994, 1996](#)). This conclusion is consistent with the results of the largest study of NE and MHPG in CSF, which found that, although MHPG levels were normal, concentrations of NE were elevated nearly twofold ([Leckman et al., 1995](#)). Given the much shorter half-life of NE compared to MHPG, the results are indicative of normal basal stress response functioning and increased acute stress responsivity.

#### SEROTONIN

A role for 5-HT has been hypothesized because of the connection between TS and obsessive-compulsive disorder ([Grad et al., 1987](#); [Montgomery et al., 1982](#); [Nee et al., 1982](#); [Pauls et al., 1986](#)). Effective treatment of obsessive-compulsive symptoms in Tourette patients with the serotonergic uptake inhibitors fluvoxamine and fluoxetine has further stimulated research on the connection between the disorders and symptoms ([Riddle et al., 1992](#)). Earlier studies of CSF 5-HIAA reported normal or slightly lowered levels in TS; however, a larger and more recent study found similar levels of CSF 5-HIAA in patients with TS, OCD, or TS plus OCD, and the normal control group ([Leckman et al., 1995](#)). No studies of 5-HT receptor functioning have been carried out in Tourette patients, and early reports of benefit from the immediate 5-HT precursor, 5-hydroxytryptophan, have not been replicated ([Van Woert et al., 1982](#)).

Research on PM brain tissue has found decreases in 5-HT, 5-HIAA, and tryptophan across nearly all cortical and subcortical areas in Tourette patients ([Anderson et al., 1992a, 1992b](#)). Further PM research is necessary in order to replicate the findings; however, the results tend to increase the possibility that 5-HT may be a factor in the symptomatology of TS. In other indolamine-related research, [Dursun et al. \(1994\)](#) reported increased levels of plasma kynurenine in Tourette patients and suggested that this may reflect a shunting of tryptophan metabolism away from the production of 5-HT.

#### OTHER STUDIES

The importance of ACh and GABA in basal ganglia neural transmission has led to treatment studies using choline and other cholinergic agents ([Dursun et al., 1996](#); [Stahl and Berger, 1981](#)), as well as GABAergic agents ([Mondrup et al., 1985](#)). However, studies of CSF acetylcholinesterase ([Singer et al., 1984](#)) and CSF GABA have not found group differences. Reports of increased red blood cell choline have continued to appear ([Sallee et al., 1992](#)) and muscarinic receptor binding in white blood cells has been reported to be drastically lowered in TS ([Rabey et al., 1992](#)).

Immunohistochemical study of met-enkephalin, substance P, and dynorphin in basal ganglia areas of PM brain has suggested that dynorphin is reduced in the lateral globus pallidus in TS, whereas the other peptides appear normal ([Haber et al., 1986](#); [Haber and Wolfer, 1992](#)). Levels of dynorphin measured in CSF now appear to be unaltered in Tourette subjects ([Leckman et al., 1987](#); [van Watum et al., 1999](#)). In other studies of opioid systems in TS, small treatment effects were seen with naloxone ([Chappell et al., 1992](#)), whereas little effect was seen after the administration of the  $\kappa$  agonist, spiradoline ([Chappell et al., 1993](#)). The behaviorally important and related neuropeptides arginine-vasopressin and oxytocin also have been measured in CSF in Tourette patients; the results are inconclusive at this time ([Altemus et al., 1992](#); [Leckman et al., 1994](#)).

The amino acid neurotransmitters have been little studied. In the one study of central excitatory amino acids, PM brain levels of glutamate were lowered in the three projection areas of the subthalamic nucleus ([Anderson et al., 1992a,b](#)). It was hypothesized that this might lead to disinhibition of the thalamocortical circuit. This would tend to place Tourette in the group of hyperkinetic movement disorders, including Huntington's disorder and hemiballismus. As reviewed by [Swerdlow and Young \(2001\)](#), further research is needed to clarify basal ganglia functioning in TS. Imaging studies ([Peterson, 2001](#); [Peterson et al., 1993](#)) and the PM research have provided interesting leads to consider with respect to the functioning of cortico-striato-pallido-thalamocortical pathways.

## CONCLUSION AND FUTURE RESEARCH

The underlying mechanisms that regulate the unfolding maturation of the CNS are regulated by genetic factors concerned with the timing of expression of particular genes. Findings concerning homeobox genes and other regulators of gene expression are relevant to the investigation of the onset of specific disorders at certain phases of brain maturation (e.g., autism very early on, ADHD in the earliest school-age years, TS somewhat later, and obsessive-compulsive disorder several years later). Many steps from genetic to neuronal functioning have been characterized for model systems, including the localization, cloning, and sequencing of the genes for important enzymes and receptor systems. Gene activity can be assessed through measurement of messenger RNA expression (the “transcriptome”), synthesized proteins (the “proteome”), and the full range of small molecules produced through enzymatic activity. Basic neuroscience research will shed more light on the steps involved in synthesis, storage, release, and reuptake of transmitter compounds; mechanisms of coupling between transmitter and receptors; and the cascade of events that follows on receptor stimulation (alterations in membrane channels and other membrane changes, reconfiguration of receptors, activation of second-messenger systems, and altered gene expression).

The neurochemical approach to brain functioning is increasingly being integrated with other perspectives, including the neuroanatomic, neurophysiologic, and developmental. There is an ongoing reappraisal of the role of traditional neurochemical approaches, including measurements of neurotransmitters, enzyme systems, specific proteins, and metabolites. There are sound reasons for the continued prominence of the neurochemical approach—the role of neurochemical research in understanding drug action, the search for mechanisms underlying the range of expression of specific genes, and the recognition that for many disorders there are likely to be polygenic contributions, as well as gene–environment interactions, that are expressed in neurochemical systems. Neurochemical concepts underlie and are being enriched by the availability of methods of brain imaging such as PET, magnetic resonance spectroscopy (MRS) and SPECT, which provide information about brain functioning. With the discovery of more specific ligands for brain neurotransmitter receptors, it is becoming possible to perform neuropharmacologic studies (e.g., localization of receptors and determination of receptor numbers, affinities, and occupancy) in humans that previously were feasible only with isolated brain slices. The detection of specific sites of neurochemical abnormality in PM brain specimens, in turn, may provide suggestions for where to look in the human brain using brain-imaging techniques.

Determining neurochemical phenotypes may make critical contributions to pulling apart disorders. As has been pointed out with respect to schizophrenia, “Instead of . . . mapping (the disorder) per se, it may be fruitful to map the genetic basis for atypical biochemical or physiological responses found in (the disorder)” ( [Lander, 1988](#)). In fact, there should be occasions where biochemistry or neurochemistry can become the independent variable, creating meaningful subcategories for fruitful exploration in a fashion analogous to that seen in other more biologically based fields of medicine ( [Feinstein, 1985](#); [Heninger, 1999](#)).

[Development of Event-Related Potentials](#)  
[Exogenous Event-Related Potentials](#)  
[Endogenous Event-Related Potentials](#)  
[Summary and Overview of Developmental Neurophysiology](#)  
[Chapter References](#)

During the developmental progression from infancy through early and later childhood to adolescence, the striking behavioral, emotional, and cognitive changes with which child psychiatrists are familiar accompany neuroanatomic indices of complex brain growth patterns. These include gross measures of brain growth, such as linked brain weight and head circumference measurements (human brain weight is proportional to the cube of head circumference) ([Epstein, 1979, 1986](#)), thickness of cerebral cortex and size of pyramidal cells ([Rabinowicz et al., 1977](#)), progression of regional myelination of specific brain areas ([Yakovlev and Lecours, 1967](#)), neuronal density in frontal cortex ([Huttenlocher, 1979; Rabinowicz, 1986](#)), synaptic density in frontal ([Huttenlocher, 1979](#)) and visual ([Huttenlocher et al., 1982](#)) cortex, and dendritic and axonal differentiation of prefrontal cortex neurons ([Mrzljak et al., 1990](#)).

Two types of maturational brain changes occur. There are progressive changes across the childhood and adolescent years, and maturational growth spurts at particular ages. From infancy to adulthood, there are progressive increases in brain weight ([Huttenlocher, 1979](#)), head circumference ([Epstein, 1979, 1986](#)), and cerebral cortical thickness ([Rabinowicz, 1986; Rabinowicz et al., 1977](#)), and a progressive decrease in neuronal density in cerebral cortex ([Huttenlocher, 1979; Rabinowicz, 1986](#)) and other cortical and subcortical regions ([Rabinowicz, 1986](#)). The decrease in neuronal density is precipitous before birth, with a slower decrease to about 6 to 15 months, after which time adult values are reached ([Rabinowicz, 1986](#)). Synaptic density increases from before birth to 8 months of age in visual cortex ([Huttenlocher et al., 1982](#)), to about 3 years of age in auditory cortex ([Huttenlocher and Dabholkar, 1997](#)), and to between 1 ([Huttenlocher, 1979](#)) and about 3 ([Huttenlocher and Dabholkar, 1997](#)) years of age in prefrontal cortex and then progressively declines to adult values, which are obtained between 12 years of age and midadolescence. The dendritic and axonal architecture in the different layers of prefrontal cortex appear to mature from this time to late in adolescence ([Mrzljak et al., 1990](#)). Concomitantly, there is continuing synaptic elimination throughout childhood and adolescence ([Huttenlocher and Dabholkar, 1997](#)).

These progressive changes in postnatal brain structure seem to involve two overlapping phases, a more rapid one occurring between birth and 1 and 3 years and a slower one occurring between 1 and 11 years of age with continuing changes during adolescence and young adulthood. The manifestation of these changes in prefrontal cortex are of particular importance because of their association with stages of cognitive development during childhood ([Goldman-Rakic, 1987](#)). The earlier prefrontal cortical phase involves the persistence of granular layer IV (which becomes dysgranular in the adult brain), the gradual disappearance of the subplate zone (a transient fetal-neonatal zone associated, in frontal cortex, with prolonged postnatal growth of cortico-cortical pathways) during the first 6 months of postnatal life, and overproduction of cortico-cortical axons associated with excessive synaptogenesis ([Goldman-Rakic, 1987; Kostovic, 1990](#)). In general, during this early childhood phase of progressive frontal cortical maturation, the transient preterm pattern is transformed into the "structurally adult-like pattern of cortical organization" ([Kostovic, 1990](#)). The early phase is also associated with complex changes in frontal cortical cholinergic receptor function, marked by changing acetylcholine esterase (AChE) activity ([Kostovic, 1990](#)). During the later childhood to adolescent progressive phase, the gradual increase in AChE reactivity in layer III pyramidal neurons has been associated with the innervation of cortical association neurons, synaptic reorganization, and cognitive development ([Kostovic, 1990](#)).

Some of these progressive increments or decrements in brain growth measures are not smooth; rather, they are characterized by spurts and lags in development, resulting in peaks and troughs of brain growth at particular age periods. Detailed analyses of the rate of brain weight and head circumference change have suggested peaks in brain growth rates around ages 3, 7, 11 to 12, and 15 years, with troughs in the intervening years ([Epstein, 1974a, 1979; Thatcher, 1980](#)). In the most recent reconsideration of the brain weight and head circumference data, [Epstein \(1986\)](#) concluded that the peaks in brain growth rates were statistically significant at 7, 11 to 12, and 15 years for male brains. Using a different statistical approach, [McCall and colleagues \(1983\)](#) were able to confirm the significance of only the 15-year-old peak. However, detailed neuroanatomic studies of cortical thickness, pyramidal cell development, neuronal density, and myelination document the validity of the earlier stages. Progressive increases in cortical thickness are interrupted by maturational troughs at 2 and 6 years, followed by accelerated growth between 2 to 4 years and 6 to 10 years ([Rabinowicz, 1986; Rabinowicz et al., 1977](#)). (This is a general statement. Particular cortical regions vary somewhat in the timing of these troughs and peaks in rates of cortical thickening.) Pyramidal cell size and shape also show two periods of accelerated change, between 15 months and 2 years and between 8 and 10 years ([Rabinowicz et al., 1977](#)), and neuronal density, which reaches adult values by 15 months of age, shows a consistent small peak of cell density around 6 years of age in frontal, parietal, temporal, and limbic cortex ([Rabinowicz, 1986](#)). From the cortical thickness, pyramidal cell size and shape, and neuronal density data, [Rabinowicz \(1986\)](#) concluded that: (a) an important period in cortical maturation occurs between 15 and 24 months and (b) a period of cortical "remodeling" takes place between 6 and 8 years. He also referred to unpublished data that suggested additional periods of "cortical remodeling" between 10 and 12 years and around 18 years.

Myelination proceeds at different rates for different brain regions, but, in general, myelination of most tracts is completed at or before 2 to 3 years of age. The reticular formation, the nonspecific thalamic radiations, and the great cerebral commissures are not completely myelinated until between 8 and 10 years of age. Myelination of the intracortical association areas continues into the second and third decades ([Lecours, 1982; Yakovlev and Lecours, 1967](#)). A more recent study suggests earlier maturation of myelination ([Brody et al., 1987](#)), but data are available to only 2 years of age. Myelination of the superior medullary lamina of the parahippocampal gyrus shows a progressive increase throughout childhood. Axons in the superior medullary lamina connect limbic and cortical structures and, hence, "could play some role in the corticolimbic integration of emotional behaviors with cognitive processes" ([Benes et al., 1994](#)).

In general, there appear to be four periods of major structural change in brain development, which punctuate the progressive increases and decreases in the size of the brain and its substructures at both the macroscopic and microscopic levels. The first takes place during early childhood, between about 15 months and 4 years of age. The second occurs during or toward the end of late childhood, some time between 6 and 10 years of age. The third is associated with prepuberty, and the fourth, at least in males, occurs in midadolescence. [Epstein \(1974b\)](#) has suggested correlations between these accelerated periods of brain growth and spurts in mental age occurring during the same time periods. Although some critics have found these correlations to be unconvincing because of a paucity of behavioral data ([Fischer and Silvern, 1985](#)) and an inability to confirm concordance between spurts in brain and mental growth statistically ([McCall et al., 1983](#)), it is noteworthy that the first of these periods of brain growth overlaps the piagetian mental stages of sensorimotor and preoperational behavior, whereas the second coincides with the piagetian stage of concrete operations, and the third and fourth overlap the piagetian stage of formal operations ([Inhelder and Piaget, 1958](#)). Thus, the stages of brain growth seem to occur in association with significant mental developments that involve important advances in both cognitive and emotional functions.

Developmental neurophysiology, the subject of this chapter, focuses on the functional correlates of the structural brain changes that occur during development. These changes in brain function should relate to the behavioral changes occurring during the developmental progression from infancy, through childhood, to adolescence and adulthood. Neurophysiologic studies of development fall into two broad categories: the study of the brain in its resting state and the study of the brain perturbed by external stimuli. The former involves primarily studies of changes in electroencephalogram (EEG) frequencies in the waking state and changes in sleep parameters, notably the tonic and phasic components of rapid eye movement (REM) sleep. The latter includes the startle response and its modulation, nystagmus evoked by vestibular stimulation, and exogenous and endogenous event-related potentials. This chapter is limited for the most part to studies that encompass all or the greater part of childhood, from the preschool period to adolescence, and provide quantitative data permitting the evaluation of maturational changes. Studies from early infancy are included only when comparable data are available later during childhood. The many important studies confined to the newborn and very young infant are not included; an excellent review of these can be found in [Graham and associates \(1983\)](#) in the context of orienting responses.

### DEVELOPMENTAL CHANGES IN THE EEG

[Niedermeyer \(1993\)](#) provides an excellent comprehensive review of *qualitative* descriptions of the maturation of the EEG, including EEG patterns in the premature and full-term newborn. This chapter focuses on *quantitative* studies of changes in EEG frequencies with maturation. Developmental EEG studies have utilized hand

measurement of EEG frequencies ([Eeg-Olofsson, 1980](#); [Lindsley, 1936, 1939](#); [Petersen and Eeg-Olofsson, 1971](#)), analog frequency analysis ([Matousek and Petersen, 1973](#)), spectral analysis ([Matthis et al., 1980](#); [Thatcher et al., 1987](#)), and more recently measures derived from the theory of nonlinear dynamics and deterministic chaos ([Anokhin et al., 1999](#)).

In general, regardless of the method used, EEG maturation between about 5 and 11 years of age has been characterized by a reduction in slower frequencies (those in the delta and theta bands) and an increase in higher frequencies (primarily the alpha band) ([Eeg-Olofsson, 1980](#); [Matousek and Petersen, 1973](#); [Matthis et al., 1980](#)). Some of the slower frequencies tend to increase from 1 to between 5 and 8 years of age and then decrease to 15 years of age ([Petersen and Eeg-Olofsson, 1971](#)). Theta activity shows a developmental peak at 4 years of age ([Matousek and Petersen, 1973](#)). Between 6 and 11 years, the power in the theta band decreases linearly with age. Also, the latency of the theta activity evoked by auditory stimuli decreases with age, and this decrease is highly correlated with the developmental decrease in the latency of the P300 component of the event-related potential (ERP) evoked by the same stimuli ([Yordanova and Kolev, 1997](#)). The frequency of the more extensively studied occipital alpha rhythm increases progressively from 3 months of age to adulthood ([Lindsley, 1936, 1939](#); [Petersen and Eeg-Olofsson, 1971](#)). The relative spectral power of alpha in the 9.5- to 12.5-Hz band increases between 4 and 11 years of age ([Matthis et al., 1980](#)), the amplitude of 9.5- to 12.5-Hz alpha increases from 1 to 21 years of age ([Matousek and Petersen, 1973](#)), and the mean absolute phase of 7- to 13-Hz alpha increases from birth to adulthood ([Thatcher et al., 1987](#)). Most of these progressive increases in alpha activity are exponential, with rapid increases from birth to about 5 or 6 years of age, followed by slower rates of change to adulthood; these changes closely parallel a similar exponential growth curve for brain weight ([Huttenlocher, 1979](#)). A study of nonlinear aspects of EEG organization utilized a measure of EEG complexity to reveal a highly significant effect of age, from infancy through childhood to adulthood. This increasing EEG "complexity" with age is thought to reflect "the evolution of complexity of underlying brain activity" with maturation ([Meyer-Lindenberg, 1996](#)).

The progressive developmental changes in alpha activity are punctuated by spurts and lags. [Epstein \(1979, 1980, 1986\)](#) analyzed the developmental EEG data of [Matousek and Petersen \(1973\)](#) in terms of biennial increments of change and demonstrated EEG developmental stages with peaks of alpha activity around 4, 7 to 8, 11 to 12, and 15 years, and intervening troughs at 6, 9 to 10, and 13 years. These EEG developmental stages coincide quite well with the brain growth stages based on analyses of brain weight-head circumference data, cortical thickness data, pyramidal cell dimensions, and neuronal density changes, as described. The well-defined trough in the development of alpha activity at 6 years, followed by the peak at 7 to 8 years ([Epstein, 1980, 1986](#)), coincides with the beginning of a brain development stage that [Rabinowicz \(1986\)](#) describes as "a remodeling of the cortex." This restructuring of cortical substance involves a relative decrease in cortical thickness, a corresponding decrease in length and increase in width of the Betz cells, and an increased cell density. Thus, functional and structural brain changes coincide at a critical age in child development, the age that for most children is associated with the readiness to learn in a school setting, or, in piagetian terms, to engage in operational thinking.

Using measures of EEG coherence and phase, [Thatcher and colleagues \(1987\)](#) confirmed EEG periods of growth and change around 4 to 6, 8 to 10, 11 to 14, and 15 years and demonstrated hemispheric differences in participation in these developmental stages. The 4 to 6 years period involves spurts in left hemispheric (frontal-occipital and frontal-temporal) coupling and right frontal pole pairing, whereas the 8 to 10 years period is notable for accelerated development of right hemispheric (frontal-temporal) connections. The preadolescent and adolescent periods are bilateral, involving primarily frontal lobe connections. Comparison of the [Thatcher and coworkers \(1987\)](#) findings and further mathematical analysis of the [Matousek and Petersen \(1973\)](#) data by [Hudspeth and Pribram \(1990\)](#) showed "a striking similarity to the timing and sequencing" of the EEG growth spurts ([Thatcher, 1991](#)).

Although relatively little is known about the development of hemispheric differences, it is most interesting to note recent evidence of a developmental shift in dendritic prominence (total dendritic length) from the right to left motor speech areas ([Simonds and Scheibel, 1989](#)). This shift to left-sided primacy of language-related areas occurs during the same 4- to 6-year period during which the spurt in left frontal-temporal EEG coupling occurs ([Thatcher et al., 1987](#)). This ontogenetic shift in hemispheric structure and function parallels an evolutionary trend toward lateralization of auditory cortex ([Thatcher, 1980](#)).

## DEVELOPMENT OF SLEEP PATTERNS

Between birth and late adolescence the total time spent asleep is reduced from about 16 to about 8 hours ([Roffwarg et al., 1966](#)). Of greater interest for the neurophysiology of development is the fact that REM sleep accounts for 50% of total sleep time at birth but only 20% by 3 years, at which time adult values are approached.

The anlage of the REM state makes its appearance in the fetus before birth. By 28 to 30 weeks it is possible to begin to identify REM and non-REM sleep states ([Parmelee and Stern, 1972](#)). At birth REM sleep is relatively "undifferentiated" in comparison with REM sleep in older children ([Emde and Metcalf, 1970](#)). Two major changes mark the differentiation of REM sleep within the first 3 months of life: Starting at approximately 2½ months of age, sleep begins with a non-REM instead of REM period ([Emde and Metcalf, 1970](#)), and the initial high variability in physiologic patterning of neonatal REM sleep becomes organized, so that behavioral and electrophysiologic events uncharacteristic of REM sleep become segregated out of REM sleep and into drowsy and non-REM states. For example, EEG activity during REM sleep in the frequency range of stage 2 sleep spindles in 6- to 8-month-old babies is significantly reduced by 19 to 45 months ([Ornitz et al., 1971](#)). Concomitant with this increasing organization, there is a decrease in REM period length and the percent of total sleep time occupied by REM sleep ([Parmelee and Stern, 1972](#); [Roffwarg et al., 1966](#)) to approximately 40% by 3 to 5 months of age and to 30% by 6 to 23 months ([Roffwarg et al., 1966](#)). By 3 years, although total sleep time has decreased from 16 to 11 hours per day, REM sleep time has decreased from 8 to about 2 hours per day ([Roffwarg et al., 1966](#)). REM sleep is an activated state of consciousness, with a low-amplitude, high-frequency EEG similar to the waking EEG record and a tonic muscular atonia, punctuated by phasic motor and autonomic behavior such as the bursts of rapid eye movements, twitching movements of the extremities, and increased fluctuations of cardiovascular and respiratory activity, and phasic inhibition of responses to sensory input. [Roffwarg and associates \(1966\)](#) suggested that the REM state serves the newborn and young infant as an endogenous source of stimulation when less exogenous stimulation is available. It is notable that the sum of waking time (8 hours) and REM sleep time (8 hours) in the newborn is almost the same as the sum of waking time (13½ hours) and REM sleep time (2 hours) in the 5- to 9-year-old child, supporting the idea that one function of REM sleep during early development is to compensate for reduced time awake. It is most noteworthy, however, that the percent of total sleep time required for REM sleep has decreased to the adult level around 3 years of age, the time of completion of myelination of many subcortical pathways and the first major spurt in brain growth.

The ontogenetic changes in the percent of REM sleep time are accompanied by developmental changes in the phasic motor activity of REM sleep. After adjustment for the differences in the time of night during which REM sleep episodes occur in the course of early childhood development, [Tanguay and associates \(1976\)](#) showed that the rapid eye movements of REM sleep clustered significantly more tightly into bursts with increasing age from 3 months to about 6½ years. This increasing organization of eye movement activity is accompanied by increasing inhibition of the relative amplitude of evoked responses to auditory stimuli during the eye movement bursts, with increasing age from 6 months to about 6½ to 9 years, during which time adult levels of phasic inhibition are reached ([Ornitz, 1972](#); [Ornitz et al., 1969](#)). Hence, neither the phasic motor excitation nor the phasic sensory inhibition of REM sleep are well defined in early infancy; however, these concurrent neurophysiologic processes develop rapidly during early childhood and mature after the preschool period. The phasic activity of REM sleep is generated in the parabrachial reticular formation and mediated by the medial vestibular nucleus (MVN) ([Pompeiano, 1967a,b, 1980](#)). The contribution of the MVN, a central vestibular structure, to the development of phasic motor activity during REM sleep is particularly interesting, as is presented in the next section where we consider the developmental changes in vestibular function in the waking child.

Tonic muscle atonia is an important neurophysiologic component of REM sleep. This atonic state is interrupted by episodes of phasic muscle activity that are most intense in early infancy and show increasing inhibition with maturation, reaching adult levels between 6 and 12 years of age ([Kohyama et al., 1997, 1999](#)). This activity, manifest and measured as chin muscle twitches, occurs simultaneously with the rapid eye movement bursts at a high rate in the newborn. By 4 to 6 months of age, the rate of concurrence of the muscle twitches and rapid eye movement bursts has dropped to adult levels ([Kohyama, 1996](#); [Kohyama et al., 1999](#)); therefore, maturation of the organization of the rapid eye movement bursts (increased clustering) during infancy and childhood is accompanied by both increased sensory inhibition (suppression of auditory evoked responses) and increased motor inhibition (dissociation from the phasic muscle activity).

The functions of the phasic events of REM sleep have rarely been discussed. However, these short, intermittent, recurrent periods of very intense motor activation (e.g., bursts of rapid eye movements, twitching of the muscles of the middle ears, vibrissae, and extremities) are embedded in the longer REM sleep periods, whose function is thought to be the activation of the brain during sleep without arousal of the organism ([Vertes, 1984, 1986](#)). This view is consistent with that of [Roffwarg and coworkers \(1966\)](#), who postulated that REM sleep "serves as an endogenous source of stimulation" in early infancy. Presumably, the need for such endogenous stimulation becomes less with maturation during childhood, as waking time increases and the quality of waking life becomes increasingly active. Hence, as the percent of REM sleep time declines precipitously during the first 3 years of early childhood ([Roffwarg et al., 1966](#)), the phasic motor activity of REM sleep becomes more concentrated in discrete periods of time ([Tanguay et al., 1976](#)), and the phasic sensory inhibition becomes more pronounced ([Ornitz, 1972](#); [Ornitz et al., 1969](#)). The increase in phasic sensory inhibition with maturation may serve to protect the developing child from the waking effect of exogenous stimulation at the time of the most intense motor excitation.

A change in the sleep EEG pattern of non-REM sleep also occurs around 3 years of age. The percent time and number of the 12- to 14-Hz sleep spindles and the duration of the spindles during stage 2 sleep all decrease from 4 months of age, reaching minimal values at 3½ years, and then increase between 4 and 5 years of age ([Tanguay et al., 1975](#)). Spindle rhythms are thought to be generated in reticular thalamic neurons that project to thalamocortical neurons, and brain stem reticular activity blocks the generation of EEG spindling by inhibitory projections to the reticular thalamic neurons ([Steriade, 1988](#)). Perhaps the decrease in EEG spindles around 3½ years of age reflects a peak period of brain stem reticular or reticular thalamic activity associated with the first major spurt in brain maturation.

## DEVELOPMENTAL CHANGES IN VESTIBULAR NEUROPHYSIOLOGY

Vestibular reflexes serve primarily to stabilize gaze during head movements and maintain equilibrium during body movements and are influenced by, and interact with, visual and proprioceptive inputs. The development of these aspects of vestibular reflexes are addressed in this section. Other functional roles for vestibular reflexes, such as compensation for changes in the direction of the force of gravity and maintenance of tonic muscular tone ([Baloh and Honrubia, 1979](#)), have not been systematically studied in the human child and are not considered here.

Vestibular function is most readily studied by quantifying changes in the vestibulo-ocular reflex (VOR). Quantification of the VOR is facilitated by measurement of certain parameters of the ocular nystagmus induced by angular acceleration, and understanding of human vestibular function and its development has depended primarily on this approach. The nystagmus consists of alternating slow and fast conjugate deviations of the eyes. The velocity of the slow deviation in the opposite direction to that of the acceleration reflects vestibular activity. The VOR is the output of a first-order open-loop control system, best characterized by its gain and time constant. In response to constant or impulsive accelerations, the gain is the nystagmus slow-component velocity (SCV) relative to the head acceleration or to the sudden change in velocity. The time constant (the exponential rate of change of the SCV in response to the acceleration) reflects the viscoelastic properties of the cupula (peripheral time constant) and the effect of a central integrator that prolongs the peripheral time constant to that of the nystagmus. In response to sinusoidal accelerations, the gain is the nystagmus SCV relative to the head velocity, and the time constant can be computed from the phase shift between nystagmus and head velocities ([Honrubia et al., 1982](#)).

The vestibular system is both anatomically complete and functionally responsive at or before birth. Histologically, the vestibular apparatus appears complete in the human fetus at 9½ weeks of gestation ([Hooker, 1952](#)). The large neurons of the vestibular nuclei are "unquestionably functional" at 21 weeks of gestation ([Humphrey, 1965](#)). The myelination of the vestibular system is well advanced at 6 months of gestation ([Langworthy, 1933](#)). The endolymphatic and bony labyrinths ([Dayal et al., 1973](#)) and the number of myelinated vestibular nerve fibers ([Bergstrom, 1973](#)) and vestibular hair cells ([Rosenhall, 1972](#)) are mature at birth. Newborn infants respond to acceleration, the slow component of nystagmus deviating in the expected direction (i.e., opposite to that of the acceleration) ([Tibbling, 1969](#)), although the fast component, which is of pontine origin ([Cohen, 1972](#)), may not occur.

There are functional changes in the vestibular system during development from early infancy to adolescence that suggest considerable plasticity of the nervous system during childhood. Vestibular responses to an equivalent stimulus, be it caloric or rotational, differ markedly in preadolescent children from that found in adults ([Conraux and Collard, 1970](#); [Jongkees and Gasthuis, 1973](#)). The responses of children to vestibular stimulation are not only different from the responses of adults but also differ within the childhood age span, with the most marked maturational changes taking place in preschool children ([Ornitz, 1985](#); [Ornitz et al., 1979](#)). During the first year of life, the vestibular system is functioning at its highest level of reactivity, a level that decreases with subsequent development. At the same time, suppression of the VOR by visual fixation is minimal or absent ([Ornitz and Honrubia, 1988](#)). The peaking of vestibular activity during the first year of life is associated with overflow phenomena in the form of behaviors such as rocking and is followed by a subsequent rapid decrement in vestibular reactivity. These features of the maturation of vestibular function suggest that important modifications of vestibular mechanisms take place rapidly during the first few years of life and continue to do so, albeit at a slower pace, throughout childhood ([Ornitz, 1983, 1988](#)).

Those studies that have measured appropriate nystagmus parameters (i.e., the SCV or its expression as VOR gain) have demonstrated the following developmental sequence. Nystagmus is present in the full-term newborn, subject to sufficient arousal, and also in the premature and small-for-dates neonate. Nystagmus is weaker in the latter groups, but after several months of postnatal life, the differences are no longer apparent. The maximum intensity of the vestibular response probably occurs by 6 months, and it is about this time that spontaneous vestibular self-stimulation first occurs, indicating a period of heightened vestibular reactivity. After the first year, the intensity of vestibular nystagmus and spontaneous vestibular behavior decrease rapidly until about 30 months of age, following which there is a gradual decrease toward adult values between 7 and 10 years. This decrease in the intensity of the vestibular response (reduced velocity of nystagmus and reduced VOR gain) is associated with increasing time constants ([Ornitz, 1985](#); [Ornitz et al., 1985](#)). The association of decreasing gain with increasing time constants during development suggests that the immature human vestibular system is characterized by relatively deficient modulation of vestibular reflexes. It can be postulated that the decreasing gain reflects increasing modulation of vestibular function with development and that increasing time constants reflect the development of the modulating mechanisms. Both pharmacologic ([Blair and Gavin, 1979](#)) and neurophysiologic ([Buettner et al., 1978](#)) investigation suggest that the modulating mechanisms reside in reverberating brain stem reticular formation neuronal networks.

Studies of the development of vestibular adaptation to constant acceleration also suggest that the postnatal development of the vestibular system involves central mechanisms. The adaptive process that shapes the time course of the total nystagmus response to constant angular acceleration begins during the decline of the postacceleration primary nystagmus and is amplified during the subsequent secondary nystagmus (nystagmus with slow components in the opposite direction to that of the primary nystagmus) ([Malcolm and Melvill-Jones, 1970](#)). The maximum SCV in all adults occurs at the same time during secondary nystagmus, regardless of stimulus magnitude ([Sills et al., 1978](#)). [Sills and coworkers \(1978\)](#) attribute this consistency to a central, stimulus-independent process. In children, the maximum SCV during secondary nystagmus varies according to age and by 10 years of age is close to the values of Sills and associates for adults ([Ornitz, 1983](#)). These data, together with developmental changes in secondary nystagmus/primary nystagmus peak SCV ratios ([Ornitz et al., 1979](#)), show strong age-dependent effects on adaptation during the childhood years. The maturational changes in VOR gain and time constant ([Ornitz et al., 1985](#)), vestibular adaptation ([Ornitz, 1983](#); [Ornitz et al., 1979](#)), and visual-vestibular interaction ([Ornitz and Honrubia, 1988](#)) all support the notion that the postnatal development of the human vestibular system involves central modulating mechanisms.

The preceding considerations apply to the development of the mechanisms underlying the slow components of nystagmus, which originate in the vestibular nuclei and are modulated by brain stem reticular formation (BSRF) activity. The fast components, on the other hand, are generated in the BSRF, more specifically in the parabrachial reticular formation (PPRF) ([Cohen, 1972](#)). The likelihood of generating fast components in response to near-threshold vestibular stimulation increases progressively from early childhood to young adulthood ([Fuster et al., 1994](#)). Because the same PPRF neurons generate both vestibular fast components and saccades, the maturation of fast component activity may parallel the fine tuning of saccade-mediated vestibulo-ocular mechanisms, which mature throughout childhood. Because the gain of the slow component decreases with development, whereas the fast component and saccadic activity increase, it can be postulated that vestibular responsivity is modified by visuovestibular interaction with maturation ([Ornitz and Honrubia, 1988](#)). This developing interaction, in turn, is mediated by the development of the same BSRF circuits in the PPRF, which lengthen the nystagmus time constant and modulate vestibular output ([Fuster et al., 1994](#)). For more complete reviews of the development of vestibular function during childhood, see [Ornitz \(1983, 1988\)](#).

## DEVELOPMENTAL CHANGES IN STARTLE MODULATION

The magnitude of the startle blink reflex in the human adult can be modulated by nonstartling prestimulation in three ways ([Anthony, 1985](#); [Graham, 1975](#)). Inhibitory modulation of the startle response to an intense sudden stimulus follows brief (20-msec), low-intensity, nonstartling stimuli presented at short intervals (30 to 240 msec) prior to the startling stimulus ([Graham, 1975](#); [Graham and Murray, 1977](#)). At these short prestimulation intervals, the same amplitude inhibition may ([Graham and Murray, 1977](#)) or may not ([Blumenthal and Levey, 1989](#)) occur when the prestimulation is sustained continuously throughout the warning interval, depending on the prestimulation intensity and other experimental parameters. Facilitation of startle magnitude follows longer (>1,400 msec) prestimuli that are sustained continuously throughout the prestimulation interval preceding the startling stimulus ([Graham, 1975](#); [Graham et al., 1975](#)). Facilitation following these long, sustained prestimuli can occur in experimental designs in which the prestimulation interval is constant or is variable in duration ([Anthony, 1985](#); [Graham, 1975](#); [Graham et al., 1975](#)). In contrast, a brief (20-msec) stimulus presented 2,000 msec prior to the startling stimulus induces startle facilitation only in the context of variable prestimulation intervals and not when the prestimulation interval is constant ([Graham, 1975](#); [Graham et al., 1975](#)). Because of the uncertainty associated with the variable prestimulation intervals, the facilitating effect was attributed to an orienting-attentional mechanism. Subsequent research has shown that in the adult human a third type of startle modulation involving nonstartling prestimulation is due to orienting-attentional influences, and the effect can be facilitatory or inhibitory, depending on whether attention is directed toward or away from either the prestimulus or startling stimulus ([Anthony, 1985](#)).

Inhibitory startle modulation is a brain stem function involving the processing of sensory input. Startle inhibition by prestimulation is mediated by an inhibitory pathway in the brain stem tegmentum as demonstrated by lesion ([Leitner and Cohen, 1985](#); [Leitner et al., 1981](#)) and stimulation ([Saitoh et al., 1987](#)) studies in the rat. This

pathway impinges on the primary startle pathway (Davis et al., 1982) at, or prior to, the medial pontomedullary reticular formation (Wu et al., 1988). As with the modulation of vestibular responses by polysynaptic brain stem reticular formation neuronal networks (Buettner et al., 1978) as described, startle modulation also matures between 6 and 10 years of age (Ornitz et al., 1986, 1990, 1991). Thus, a synchronous maturational effect involves two related functions, startle and vestibular modulation, because the motor component of the startle blink reflex, the facial motoneuron, receives vestibular projections (to the facial nucleus) (Shaw and Baker, 1983). Their suggested role is the coordination of facial movements, including blinking, with eye and head movements, all of this being motor activity, modulated in the brain stem, that is involved in the response to sudden sensory input.

Systematically collected data on startle modulation by prestimulation from infancy throughout childhood are available for only experimental paradigms that have not attempted to manipulate the direction of attention (Ornitz et al., 1986, 1990, 1991). Graham and colleagues have carried out such experiments during the first year of life and have reported on differences from adult responses (Anthony and Graham, 1983, 1985; Balaban et al., 1985, 1989; Graham et al., 1981). Anthony and Putnam (1985) compared startle modulation effects in 5-year-olds and adults. Prior to about 4 years of age, inhibitory startle modulation is characterized by fluctuating weak inhibition (25% response inhibition in 2- to 6-month-olds) (Graham et al., 1981), nonsignificant facilitation (17% response increase in 15-month-olds) (Balaban et al., 1989), and again, weak inhibition (23% response inhibition) in 3-year-old boys (Ornitz et al., 1986). In 4-year-old girls and boys, there is nonsignificant startle amplitude facilitation (about 10% and 22%, respectively) 120 msec following prestimulation. In 5-year-old boys, 30% response inhibition has developed. By 8 years, both girls and boys show strong significant response inhibition, 50% and 75%, respectively, approximating adult values. Similar developmental response patterns occur following prestimulation at 250 msec (Ornitz et al., 1986, 1991). Facilitatory startle modulation in response to prolonged sustained prestimulation follows a similar developmental course (Ornitz et al., 1986, 1991).

Both inhibitory and facilitatory startle modulation show, respectively, significant peak losses in startle inhibition and peak gains in startle facilitation at about 4 years of age, followed by a progressive increase in inhibition and decrease in facilitation until 8 years of age, when mature values are obtained (Ornitz et al., 1986, 1990).

Startle can also be modulated by habituation. In response to glabellar taps, the number of reflex blinks to habituation increased from the first year of life until 3 to 5 years of age. Habituation recurred at 6 years of age and became progressively stronger until adulthood (Zametkin et al., 1979). Hence, startle modulation by habituation shows the same loss of inhibitory modulation around 4½ years of age as does startle modulation by prestimulation. In a study of 7- to 11-year-old boys (Ornitz et al., 1996), habituation of acoustic startle occurred at the same rate as in young adults (Ornitz and Guthrie, 1989). Startle and its habituation were found to be independent of association with accompanying autonomic, alpha EEG, and tonic electromyogram (EMG) activities; whereas the startle response habituated, prestartle and poststartle cardiac, alpha, and myogenic levels did not (Ornitz et al., 1996). Tonic heart rate actually increased as startle habituated, suggesting sensitization of the state of these subjects during the experiment, a result consistent with the dual-process theory of habituation (Groves and Thompson, 1970).

Startle is also modulated by the affective state of the subject (Lang et al., 1990). Of the various experimental paradigms used to affect the emotional response to the startling stimulus, the fear-potentiated startle response has been of particular interest because of its application to both animal and human studies (Davis et al., 1993; Grillon et al., 1991). Until recently, however, there has been very little application to children. Infants who had shown strong motor responses and *negative* affect to test stimuli at 4 months showed potentiation of startle in the presence of a stranger at 9 months. In comparison, infants who had shown strong motor responses and *positive* affect at 4 months, showed reduced startle in the presence of a stranger at 9 months (Schmidt and Fox, 1998). Thirteen- to 17-year-old adolescents showed fear-potentiated startle both to threat of an air blast directed to the larynx and by darkness (Grillon et al., 1999). Based on animal studies (Davis, 1992; Gewirtz et al., 1998), these findings indicate that mediation by limbic structures, particularly the amygdala and bed nucleus of the stria terminalis, occurs throughout childhood, from infancy through adolescence.

For further review of the development of startle modulation during childhood, see Ornitz (1999).

As described, of the various types of startle modulation, the developmental sequence throughout infancy and childhood has only been completely described for inhibitory startle modulation. Inhibitory startle modulation matures during a critical period of human neurologic growth and development that is characterized by many important structural brain and functional neurophysiological changes, as described. Myelination of the brain stem reticular formation and the great cerebral commissures is not completed until sometime between 8 and 10 years (Yakovlev and Lecours, 1967). Rabinowicz (1986) describes a period of cortical "remodeling" characterized by changes in cortical thickness, pyramidal cell size and shape, and neuronal density that occurs between 6 and 8 years. Epstein (1986) describes a peak of brain growth (inferred from head circumference data) at 7 years, which he attributes to increased neuronal arborization. Epstein (1979, 1980, 1986) has demonstrated several peaks of alpha activity in the developmental EEG data of Matousek and Petersen (1973), one of which is a well-defined trough of alpha activity at 6 years, followed by a peak at 7 to 8 years. Between 8 and 10 years, EEG coherence and phase studies suggest accelerated development of right hemispheric frontotemporal connections (Thatcher et al., 1987).

All of these structural and functional changes in the human nervous system occur during that period of childhood when children are able to engage meaningfully in learning and, in most cultures, are enrolled in school. This is approximately the piagetian period of concrete operations (Inhelder and Piaget, 1958), during which time the child's concept of reality becomes less egocentric and less anthropomorphic, permitting the initial development of logical thinking. Hence, the maturation of inhibitory mechanisms in the brain stem that damp the response to strong external stimuli and the reduction of excitation following sustained stimulation (sensory modulation) parallel the development of cortical (cognitive) processes that require the capacity of the child to separate affectively and conceptually from external objects and events, a capacity that would seem to require inhibitory functions. In fact, tests of frontal lobe functions indicate an accelerated development of the capacity to inhibit the retroactive interference of a stimulus set on the recall of a prior stimulus set during this period of childhood (Passler et al., 1985).

## DEVELOPMENT OF EVENT-RELATED POTENTIALS

Event-related potentials (ERPs) are responses to stimuli in the EEG that may be exogenous or endogenous. The exogenous ERPs are always elicited by external events; they are obligatory responses whose characteristics (e.g., latency and amplitude) vary with the physical parameters of the stimuli. The endogenous ERPs are nonobligatory responses to stimuli, may occur in the absence of an expected stimulus, and are relatively unaffected by the physical parameters of the stimulus (Donchin et al., 1978). Hence, the exogenous ERPs represent relatively lower levels of sensory processing (stimulus registration), whereas the endogenous ERPs represent relatively higher levels of processing of the information conveyed by sensory stimuli (e.g., expectation, importance, or relevance of the stimulus, recognition of novelty). The endogenous ERPs are evoked by experimental conditions that influence attention and give significance to stimuli.

### Exogenous Event-Related Potentials

The extensive literature prior to 1978 on the maturation of exogenous ERPs during childhood has been thoroughly reviewed by Klorman and coworkers (1978). They found that, in general, the latencies of these responses to auditory, visual, and somatosensory stimuli decreased rapidly during the first year of life and changed more slowly or not at all from early childhood to adolescence. Because the exogenous ERP components are characterized by latencies less than 200 msec, the more marked decreases in latency during the first year were attributed to the early completion of myelination of specific thalamocortical sensory pathways. In contrast, the endogenous ERP components, which have longer latencies, show maturational changes throughout childhood, and these changes were attributed to the much later myelination of nonspecific brain stem and reticular thalamic pathways (Klorman et al., 1978). In the auditory system Eggermont (1992) has shown that the *rate* of maturation (during the first 2 years) of P2 and N2, ERP components occurring around 200 msec that may have either exogenous or endogenous ERP characteristics, depending on the conditions in which they are evoked, is the same as the rate of maturation of wave 5 of the exogenous brain stem auditory evoked response (BSAER) suggesting similar developmental rates for responses mediated by brain stem and more rostral auditory pathways.

The exogenous ERPs occur in all sensory modalities and include the very early brain stem and certain later auditory-evoked responses (AERs), the somatosensory-evoked potentials (SEPs), and the pattern reversal visual-evoked potentials.

### BRAIN STEM AUDITORY-EVOKED RESPONSE

The *brain stem auditory-evoked response* (BSAER) is composed of a series of five waves with peak latencies from about 1 to 6 msec (in adults). Based on experimental animal and clinical patient studies (Fabiani et al., 1979), these peaks represent auditory transmission from the auditory nerve (wave 1), through the cochlear nucleus (wave 2), the superior olivary complex (wave 3), to more rostral regions of the brain stem (waves 4 and 5). Thus, wave 1 represents peripheral auditory transmission, and the remaining components represent progressive central auditory transmission through the brain stem. With maturation during infancy and early childhood, the latencies of the several BSAER components shorten but at different rates. The peripheral transmission (wave 1) matures early, reaching the adult latency between the sixth week (Salamy and Mckean, 1976) and second month (Mochizuki et al., 1983) of postnatal life. The central transmission time, measured as the brain stem transmission time between waves 1 and 5, matures more slowly. Adult values are approached between ages 3 and 5 years (Fabiani et al., 1979);

Mochizuki et al., 1983) and finally reached at 8 years (Fabiani et al., 1984), the same time that another measure of brain stem development, startle modulation, matures (Ornitz et al., 1986, 1990, 1991).

Developmental amplitude changes in BSAER components have received less attention than latency changes (Jiang et al., 1993). Jiang and colleagues (1993) have observed an increase in wave 5 amplitude from birth to 5 years of age, followed by a gradual decrease in amplitude toward adult values. This peak of BSAER activity coincides developmentally both with the peak loss of inhibitory prestimulation modulation of startle (PMS) and the peak increment of facilitatory PMS (see the preceding) and the peak increment of the P300 component of the auditory ERP (see the following). The implications of these several manifestations of heightened responsivity to sensory stimuli are discussed later in this chapter.

#### AUDITORY-EVOKED RESPONSE

*Auditory-evoked response* (AER) peaks occurring between 50 and 200 msec can have both exogenous (i.e., obligatory) and endogenous (i.e., nonobligatory) characteristics, depending on the experimental conditions. These include the positive potentials P1 (at about 50 msec) and P2 (between 140 and 170 msec) and the negative potentials N1 (about 100 msec) and N2 (220 and 270 msec). The latencies refer to established adult values. Ponton and associates (2000) have provided systematic data on the maturational changes that occur between 5 and 20 years of age when these AER peaks are evoked by simple monaural auditory stimuli (a brief train of clicks) at a rapid stimulation rate, under experimental conditions that minimize the influence of attention, and are recorded at multiple electrode sites. It is emphasized that all of these experimental conditions may affect the assessment of maturational sequences and the exogenous or endogenous characteristics of the evoked activity. Under these conditions (Ponton et al., 2000), the P1 latency decreases exponentially from 80 to 110 msec at age 5 years to 30 to 50 msec at age 20 years and does not become adult-like until age 15 years. When recorded at lateral scalp electrodes, the P1 amplitude shows a striking step-like increase and decrease between ages 10 and 11 years. In contrast to the considerable developmental changes in P1, the later positive wave P2 shows no age-related latency changes and only a modest decrease in amplitude. The N1 latency shows an exponential decrease similar to that of P1; the N1 amplitude, recorded frontocentrally, does not develop a consistent negativity until about age 16 years. The negativity at N2 shows an exponential increase in latency and, at lateral electrode sites, an increased amplitude negativity at age 10 years followed by an abrupt decrease in amplitude. Hence, the pattern of developmental change described by Ponton and colleagues (2000) includes a shift from an exponential maturational latency decrease in the earlier peaks (P1 and N1), no maturational latency effect on P2, and a maturational increase in the later N2, and an abrupt change in amplitude at age 10 years for peaks P1 and N2. The maturational latency decrease for waves P1 and N1 has also been found in children in response to simple verbal stimuli (Paetau et al., 1995; Sharma et al., 1997). Other studies of the exogenous auditory-evoked N1 also found latency decrements with increasing age, across the age range 8 to 17 years (Tonquist-Uhlen et al., 1995) and longer latencies in 4- to 8-year-olds than in adults (Bruneau et al., 1997). The latencies of the N1 recorded from temporal scalp regions in response to both tones and speech sounds also decreased across the age range 3 to 16 years (Pang and Taylor, 2000). In contrast to the slow development of N1 negativity recorded at fronto-central sites (Ponton et al., 2000) as described, the amplitude of the auditory N1 was found to be greater over the temporal cortices in 4- to 8-year-old children than in adults (Bruneau et al., 1997; Pang and Taylor, 2000; Tonquist-Uhlen et al., 1995). A shift in N1 amplitude from a parietal to a fronto-central predominance occurred after 8 years of age in two studies (Bruneau et al., 1997; Tonquist-Uhlen et al., 1995) but not until 15 years of age in a recent study using relatively more rapid stimulation (Pang and Taylor, 2000). It should be noted that the maturational increase in latency of N2 reported by Ponton and colleagues (2000) is at variance with the maturational decrease reported in other studies of N2, most of which have used binaural stimulation and task-related conditions that elicit endogenous characteristics of this event-related potential. These studies are reviewed in the following discussion of wave N2 as an endogenous ERP component. Also, in response to verbal stimuli, and longer interstimulus intervals than those used by Ponton and associates (2000), the latency of the exogenous N2 decreased in children between 3 and 15 years of age (Paetau et al., 1995).

#### SOMATOSENSORY-EVOKED POTENTIALS

The *somatosensory-evoked potentials* (SEPs) comprise a series of scalp-recorded negative and positive peaks that vary in peak latency from about 20 to 200 msec following electrical stimulation of the fingers or the median nerve at the wrist (Klorman et al., 1978). Desmedt and his colleagues (Desmedt et al., 1980) have carried out the most extensive studies of the maturation of the SEP, focusing on the negative neonatal component with a peak latency of about 30 msec and a duration of over 15 msec. By adulthood, this broad, prominent peak has evolved into a narrow, smaller negative component with a peak latency of 22 msec and a duration of less than 5 msec (Desmedt et al., 1980). To assess the significance of these changes in terms of the known increase in conduction velocity with maturation, it is necessary to consider the onset latency of this SEP component in relation to body growth. When the onset latency is divided by body length, the resulting negative exponential function shows a rapid decrease in conduction time relative to somatosensory pathway length, from 46 msec/m in the newborn to less than 20 msec/m by 1 year of age to a mature (adult) value of 11 msec/m by 8 years of age (Desmedt et al., 1980). These maturation changes in overall conduction times along the entire somatosensory pathway reflect maturational changes in both peripheral and central conduction velocities. Desmedt and associates (1980) have estimated the peripheral conduction velocity at birth to be about 27 m/sec; adult values around 65 m/sec are obtained by 1 or 2 years of age. In contrast, the central conduction velocity of the SEP is about 10 m/sec at birth and reaches an adult value of 50 m/sec by 8 years of age. Hence, the SEP shows a similar maturational progression to that of the BSAER: rapid maturation of the peripheral system and slower maturation of the central brain stem pathway. For both systems, about the 8th year appears to be a critical period for brain stem maturation.

#### VISUAL-EVOKED POTENTIALS

The *visual-evoked potentials* (VEPs) can be evoked in the EEG by simple flashes or by more complex visual stimuli. Because of the variability of the evoked response to flashes, most modern investigations of the VEP utilize the method of pattern reversal. The pattern reversal VEP is evoked by, for example, the alternating dark and light squares of a checkerboard pattern. Developmental studies carried out prior to 1978 utilized the flash-evoked VEP method, and reviews of these early studies suggested both latency increases (Klorman et al., 1978) and decreases (Moskowitz and Sokol, 1983) with increasing age during childhood. One current study of the flash-evoked VEP found significantly decreased latencies and increased amplitudes of the visual N1 wave (a negative deflection between 80 and 180 msec) across the age range 8 to 15 years (Carillo-de-la-Peña et al., 1999).

Using the pattern reversal VEP and measuring the consistent prominent positive component at 100 to 120 msec in adults, Moskowitz and Sokol (1983) found that the latency in response to a pattern of large checks decreased rapidly during the first year of life, reaching adult values at about 1 year of age. In response to a pattern of small checks, developmental changes were slower, so that by 5 years of age, adult values were still not obtained. Similar developmental differences in response to the two sizes of checks were also observed in earlier studies (Sokol and Jones, 1979), and Spekreijse (1978) found that the latency for VEP responses to small checks matured at about 10 years of age.

The source of the differential developmental response to large and small pattern elements is not well understood. Moskowitz and Sokol (1983) have drawn attention to reviews of the neurophysiologic and neuroanatomic evidence for the presence of two parallel pathways from the retina to the lateral geniculate nucleus to the visual cortex that process different aspects of visual input. One system consists of cells (Y cells) that respond with short latencies to *transient* events and functions, to detect movement and gross patterns; the second system is comprised of cells (X cells) that respond with long latencies to *sustained* input and functions, to discriminate fine patterns (Breitmeyer and Ganz, 1976; Lennie, 1980). Moskowitz and Sokol (1983) suggest that it is the short latency, transient system, which responds to large patterns, that matures rapidly, and the long latency, sustained system, which responds to small patterns, that matures more slowly. However, neuroanatomic studies of the human lateral geniculate nucleus (LGN) (Hickey, 1977) and neurophysiologic studies of the kitten LGN (Daniels et al., 1978) suggest that it is the sustained (X cell) system that matures earlier and the transient (Y cell) system that matures later. These results are not completely comparable to those of Moskowitz and Sokol (1983) because the time course for the increase in size of human LGN cells in both systems (adult size is attained by cells associated with the sustained system by 12 months of age and by cells associated with the transient system by 24 months) is much shorter than the time course for development of VEPs in response to large and small checks (mature responses by 1 year and by 5 to 10 years of age, respectively).

The issue of differential development of transient and sustained response systems is important because the dual functioning of these two systems seems to be a characteristic of a more general principle of the processing of sensory information in the nervous system (Graham et al., 1981). In the auditory modality, Graham and Murray (1977) have proposed that inhibitory and facilitatory startle modulation (see description in the previous section) are associated with two neuronal systems, described by Gersuni (1971), that transmit auditory information about transient and sustained events. Neurons in the auditory system capable of detecting the onset of a signal (transient event) with great precision (short-time constant neurons) and other neurons capable of temporal accumulation of information (sustained event) about the signal (long-time constant neurons) are found in both the cochlear nucleus (Radionova, 1971) and the inferior colliculus (Gersuni et al., 1971). In contrast to the early development during infancy of VEP responses to large checks, which Moskowitz and Sokol (1983) associate with the transient system, inhibitory startle modulation, which Graham and her colleagues (Graham and Murray, 1977; Graham et al., 1981) also associate with the transient system, develops late during childhood (Graham et al., 1981; Ornitz et al., 1986, 1991). For both the visual system (Breitmeyer and Ganz, 1976) and the auditory system (Gersuni, 1971), the transient system is responsive to novel patterns, stimulus onsets, or other aspects of environmental change, while the sustained system is involved with more elaborate processing and analysis of the information in the stimulus. For visual responses to nonstartling stimuli, there is agreement that the transient system (Y cells) also functions to inhibit (or regulate the tonic inhibition of) the activity of the sustained system (X cells) (Breitmeyer and Ganz, 1976; Lennie, 1980) in order to adjust

information processing to the requirements of response to new input. For responses to startling stimuli, it has been suggested that the transient system inhibits responses to new input in order to protect information processing (i.e., processing of sustained stimuli) from distraction by responses to new sensory input ( [Graham and Murray, 1977](#)). These somewhat contradictory hypotheses and the differing developmental sequences should generate fruitful research concerning the neurophysiology underlying the development of attentional mechanisms and cognitive processes in different sensory systems during childhood.

Studies of the pattern onset visual-evoked potential have identified a striate cortex component, which changes as a function of age. A single positive peak at about 130 msec in children under 8 years of age evolves into a negative-positive complex with peak latencies of about 100 and 150 msec between 9 and 16 years of age ( [Ossenblok et al., 1992](#)). This change is attributed by Ossenblok and colleagues, to the changes in synaptic connectivity in striate cortex that occur in comparable age periods ( [Huttenlocher et al., 1982](#)).

A general characteristic of the maturation of the auditory, somatosensory, and visual exogenous event-related potentials is the presence of at least two developmental sequences, a rapid maturational progression that is completed during the first or second year of life and a slower progression that is not completed until after 5 years of age and that may extend more slowly until 8 to 10 years of age or even until adulthood. [Eggermont \(1988\)](#) has provided a mathematical model that represents the developmental latency changes as the sum of a series of decaying exponential functions that apply equally to the three stimulus modalities. The time constants derived from these functions describe these two different rates of development of the exogenous ERPs as well as a third very rapid developmental process during the first few weeks of life.

### Endogenous Event-Related Potentials

Many endogenous ERPs have been described in experiments incorporating tasks designed to require meaningful responses to stimuli. These include negative and positive ERP components of different latencies and durations. The earlier (<300 msec) negative and positive components tend to reflect various aspects of orienting to stimuli, whereas later (>300 msec) components tend to reflect utilization of the information contained in stimuli ( [Hillyard and Picton, 1987](#)).

Several prominent negative endogenous ERP components have been identified. Wave N1 (peak latency around 100 msec) is sensitive to transient aspects of stimuli ( [Näätänen and Picton, 1987](#)) and reflects feature detection ( [Näätänen et al., 1988](#)), increasing in amplitude with increasing confidence in correct detection ( [Hillyard and Kutas, 1983](#)). Developmentally, in 175 normal subjects of both sexes, the latency (but not the amplitude) of wave N1 in response to auditory stimuli decreased linearly from 4 to 16 years of age ( [Fuchigami et al., 1993](#)). In a smaller study (40 subjects between 7 and 20 years of age) limited to girls, [Johnson \(1989\)](#) found neither amplitude nor latency changes in wave N1 with maturation in response to *auditory* stimuli, whereas demonstrating a linear latency decrement (but no amplitude changes) in response to *visual* stimuli, in wave N1 across the same age range. However, [Johnstone and associates \(1996\)](#) reported decreasing amplitude of N1 at frontal sites in response to attended tones across the age range 8 to 17 years. The latter result in an experiment using target stimuli that evoke an endogenous response is contrary to the increasing frontal N1 with maturation found in those experiments structured to evoke exogenous responses, as described earlier in this section.

Direct measurement of wave N1 has been augmented by the study of difference waves wherein the difference between the negative event related potentials in the latency range of N1 (and extending into that of N2, see the following) in two conditions (e.g., while attending or ignoring a stimulus) is measured. This provides neurophysiological correlates of stimulus discrimination and of selective attention. Two types of difference waves have been defined and used to study the development of these two functions throughout childhood and adolescence ( [Oades et al., 1997](#)). Component Nd, the difference negativity, also referred to as the processing negativity, overlaps wave N1 when an attended (e.g., targeted) auditory stimulus is differentiated from an ignored stimulus ( [Näätänen and Picton, 1987](#)). This increased and more prolonged negativity reflects an early stage of stimulus processing that preferentially extracts information from the attended auditory stimulus ( [Hillyard and Hansen, 1986](#); [Hillyard and Kutas, 1983](#); [Hillyard and Picton, 1987](#)). Hence, the processing negativity reflects selective attention. In response to visual stimuli, an analogous ERP component NA has been associated with stimulus recognition and compared to the auditory processing negativity ( [Ritter et al., 1983, 1988](#)). The mismatch negativity (peak latency about 150 to 200 msec) reflects a response to relationships between two stimuli ( [Näätänen and Picton, 1987](#)), evaluating novel or deviant stimuli against the background of standard or expected stimuli ( [Näätänen et al., 1989](#)). Hence, the mismatch negativity reflects automatic detection of stimulus change.

In preadolescent children, compared with adolescents and young adults, the processing negativity in response to targeted longer-duration syllables interspersed among "irrelevant" shorter-duration syllables is significantly smaller, suggesting a neurophysiologic correlate of the child's reduced efficiency in directing attention among competing inputs ( [Berman et al., 1990](#); [Friedman, 1991](#)). Between 7 and 24 years of age, the amplitude of an occipitally derived difference wave for attended vs ignored visual stimuli with a latency between 150 to 300 msec becomes increasingly negative with increasing age, indexing increasing capacity for visual selective attention with greater maturity ( [Van der Stelt et al., 1998](#)). A scalp topography study of the development of auditory event related potentials was consistent with these findings: Processing negativity did not mature until 17 years of age ( [Oades et al., 1997](#)).

In contrast to the late maturing processing negativity, the mismatch negativity (MMN) develops earlier, by 14 years of age in children and adolescents studied between 8 and 22 years old ( [Oades et al., 1997](#)). In other studies, the mismatch negativity evoked by barely perceptible differences in speech sounds had already reached adult levels in school age children ( [Ceponienė et al., 1998](#); [Kraus et al., 1993, 1999](#)) and mismatch negativity has actually been demonstrated in premature infants born 30 to 35 weeks after conception ( [Cheour-Luhtanen et al., 1996](#)). With consideration for state-of-consciousness (i.e., the sleep cycle) and some scalp topographical differences, the MMN in the newborn ( [Alho et al., 1990](#); [Leppänen et al., 1997](#)), at 3 months of age ( [Cheour et al., 1997](#)) and at 8 months of age ( [Pang et al., 1998](#)) is remarkably similar to that of older children and adults. [Cheour and colleagues \(2000\)](#), in a comprehensive review, find "that a prominent, developmentally stable MMN can be obtained from children and even infants," that, as in adults, the MMN is not affected by attention and that it is a response to a change in the stimulus. The developmental differences are limited to a broader and more central scalp distribution and longer latency in infants than adults, and to the fact that the MMN can be obtained in sleep in infants but not in adults ( [Cheour et al., 2000](#)).

The effect of distractibility in children suggests the potential functional utility of the mismatch negativity. In distractible children, compared to nondistractible children, the late component of the mismatch negativity was significantly reduced and current density maps of that component revealed weaker frontal lobe activation ( [Kilpeläinen et al., 1999d](#)). Because the mismatch negativity reflects frontal lobe mediation of auditory sensory memory functioning ( [Näätänen and Winkler, 1999](#)), it is suggested that distractibility in children may reflect dysfunction in frontally mediated aspects of auditory sensory memory ( [Kilpeläinen et al., 1999d](#)). Also, the significantly attenuated MMN in response to frequency differences in young dysphasic children suggests a defect in the central automatic processing of auditory frequencies ( [Holopainen et al., 1997](#)). Although these findings suggest potential clinical utility of the MMN in infants and children with auditory processing impairment ( [Kraus et al., 1999](#)), the relatively low stability of the MMN in individual children and the greater intersubject variability (relative to adults) make diagnostic application in children unlikely at the present time ( [Cheour et al., 2000](#); [Kurtzberg et al., 1995](#); [Uwer and von Suchodoletz, 2000](#)).

Wave N2 (peak latency about 200 msec) also reflects registration of stimulus deviance from a steady-state background ( [Hillyard and Kutas, 1983](#)). It seems to reflect a stage of discriminative stimulus processing, associated with stimulus classification ( [Ritter et al., 1983](#)), that precedes the further processing associated with later ERP components ( [Hillyard and Picton, 1987](#)). A late slow wave with negative polarity that develops around 1,200 msec and persists beyond 2,700 msec has been associated with increasing conceptual difficulty ( [Ruchkin et al., 1988](#)).

Wave N2 has been studied developmentally. It was first described in 5- to 11-year-old children by [Symmes and Eisengart \(1971\)](#) as a large negative wave in response to attention-getting stimuli and later referred to as Nc by [Courchesne \(1977, 1978\)](#), who described it both in response to surprising or novel stimuli and also to target stimuli that must be discriminated from background stimuli ( [Courchesne et al., 1987](#)). This negative ERP component is large and long in latency, between 4 and 7 months of age, after which time there is a progressive reduction in amplitude and latency throughout childhood and adolescence ( [Courchesne, 1978](#); [Courchesne et al., 1987](#); [Enoki et al., 1993](#); [Friedman et al., 1984](#); [Fuchigami et al., 1993](#); [Johnstone et al., 1996](#); [Van der Stelt et al., 1998](#)). [Fuchigami and associates \(1993\)](#) did not find developmental amplitude changes in N2, which, however, was measured peak-to-peak from the preceding wave P2. By late adolescence, this wave has assumed the adult form of wave N2 ( [Friedman et al., 1984](#)). Its latency is about 700 msec in infancy, 400 msec during childhood ( [Courchesne et al., 1987](#)), and 200 to 250 msec in adolescence ( [Enoki et al., 1993](#); [Friedman et al., 1984](#)). Its changing stimulus parameters seem to parallel the changing perceptual styles and interests that occur with maturation. In this regard, it is noteworthy that children under 13 years of age show a similar wave N2 to that of adolescents and adults in response to the requirement to identify a target stimulus, but show a large delayed negative wave in response to surprising novel stimuli. (See Fig. 7 in [Courchesne, 1978](#), where the large N2 in preadolescent children in response to novel stimuli was labeled Nc.) Although described as a special ERP component found in childhood and given a special label ( [Courchesne, 1977](#); [Courchesne et al., 1987](#)), there seems to be little reason not to consider this component as a developmental precursor of wave N2, with a changing configuration throughout its developmental course ( [Friedman et al., 1984](#)). In both children ( [Courchesne, 1978](#)) and adults ( [Knight, 1984](#)), it has a predominantly fronto-central scalp topography and increases in amplitude when elicited in response to novel as compared to target stimuli. Hence, wave N2, which reflects stimulus classification, undergoes striking developmental changes in both latency and amplitude. Its developmental precursor, Nc, seems to reflect the earliest ERP evidence of cognitive processing since as early as 4 to 7 months of age it shows increased amplitude and longer

latency in response to infrequent compared to frequent events ([Courchesne et al., 1981](#); [Karrer and Ackles, 1987](#)). It is during this period, the first 6 months of postnatal life, that major changes in frontal cortical laminar structure and cortico-cortical connectivity occur ([Kostovic, 1990](#)).

Positive endogenous ERP components have also been described. These include the P2, the P3a, the slow wave, fronto-central positivities, and the P300 ([Donchin and Coles, 1988](#); [Fabiani et al., 1987](#); [Ruchkin et al., 1988](#)). The *endogenous P2 increases* in amplitude with increasing age from 8 to 17 years in response to both standard and target stimuli presented in the oddball paradigm ([Johnstone et al., 1996](#)). The oddball paradigm elicits endogenous ERP components, as discussed in respect to P300 elicitation (see the following). This maturational effect is in contrast to the modest *decrease* in amplitude with increasing age that occurs when the experimental conditions elicit an exogenous P2 (see the preceding). The P300, also labeled P3 and P3b, and the related P3a have received the greatest experimental attention and theoretical analysis ([Donchin and Coles, 1988](#); [Donchin et al., 1986a,b](#); [Fabiani et al., 1987](#); [Johnson, 1988](#)) and have received considerable developmental investigation in children and adolescents ([Courchesne, 1978, 1983](#); [Courchesne et al., 1987](#); [Finley et al., 1985](#); [Friedman et al., 1984](#); [Goodin et al., 1978](#); [Martin et al., 1988a,b](#)).

The P300 is a positive peak in the ERP, occurring from somewhat less than 300 msec to nearly 1000 msec after a stimulus ([Hillyard and Kutas, 1983](#)) with maximum amplitude over the parietal scalp. Human neurosurgical/neurophysiologic studies have suggested multiple generators of the P300, particularly the medial temporal lobe ([Halgren, 1988](#)), the temporal-parietal junction ([Knight et al., 1989](#)), the frontal lobe ([Wood and McCarthy, 1985](#)), and the thalamus ([Velasco et al., 1986](#); [Yingling and Hosobuchi, 1984](#)). Lesion studies in the monkey suggest that noradrenergic projections to these structures from the locus ceruleus are important in the generation and modulation of the scalp-recorded P300 ([Pineda et al., 1989](#)).

The amplitude of P300 increases with increasing relevance of a task associated with a stimulus and with decreasing probability that the stimulus will occur ([Donchin et al., 1986a,b](#)). Hence, P300s are usually elicited in experiments in which the subject is asked to identify certain stimuli (e.g., higher-pitched tones) that occur infrequently during a series of frequently occurring and ignored stimuli (e.g., lower-pitched tones). This is usually referred to as the oddball paradigm and the P300 evoked in this paradigm is often referred to as the P3b. The P3b is larger in response to the less frequent target stimulus and shows a parietal predominance. In contrast, the P3a (also called the novelty P3) designates a P300 response to novel or deviant but nontarget stimuli. The P3a shows a frontal predominance in contrast to the parietally predominant P3b, and its latency is considerably shorter than that of the P3b. More generally, the peak amplitude of the P300 appears to be responsive to the distinctiveness of stimuli, reflecting the mental evaluation of surprising events, and hence to reflect mental activity associated with revisions of the subject's current model of the environment ([Donchin and Coles, 1988](#); [Donchin et al., 1986b](#)). The peak latency of P300 is thought to reflect the time required to categorize stimuli ([Hillyard and Kutas, 1983](#)) and thus to update the subject's model of the environment ([Donchin and Coles, 1988](#); [Donchin et al., 1986b](#)). More difficult discriminations result in longer latencies ([Donchin et al., 1986b](#)), suggesting that the level of mental abstraction utilized in performing a task may be reflected in the peak latency of P300 ([Donchin et al., 1986a](#)). [Johnson \(1988\)](#) has discussed the control of P300 amplitude and latency in the context of information theory: The degree to which P300 amplitude and latency are affected by stimulus probability and task relevance (which is affected by task and stimulus complexity as well as stimulus value) is modified by the degree to which the subject is uncertain about having correctly identified the stimulus. Greater uncertainty means that a smaller proportion of information is transmitted; this is reflected in decreased amplitude and increased latency.

Hence, in the human adult, the P300 wave reflects a considerable degree of information processing, becoming larger and occurring earlier as a greater proportion of information is transmitted, that is, as prior uncertainty is resolved by a stimulus or, in information theory terms ([Shannon and Weaver, 1963](#)), as equivocation is reduced ([Hillyard and Kutas, 1983](#); [Johnson, 1988](#)).

Developmentally, the P300, which is not present in infancy ([Courchesne et al., 1981](#)), has been demonstrated in response to infrequently presented target stimuli in 3-year-old children ([Courchesne, 1983](#); [Courchesne et al., 1987](#)). Its small amplitude increases to maximum values between 3.7 and 6 years of age, after which amplitude may decrease to adult values between 10 and 13 years of age ([Courchesne, 1978, 1983](#); [Courchesne et al., 1987](#); [Wijker et al., 1989](#)), show no further change until adulthood ([Fuchigami et al., 1993](#); [Martin et al., 1988b](#); [Mullis et al., 1985](#)), or actually increase ([Polich et al., 1990](#)). Although differential effects of target stimulus probabilities, stimulus modality, or the nature of the required response to the target stimulus have been proposed to explain these differences, perusal of the preceding literature revealed no consistent relationship between these experimental variables and the discrepant developmental results. In one study ([Johnson, 1989](#)), both visual and auditory stimuli and two types of responses to target stimuli were used. Stimulus modality had no effect on P300 amplitude between 7 and 20 years of age, but P300 amplitude decreased with age when the subjects were asked to press a button to the target stimuli and showed no developmental effect when subjects were asked to count the targets. In response to orthographic and phonologic targets, a developmentally maximum amplitude occurred around 11 years of age ([Taylor, 1993](#)), followed by a decrease in P300 amplitude until young adulthood.

Regardless of the developmental course of P300 amplitude changes following the preschool period, the earliest manifestation of increased P300 amplitude in response to target stimuli relative to background stimuli, that is, information processing, occurs some time between 3 and 5 years of age ([Courchesne et al., 1987](#)). This developmental neurophysiologic landmark coincides with the developmental peak loss of inhibitory startle modulation and the associated peak increment of facilitatory startle modulation ([Ornitz et al., 1986, 1990, 1991](#)), the developmental peak dishabituation of the startle blink ([Zametkin et al., 1979](#)), and an early maturational period of EEG changes characterized by developmental peaks of theta ([Matousek and Petersen, 1973](#)) and alpha ([Epstein, 1979, 1980, 1986](#)) activity and coherence and phase changes, suggesting increased left fronto-occipital and frontotemporal coupling and right frontal pole pairing ([Thatcher et al., 1987](#)). Hence, the P300, reflecting responsiveness to the distinctiveness of stimuli and the transmission of information, becomes functional during a major developmental period of functional cortical reorganization (reflected in EEG changes) and reduced brain stem control over response to sensory input (reduced inhibitory and increased facilitatory startle modulation). This constellation of endogenous ERP, EEG, and startle modulation changes, peaking around 4 to 5 years of age, coincides with the piagetian mental stage of preoperational behavior and may reflect or be part of a neurophysiologic developmental stage that underlies the heightened awareness and capacity to absorb new information from the environment and the relative inability to modulate reactions to the environment that is so characteristic of the preschool child. This preschool stage of neurophysiologic development follows the end of the first major period of structural brain maturation, which occurs between 15 months and 4 years and includes accelerated increases or changes in brain weight ([Epstein, 1979](#)), cortical thickness ([Rabinowicz et al., 1977](#)), pyramidal cell size and shape ([Rabinowicz, 1977](#)), neuronal density ([Rabinowicz, 1986](#)), and completion of myelination of the sensory-specific thalamic radiations ([Lecours, 1982](#); [Yakovlev and Lecours, 1967](#)). It precedes the second period of brain growth and restructuring, which begins around 6 years of age ([Epstein, 1986](#); [Rabinowicz, 1986](#)).

The latency of P300 follows a different developmental pattern than that of amplitude. It decreases exponentially with maturation in response to both target and background stimuli, from over 800 msec in 3-year-olds to 300 to 400 msec in adolescents and young adults ([Courchesne, 1978](#); [Courchesne et al., 1987](#); [Finley et al., 1985](#); [Fuchigami et al., 1993](#); [Goodin et al., 1978](#); [Howard and Polich, 1985](#); [Johnson, 1989](#); [Johnstone et al., 1996](#); [Martin et al., 1988a,b](#); [Oades et al., 1997](#); [Taylor, 1993](#); [Van der Stelt et al., 1998](#)). Unlike P300 amplitude, the maturational changes in latency are continuous from the earliest demonstration of the P300 response and seem to be independent of the response to the target ([Johnson, 1989](#)). According to the interpretation of P300 latency as reflecting the time required to categorize stimuli ([Hillyard and Kutas, 1983](#)), the decrease in P300 latency with maturation may index the development of this aspect of information processing. The decrease in P300 latency between 5 and 14 years of age also correlates strongly with increasing scores on tests measuring memory span ([Howard and Polich, 1985](#); [Polich et al., 1990](#)), and in 4- to 7-year-olds, P300 latencies are significantly shorter in children with IQs greater than 140 ([Martin et al., 1993](#)).

It should be noted, however, that factors other than maturation and more efficient information processing can affect P300 latency in children. For example, when the intervals between target stimuli in the oddball task are prolonged, more distractible children actually have shorter latency P300s than less distractible children, possibly because the stimulus processing in the more distractible children shifts from an information processing mode to an orienting mode (orienting to novel events is known to generate shorter latency responses ([Kilpeläinen et al., 1999a](#))). The shorter latency P300 generated in response to the less frequent target stimuli by the more distractible children also showed a frontal rather than the usual parietal predominance, providing further evidence that distractible children processed the target stimuli as if they were novel events, that is, they oriented to rather than cognitively processed the target stimuli ([Kilpeläinen et al., 1999b](#)). When normal 9-year-old children were compared with adults, the children's P300 responses were more affected than the adults' by the intervals between target stimuli. When the intervals between target stimuli were prolonged, there was marked shortening of P300 latency for the children and little effect for the adults, suggesting that children are more likely than adults to process infrequently occurring target stimuli as if they were novel stimuli ([Kilpeläinen et al., 1999c](#)). The greater vulnerability of distractible children than nondistractible children and of children than adults to react to infrequent target stimuli as if they were novel stimuli and hence respond with a P3a, or novelty P3, instead of a P3b suggests that the neurophysiologic representation of the target stimulus during a long intertarget interval decays more rapidly in children. Hence, each successive target is reacted to as if it were novel. The capacity to generate a neurophysiological response to novel stimuli, the P3a or novelty P300, is intact throughout childhood from at least 5 years of age ([Cycowicz et al., 1996](#)). A short latency P3a-like response to very strong sudden stimuli that evoke startle responses occurs in children as well as adults and is modulated by prepulse modulation ([Sugawara et al., 1994](#)) and habituation ([Hirano et al., 1996](#)) as is the startle response itself.

Recent attempts to apply topographical analyses (variations in ERP waveforms across scalp locations) to developmental changes in ERPs during complex cognitive tasks (picture matching and continuous recognition memory) have led to the conclusion that by 7 years of age late ERPs, P300 and a negative deflection at 400 msec (probably a variant of wave N2), are similar in children and young adults, except for the longer latencies in children, reflecting the reduced efficiency in speed of

stimulus evaluation and information processing ( [Friedman, 1991](#); [Friedman et al., 1988](#)). A recent innovation in developmental ERP studies has utilized topographic analysis of long-latency ERP changes in response to tasks which measure the cognitive transitions from the piagetian preoperational stage (2 to 7 years) to the stage of concrete operations (7 to 11 years) and from the latter to the stage of formal operations (11 to 15 years). In this complex study, [Stauder \(1992\)](#) recorded ERPs to pictorial analogs of the piagetian liquid conservation task in 5- to 7-year-olds and to pictorial analogs of the Raven Standard Progressive Matrices in 9- to 11-year-olds. In the younger children, the transition from nonconservation (preoperational level) to conservation (stage of concrete operations) was associated with a reduction in a broad late (up to 1,000 msec) ERP positivity over frontal electrode sites. In the older children, the transition to improved performance on the Standard Progressive Matrices (at the onset of the stage of formal operations) was associated with the reduction of a broad late (700 to 2,000 msec) negativity in the ERP in the more anterior scalp locations. In a related study, 5- to 7-year-old girls were classified as nonconservers or conservers. The ERPs evoked by the choice stimulus in a piagetian liquid conservation task were more positive (in the P300 latency range) frontally in the nonconservers and more positive parietally in the conservers ([Stauder et al., 1993](#)). This demonstration of ERP changes in response to actual performance on tasks indexing developmental transitions is currently the most direct approach to the neurophysiology of cognitive development. These findings of neurophysiologic transitions between developmental stages are congruent with the delineation of the three neurophysiologic stages described in this chapter and with their relationship to the three piagetian stages of preoperational behavior, concrete operations, and formal operations. The ERP topographic findings also point to the predominance of frontal cortical structural and functional change during childhood, a progressive development that is accompanied by the changing response to tests of frontal lobe functioning throughout childhood ( [Levin et al., 1991](#); [Welsh and Pennington, 1988](#)).

Further discussion of the complex effects of scalp topographical changes on the sequences of event related potential development is beyond the scope of this review. For the interested reader, [Oades et al. \(1997\)](#) and [Van der Stelt et al. \(1998\)](#) provide data and detailed reviews of this important topic.

## SUMMARY AND OVERVIEW OF DEVELOPMENTAL NEUROPHYSIOLOGY

Neurophysiologic development during childhood must be considered against the background of what is known about the maturation of the structure of the human brain. Both brain maturation and neurophysiologic development are characterized by progressive changes throughout long periods of childhood and by accelerations, usually followed or preceded by decelerations, in the rate of change, resulting in peaks and troughs of both structural and functional change. Although there is a tendency for the neurophysiologic spurts in development to coincide with structural spurts in maturation, there may be lags, such that important periods of functional change occur during slowdowns in structural growth or between periods of structural reorganization.

Following very rapid developmental and structural changes occurring from the end of gestation through the early weeks of postnatal life (not considered in this chapter), there are two major progressive structural sequences.

The first and more rapid takes place between birth and 1 to 3 years and includes general reductions in neuronal densities, increases in synaptic densities, and completion of myelination of the sensory-specific thalamic radiations. Many important early progressive neurophysiologic changes are associated with these structural developments. These include the marked reduction in REM sleep time and the rapid early reductions in BSAER transmission time, peripheral conduction velocity, and latency of VEPs in response to large pattern changes, and the early development of the mismatch negativity.

The second progressive sequence of neuroanatomic change is slower and includes a gradual increase in brain weight and cerebral cortical thickness from infancy to adulthood, a decrease in synaptic density between 1 and 11 years of age, and continuing myelination of the reticular formation, nonspecific thalamic radiations, and cerebral commissures until 8 to 10 years, and of the intracortical association areas until the second and third decades of life. Associated neurophysiologic events include progressive increases in EEG alpha activity between infancy and adulthood and decreases in slower EEG frequencies between 5 years and adulthood; increased organization of the phasic motor activity and phasic sensory inhibition during REM sleep between infancy and 9 years of age; progressive changes in vestibular function (increased gain, prolongation of time constants, and changes in adaptation) between infancy and 10 years of age; further reduction in BSAER transmission time, SEP central conduction velocity, and VEP latency in response to fine pattern changes between early childhood and 8 to 10 years of age; and reduction of latency of the P1, N1, and P300 components of the event-related potential between infancy and adolescence.

The progressive changes in brain growth are punctuated by four maturational spurts. The first takes place between about 15 months and 4 years of age. It includes an acceleration in cerebral cortical thickening and changes in pyramidal cell size and shape. Associated neurophysiologic changes include a spurt in EEG alpha activity and a developmental peak of theta activity at the end of this period.

The second spurt in brain maturation takes place between 6 and 10 years of age. Brain changes include a second acceleration in the rate of cerebral cortical thickening, a small increment in cortical and subcortical neuronal density, accelerated synaptic elimination, and further changes in pyramidal cell size and shape. Myelination of reticular tissue is also completed during this period. Associated neurophysiologic activity includes a spurt in EEG alpha activity, a peak in EEG coherence and phase, suggesting accelerated development of right hemispheric frontal-temporal connections, and an abrupt increase followed by a steplike decrease in amplitude of the event-related potentials P1 and N2. During this second major spurt in brain growth and change, the developmental progressions of several important neurophysiologic functions are completed. The organization of rapid eye movements into bursts and phasic sensory inhibition during REM sleep, the gain and time constant of vestibular nystagmus, the modulation of startle by inhibitory and facilitatory prestimulation, the central transmission time of the BSAER, the central conduction velocity of the SEP, and the latency of the VEP in response to fine patterns all reach adult values. Hence, by the end of this second spurt in structural and functional brain development, at around 10 years of age, many significant subcortical functions have matured, and accelerated development of some measures of cortical activity have taken place. This period coincides with the piagetian period of concrete operations, that is, the beginnings of logical thinking (Chapter 10). Many of the mature subcortical mechanisms are of an inhibitory nature, suggesting a relationship between the capacity to inhibit and the readiness for higher cognitive processes. During this period, there is an accelerated development of the ability to inhibit the retroactive interference of a second set of stimuli on the recall of a prior set. This is a frontal lobe function. It is suggested that the developing capacity to inhibit, which is requisite for frontal lobe mediated cognition, may be linked to the development of subcortical inhibitory mechanisms.

Prior to the second maturational spurt in brain growth and change, and following the first such spurt (i.e., between 4 and 6 years), there is an important period of neurophysiologic development characterized by a particular constellation of EEG, ERP, and startle physiology changes. Initiated around 4 years of age by developmental peaks in EEG alpha and theta activity and changes in EEG coherence and phase, suggesting advances in frontal cortex connectivity, this period is notable for a peak increment in event-related potential activity ranging from the exogenous wave 5 of the BSAER to the endogenous P300 and a concurrent peak deficit in inhibitory startle modulation. This stage of neurophysiologic development involving increased reactivity to stimuli at both cortical and subcortical levels, occurring between an earlier period of cortical maturation and a later period of cortical "remodeling" (per Rabinowicz), coincides with the piagetian stage of preoperational behavior. The neurophysiologic characteristics suggest the heightened awareness coupled with the inability to inhibit that characterize the preschool child.

Brain weight changes and histologic evidence for cortical remodeling suggest two additional spurts in brain maturation and change around puberty and during midadolescence. These late brain growth periods are also accompanied by neurophysiologic changes manifested by peaks of EEG alpha activity and changes in coherence and phase measures involving frontal cortex connectivity. During adolescence, the N1 component of the ERP develops a consistent negativity, and the progressive changes in the ERP components N2 and P300 terminate in adult values.

An overview of the relationships between neurophysiologic development and brain growth suggests a general but not absolute concordance. There is evidence for considerable plasticity in neurophysiologic development, such that important developmental neurophysiologic changes occur long after structural change seems to be complete (as exemplified by the course of vestibular development) or during lulls in structural change. A major component of plasticity in neurophysiologic development may also be attributed to neuronal plasticity in the case of cerebral cortex. Here there is overproduction and redundancy of synaptic connections early in childhood, with synapse elimination with maturity. [Huttenlocher \(1990\)](#) has suggested that neural plasticity can be understood as the incorporation of some of the excessive synaptic contacts into functioning systems. These synaptic contacts become stabilized, while "labile contacts that fail to be incorporated" are eliminated. Developmental neurohistological studies in primates indicate a similar early synaptic excess followed by elimination of excessive synapses with maturity ([Goldman-Rakic, 1987](#)). Similar cognitive functions of delayed response in the monkey and object permanence in the infant emerge during the period of synaptic excess; [Goldman-Rakic \(1987\)](#) has suggested that whereas a critical mass of synapses is associated with the emergence of this type of cognition, "mature capacity may depend upon the [later] elimination of excess synapses." It is significant that important neurophysiologic development changes, notably those that are related to the ability to inhibit, either emerge or attain adult values during the school-age years (i.e., between 6 and 12 years of age). This is the period when, regardless of cultural differences, children are engaged in some type of formal learning. This is also the time when, following a period of cortical remodeling ( [Rabinowicz, 1986](#)), there is an extended period of synaptic elimination ( [Huttenlocher and Dabholkar, 1997](#)).

An overview of the relationships between neurophysiologic development and behavior suggests three significant stages that, not surprisingly, coincide with the

preschool- and school-age periods of childhood and early adolescence. Between 3 and 5 years, there is a neurophysiologic stage of increased receptivity coupled with disinhibition in response to environmental stimuli. Between 6 and 10 years, there is a neurophysiologic stage of increased inhibition in response to stimuli, coupled with increasing development of neurophysiologic indices of information processing. In early adolescence, there is a third stage of development during which there is neurophysiologic evidence for further development of intracortical, particularly frontal, connectivity and final maturation of event-related potential indices of information processing. These three neurophysiologic stages coincide with the piagetian stages of preoperational behavior, concrete operations, and formal operations. Hence, the developing neurophysiologic capacity to register, process, and extract information from stimuli, coupled with the increasing ability to inhibit responses to stimuli, appears to underlie the changing style of learning that progresses from the egocentric (preschool child) to the more objective but concrete (school child) and finally to abstract thinking (adolescence).

Psychoneuroimmunology is the study of interactions among behavior, central- and peripheral nervous systems, neuroendocrine hormones, and the immune system. Although research in this field is relatively new, emergent observations suggest that these interactions constitute one mechanism by which factors such as stress or depression influence health. Substantial data are now available to show that both acute and chronic psychological factors can influence the numbers and functional capacities of multiple immune cells, including lymphocyte and granulocyte function. Less is known about the effects of stress on the immune system of a developing organism, although perturbations occurring in early life, or even before birth, may alter the developmental course of the immune system and result in altered immune responses throughout life.

This chapter reviews experimental evidence concerning the neural and endocrine pathways by which the central nervous system (CNS) may regulate immune function as well as the short- and long-term immunologic effects of fetal or childhood experiences. Preclinical and clinical investigations are presented that document the influence of both stressors and psychosocial processes on immunity. Before beginning the discussion of interactions among the brain, behavior, and immunity, we provide a brief overview of the immune system.

### OVERVIEW OF THE IMMUNE SYSTEM

The immune system functions to discriminate “self” from “non-self” cells, protecting the organism from invasion by pathogens such as viruses and bacteria or from abnormal internal cells such as cancer cells (Cohn, 1985; Hood et al., 1985). The immune response consists of three stages or phases. During the induction phase, foreign or other non-self antigens are detected. The activation phase then involves mobilization and/or proliferation of specific immunocytes. Finally, during the effector phase, these foreign or non-self antigen sources are destroyed, neutralized, and removed (Abbas et al., 1994). These immune functions are closely regulated and usually performed without damage to the host, although an overresponsive immune system is purported to lead to autoimmune disease in which the organism's own tissues are attacked (Cohen, 1988; Morimoto et al., 1987; Paul, 1984; Strakosch et al., 1982; Talal, 1980).

The organs of the mammalian immune system include the thymus, spleen, bone marrow, and lymph nodes (Hood et al., 1985; Paul, 1984). The working cells of the immune system are represented by distinct populations: lymphoid type cells, including lymphocytes comprised of T and B cells and natural killer (NK) or large granular lymphocytes; and myeloid derived cells including granulocytes and monocytes (Hood et al., 1985; Paul, 1984; Ritz, 1989).

Surface markers that are thought to reflect cell functions identify cells of the immune system. These markers are referred to as cluster designation numbers or CD, which are identified by monoclonal antibodies to these cell surface antigens for identification purposes. Immature or stem cells have the CD marker number 34; therefore, they are called CD34-positive cells. Similarly, the CD56 marker often identifies NK cells. Two or more CD markers identify subtypes of particular cell types; for example, T helper/inducer cells are CD3- and CD4-positive, whereas T-suppressor or cytotoxic cells are CD3- and CD8-positive. Conceptualizations of immunocytes have changed over time. Cells of the immune system were first named by their putative function and more recently by CD designations.

All cells of the immune system are derived from the pluripotent stem cell in the bone marrow, which becomes either a myeloid or lymphoid cell precursor. These cells further differentiate within the thymus, bone marrow, or at other sites in the body.

T lymphocytes develop from stem cells in the bone marrow and migrate to the thymus, where they mature into several subsets, including cytotoxic T cells, T-helper cells, and T-suppressor cells (Hood et al., 1985). These T cells circulate into the periphery and are found in the lymph nodes, blood vessels, and spleen. Briefly, the cytotoxic T cell is characterized by its ability to seek out and destroy either cells infected with viruses or tumor cells that have acquired foreign non-self antigens (Henney and Gillis, 1984; Zinkernagel and Doherty, 1979). In the development of the cytotoxic T-cell response, a foreign antigen is first encountered and incorporated onto the surface of an antigen-presenting cell such as a macrophage. After the antigen is presented to the T cell, recognized, and bound by a specific receptor on the T cell, the T cell multiplies and becomes capable of attacking any cell that presents that specific foreign surface-antigen (Henney and Gillis, 1984). Other types of T lymphocytes, such as T helper cells, secrete interleukin-2 (IL-2) and regulate the proliferative response of the T cell to antigenic stimulation (Henney and Gillis, 1984). Reexposure of the cytotoxic T cell to an antigen produces a more rapid and extensive reaction than that found on initial presentation.

The B cell is primarily involved in the humoral response. Like the T cell, the B cell arises from a precursor stem cell in the bone marrow, although in humans its site of maturation remains unknown (Hood et al., 1985), but likely includes the bone marrow and lymph nodes. Following initial antigen processing by the macrophage, the antigen-MHC complex on the accessory cell surface engages the receptors of an appropriate T-helper cell antigen and the macrophage releases interleukin-1 (IL-1). Thus stimulated, the T helper cell proliferates forming a clone, and secretes factors such as IL-2, which stimulate T- and B-cell growth. The activated B cell, in turn, proliferates and differentiates into plasma cells that synthesize and secrete antigen-specific antibodies, of which the five major classes of immunoglobulins (Igs) are

IgM, IgG, IgA, IgE, and IgD (Goodman, 1991). IgM is produced soon after antigenic stimulation. Cytokines liberated by activated T helper cells, such as IL-4 and IL-5, subsequently promote the switch from IgM production by plasma cells to the production of other isotypes such as IgG (Nossal, 1987; Oppenheim et al., 1991). IgA is found primarily in the secretions of the body (i.e., nasal mucus, saliva, etc.). IgE in combination with a specific antigen binds to mast cells and mediates the immediate hypersensitivity response. IgE may also be important in the development of allergic reactions (Oppenheim et al., 1991). The function of IgD is not known, although its prominence on B cell surfaces during certain stages of development suggests that it may be involved in cell differentiation (Goodman, 1991).

A distinct subpopulation of lymphocytes comprised of NK cells has been described in addition to T and B cells. The NK cell is immunologically nonspecific and does not require sensitization to specific antigens to perform its cytotoxic activity (Herberman, 1980; Lotzova and Herberman, 1986; Trinchieri, 1989). Thus, the NK cell responds to a variety of cell surface markers, as long as the markers differ from "self" markers, and lyses a wide variety of cell types. Although the role of the NK cell in tumor surveillance remains controversial (Lotzova and Herberman, 1986; Ritz, 1989), substantial evidence has demonstrated the importance of the NK cell in the control of herpes and cytomegalovirus (CMV) infections in humans (Biron et al., 1989; Padgett et al., 1968; Ritz, 1989; Sullivan et al., 1980) and animals (Bancroft et al., 1981; Bukowski et al., 1985; Habu et al., 1984).

Granulocytes and macrophages are derived from myeloid rather than lymphoid cell precursors. These cells mature in the bone marrow and are sent out into the peripheral circulation from whence they are sent to inflammatory sites throughout the body as needed. These cells engulf or phagocytize bacteria or other materials (e.g., foreign proteins or apoptotic cells) and destroy the bacteria while it is within the cell body likely through the production of superoxides or nitric oxide. Granulocytes then remove the deactivated or dead cells. Myeloid derived cells (monocytes, antigen presenting cells) also are important in lymphoid cell function, as described.

The immune responses of lymphoid cells are typically divided into two important components: cellular immunity and humoral responses (Gilliland, 1983; Nossal, 1987; Paul, 1984). There is evidence that T and B cells interact and cooperate in many cellular immune responses and most humoral immune responses, although cellular immunity is mediated primarily by T lymphocytes and humoral responses by B lymphocytes and their soluble products (Hood et al., 1985).

Regulation of immune responses involves the secretion of cellular factors known as cytokines or lymphokines (Oppenheim et al., 1991). These cytokines together form a network of regulatory signals that show considerable overlap in activity and patterns of synergism, as well as antagonism. For example, the lymphokine 1 IL-1 is produced by nearly all immunologic cell types including NK cells, T and B lymphocytes, brain astrocytes, microglia, and macrophages (Dinarello and Mier, 1987). IL-1 acts mainly as an endogenous adjuvant serving as a cofactor during lymphocyte activation, inducing the synthesis of other lymphokines and activation of resting T cells (Dinarello and Mier, 1987). For example, IL-1 stimulates T lymphocytes to synthesize and release IL-2, and IL-1 further acts on NK cells to induce the expression of the IL-2 receptor. Binding of IL-2 by its receptor on the NK cell is a crucial step in the activation of such cytotoxic cells (predominantly large granular lymphocytes) to form lymphokine activated killers that are able to lyse a wide range of target cells in a non-major-histocompatibility-complex restricted manner (Henney and Gillis, 1984).

## MEASURES OF IMMUNE FUNCTION

The immune system can be evaluated by measures that assess the *number* of different cell types as well as the *function* of various components of cellular and humoral immunity. To quantitate the number of cells in various subpopulations, specific monoclonal antibodies are available that bind to unique surface markers (CD) on cell types such as T helper, T suppressor, and NK cells (Bernard and Boumsell, 1984). Although enumeration of cell types reveals the balance of different cell types needed for the optimal immune response, numbers of different cell types do not necessarily correlate with functional capacity, and changes of cell numbers in the peripheral circulation may merely reflect a redistribution of cell types from various immune compartments (Murray et al., 1992).

Measurement of the *function* of the immune system can involve *in vivo* and *in vitro* techniques. Two examples of *in vivo* assays of immunity are measurement of the delayed type hypersensitivity (DTH) response following administration of skin tests and measurement of antibody responses to a specific antigen. Both techniques provide valuable data about the physiologic response of the organism to an antigenic challenge, and they have been proposed to be more relevant in the clinical assessment of immunocompetence than *in vitro* measures of immune function. However, these assays are expensive to perform, and they cannot be utilized in longitudinal studies because subsequent immunologic evaluations are altered by primary immunization.

An indirect assessment of cellular immune function includes the measurement of antibody titers to latent viruses (Glaser et al., 1985). The cellular immune response is thought to be important in controlling latent viral infections; reactivation of such viruses as herpes viruses can occur during conditions in which cellular immunity is compromised. In turn, synthesis of virus or viral proteins is increased and elevations in antibody titers are detected in serum.

Two *in vitro* correlates of cellular immune function, mitogen-induced lymphocyte proliferation, and NK-cell activity (NKCA), have been widely used to assess cell-mediated immune function. Both of these assays evaluate the function of cells *ex vivo* outside the body. Mitogen-induced lymphocyte stimulation determines the proliferative capacity of lymphocytes following activation *in vitro* either with plant lectins such as concanavalin A (Con A) or phytohemagglutinin (PHA), which predominantly activate the T lymphocyte to divide, or with pokeweed mitogen that induces proliferation of B cells (Keller et al., 1981). The proliferative response is quantitated by the cellular incorporation of radioactively labeled thymidine or idoxuridine into newly synthesized deoxyribonucleic acid (DNA).

The other frequently used *in vitro* assessment of cellular immunity involves measurement of NK activity. Assay of NK lytic activity is carried out by the coincubation of isolated "effector" lymphocytes with radioactively labeled "target" tumor cells. The release of radioactivity by the lysed target cells is proportionate to the activity of the effector NK cells (Herberman and Ortaldo, 1981; Irwin et al., 1987).

Humoral immune function is generally assessed by the measurement of plasma concentrations of specific immunoglobulins, particularly IgM and IgG. Typically, enzyme linked immunosorbent assays (ELISA) are utilized. Immunoglobulin levels in serum provide an index of B-cell responses but do not assess the mechanisms by which this response is regulated (Schleifer et al., 1986).

Assessment of granulocyte function involves measuring both phagocytic and killing ability of these cells, by an assay originally developed by Weir (1967) and subsequently refined by Keller and colleagues (1981). Phagocytes are separated from whole blood until the composition of the cell population is predominantly neutrophils (PMNs), with a small percentage (<5%) of monocytes. Cultures are maintained on blood agar plates and fresh cultures are used for each assay. Then bacteria, *Staphylococcus aureus* (American Type and Culture collection #29213) are first mixed with normal human serum for 25 minutes for opsonization. Phagocyte function is assessed by incubation of the phagocyte cells with the opsonized *S. aureus* for 10 minutes at a 100:1 bacteria to phagocytic cell ratio. Cells are then washed and divided into five aliquots. Aliquot 1 is lysed immediately and the supernatant placed on blood agar to obtain the number of *S. aureus* phagocytized. This time zero plating is a sensitive *in vitro* measure of the adherence of bacteria to the cells and of the cells ability to phagocytize the bacteria. Aliquots 2 and 3 are incubated at 37°C, aliquot 2 for 1 hour and aliquot 3 for 2 hours, prior to lysis and *S. aureus* counts. Aliquots 4 and 5 are kept on ice, aliquot 4 for 1 hour and aliquot 5 for 2 hours as laboratory controls. Results of killing ability are expressed as the number of *S. aureus* colonies that grow after 1 or 2 hours incubation, subtracted from the number phagocytized.

Assay of levels of lymphokines (e.g., IL-1, IL-2, interferon [IFN]) in the plasma or following lymphocyte stimulation recently have been employed to quantitate possible alterations in the regulation of these cellular factors important in humoral and cellular immune responses (Glaser et al., 1990). IL-1 promotes lymphocyte differentiation via increased expression of IL-2 receptors, whereas IL-2 provides a signal for the proliferation and differentiation of immune cells (Oppenheim et al., 1991). Assay of these lymphokines is proposed to provide information about the immunologic mechanisms that may be related to changes in *ex vivo* measures such as lymphocyte proliferation or NK activity (Glaser et al., 1990; Maes et al., 1991).

## REGULATORS OF IMMUNITY

The day-to-day function of the immune system is influenced by many factors (Lawrence and Kim, 2000), including products of the immune system itself (e.g., cytokines), neurotransmitters, hormones, neuropeptides, ambient or environmental antigens or pathogens, and temperature. Immunity and these immunomodulators can vary with age, gender, and race. For example, during puberty the hormonal milieu in which the immune system functions changes drastically with respect to many hormonal immune modulators. In animal studies, altered noradrenergic innervation of spleen, lymph nodes, and the thymus have been reported in association with aging (Madden et al., 1998). Further, replacement of growth hormone in animals and humans has been reported to reverse some of the age-associated changes in the immune system and thymus (Burgess et al., 1999). The following is a review of some of the relevant and important immune regulators.

## Central Nervous System

A multitude of experimental evidence now exists that the brain can influence immune function, in part by coordinating the autonomic nervous system (ANS) and neuroendocrine pathways. Early experiments placed electrolytic or other destructive lesions in the hypothalamus and demonstrated alterations in lymphoid tissue architecture ([Cross et al., 1980](#); [Isakovic and Jankovic, 1973](#)), either impairment or enhancement of lymphoid cell activation ([Brooks et al., 1980](#); [Cross et al., 1988](#); [Keller et al., 1980](#); [Roszman et al., 1982](#)), impairment of delayed type hypersensitivity ([Macris et al., 1970](#); [Stein et al., 1976](#)), and suppression of NKCA ([Cross et al., 1984](#)). Less focal lesions in cortical tissue have revealed not only that cellular and humoral immune responses are modulated by ablation of parieto-occipital neocortex, but also that these effects are observed only following right hemisphere lesions ([Barneoud et al., 1987](#)).

Stroke represents a naturally occurring CNS lesion in humans. In a study of ischemic stroke, [Fiorina and colleagues \(1999\)](#) reported impaired cellular immunity and energy in association with diminished nocturnal melatonin secretion, altered sleep patterns, and mood disturbance. Although this study did not consider location of the lesion, mood disturbances following stroke have been linked to frontal lesions ([Singh et al., 2000](#)).

[Kang and associates \(1991\)](#) found that women with extreme right frontal activation as measured by electroencephalography (EEG) had lower levels of NK activity than did left frontally activated individuals. These observations are intriguing in light of psychophysiologic evidence that emotions are asymmetrically processed in the frontal cortex, with negative emotions (e.g., disgust) producing greater relative right frontal activation, and positive emotions (e.g., amusement) producing greater relative left frontal activation ([Wheeler et al., 1993](#)). Furthermore, clinical depression and a history of clinical depression are both associated with decreased relative left frontal activation ([Henriques and Davidson, 1990, 1991](#)).

## Autonomic Nervous System

The autonomic nervous system (ANS) is a pathway for direct communication from the brain to cells of the immune system. Anatomic studies have revealed an extensive presence of autonomic fibers in both primary and secondary lymphoid organs ([Bulloch and Pomerantz, 1984](#); [Felten et al., 1981, 1984, 1985](#); [Felten and Olschowka, 1987](#); [Kendall and al-Shawaf, 1991](#); [Leposavic et al., 1992](#)), innervating both the vasculature and parenchyma of the tissues. In a pattern of classic anatomic connection, preganglionic cell bodies located in the intermediolateral column of the spinal cord synapse with the ganglionic cells that are found either in the sympathetic chain or collateral ganglia ([Felten and Olschowka, 1987](#)). Immunohistochemical studies have demonstrated that nerve fibers enter the lymphoid organs, such as the spleen, along with the vasculature and branch into the parenchyma ([Felten et al., 1985](#)) and areas in which lymphocytes (primarily T cells) reside ([Ackerman et al., 1987](#); [Felten et al., 1985](#)). These noradrenergic fibers are not only adjacent to sites where T cells congregate but, at the electron microscopic level, end in synapse-like contacts with lymphocytes in the spleen ([Felten and Olschowka, 1987](#)). Together, these observations establish an anatomic link between the brain and immune system.

It has been hypothesized that the development and differentiation of lymphoid tissue are guided by the ANS ([Ackerman et al., 1987](#); [Bulloch, 1985](#); [Bulloch et al., 1987](#)). For example, the thymus was penetrated by vagal fibers before its immune and endocrine functions develop ([Hammar, 1935](#)). Furthermore, in the spleen, development of catecholaminergic nerves in the periarteriolar lymphatic sheaths parallels changes in T-cell compartmentalization ([Ackerman et al., 1987](#)), suggesting that norepinephrine influences lymphocyte movement into the spleen and the development of T- and B-cell compartments shortly after birth. Sympathetic innervation of the spleen also may be essential for the development of splenic immune cell function. Fischer 344 rats that were chemically sympathectomized with the neurotoxin 6-hydroxydopamine (6-OHDA) in the first week of life showed impaired NK cytotoxicity, mitogen-stimulated lymphocyte proliferation, and antibody responses lasting up to 3 months as compared to saline-treated controls ([Ackerman et al., 1991](#); [Madden et al., 1993](#)).

In addition to direct neuronal influence by the ANS, chemicals released during ANS activity influence immunity. In the adult animal, norepinephrine appears to act as a neurotransmitter in the spleen. Norepinephrine is released within the spleen; early studies by [Von Euler \(1946\)](#) found that splenic nerve stimulation yields a release of norepinephrine. Furthermore, *in vivo* dialysis techniques documented a 1- $\mu$ m concentration of norepinephrine in the rat spleen ([Felten et al., 1986](#)), a concentration that is more than 100-fold higher than that in blood, suggesting local release of norepinephrine within the spleen.

Lymphocytes have been found to receive signals from sympathetic neurons by adrenoceptor binding of norepinephrine, epinephrine, and dopamine ([Aarons and Molinoff, 1982](#); [Bidart et al., 1983](#); [Brodde et al., 1981](#); [Miles et al., 1984](#); [Motulsky and Insel, 1982](#); [Williams et al., 1976](#)). These b-receptors are linked to adenylate cyclase ([Katz et al., 1982](#); [Strom et al., 1977](#); [Watson, 1975](#)) and appear to have a functional role in the modulation of cellular immunity. *In vitro* incubation of lymphocytes with varying concentrations of either norepinephrine or epinephrine decreases NK activity ([Hellstrand et al., 1985](#)) and mitogenic responses ([Hadden et al., 1970](#)). As preincubation with a b-antagonist reverses the inhibitory effects of norepinephrine *in vitro* ([Hellstrand et al., 1985](#)), b-adrenoceptor binding is believed to mediate an inhibition of cellular immunity ([Livnat et al., 1985](#)). *In vivo* studies have shown that either surgical denervation of the spleen or chemical sympathectomy with 6-OHDA produces an augmented antibody response to thymus-dependent antigens such as sheep red blood cells ([Besedovsky et al., 1979](#)), an enhanced plaque-forming cell response to thymus-independent antigens ([Miles et al., 1981](#)), and altered T- and B-cell responsiveness to mitogen stimulation (Hall and Goldstein, 1981; [Livnat et al., 1985](#)). Others have found in animals and humans that infusion of adrenergic agonists results in a down-regulation of b-adrenergic receptors in circulating mononuclear cells ([Aarons and Molinoff, 1982](#); [Krall et al., 1980](#)) and acute changes in NK-cell function and lymphocyte responses to mitogens and a specific antigen ([Heilig et al., 1993](#); [Livnat et al., 1985](#); [Pezzone et al., 1992](#); [Schledowski et al., 1993](#); [Tonnesen et al., 1984](#)). Endogenous release of sympathetic catecholamines appears to mediate the immunomodulatory effects of acute stress. Animals exposed to aversive stress or central doses of neuropeptides such as corticotropin-releasing hormone (CRH) that activate sympathetic outflow show suppression of cellular immunity or *in vivo* specific antibody responses that can be reversed by autonomic blockade ([Irwin et al., 1988](#)), or chemical sympathectomy ([Irwin et al., 1990](#)). Pharmacologic blockade of b-adrenergic receptors restores suppressed splenic lymphocyte responses to Con A produced by foot shock stress and conditioned immunosuppression ([Cunnick et al., 1990](#); [Luecken and Lysle, 1992](#)).

In human studies, the importance of the sympathetic nervous system (SNS) in altered immunity is underscored by the rapidity of change following an acute laboratory stressor. Further, the immune changes reported were even greater in subjects who also had elevated cardiovascular responses to the stressors ([Herbert et al., 1994](#)). In a study of immunity in spinal cord injured (SCI) patients, only those patients with high levels of injury (cervical), and loss of SNS integrity were found to have altered lymphocyte function compared to normal healthy matched controls ([Campagnolo et al., 1994](#)). Similarly, tetraplegic but not paraplegic SCI patients were found to have impaired phagocytic ability compared to matched, healthy controls ([Campagnolo et al., 1997](#)).

Chronic elevation of sympathetic tone has also been found to mediate a reduction of immunity ([Irwin et al., 1991](#)). In animals, for example, induction of a chronic hyperadrenergic state (experimental congestive heart failure) or 2-week infusion of the b-agonist isoproterenol reduces NK activity, *in vivo* antibody responses, and lymphocyte proliferation ([Waltman et al., 1992](#)). Similar to findings following acute stress, the immunosuppressive effect of chronic elevated sympathetic tone is completely antagonized by B-receptor blockade. In humans, chronic elevated sympathetic tone may also contribute to the modulation of immune function during severe life stress and depression as reflected by circulating concentrations of neuropeptide Y ([Irwin et al., 1991](#)). Neuropeptide Y is present in peripheral sympathetic nerves and is released following emotional stress potentiating the effects of vasoactive catecholamines and other pressor substances ([Romano et al., 1991](#)). [Irwin and associates \(1991\)](#) have shown that plasma concentrations of neuropeptide Y are elevated in depressed patients, as well as aged individuals and persons undergoing severe Alzheimer caregiver stress. Furthermore, activation of the SNS and release of neuropeptide Y is associated with a reduction of natural cytotoxicity in depression and life stress. Additional findings also support the hypothesis that elevated sympathetic activity in depression is associated with immune alterations. In depressed patients, excretion of 3-methoxy-4-hydroxy-phenylglycol (MHPG) has been used as an index of total body noradrenergic turnover or sympathetic activity and MHPG excretion was inversely related with lymphocyte proliferative responses in depressed patients ([Maes et al., 1989](#)).

Together, these data suggest that the ANS is important in immune function. Further, they suggest that elevated sympathetic tone in patients with major depressive disorder and/or in persons undergoing life stress is inversely correlated with cellular immune function.

## Endogenous Opioid Peptides

Pharmacologic evidence has shown that some cells of the immune system have opioid receptors ([Sibinga and Goldstein, 1988](#)). Opioid binding on immune cells was first suggested by the finding that nanomolar concentrations of opioids affect active rosetting of human T lymphocytes ([Wybran et al., 1979](#)). Morphine inhibits rosetting, whereas met-enkephalin stimulates it, and both effects are blocked by naloxone. Using radiolabeling techniques, specific opioid binding on human phagocytic leukocytes ([Falke et al., 1985](#); [Farrar, 1984](#); [Lopker et al., 1980](#)), platelets ([Mehrishi and Mills, 1983](#)), and lymphocytes ([Mehrishi and Mills, 1983](#); [Ausiello and Roda, 1987](#)) has been demonstrated.

Endogenous opioid peptides are able to influence *in vitro* the function of most cell types of the immune system; both inhibitory and immunoenhancing effects of opioid peptides have been described. [Johnson and coworkers \(1982\)](#) found that  $\alpha$ -endorphin, met-enkephalin, and leu-enkephalin (all with approximately equal potency) decrease the proliferation and antibody production of splenocytes in the plaque-forming assay; an effect that is blocked by naloxone. Confirming these results, [Heijnen and colleagues \(1986\)](#) demonstrated that (des-tyr) b-endorphin is also active in suppressing the plaque-forming cell response. PHA induced proliferation is affected by opioid peptides, although both stimulatory ([Bocchini et al., 1983](#); [Farrar, 1984](#); [Gilman et al., 1982](#)) and inhibitory effects ([McCain et al., 1986](#); [Puppo et al., 1985](#)) have been reported, and these opioid effects on mitogen-induced lymphocyte proliferation, and IL-2 production are not blocked by the specific opiate antagonist naloxone ([Gilmore and Weiner, 1988](#)).

A naloxone reversible enhancement of human natural cytotoxicity by very low concentrations of b-endorphin (10 fM) and met-enkephalin (10 pM) has also been reported. However, some studies have described an inverted U-shaped dose response for B endorphin and a bidirectional effect of the enkephalins and selective opiate agonists on human NK activity; subjects with "low" (below the median) NK activity show stimulation with enkephalin, whereas the cytolytic activity of cells from the "high" group is inhibited by similar doses of enkephalin ([Oleson and Johnson, 1988](#)). Recent evidence suggested that endorphins modulate NK activity through the (6–9) amino acid region (i.e., the  $\alpha$ -helix portion of b-endorphin) ([Kay et al., 1987](#)).

Systemic administration of opioids, as well as the release of opiate peptides following stress, appear to modulate changes of NK cytotoxicity in animals, although the physiologic importance of opioid modulation of other *in vitro* correlates of immune function can not yet be adduced with confidence. In rats repeatedly administered intermittent inescapable foot shock over four consecutive days ([Shavit et al., 1984](#)), a significant suppression of NK activity occurs that can be completely antagonized by the preadministration of naltrexone. Unconditioned (foot shock) and conditioned suppression of lymphocyte proliferation responses can be attenuated by naltrexone ([Lysle et al., 1992](#)). Daily injection of morphine for 4 days at doses of 10, 30, or 50 mg/kg produces a similar suppression of cytotoxicity ([Shavit et al., 1984, 1986](#)). In contrast, inhibition of NK cytotoxicity in a forced-swimming paradigm was unaffected by pretreatment with naltrexone ([Ben-Eliyahu et al., 1990](#)), and naltrexone dose-dependently aggravated reductions in primary and secondary antibody responses to sheep red blood cells induced by restraint stress ([Ray et al., 1992](#)).

Nevertheless, direct peripheral effects of opioid agonists on the immune system are also possible, because opioid agonists bind on specific receptors on cells of the immune system ([Carr et al., 1988](#)). Indeed, experimental and correlative evidence suggest that peripheral increases of endogenous circulating concentrations of b-endorphin stimulate NK activity, similar to the findings generated *in vitro*. In the rat, release of b-endorphin into the plasma following acute exposure to forced immobilization are correlated with immediate, poststress increases of splenic NK activity ([Irwin and Hauger, 1988](#)). Likewise, clinical research has found exercise-induced enhancement of NK cytotoxicity is completely antagonized by the preadministration of the opiate antagonist naloxone ([Fiatarone et al., 1988](#)). Finally, plasma levels of b-endorphin are positively correlated with NK activity in depressed patients ([Darko et al., 1992](#)).

Opiate-induced modulation of NK cytotoxicity is also mediated in part by the CNS. A reduction of splenic NK activity is achieved by the administration of a dose of morphine given into the cerebral ventricle that is a thousand times smaller than that required when given systemically ([Shavit et al., 1986](#)). Peripheral administration of a morphine analog (one that does not cross the blood–brain barrier to enter the CNS) is not effective in altering NK activity ([Shavit et al., 1986](#)). Moreover, intracerebral infusion of morphine into the periaqueductal gray, but not other brain regions, produces a suppression of splenic NK activity ([Weber and Pert, 1989](#)). Finally, peripheral administration of naltrexone has been shown to block conditioned suppression of lymphocyte proliferation responses, but N-methyl naltrexone, which does not cross the blood–brain barrier, is unable to reverse the suppression ([Lysle et al., 1992](#)).

### Serotonin

Serotonin is a neurotransmitter that appears to mediate nervous system and immune system interactions ([Mossner and Lesch, 1998](#)). Substantial evidence has demonstrated that serotonergic systems are altered in depression, and *in vitro* data have shown that serotonin modulates delayed type hypersensitivity responses, T-cell activation, and NK and macrophage activity ([Mossner and Lesch, 1998](#)). Further, serotonin suppresses lymphocyte response to PHA *in vitro* ([Bonnet et al., 1984](#)), whereas the addition of serotonin to enriched mononuclear cells induces a twofold, dose-dependent enhancement of NK activity, similar to the stimulation induced by IL-2 ([Hellstrand and Hermodsson, 1987](#)).

The induction of NK activity is monocyte-dependent and likely mediated by specific binding of serotonin at the 5HT<sub>1</sub> receptor on the monocyte; the enhancing properties of serotonin are mimicked by the 5-HT<sub>1</sub>-specific receptor agonist 8-OH DPAT and completely antagonized by the serotonin receptor antagonist cyproheptadine. Clinical studies have not yet characterized whether expression and regulation of the 5-HT<sub>1A</sub> receptor on monocytes is altered in depressed patients, and it is not known whether monocyte 5-HT<sub>1A</sub> activity has a role in the reduction of NK activity in depression.

## NEUROENDOCRINE INFLUENCES ON IMMUNITY

The neuroendocrine system is an important regulator of immune responses ([Anisman et al., 1996](#); [Marx et al., 1998](#)). The following is a brief review of some of the more important hormonal effects on immunity.

### Corticotropin-Releasing Hormone

Corticotropin-releasing hormone (CRH) has been postulated to be a physiologic CNS regulator that integrates biological responses to stress ([Axelrod and Resine, 1984](#); [Taylor and Fishman, 1988](#)) and that may affect the susceptibility to various illnesses, including autoimmune, infectious, and neoplastic disease ([Elenkov et al., 1999](#)). Its role in modulating immune function through a central site of action has been examined ([Irwin et al., 1987](#)). In addition to its well-established role as a hypothalamic regulator of the pituitary secretion of ACTH and b-endorphin ([Vale et al., 1981](#)), CRH is also found to act in the CNS at extrahypothalamic sites inducing an increase in the firing rate of the locus ceruleus ([Valentino et al., 1983](#)), activating the ANS as reflected by increased plasma concentrations of norepinephrine and epinephrine ([Fisher et al., 1982](#)), and producing a pattern of behavioral responses such as decreased feeding and increased locomotor activity ([Britton et al., 1982](#); [Sherman and Kalin, 1985](#); [Sutton et al., 1982](#)). Moreover, central administration of CRH induces a dose-dependent suppression of splenic NK activity ([Irwin et al., 1987](#)), which is mediated by central activation of the SNS ([Irwin et al., 1988](#)). Finally, recent data suggested a physiologic role for the release of central endogenous CRH in stress-induced suppression of cellular immunity; central administration of an antiserum to CRH completely antagonizes the effects of inescapable shock on splenic NK activity and lymphocyte proliferation ([Irwin et al., 1990](#); [Saperstein et al., 1992](#)). Consistent with the previous findings that show that activation of the pituitary adrenal axis is dissociated from acute stress-induced changes in cellular immunity ([Keller et al., 1983, 1988](#)), peripheral administration of antiserum to CRH antagonizes stress-induced release of ACTH and corticosterone but has no effect on the suppression of NK activity ([Irwin et al., 1990](#)).

### Glucocorticoids

Cortisol has many effects on the immune system ([Byron et al., 1992](#)), and the secretion of corticosteroids has long been considered as the mechanism of stress-induced and/or depression-related suppression of immune function ([Cupps and Fauci, 1982](#); [Munck et al., 1984](#); [Parrillo and Fauci, 1978](#); [Riley, 1981](#); [Selye, 1976](#)). Specific intracytoplasmic corticosteroid receptors have been identified in normal human lymphocytes ([Lippman and Barr, 1977](#)), and these receptors bind corticosteroids and appear to play a role in the regulation of cellular function through modulation of cyclic AMP levels ([Parker et al., 1973](#)). Glucocorticoids have widespread effects on the immune system, including the trafficking of immune cells and the secretion of cytokines ([Chrousos, 1995](#)).

*In vitro* studies have further demonstrated that glucocorticoids act to inhibit IL-2 production *in vitro* with resulting suppression of lymphocyte responses to mitogenic stimulation ([Gillis et al., 1979](#)), natural killer cell activity (antibody-dependent cytotoxicity is relatively refractory to glucocorticoids) ([Parrillo and Fauci, 1978](#)), and the differentiation and function of macrophages ([Baybutt and Holsboer, 1990](#)). In the thymus, glucocorticoids influence apoptosis of thymic lymphocytes and the clonal deletion. This effects removal of self-antigen responsive cells ([Wilder, 1995](#)).

Even though pharmacologic data from *in vitro* and *in vivo* studies demonstrated that corticosteroids suppress a number of parameters of immunity ([Cupps and Fauci, 1982](#)), increased adrenocortical activity is not always correlated with changes in immune function in an organism responding to aversive stressors. For example, acute administration of either forced immobilization ([Irwin and Hauger, 1988](#)) or audiogenic stress ([Irwin et al., 1989](#)) produces an activation of adrenal steroid secretion but does not alter immune function as measured by NKCA. Likewise, with repeated exposure to the stressor, pituitary adrenal activation is dissociated from a reduction in cytotoxicity ([Irwin and Hauger, 1988](#); [Irwin et al., 1989](#)). Finally, stress-induced suppression of lymphocyte function following unpredictable, unavoidable tail shock occurs both in adrenalectomized ([Keller et al., 1983](#)) and in hypophysectomized animals ([Keller et al., 1988](#)). Nevertheless, stress-related reductions of

lymphocyte and antibody responses in which adrenal activation clearly participate have been reported ([Cunnick et al., 1990](#); [Dobbs et al., 1993](#)). A possible resolution of these discrepancies may lie in the site of action for adrenal corticoids. Stress-induced decreases in splenocyte mitogen responses can be abolished by pharmacologic blockade of  $\beta$ -adrenergic receptors, but the responses of peripheral blood lymphocytes are only partially restored ([Cunnick et al., 1990](#); [Pezzone et al., 1992](#)). In contrast, adrenalectomy prevents stress-induced inhibition of mitogenic responses in peripheral blood, but not splenic lymphocytes in rats, and use of the glucocorticoid receptor antagonist RU486 attenuates stress-induced reductions in antibody responses to herpes simplex virus in mice ([Pezzone et al., 1992](#)).

Clinical research has found no relationship between adrenocortical activity and immunity in depressed patients and stressed persons. In depressed patients, decreased lymphocyte responses to mitogens are not associated with dexamethasone nonsuppression ([Kronfol and House, 1985](#)) or with increased excretion rates of urinary free cortisol ([Kronfol et al., 1986](#)). Furthermore, in bereavement in which a reduction of NK activity has been demonstrated, this immunologic change occurs even in subjects who had plasma cortisol levels comparable to control subjects ([Irwin et al., 1988](#)).

## ACTH

A receptor for ACTH has been identified on lymphocytes, also raising the possibility that some aspects of altered lymphocyte function in depression are regulated by this peptide. *In vitro* studies have shown that ACTH inhibits the antibody response at an early state in the antibody response ([Johnson et al., 1992](#)). In regard to cellular immunity, [McGlone and coworkers \(1991\)](#) evaluated the effects of ACTH administered *in vitro* and *in vivo* on NK cell function. Exogenous, peripheral administration of ACTH at physiologic concentrations increases both NK activity and IL-2 stimulated NK cytotoxicity compared to levels in saline controls. Because *in vitro* doses of ACTH have no effect on NK activity ([McGlone et al., 1991](#)), the action of this peptide *in vivo* is likely by an indirect mechanism (i.e., alteration of leukocyte traffic or suppression of central CRH). Finally, one clinical study of 26 depressed patients failed to demonstrate an association between plasma concentrations of ACTH and lymphocyte proliferation ([Darko et al., 1989](#)), although the effects of ACTH on NK activity have not yet been evaluated.

## DHEA

Dehydroepiandrosterone sulfate (DS) and its active metabolite dehydroepiandrosterone (DHEA) are also adrenal hormones, which play an important role in immune regulation. DHEA has been related to greater production of IL-2 and enhanced T-cell cytotoxic function ([Suzuki et al., 1991](#)). In a study of postmenopausal women, treatment with DHEA was associated with a decrease in CD4+ cells and an increase in T-helper cells ([Casson et al., 1993](#)). Several studies of the influence of DHEA on immune response to the influenza vaccine in elderly patients found different results, two suggesting that the response was enhanced ([Araneo et al., 1995](#); [Evans et al., 1996](#)) and one noting no effect ([Dannenbergh et al., 1997](#)).

## Prolactin

Prolactin (PRL) is involved in the regulation of the immune system ([Bernton et al., 1989](#)). Prolactin receptors have been found on T and B lymphocytes ([Russell et al., 1985](#)) and prolactin effects NK activity ([Nagy et al., 1983](#)) and lymphocyte proliferative responses ([Hiestand et al., 1986](#)). However, understanding the effects of PRL on the immune system has been complicated by the discovery that lymphocytes and uterine tissue can synthesize and secrete PRL ([Montgomery et al., 1992](#); [Pellegrini et al., 1992](#)). The question of which PRL, perhaps all, serves as a signaling molecule in the immune system remains to be answered ([Matera, 1996](#)). Basically, PRL levels are thought to correlate positively with immunity, meaning that higher levels are stimulatory, whereas lower levels are inhibitory ([Yu-Lee, 1997](#)). Further, there is speculation concerning how PRL affects immunity. Although there are PRL receptors on immunocytes, the effects are mediated at least in part by influencing interferon regulatory factor-1 (IRF-1) ([Yu-Lee, 1997](#)). However, PRL also influences thymic hormone release, and effects on T cells appear to be dependent in part on their stage of maturity or differentiation ([Murphy et al., 1992](#)).

Impairment of both humoral and cell-mediated immune response has been demonstrated in hypophysectomized rats as well as animals treated with bromocriptine, a dopamine agonist that inhibits prolactin secretion. This impairment can be reversed by treatment with exogenous, physiologic doses of prolactin ([Bernton et al., 1988](#)). In addition, antibodies to prolactin have been reported to inhibit lymphocyte proliferation ([Hartmann et al., 1989](#)).

In humans, preliminary observations by [Darko and colleagues \(1989\)](#) have found that plasma levels of prolactin positively correlated with T-cell mitogen proliferation, although [Clodi and associates \(1992\)](#) failed to show any immune alteration as reflected by serum concentrations of immunoglobulin, IL-1, soluble IL-2 receptor, lymphocyte subsets, and NK activity in patients with prolactinomas. The effects of hyperprolactinemia have been conflicting with respect to NK activity; some studies show decreased NK cell function ([Matera, 1996](#)). Chronic prolactin elevation may lead to adaptive changes that effectively abolish the immunomodulatory effects of prolactin.

## Growth Hormone

Growth hormone (GH) is a polypeptide that plays a pivotal role in growth and development. In addition to its endocrine and metabolic effects, growth hormone is likely to have significant effects on the immune system ([Murphy et al., 1992](#)), particularly T-cell development ([Weigent and Blalock, 1990](#)). In growth hormone-deficient mouse strains, hematopoietic and B-cell progenitor deficiencies, marked atrophy of the cortical region of the thymus, and impairment of cell-mediated immunity have been found and can be reversed by treatment with growth hormone ([Dumont et al., 1979](#); [Murphy et al., 1992](#)). Likewise, thymic size in the aged rat can be increased by GH ([Kelley et al., 1986](#)). In adult rats, GH is reported to stimulate macrophage superoxide release ([Edwards et al., 1992a, 1992b](#)) and confer resistance to bacterial infection ([Edwards et al., 1992](#)). In contrast with these observations, [Cross and colleagues \(1992\)](#) have indicated that hypopituitary mice lag behind heterozygous litter mates with respect to development of immunocompetence but that normal immune responsiveness does fully develop.

Exploratory clinical studies in depression have failed to identify any relationship between growth hormone and immune function ([Darko et al., 1989](#)), although the numbers of depressed subjects studied is small.

Investigation of the effects of GH (and PRL) on the immune system is complicated by the ability of GH to bind to PRL receptors; however, data suggest that GH may have both stimulatory and inhibitory effects on the immune system in humans. Several studies in children have investigated GH and other growth related factors and immunity. In a study by [Yang and coworkers \(1999\)](#), growth hormone and insulin-like growth factor I (as well as insulin-like growth factor binding proteins 1–6) are expressed by immunocytes and in immune organs where they are thought to function in an autocrine or paracrine fashion. In the study of children with GH deficiency, impaired phagocytic ability of neutrophils and monocytes was reversed with long-term GH replacement therapy (RT) ([Manfredi et al., 1994](#)). [Rapaport and colleagues \(1986\)](#) also studied *in vivo* effects of human GH RT on peripheral blood leukocytes. Although no changes in immunoglobulins, polymorphonuclear leukocyte function, or T-cell percents were found, a decreased percentage of B cells were reported. Similar findings were also reported by [Bozzola and coworkers \(1988\)](#); when immunocytes from both HGH deficient patients and normal controls were exposed to HGH *in vitro*, B cells were decreased and lymphocyte proliferative responses were enhanced.

## SUBSTANCES OF ABUSE AND IMMUNITY

Substances of abuse, including alcohol, nicotine, cocaine, and heroin, can influence the immune system. The effects may relate to prenatal exposure, as in cases of fetal alcohol syndrome, or substance use of the individual. The common substances of abuse, including alcohol, nicotine, cocaine, marijuana, and opiates, have been reported to influence immunity. Even single dose or acute exposure to these substances is shown to impact on immune responses. Further, early or *in utero* exposure to these substances may impact immunity and even have prolonged effects, such as those reported in fetal alcohol syndrome. The following is a brief review of human studies concerning these substances of abuse and their effects on immunity.

Chronic alcohol use and alcoholism are associated with immune alterations such as decreased defenses against infection ([MacGregor, 1986](#); [Szabo, 1999](#)) and increased infectious morbidity and mortality ([Adams and Jordan, 1984](#)). More recently, reports of acute exposure, both *in vitro* and *in vivo*, suggest that immune effects are seen in nonalcoholic subjects, especially regarding monocytes. [Szabo \(1998\)](#) reported that as little as 2 mg/kg of vodka consumed over 30 minutes led to transient (at 4 hours postconsumption) increases in IFN- $\gamma$  and IL-12 following monocyte stimulation with bacteria. In addition, alcohol had a biphasic effect on IFN- $\gamma$  production; bacterial stimulation of monocytes at 16 hours postconsumption was associated with decreased IFN- $\gamma$  production. [Girouard and coworkers \(1998\)](#) also investigated alcohol effects on cytokine production of monocytes from nonalcoholic subjects. Monocytes were exposed to alcohol and stimulated with bacteria or cytokines. Production of IL-10 and IL-12 was affected; specifically, IL-10 production was secondarily increased after exposure to alcohol with attendant enhancement of IL-12 production. Consistent with these data, [Irwin and Miller \(2000\)](#) reported that African-American alcoholics showed increased stimulated production of IL-10 and decreased expression of IL-6 as compared to matched comparison controls. However, in another study investigating lymphocyte numbers, type, and function, but not cytokine production, no differences were found between healthy nonalcoholic controls and healthy alcohol-dependent subjects ([Schleifer et al., 1999](#)). In that study,

however, granulocyte phagocytic ability was diminished in the alcohol-dependent subjects. Further, [Singhal and colleagues \(1999\)](#) reported increased apoptosis of macrophages following an alcohol binge in healthy subjects. These data strongly suggest that alcohol influences the immune system and that myeloid derived cells are particularly susceptible.

Cigarette smoking has long been considered a major health risk, with effects on immunity via direct actions or possibly endocrine-mediated mechanisms ([Sopori and Kozak, 1998](#)). Nicotine is reported to affect the HPA axis ([Rosecrans and Karin, 1998](#)) as well as to affect humoral and cellular immunity ([McAllister-Sistilli et al., 1998](#)). Additional research supports the notion that specific immunologic alterations occur in adult smokers, affecting a variety of parameters. Adult male smokers have been found to exhibit higher white blood cell (WBC) counts and lower NK activity than nonsmoking controls. [Tollerud and coworkers \(1989\)](#) reported elevated WBC and lymphocyte numbers but lower NK cell counts in adult smokers compared to nonsmokers. In the only study of adolescent smoking effects on immunity, Keller and colleagues (in review) reported decreased cell numbers but not lower NKCA in adolescents (12 to 18) who reported smoking for 1 year or more.

Smoking also has been associated with elevated levels of IgM and IgA rheumatoid factor (RF), with a more persistent elevation of RF than nonsmokers, indicating that tobacco use increases the production of IgM and IgA RF. These findings are similar to results reported by [Von Herzen and colleagues \(1998\)](#), who found that smoking in adult male twin pairs was significantly associated with elevated IgA antibody levels in smokers with implications for chronic *Chlamydia pneumoniae* infection.

Pulmonary immune function is also a focus of recent studies. IL-8 concentration in bronchoalveolar lavage fluid was significantly higher in smokers than nonsmoking adult subjects. Finally, cigarette smoking also alters nasopharyngeal lymphoid tissue. [Finkelstein and coworkers \(1997\)](#) reported that smokers exhibited deformed and migrating cytotoxic lymphocytes in the nasopharyngeal mucosa, which were attached to epithelial, ciliated, and goblet cells. Cell damage, particularly mucosal invasion and epithelial cell damage, occurred as a result of the uncommon amount of migrating T lymphocytes in the smoking subjects.

Perhaps most notably, depression and smoking status interact to produce greater declines of NK activity than that found in depressed or smoking groups alone ([Jung and Irwin, 1999](#)).

Use of hashish or marijuana, both of which are derived from *Cannabis sativa*, is thought to diminish host resistance to infections ([Cabral and Dove Pettit, 1998](#)). The primary psychoactive component, d-9-tetrahydrocannabinol (THC) and other cannabinoids purportedly are immunosuppressive, affecting lymphocytes, macrophages, and NK cells ([Cabral and Dove Pettit, 1998](#)). THC has been reported to diminish ([Specter et al., 1990](#)) or produce variable change ([Luo et al., 1992](#)) in response to mitogen stimulation and to have indeterminate effects on antibody production ([Nahas and Osserman, 1991](#)) in humans. Although phagocytosis and killing activity by human monocytes are reportedly decreased ([Specter et al., 1991](#)), cannabinoids are reported to both increase and decrease individual immune parameters, depending on dose, chronicity, and timing of exposure ([Klein et al., 1998](#)). Actual health risk of cannabinoid use to humans requires further study.

Opiates such as morphine are thought to affect the immune system via CNS pathways and direct effect on some types of immunocytes ([Eisenstein and Hilburger, 1998](#)). Primarily, the indirect opiate-neural-immune pathway has an immunosuppressive effect, down-regulating all subtypes of immune cells, whereas morphine appears to directly diminish macrophage and granulocyte function but not NK cell or B-cell function ([Eisenstein and Hilburger, 1998](#)). Further, chronic exogenous opioids impact on IL-1 mediated immunity, substantially influencing the body's defense mechanisms ([Chang et al., 1998](#)).

## STRESS AND IMMUNITY: PRECLINICAL STUDIES

### Aversive Stressors and Disease Susceptibility

Many workers have identified links between the stress associated with physical and psychological stimuli and the increased susceptibility of animals and humans to a number of immune-related disorders such as infectious and neoplastic disease ([Griffin, 1989](#); [Rozlog et al., 1999](#)). To evaluate altered resistance to infections, a number of different aversive stressors have been used in rodents. Psychosocial stimulation of animals involving either avoidance conditioning, physical restraint, or auditory stimulation is associated with decreased resistance to herpes simplex, Coxsackie B, poliomyelitis, or vesicular stomatitis virus, and tuberculosis ([Friedman and Glasgow, 1966](#)). High population density affects the susceptibility of mice to the malarial parasite *Plasmodium berghei* ([Plaut et al., 1969](#)) and isolation housing is associated with increased risk of encephalomyocarditis virus infections ([Friedman et al., 1969](#)). Restraint stress was reported to diminish cellular immune and inflammatory responses to viral infection in mice ([Hermann et al., 1994](#)), an effect mediated by corticosterone and catecholamines ([Dobbs et al., 1993](#)). It appears that both the virulence of the organism as well as the psychophysiological state of the animal affects disease risk. If the infectious agent produces a chronic or insidious infection and the animals are stressed at the time of exposure, then symptoms of disease are more likely ([Ader, 1983](#); [Friedman et al., 1965](#); [Griffin, 1989](#)). Preliminary research with macaque monkeys infected with simian immunodeficiency virus (SIV) found that early psychosocial factors, such as rearing condition (i.e., with mother or peers) and the number of changes in housing (i.e., from a familiar social group to an unfamiliar group or to isolation) were significantly correlated with disease-related variables such as latency to leukopenia, weight loss, and survival ([Capitanio and Lerche, 1991](#)).

Findings from studies of the role of stress in susceptibility to neoplastic disease are heterogeneous, depending on the age and species of the animal, the type of tumor (viral or chemically induced), the timing of the stressor in relation to tumor inoculation, and the quality of the stressor (inescapable or escapable) ([Griffin, 1989](#); [Justice, 1985](#); [Riley, 1981](#); [Sklar and Anisman, 1981](#)). In general, it appears that simultaneous exposure of rats or mice to inescapable shock and tumor cells facilitates tumor growth, whereas administration of the stressor before implantation inhibits its growth ([Shavit et al., 1985](#)). Exposure to escapable shock has no impact on tumor development ([Shavit et al., 1985](#)).

### Effects of Stressors on Immune Responses

Behavioral responsiveness to inescapable aversive stimulation has provided an animal model to investigate clinical depression ([Irwin et al., 1989](#)). Aversive stressors such as sound exposure ([Irwin et al., 1989](#); [Monjan and Collector, 1977](#)), rotation ([Kandil and Borysenko, 1987](#); [Riley, 1981](#)), intermittent shock ([Keller et al., 1981, 1983](#); [Shavit et al., 1984](#)), and forced immobilization ([Irwin and Hauger, 1988](#)) have been shown to affect lymphocyte responses to mitogen stimulation and/or NK activity in a manner that depends on their dose- and time-response profiles. For example, using an audiogenic stressor repeated at daily intervals, [Irwin et al. \(1989\)](#) have replicated the findings of [Monjan and Collector \(1977\)](#), who found that the initial stress-induced immune suppression is followed by an increase or enhancement of natural cytotoxicity. [Keller and associates \(1981\)](#) have demonstrated a relationship between the intensity of an acute stressor and the degree of suppression of T-cell function. A progressive decrease of PHA-induced stimulation is found in animals that receive apparatus, low-level tail shock, or high-level electric tail shock, respectively, as compared to home cage controls ([Keller et al., 1981](#)). Further, stress, specifically the stress of social isolation, has been related to decreased proliferative responses, NKCA and macrophage-mediated cytotoxicity, as well as increased tumor metastases and greater tumor burden ([Wu et al., 2000](#)).

Cellular *in vivo* immune responses and antibody responses are also altered by aversive stressors. Delayed hypersensitivity reaction are decreased in mice exposed to heat stress ([Pitkin, 1965](#)) and the graft-versus-host response is suppressed in animals subjected to limited feeding ([Amkraut et al., 1973](#)), an effect that is independent of adrenocortical levels ([Amkraut et al., 1973](#)). Reduced antibody responses are found in monkeys exposed to a number of aversive stimuli ([Felsenfeld et al., 1966](#); [Hill et al., 1967](#)), in mice housed in high- versus low-density grouping ([Solomon, 1969](#)), and in mice subjected to changes in housing condition (either from individual to group housing or from a group to the return to an individual cage) ([Edwards et al., 1980](#)). Similar to the effects of stressor timing on susceptibility to infectious or neoplastic disease, restraint produces a significant reduction in antibody response to sheep red blood cells only if the stress is applied before the time of immunization; there is no change in antibody production when the stress is applied after antigen injection ([Okimura et al., 1986](#)). Further, NKCA was reported to decline during captivity in free-range rhesus monkeys ([Laudenslager et al., 1999](#)), suggesting that continued or prolonged stress can produce continued immune alteration.

### Modulation by Psychological Factors

In addition to the effects of stressor characteristics, the psychological characteristics or response of the animal to the stressor has been related to the immunologic consequences of the stress. [Laudenslager and colleagues \(1983\)](#) found that rats exposed to inescapable uncontrollable electric tail shock have reduced lymphocyte activity, whereas animals that receive the same total amount of shock but are able to terminate it did not show altered immunity. Furthermore, [Mormede and coworkers \(1988\)](#) reported that even stressor predictability, in the form of a warning stimulus preceding inescapable foot shock, completely reverses the shock-induced suppression of lymphocytes. Consistent with the hypothesis that fear ultimately determines the amount of immunosuppression induced by aversive stimuli, a nonaversive stimuli associated with electric shock can be conditioned to impair lymphocyte proliferation independent of the direct effect of the physically aversive stimulation ([Lysle et al., 1988, 1992](#)).

In a study of nonhuman primates, [Cohen and colleagues \(1997\)](#) found that lower social status was associated with increased risk of infection following exposure to an

adenovirus. They also found that lower social status was associated with lower body weight, less aggressive behavior, and greater cortisol responses to social change stress.

### Immunologic Consequences of Early Life Experiences

Infancy has been suggested to be a period of life during which the organism is particularly sensitive to psychological perturbation, and stressful experiences during this period may have long-term physiologic impact. Early life experiences such as premature maternal separation produce alterations in many processes regulated by the hypothalamus, including body temperature, sleep, metabolic rate, and maturation of autonomic processes ( [Ackerman et al., 1979](#); [Hofer, 1984](#)). There is now evidence that the physiologic effects of these experiences also include changes in immune function.

Because of their social nature, nonhuman primates have been the subjects of many studies involving the effects of psychological stress on immune responses in young animals ( [Coe, 1993](#)). One of the earliest studies reported that lymphocyte proliferation responses to stimulation with Con A and PHA were reduced in two pairs of infant pigtail macaques undergoing separation from their peers ( [Reite et al., 1981](#)). This effect was later reproduced in infant bonnet macaques briefly separated from their mothers ( [Laudenslager et al., 1982](#)). In both of these studies, lymphocyte responses were reduced for the 2-week period of separation and returned to their original levels following reunion.

Since that time, numerous experiments involving multiple species of New and Old World nonhuman primates have replicated these early findings and extended them to other measures of immunity, including lymphocyte subset numbers, levels of complement proteins and immunoglobulins, macrophage chemiluminescence, and DTH responses ( [Boccia et al., 1989](#); [Coe et al., 1988a,b](#); [Friedman et al., 1991](#); [Gordon et al., 1992](#); [Gust et al., 1992](#); [Laudenslager et al., 1990](#)). Immune responses and cell numbers have proven to be sensitive to psychosocial stressors ranging from mother–infant separation to the formation of novel social groups.

Some of these studies also have shown, however, that animals' physiologic responses to these stressors are influenced by a number of psychological factors. The largest stress-related differences in immune function are typically found in the monkeys that are observed to have the most severe behavioral responses to both experimental ( [Laudenslager et al., 1990](#)) and natural stressors ( [Laudenslager et al., 1993](#)). The magnitude of change in immune function following psychosocial stress also depends on several factors, including the time at which immunity is measured, the environment in which the animal experiences the stressor, and the age of the animal at the time of the stressor ( [Coe, 1993](#)). Stress-related reductions in antibody responses to a bacteriophage, for example, are attenuated in monkeys housed with familiar, but not unfamiliar, companions or in a familiar location for the duration of the separation ( [Coe, 1993](#)).

Longitudinal assessments of immunity have revealed that early life experiences like those described in the preceding may have long-term immunologic consequences. Pigtail monkeys briefly separated from their mothers during the first year of life showed greater reductions in lymphocyte proliferation responses as adults than control monkeys ( [Laudenslager et al., 1985](#)). In 40-day-old rats separated from their mothers on postnatal day 15, lymphocyte responses are lower than responses in rats that remained with their mothers until day 22 ( [Ackerman et al., 1988](#)). Mice that were maternally deprived and weaned at 15 days postpartum show a depressed antibody response to sheep erythrocyte immunization at 7 and 8 weeks of age, but no differences in body or adrenal weight. Finally, preliminary evidence suggests that rats prematurely separated 100 days after weaning may show greater susceptibility to severe respiratory infection ( [Schleifer et al., 1986](#)).

Several reports have provided additional data that tumor growth in the adult animal is affected by early life experience. Daily handling of mice prior to weaning leads to increased rates of mortality following implantation of a lymphoid leukemia ( [Levine and Cohen, 1959](#)), and handling of rats during the first 3 weeks of life affects the growth of a carcinosarcoma ( [Ader and Friedman, 1965](#)).

More chronic early life experiences, such as rearing environment, have been shown to exert long-term influence on the immune system. Infant rhesus monkeys reared in a nursery by human hands for the first 6 months of life showed greater lymphocyte responses to stimulation with Con A than monkeys reared with their mothers ( [Coe et al., 1989](#)). These differences persisted through 2.5 years of age, despite that fact that both groups of monkeys were housed with peers after their first year ( [Coe et al., 1989](#)). The augmented lymphocyte responses, which contrast with the reduced responses typically reported following acute stress, may be the product of an abnormally high T-helper to T-suppressor cell ratio in nursery-reared monkeys (Lubach et al., 1994).

New evidence suggests that early vulnerability to environmental stressors may begin before birth. Rhesus monkey neonates whose mothers experienced psychosocial stress or ACTH treatment during pregnancy exhibited abnormal postnatal development of neuromotor reflexes ( [Schneider et al., 1992](#); [Schneider and Coe, 1993](#)). Ongoing studies indicate that these monkeys also exhibit reduced lymphocyte proliferation responses in mixed lymphocyte reactions, reduced cytotoxic responses, and altered lymphocyte b-adrenergic receptor expression ( [Coe, 1993](#)).

## STRESS AND IMMUNITY: CLINICAL STUDIES

### Limitations of Current Studies

Research has suggested that stress leads to altered immunity and may lead to increased susceptibility to disease ( [Glaser et al., 1999](#); [Rozlog et al., 1999](#)). No study in humans has yet delineated a causal chain showing that severe life stress or a particular psychological state produced an immunologic response that then resulted in an altered clinical outcome. In one of the few prospective studies in this area, [Cohen and associates \(1991\)](#) recently showed that psychological stress was associated in a dose–response manner with an increased risk of acute infectious respiratory illness. Importantly, this association was owing to increased rates of infection rather than an increased frequency of symptoms after infection; however, measures of cellular immune function were not obtained in this study.

To understand the relationship between stress and disease, all the processes involved in an “X” to “Y” to “Z” model must be studied. Some studies, like that of [Cohen and colleagues \(1997, 1998\)](#) have shown that life events and psychological processes influence the development of disease, whereas other studies have demonstrated that psychological processes result in immune changes. Neither is sufficient because these psychosocial factors could produce independent and unrelated effects both on immune function and disease states ( [Ader, 1987](#)). Prospective studies are needed that examine all these links simultaneously ( [Braveman, 1987](#)). Furthermore, *in vitro* immune measures may not accurately reflect immunologic competence *in vivo* and, thus, may not be useful predictors of increased illness susceptibility ( [Calabrese et al., 1987](#); [Hood et al., 1985](#)). For example, increased numbers might compensate a decrease in one immune parameter such as NK activity or function of other cell types with no resultant increased risk for acute viral infections. Despite these caveats regarding biological relevance, changes in the immune system in persons undergoing stress may have clinical implications and the hypothesis is presented that immunologic alterations mediate the relationship between stressful life events and poor health outcome.

### MORBIDITY AND MORTALITY IN BEREAVEMENT

In the past 20 years, studies of conjugal bereavement have demonstrated an elevated mortality rate among bereaved spouses that varies with age, sex, and time elapsed after the loss ( [Bowling and Benjamin, 1985](#); [Clayton, 1974](#); [Cox and Ford, 1964](#); [Ekblom, 1963](#); [Kaprio et al., 1987](#); [Kraus and Lilienfeld, 1959](#); [Mellstrom et al., 1982](#); [Parkes et al., 1969](#); [Rees and Lutkins, 1967](#); [Ward, 1976](#); [Young et al., 1963](#)). The results are heterogeneous, although there appears to be an increased mortality during the early periods succeeding the loss, particularly among the middle-aged to older widowers ( [Helsing et al., 1981](#)). Besides an increase in mortality, widowhood is associated with the onset of specific immune related medical disorders such as influenza and pneumonia, as well as other diseases including cardiovascular problems ( [Jacobs and Ostfeld, 1977](#); [Klerman and Izen, 1977](#); [Parkes, 1970](#)), possible increases in physician consultations and hospitalizations ( [Maddison and Viola, 1968](#); [Mor et al., 1986](#); [Parkes, 1964](#)), and decreases in general well-being ( [Maddison and Viola, 1968](#); [Parkes, 1970](#)).

### Depression and Illness

#### ADULT STUDIES

Both the onset and course of medical illness may be affected by stress ( [Keller et al., 2000](#)). In a study of 42 patients admitted to a general medical service, 31 of these patients had experienced the onset of their illness within 1 week of a significant loss ( [Schmale and Iker, 1966](#)). In addition, available data suggest an association between depressive profiles and the development of cancer ( [Kielcolt-Glaser and Glaser, 1999](#); [Spiegel, 1996](#)). In 40 women hospitalized for cone biopsies having class III Pap smears, feelings of hopelessness identified at patient interview correctly classified eight of the 14 women with cancer and 23 of the 26 women without cancer ( [Schmale and Iker, 1966](#)). In a 10-year longitudinal study, feelings of hopelessness and depression at baseline are associated with an increased incidence of cancer among 1,353 persons examined in a Yugoslav village ( [Grossarth-Maticcek et al., 1985](#)). Finally, the Western Electric Study has demonstrated, with 20 years of follow-up, an association between depression as measured by the *Minnesota Multiphasic Personality Inventory* and an increased incidence in mortality for cancer

([Persky et al., 1987](#)). Even after adjustment for age, number of cigarettes smoked, alcohol intake, occupational status, and family history of cancer, the relationship between depressive personality and cancer persisted. Conversely, one study found that depressive symptoms are not significant predictors of cancer morbidity with or without adjustment for age, sex, marital status, smoking, family history of cancer, and hypertension ([Zonderman et al., 1989](#)).

In general, the findings of increased cancer incidence in clinically depressed patients are consistent with a "null or weak relationship" ([Fox, 1989](#)). Nevertheless, several follow-up studies have demonstrated a relationship between affective disorders and clinical depression and increased cancer morbidity and mortality, particularly in male patients over age 40 who had primary diagnoses of affective disorders ([Kerr et al., 1969](#); [Varsamis et al., 1972](#); [Whitlock and Sisking, 1979](#)).

PNI investigations have also suggested that psychiatric interventions that reduce psychological distress may have beneficial effects on cancer survival ([Sellick and Crooks, 1999](#)). [Spiegel and coworkers \(1989\)](#) found that group psychotherapy of breast cancer patients improved quality of life and extended life expectancy for patients with metastatic breast cancer. [Fawzy and colleagues \(1990, 1993\)](#) showed that other types of cancer patients improve both psychologically as well as immunologically with psychosocial group therapy. Additionally, in a study of lymphoma, leukemia patients, [Richardson and coworkers \(1990\)](#) found similar quality and quantity of life enhancements.

#### CHILD STUDIES

The relationship between life events and occurrence of medical disease in children has been less extensively studied than that in adults. However, the onset and course of several immune-related diseases have been linked to stressful life experiences. Bronchial asthma and allergic rhinitis, two disorders thought to be mediated by humoral immune responses, occur more frequently in children undergoing life events who have limited abilities to cope psychologically with these changes ([Czubalski and Zawisza, 1976](#); [DeAraujo et al., 1973](#); [Holmes et al., 1951](#); [Knapp, 1969](#)). Streptococcal infections and increased antibodies to streptolysin-O are more likely in members of families in which high levels of stress are noted ([Meyer and Haggerty, 1962](#)). Serious, and often fatal, viral infections have been found in emotionally deprived children ([Spitz, 1965](#)).

One study in children examined prospectively the relationships between stress, immunologic change, and respiratory illness in children. In this study ([Boyce et al., 1993](#)) healthy children were studied immunologically before and after starting kindergarten. During the course of the study, an earthquake struck the area, adding a second stressor to the study. The data showed that children differed in their response to entering kindergarten with respect to changes in immune parameters. However, more importantly, those children who tended to have increases in immune measures (CD4+/CD8+, response to PWM) following entrance into kindergarten also had higher numbers of respiratory infections following the earthquake.

The role that psychological and emotional factors play in increasing the susceptibility of youngsters to medical illnesses including cancers is not yet known, although [Greene and Miller \(1958\)](#) and [Jacobs and Charles \(1980\)](#) have conducted investigations of the relationship of such factors to the onset of leukemia and lymphoma in children and adolescents. Experiences of separation and loss appear to be one of multiple factors that are associated with the development of leukemia in children. For example, of 33 patients with lymphocytic and myelogenous leukemia, 31 are found to have experienced one or more losses or separations in the 2-year period prior to the onset of their illness, with half of these experiences occurring in the 6 months prior to that time ([Greene and Miller, 1958](#)). Further, [Drummond and Hewson-Bower \(1997\)](#) have reported that stress in children was associated with a history of recurrent colds and flu and lower salivary IgA.

#### Life Events and Immune Changes

Although there has often been disagreement about the existence of changes in immunity related to life stressors, a recent metaanalysis of the relationship between stress and immunity concluded that there is substantial evidence for stress-induced modulation of the numbers and functional capacities of multiple immune cell types ([Herbert and Cohen, 1993b](#)). Important variables influencing immunity included stressor duration and the extent to which the stressor involved social (e.g., loss of spouse) rather than nonsocial (e.g., loss of job) events ([Herbert and Cohen, 1993b](#)). A more detailed consideration of the types of stressor that have been linked to altered immunity follows.

#### Clinical Studies of Bereavement

Clinical studies of immune function in bereaved subjects have demonstrated altered immunity, including suppression of lymphocyte responses to mitogenic stimulation, reduced NKCA, and alterations of T-cell subpopulations. The relationship between bereavement and immunologic functioning was first reported by [Bartrop and colleagues \(1977\)](#) who compared measures of lymphocyte responses to mitogen stimulation between 26 men and women whose spouses had died and 26 age- and sex-matched control subjects. At both 3 and 6 weeks after the death of the spouses, during which time active bereavement occurs, T-cell responses to low doses of PHA and Con A are reduced in the bereaved group. T- and B-cell numbers do not differ between groups. Using several specific antigens (streptokinase, mumps antigen, and purified protein derivative of tuberculin), delayed hypersensitivity reactions on routine skin testing are also not different. In a prospective study, [Schleifer and colleagues \(1983\)](#) replicated the earlier findings, demonstrating a significant suppression of lymphocyte responses during the first 2 months following the death of a spouse and an intermediate level of mitogen responsivity during the 4- to 14-month period after bereavement.

Other *in vitro* parameters of cell-mediated immune function are also found to be altered during bereavement. Measures of NK cell cytotoxicity, total lymphocyte counts, and T-helper and T-suppressor cell numbers were compared among three groups of women: those whose husbands were dying of lung cancer, those whose husbands had recently died, and women whose husbands were in good health ([Irwin et al., 1987a,b](#)). In the groups who were undergoing moderate or severe life stress (comprised significantly by women anticipating or bereaving the death of their spouse), a reduction of NKCA is found as compared to the values in the low stress, nonbereaved comparison subjects. Neither the absolute number of lymphocytes nor T-cell subpopulations including number of T-helper, T-suppressor/cytotoxic cells and ratio of T-helper to T-suppressor/cytotoxic cell is different between the groups.

Psychological responses, not merely the event, might contribute to the immune changes in bereavement. Consistent with this hypothesis, severity of depressive symptoms is correlated with reduced NKCA, a loss of T-suppressor/cytotoxic cells, and an increase in the ratio of T-helper to T-suppressor/cytotoxic cells ([Irwin et al., 1987a](#)). Using various measures of humoral and cell-mediated immunity, [Linn and colleagues \(1984\)](#) found reduced lymphocyte responses to the mitogen PHA only in bereaved subjects who had high depression scores but not in those bereaved subjects who had few signs of depression. Other immunologic measures, including lymphocyte responses to Con A and pokeweed mitogen, serum levels of IgG, IgA, and IgM, *in vivo* responses to skin tests, and neutrophilic chemotaxis were comparable to those found in the controls.

Finally, in a study of depression in bereaved women ([Zisook et al., 1994](#)) only that subset of bereaved women who also met criteria for major depressive disorder (DSMIII-R) were found to have altered immunity, specifically lower NKCA and lower responses to mitogen stimulation.

#### Effects of Examination Stress

Relatively minor aversive events such as the stress of academic examinations are also associated with altered immunity. [Dorian and associates \(1982\)](#) reported higher white blood cell counts, an increased absolute lymphocyte count, a reduction in PHA reactivity, and a reduction in plaque forming cell response (an index of B-cell function) in eight psychiatry trainees taking their oral examinations as compared to the values in 16 psychiatrists not taking examinations. In a series of other studies conducted by [Kiecolt-Glaser and colleagues \(1984\)](#), the initial observations of examination-related alterations of cellular immunity have been confirmed and extended. Medical students demonstrate significantly lower levels of NKCA and blastogenesis (in response to both Con A and PHA) during final examinations as compared to baseline samples taken 1 month earlier ([Kiecolt-Glaser et al., 1984](#)). Additionally, the students exhibit stress-related decreases in the percentages of total T lymphocytes, helper T lymphocytes, and suppressor T cells ([Glaser et al., 1985](#)) and significant increases in plasma levels of IgG, IgM, and IgA ([Glaser et al., 1986](#)). Moreover, these researchers have speculated that these immunologic changes may be important for the control of recurrent latent herpes virus infections and found that antibody titers to Epstein-Barr virus (EBV), CMV, and herpes simplex virus (HSV) are significantly increased during the first day of examination as compared to either the month before examination or on return from summer vacation ([Kiecolt-Glaser et al., 1984](#)). The same stressor was also associated with significant decreases in the number and synthesis of IL-2 receptors on peripheral blood leukocytes and with increased release of IL-2 by these cells ([Glaser et al., 1990](#)).

In a more recent study, [Borella and colleagues \(1999\)](#) studied military cadets in Italy both during academic stress (examinations) and in periods of no particular academic stress. Their results suggest that examination stress per se did not result in altered NKCA in the group as a whole. Rather, they found that emotionally stable (not anxious) cadets showed increased NKCA at times of academic stress, whereas cadets who were less emotionally stable (more anxious) had decreased

NKCA compared to baseline.

## Coping and Social Support

Style of coping and quality of social support are postulated as determinants of whether severe adversities such as bereavement or caregiving become translated into psychological and physical morbidity. In this regard, discord or dissatisfaction within the marital relationship are found to have effects on immune function ([Kiecolt-Glaser et al., 1987](#)); poor marital quality is associated with reduced immunologic functioning (lower percentages of NK and helper cells, poor mitogen responsiveness, and higher antibodies to some herpes viruses) among married women ([Kiecolt-Glaser et al., 1987](#)) and married men ([Kiecolt-Glaser et al., 1988](#)).

Despite a demonstrated link between coping and psychological adjustment during stress, few studies have evaluated the role of coping responses as defined by [Lazarus and Folkman \(1984\)](#) in mediating stress-induced alterations in immune function. Instead, most studies have evaluated coping responses indirectly, postulating that a diminished capacity to adapt, as indicated by psychiatric symptoms, is a measure of coping. For example, [Locke and coworkers \(1984\)](#) rated the severity of life events in 114 students and on the basis of these reports and measures of psychiatric symptoms divided the sample into four groups; low stress/low symptoms, high stress/high symptoms, high stress/low symptoms, and low stress/high symptoms. Those subjects with few psychologic symptoms in the face of large amounts of stress ("good copers") have significantly higher NKCA than those experiencing high levels of both symptoms and stress. Temoshok (1986) has also found that one factor influencing survival among AIDS patients is the degree of control they experienced over their lives; those who felt they could exert little control died more quickly. Finally, consistent with the findings generated in preclinical studies, administration of an uncontrollable (but not controllable) stress produces greater elevations in the plasma concentration of ACTH and epinephrine in humans ([Breier et al., 1987](#)).

## Chronic Stress and Immune Dysfunction

In addition to the effects of acutely occurring severe, as well as relatively minor, aversive events, chronic stressors that last over periods of one or more years have also been found to result in alterations in immune function. The stresses of Alzheimer's disease caregiving often place family members at risk for depression ([Eisdorfer et al., 1983](#)) and are associated with decreased life satisfaction ([George and Gwyther, 1986](#)) and increased levels of psychiatric symptoms ([George and Gwyther, 1986](#)). Furthermore, immunologic analyses have revealed significantly higher antibody titers to EBV and reduced percentages of total T lymphocytes and helper T cells in 34 Alzheimer caregivers versus 34 matched controls ([Kiecolt-Glaser et al., 1987](#)). Neither T-suppressor cells nor numbers of NK cells differed between the two groups. In another study, [Mills and colleagues \(1997\)](#) found that chronic stress in Alzheimer caregivers was associated with altered lymphocyte B<sub>2</sub>-adrenergic receptors. These changes in immunity may have health consequences, as Alzheimer caregiving has also been associated with significant increases in episodes of infectious illness and illness-associated physician visits ([Kiecolt-Glaser et al., 1991](#)).

## Stress and Immunity in Children

Two studies have reported an association between stress and immunity in children and adolescents. In a study by [Birmaher and coworkers \(1994\)](#) subjects with MDD or conduct disorder and healthy controls (ages 11 to 18 years, Tanner III to IV) were studied. Both lifetime and past year measures of adverse life events for the entire sample was significantly and inversely correlated with NKCA, meaning greater numbers of adverse events were predictive of lower NK activity for all the adolescents studied. In a study of 11 prepubescent (ages 8 to 12 years, Tanner I) subjects with major depression versus 11 normal matched controls, parental divorce or separation was associated with lower granulocyte killing of *staphylococcus aureus*, whereas major depression was associated with greater NKCA ([Bartlett et al., 1997](#)). No other studies of psychosocial stress and immunity have been reported in children and very few studies of stress in humans address myeloid cell function; however, physiologic stress has been reported to produce altered granulocyte function in children ([Krause et al., 1986](#); [Stroobant et al., 1984](#); [Tolone et al., 1989](#)).

## Depression and Immune Changes

Psychological response to distressing life events is an important correlate of immune dysfunction in persons undergoing severe life stress. Further, stress has long been considered a risk factor for the development of anxiety or depressive disorders with the possibility that stress-related immune changes play a role in the development of these disorders ([Leonard and Song, 1996](#)). This and the clinical similarities of bereavement and depression have led to the hypotheses that depression or anxiety may be associated with immune change. [Herbert and Cohen \(1993a\)](#) conducted a metaanalysis of studies of depression and immunity and concluded that depression is indeed significantly related to impaired cellular immunity with severity of depressive symptoms associated with greater decreases in immune cells numbers and activity ([Herbert and Cohen, 1993a](#)).

To clarify the role of depression in impairing cell-mediated immunity, several studies have compared immune responses between depressed patients and control subjects. [Cappel and associates \(1978\)](#) reported that PHA responses are lower in psychotically depressed patients during the first days of illness than following clinical remission. [Kronfol and colleagues \(1983\)](#) replicated these observations in 26 drug-free depressed patients and found blunted lymphocyte responses to mitogenic stimulation with Con A, PHA, and pokeweed during depression. [Schleifer and associates \(1984\)](#) also found suppressed lymphocyte reactivity in severely depressed patients and further described abnormalities of lymphocyte subpopulations in depression: absolute and T- and B-lymphocyte cell counts are reduced, although relative percentages are unchanged. Because no differences in immune measures have been found in mildly depressed outpatients as compared to controls, Schleifer and colleagues have concluded that the severity of depressive symptoms is an important factor associated with altered lymphocyte responses in depression ([1985](#)).

Extending these observations of altered lymphocyte proliferation responses in depression, [Irwin and colleagues \(1987b\)](#) measured the cytolytic activity of peripheral lymphocytes in two groups of subjects: Medication-free, hospitalized acutely depressed patients and age- and sex-matched control subjects studied on the same day as the patients. NKCA was significantly lower in the depressed patients as compared to the control subjects, a finding that has been replicated by [Urch and colleagues \(1988\)](#) and [Mohr and colleagues \(1987\)](#). In addition, severity of depressive symptoms was correlated with a reduction in NKCA.

In an attempt to understand why some (but apparently not all) patients with major depression show immune changes, the contribution of other factors that might affect immunity in depressed patients has been studied. [Schleifer and colleagues \(1989\)](#) have examined the role of age in the relationship between depression and altered immunity. Employing an extensive assessment of the immune system including enumeration of T-lymphocyte subsets, assay of NKCA, and measurement of mitogen-induced lymphocyte stimulation, significant age-related differences between the depressed patients and control are found for numbers of T-helper lymphocytes and mitogen responses. Age-related increases in T-helper cells and in mitogen responses are found in the controls, whereas advancing age is associated with no changes in T-helper number and decreased lymphocyte responses in depressed patients. In a 1996 study of young adults (ages 18 to 35) with unipolar depression, 21 subjects were compared to 21 healthy matched controls ([Schleifer et al., 1996](#)). In these ambulatory patients, depression was related to increased total WBC and increased circulating granulocytes but lower NK cell counts. When NK numbers were controlled in the analyses, subjects were also found to have lower NKCA; however, no changes in lymphocyte proliferative responses to PHA, Con A, or PWM were found. These findings suggest that age and severity of depression are important correlates of immune changes in depression; immune changes in major depressive disorder are present mainly in elderly, severely depressed patients.

In addition to the independent contribution of age to depression-related changes in immunity, alcohol consumption is also reported to play a role in further reducing cellular immunity in depressed patients. Alcohol use, even in moderate doses, is associated with alterations in cell-mediated immune function such as NKCA. The contribution of alcohol use to produce a greater decrement in immunity in depressives with histories of alcohol abuse as compared to depressed patients without such alcoholism has been compared ([Irwin et al., 1990](#)). Consistent with earlier reports, NKCA is significantly lower both in depressed and alcoholic patients (as compared to controls). Perhaps of more interest, patients with dual diagnoses of either alcohol abuse and secondary depression or depression with a history of alcohol abuse demonstrate a further decrease in NKCA as compared to that found in patients with either depression or alcoholism alone.

Alterations in T-cell subpopulations have also been characterized in depressed patients as compared to control subjects. Consistent with the findings of [Irwin and colleagues \(1987b\)](#), who found a relationship between severity of depressive symptoms and an increase in the ratio of T-helper to T-suppressor/cytotoxic cells in bereaved women, [Syvalahti and associates \(1985\)](#) found that depressed patients have a lower percentage of T-suppressor/cytotoxic cells and a higher ratio of T-helper to T-suppressor/cytotoxic cells than that of the control subjects. However, other studies have found no depression-related differences in quantitative measures of lymphocytes including number of T cells, B cells, T-helper, T-suppressor, and NK cells ([Darko et al., 1989](#); [Wahlin et al., 1984](#)).

NKCA alterations have also been reliably reported in depressed patients ([Irwin et al., 1987, 1990](#); [Stein et al., 1991](#)), as well as alterations in numbers of circulating NK cells ([Andreoli et al., 1993](#)), changes that appear to relate to age and gender, as well as depressive disorder ([Evans et al., 1992](#)). In a study by [Miller and colleagues \(1999\)](#) of 32 women with major depressive disorder, subjects were found to have reduced lymphocyte proliferative responses to both PHA and Con A.

However, NKCA was reduced in the older subjects but elevated in the younger subjects, suggesting age and gender play a role in alterations of both numbers and functional ability of immunocytes.

The apparent inconsistencies in psychoimmunologic investigations in humans have led to increasing sophisticated studies that have documented complexities of psychoimmunologic relationships. Confounding factors have been reported including diurnal variation in NK numbers and function in depressed patients ([Petitto et al., 1992](#)) and effects of sleep on NKCA in depression ([Irwin et al., 1992, 1994](#)). Further, the duration of depression has been found to have an age-independent effect on lymphocyte proliferative responses to PHA, PWM, and Con A and the length of time off antidepressant medication was correlated with numbers of circulating lymphocytes, T cells, and NK cells ([Andreoli et al., 1993](#)).

Few studies have investigated relationships between depression and immunity during the course of the disorder. In a study of 20 male patients with MDD and 20 matched controls, [Irwin and coworkers \(1992\)](#) found that the severity of depressive symptoms and NKCA were positively correlated over time. In a follow-up study of the young adults with unipolar depression ([Schleifer et al., 1999](#)) involving 6 weeks of treatment with nortriptyline and alprazolam, clinical improvements in severity of depressive symptoms was associated with decreased numbers of circulating lymphocytes. In addition, decreases in T cells, CD4+ and CD29+ were found; there were no changes in B cell numbers or CD8+ cells. Finally, patients also had decreased responses to PHA and Con A but not PWM. None of these changes were related to nortriptyline blood levels ([Schleifer et al., 1999](#)).

Beyond the use of more sophisticated measures of immune cell function, future investigations need to test the clinical relevance and biological significance of depression-related changes in the immune system. Furthermore, preclinical and clinical studies of the mechanisms that underlie changes in depression in such biological parameters as measures of immunity will help identify the pathways of communication among the nervous, endocrine, and immune systems.

### Depression and Immunity in Children

Only three studies have been published to date concerning immunity in children and/or adolescents with depression. [Shain and colleagues \(1991\)](#) investigated NKCA in 16 hospitalized adolescents (ages 13 to 18) with major depressive disorder and 16 age- and gender-matched controls. Although they found no between group differences in NKCA, they did find both significant age effects and a significant correlation between severity of depressive symptoms (as measured by the Reynolds Adolescent Depression Scale) and NKCA with greater severity of symptoms associated with lower levels of activity.

In [1994](#), Birmaher and colleagues reported a study comparing 20 subjects with major depressive disorder, 17 subjects with conduct disorder (CD), and 20 normal healthy controls (ages 11 to 18, post thelarche/adrenarche and Tanner stage III to IV). Many of the subjects with psychiatric disorders had comorbid conditions or different subtypes of depression. They found no between group differences in WBC counts or number or percentages of lymphocytes, T cells, or NK cells; however, B cells were increased in CD subjects as compared to controls and MDD subjects. No between-group differences were found in response to PHA stimulation, although CD subjects had lower NK activity (trend) compared to both MDD subjects and controls. In a study of immunity in prepubescent depression, [Bartlett and coworkers \(1995\)](#) investigated 20 children with MDD (Tanner stage I) and 20 healthy matched controls. The depressed children had lower NKCA and elevated response to Con A but not PHA or PWM compared to their healthy controls.

### Anxiety and Immunity

Immune changes associated with anxiety disorders including panic disorder and posttraumatic stress disorder (PTSD) have recently been under investigation. [Koh and colleagues \(1998\)](#) reported decreased lymphocyte proliferative responses to PHA in 31 patients with anxiety disorders compared to 31 matched controls. They also found that patients with anxiety disorders had diminished IL-2 production. In a study of PTSD, following a hurricane, [Ironson and coworkers \(1997\)](#) found that NKCA was related to the symptoms of PTSD with more symptoms predicting lower NKCA. The subjects who had lived through the hurricane, compared to laboratory controls, had lower numbers of circulating CD4+ and CD8+ cells and higher numbers of NK cells, as well as lower NKCA. Further, they found that new sleep disturbances mediated the relationship between NKCA and PTSD. [Boscarino and colleagues \(1999\)](#) also investigated PTSD, comparing Vietnam veterans with PTSD, to veterans with no psychiatric disorder. The veterans with PTSD had elevated leucocyte counts as well as elevated CD4+ counts.

### Behavioral/Psychiatric Symptoms Associated with Immune Phenomena

The communications between the brain and the immune system are now understood to involve bidirectional messaging ([Husband, 1993](#); [Lawrence and Kim, 2000](#); [Maier and Watkins, 1998](#); [Solomon, 1987](#)). Both immune cells and immunocyte products (cytokines) cross- and/or are actively transported across the blood-brain barrier with influences on CNS activity ([Watkins and Maier, 1995](#)). Not only are brain, behavioral, and psychological factors thought to influence immune function, but also immune factors are thought to affect brain, behavior, and psychological status.

Cytokines are reported to have behavioral and neuropsychiatric effects in addition to their role in regulating immune responses as reviewed by [Dantzer and Kelley \(1989\)](#). IL-1, IL-6, and TNF- $\alpha$  are reported to produce a group of symptoms referred to in animal studies as sickness behavior ([Kent et al., 1992a,b](#)) including symptoms of social withdrawal, decreased energy, increased sleep, and poor appetite. IL-6 has also been reported to produce diminished concentration and negatively impact mood as well as other alterations in sleep patterns (e.g., diminished time in rapid eye movement sleep) ([Spath-Schwalbe et al., 1998](#)).

There is a growing literature devoted to the impact of the immune response and soluble immune response modifiers on brain function and behavior. Interleukin-1 is an immune response modifier that has received a large amount of attention because of its pleiotropic physiologic and behavioral effects. This cytokine, when introduced into the brain, induces slow wave sleep ([Krueger and Obal, 1993](#)) increased release of hypothalamic CRH ([Sapolsky et al., 1987](#)), and increased circulating concentrations of ACTH ([Vale et al., 1981](#)). Because IL-1 plays a crucial role in regulating a number of immunologic responses [Dinarello and Mier \(1987\)](#), [Sundar and associates \(1990\)](#), and [Brown and colleagues \(1991\)](#) have investigated whether central administration of IL-1 would affect immunity, and both demonstrated that central doses of IL-1 (3.1 to 12.4 fmol) rapidly reduce *ex vivo* cellular immune responses such as NK cell activity, lymphocyte proliferative response to PHA, IL-2 production, and macrophage IL-1 secretion. Importantly, the effects of central IL-1 on immune function are blocked by the administration of an antibody to CRH, indicating that IL-1b likely mediates immunosuppression via central release of CRH ([Saperstein et al., 1992](#); [Sundar et al., 1989](#)). Consequently, the pathways by which IL-1 regulates peripheral immune function are similar to mechanisms involved in central CRH suppression of immunity. Administration of a ganglionic blocker abrogates the effects of IL-1 ([Sundar et al., 1990](#)), similar to observations that autonomic- and sympathetic nervous mechanisms mediate CRH-induced suppression of NK activity ([Irwin et al., 1988, 1990](#)).

Interferon has been used in treatment of illnesses such as cancer and neurobehavioral consequences of these treatments have been reported. Interferon- $\alpha$  has effects on both mood and cognition ([Valentine et al., 1998](#)), including reduced alertness, increased depression, impaired memory, and lack of initiative.

Less specific immune-neuropsychiatric relationships have also been reported. Perhaps the most notable childhood disorder is that of pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS). Although first reported in 1894 by Osler, PANDAS was not much investigated until the late 1980s. PANDAS consist of obsessive-compulsive and/or tic (motor or vocal) symptoms that have a waxing and waning course related to infection with group B hemolytic streptococcal infection. Abnormal neurologic findings and elevated antistreptolysin titers often accompany exacerbations of symptoms. By definition, it has a prepubescent onset that is often abrupt. Symptoms may remit or disappear entirely between episodes. Antineuronal antibodies may be present. Some symptom exacerbations may follow viral rather than streptococcal infection ([Swedo et al., 1998](#)).

## CONCLUSION

The complexities of interactions among brain, behavior, immunity, and health have been noted for centuries ([Leonard and Song, 1999](#)), but we are just beginning to understand some of the specifics of the interactions involved. Animal and adult human studies have advanced our knowledge but few actual investigations have been undertaken in children for whom psychoneuroimmunologic interactions may potentially affect their well being for their entire lifetime. Investigations of these interactions in children and adolescents are currently underway and will provide much valuable information.

The unique biologic and behavioral characteristics of newborns, infants, and children in different stages of development imply important differences between adult neuroendocrine processes and those occurring during development. Not only is the developing neuroendocrine system functioning and capable of dynamic responses to the changing environment, but also in the early stages of development, it can undergo long-lasting and permanent changes as a result of these early influences. Clear understanding of the developmental aspects of psychoneuroendocrinology would require investigations at the embryologic, fetal, neonatal, and later developmental stages and at the molecular, cellular, and architectural levels of organization in the anatomic, neurochemical, neurophysiologic, behavioral, and clinical aspects of the brain and endocrine system. This may seem like a mammoth undertaking but is very likely to be extremely informative.

In this chapter, we review the current literature on neuroendocrinology and childhood behavior and ask the question: How do these neuronal cell populations, pathways, neurotransmitters, neuroregulators, and other physiologic mechanisms develop and interact with the developing endocrine system? This approach carries the basic assumption that the same anatomic and physiologic processes, albeit immature, are used in both the developing brain and endocrine system as those utilized in the adult organism. As a result, our purpose may be reduced to investigating how such systems function in the immature state and during different stages of development; however, this approach is likely fraught with several difficulties.

First, the presently accepted view of neuroendocrine functions may be incorrect and incomplete, and searching for their ontogeny may lead to a compounding of these errors. Second, it is entirely possible, and perhaps likely, that the fetus and neonate use neuroendocrine mechanisms that are vastly different from those in the adult. Their repertoire of behavior and responses to stress are certainly different, as are the characteristics of the stressors that elicit neuroendocrine responses. Third, neuronal cell populations, connecting pathways, neurotransmitters, and other physiologic mechanisms may exist transiently during development and be lost in the adult brain and endocrine system. Some neuroendocrine mechanisms that have limited roles in the adult may indeed have sweeping and pluripotent roles in altering the development of the neuroendocrine system and secondarily altering cognitive processes and behavior during childhood. Last, the concept of “critical windows of development” does not apply to the mature brain, whereby short-lived or slight changes in cellular processing or molecular signaling may have drastic or wide-ranging effects during development by altering critical steps that have a “permissive” effect on subsequent developmental events. Many such examples are described in the ensuing sections whereby an environmental insult during a critical period can have persistent or even permanent effects on the future functioning of a neuroendocrine system, and consequently, on the health and behavior of the affected subject (Anand and Scalzo, 2000). This highly complex and vulnerable system generates enormous possibilities for altered and abnormal development or persistently altered regulation, with important implications for the practice of child and adolescent psychiatry.

### NEUROENDOCRINE REGULATION OF BRAIN DEVELOPMENT

Developmental events in the central nervous system (CNS) are regulated by a variety of genetic mechanisms, ionic gradients, neuroendocrine factors, and paracrine influences. Neuroendocrine factors that control the migration, differentiation, and maturation of neuronal cell populations include thyroid hormones, glucocorticoids, androgens and estrogens, and several neuropeptides. Much of the research on neurobiological development and the basic mechanisms of psychoneuroendocrinology has been performed in rodent species, largely rats and mice. Apart from logistic reasons such as laboratory cost and convenience, short gestation, and simple breeding and rearing conditions, three other reasons contribute to this choice. First, the cellular, molecular, and architectural events in the development of the CNS follow remarkably similar patterns in the human and rodent species. Some of the relevant data illustrating this interspecies correlation are summarized in [Table 7.1](#). The rat brain at birth (P0) has a similar developmental maturity as the brain of a 24-week-gestation human premature infant, and at 10 to 14 days of age (P10 to P14) the rat brain corresponds to the brain of a full-term newborn infant (Bass et al., 1977; Eayrs, 1968). Second, the behavior of infant and adult rats has been investigated in much greater detail than that in any other species. The rich repertoire of cognitive and behavioral tests that have been validated and published allow meaningful correlations between neurobiological events and mechanisms, experimental paradigms, drug therapies, and the resulting (often quantifiable) behavioral changes. Third, the remarkable database on mouse, in contrast to rat, genetics makes the mouse the species of choice for studies of behavior genetics. A powerful combination of these investigative advantages makes rodents the primary choice for animal models of human psychiatric and behavioral disorders. Nevertheless, when extrapolating from experimental studies to clinical situations, we must account for major differences in the complexity and adaptability between human and rodent brains. Therefore, this chapter focuses much of the discussion on developmental aspects of psychoneuroendocrinology in rodent and human species, although studies involving nonhuman primates are reviewed as well.

**Table 7.1. Correlation of Rat and Human Brain Development**

## Thyroid Hormones

Thyroid hormones influence brain development in three phases during fetal and neonatal life. Phase I includes the influence of maternal thyroid hormones, which extends up to 17 days of gestation in the rat and 10 to 12 weeks gestation in the human. A significant proportion of brain stem and cerebral neurogenesis occurs during this period, and accumulating evidence has started to define the developmental role of thyroid hormones. Placental transport of thyroid hormones occurs in humans (Vulsma et al., 1989) and rats (Morreale de Escobar et al., 1990), with localization in the fetal brain as early as E12 in the rat (Porterfield and Hendrich, 1992) and 10 weeks gestation in the human fetus (Ferreiro et al., 1988). The fetal brain selectively accumulates thyroid hormones (triiodothyronine [ $T_3$ ] > thyroxine [ $T_4$ ]), and thyroid hormone receptors are present from E14 in the rat (Perez-Castillo et al., 1985) and the first trimester of human gestation (Bernal and Pekonen, 1984). The synthesis of transthyretin in the choroid plexus may regulate the transport of thyroxine across the blood-brain barrier (Schreiber et al., 1990), where it is selectively deiodinated to form  $T_3$ , primarily through the action of Type II iodothyronine 5 $\alpha$ -deiodinase (D2) (Koibuchi and Chin, 2000). D2 is found mainly in astrocytes, suggesting that  $T_4$  is taken up from capillaries by astrocytes, deiodinated to  $T_3$ , and transferred to neurons for direct interaction with the nuclear thyroid hormone receptor (Guadano-Ferrez et al., 1997).

Destruction of the fetal and maternal thyroid gland in midgestation results in decreased messenger ribonucleic acid (mRNA) and protein synthesis in the brain (Holt et al., 1973) with specific reductions in mRNAs for constitutive tubulin isotypes Mb5 and Ma1 (Stein et al., 1989). Treatment of pregnant rats from E7 with propylthiouracil was associated with delayed cell accumulation in mesencephalic and motor nuclei (Narayanan and Narayanan, 1985). These experimental observations were correlated with cognitive deficits and delayed motor skills in children exposed to maternal hypothyroidism in early gestation (Letarte and Garagorri, 1989; Rovet, 1986).

During phase II (E17 to E21 in rats, 12 to 40 weeks gestation in humans), the fetal and maternal thyroid glands are active sources of thyroid hormones. The partial neurogenesis, neuronal migration, neurite formation, and synaptogenesis occurring in this period are exquisitely sensitive to the presence of thyroid hormones. Potter and colleagues (1986) found that reduced brain growth caused by maternal hypothyroidism was restored to normal in sheep fetuses after the onset of fetal thyroid function. Maternal hypothyroidism may alter fetal brain development by nonspecific mechanisms such as altered maternal metabolism and compromised nutrient availability, decreased placental growth, circulation, or function, or indirectly, by altering the regulation of trophic hormones (growth hormone [GH], insulin-like growth factor-1 [IGF-1], IGF-II). These specific effects are mediated directly by fetal or neonatal thyroid hormones on the growth and maturation of neuronal cell populations (Porterfield and Hendrich, 1993).

In phase III, which follows birth, brain development is entirely dependent on the activity of the neonatal thyroid gland. The small amounts of thyroid hormones present in human breast milk are insufficient to support normal brain development (Mallol et al., 1982), although breast milk may serve as a significant source of iodine because of the selective uptake of iodine from maternal plasma (Tazebay et al., 2000). Hypothyroid states in phase III mostly affect neuronal maturation and development in the forebrain and cerebellum, together with proliferation and maturation of glial cells that cause myelination throughout the nervous system. This critical period extends from birth to P21 in the rat and up to 2 years in the human, when thyroid deficiencies can cause serious and permanent brain damage. Several lines of evidence highlight the importance of thyroid hormones in the regulation of protein synthesis in neuronal and glial cells (Dussault and Ruel, 1987). Thyroid hormones function as a time clock in phase III, terminating neuronal proliferation and stimulating differentiation, particularly in the rat cerebellum. Triiodothyronine appears to regulate the expression of the genes that encode growth factors, including the neurotrophins (e.g., NT-3) and brain derived neurotrophic factor (BDNF) (Koibuchi, 1999; Koibuchi and Chin, 1999; Lindholm et al., 1993; Neveu and Arenas, 1996), and other crucial peptides including myelin basic protein, neural cell adhesion molecule and reelin (Koibuchi and Chin, 2000).  $T_3$  may also regulate the expression of genes encoding other transcription factors such as hr, Krox 24, and Rora (Koibuchi and Chin, 2000). Myelination of central tracts by oligodendrocytes is preceded by the transient expression of nuclear  $T_3$ -receptors, which are absent before the critical period of active myelination (Besnard et al., 1994).  $T_4$  is also involved in brain development; it recently has been shown to regulate the extracellular deposition of laminin on astrocytes (Farwell and Dubord-Tomasetti, 1999). Laminin provides guidance signals for migrating neurons in the rat cerebellum (Farwell and Dubord-Tomasetti, 1999). Perinatal hypothyroidism also alters the normal expression and function of G proteins in the rat cerebellum (Leung et al., 1996).

Discovery of these cellular mechanisms in neuronal and glial cells has partially defined the important roles of thyroid hormones in normal brain development. These wide-ranging functions, which are deranged by the absence of these hormones, include neuronal migration and differentiation, synthesis of the cytoskeleton and other structural proteins, regulation of transcription and growth factors, myelination of nerve tracts, and development of the signal transduction machinery for numerous neurotransmitters and neurohormones (Table 7.2). These data, therefore, highlight the robust cognitive and behavioral abnormalities resulting from the absence or relative deficiency of thyroid hormones.

Developmental feature	Thyroid Deficiency	Treatment with Thyroxine	Treatment with Corticosterone
Neuronal cell formation	Normal	Deficit	Deficit
Brain volume	Reduced	No effect (P21)	Reduced (P21)
Rate of cell migration	Reduced	Normal	Normal
Rate of synaptogenesis	Reduced (cerebellum)	Normal	Normal
Neurochemical induction	Reduced	Advanced	Normal
Conversion of glucose to glycogen	Reduced	Advanced	—
Neuronal differentiation	Reduced	Advanced	—
Dendritic arborization	Reduced	Accelerated	Transiently decreased
Dendritic spine formation	Reduced	Accelerated	Transiently decreased
Synaptogenesis	Reduced	Accelerated but transient	—
Myelination	Reduced	Normal	—
Behavioral changes	Reduced	Advanced	Reduced
Development of simple behavioral patterns	Reduced	Advanced	Normal
Retention of sets of associative behavior	Reduced	Advanced	Normal

**Table 7.2. Effects of Thyroxine and Corticosterone on Postnatal Brain Development in Rats**

## Glucocorticoids

Glucocorticoids appear to have dual roles in the developing brain, with inhibitory effects on the proliferation and growth of neuronal and glial cell populations, together with stimulatory effects on the synthesis of certain neurotransmitters and maturation of neuronal function (Table 7.2). Although direct effects of glucocorticoids on early brain development have not been demonstrated, low doses may potentiate the production of nerve growth factor (NGF), as well as the genomic and nongenomic effects of NGF and other trophic factors (Greene et al., 1983; Perez-Polo et al., 1977). Glucocorticoids seem to accelerate neurotransmitter synthesis and release, maturation of synapses, and development of ion channels that regulate membrane potential and electrolyte distribution across neuronal membranes (Baethmann, 1985; Puro, 1983). Direct effects on neuronal maturation in the cerebral cortex (Chubakov et al., 1986), reticular formation (Avanzino et al., 1983), limbic system (Telegdy and Vermes, 1975), and spinal cord (Hall et al., 1978) have been reported. These widespread changes may be related to glucocorticoid effects on the maturation of intracellular signaling, enzyme activity (e.g., Na<sup>+</sup>/K<sup>+</sup>-ATPase, glutamine synthetase, tryptophan synthetase), and neurotransmitter synthesis

(Baethmann, 1985; Leret et al., 1993; Slotkin et al., 1993; Telegdy and Vermes, 1975).

Large doses of glucocorticoids given postnatally suppress growth and cell division, particularly in glial cells and cerebellar neurons. These effects are mediated by inhibition of deoxyribonucleic acid (DNA) synthesis and increased production of myelin and gangliosides, which lead to the developmental delay of several behavioral milestones (Dussault and Ruel, 1987). Further studies on the development and distribution of glucocorticoid receptor subtypes and their genomic effects in neuronal and glial cells (O'Banion et al., 1994) will help to further define the developmental roles of glucocorticoids.

### Gonadal Steroids

Gonadal steroid hormones—including the androgens, progestins, and estrogens—seem to regulate developmental mechanisms that lead to sexual dimorphism in the mammalian CNS. However, there is early evidence suggesting that some sexually dimorphic development in the brain is also triggered by genetic, nonhormonal signals (Arnold, 1996). The regulatory role of gonadal steroids was first suggested by Pfaff (1966) based on observations of morphologic changes in the adult male rat following neonatal castration and were supported by the pioneering studies of Raisman and Field (1971b). There are well-defined sensitive periods for the development of sexually dimorphic behavior in many animal species; these changes are mostly androgen-dependent. For example, for a permanent feminizing effect, the castration of male rat pups must occur within the first few days after birth and not later than P7, whereas androgen therapy in female rat pups has long-term masculinizing effects if given during the same period (Bermant and Davidson, 1974). The changes in brain development relate not only to sexual behavior, but also to other forms of behavior that differ between the sexes. The critical periods for sexually dimorphic brain development vary between species and do not bear a constant relationship to birth (being prenatal in guinea pig and rhesus monkey, perinatal in the dog, and postnatal in the rat, mouse, hamster, and ferret) (Goy and McEwen, 1980). Raisman and Field's studies (1971a,b) described the differential neuronal development in the preoptic area and hypothalamus, with differences in synaptogenesis, dendritic arborization, and cellular features. Gonadal steroids mediate their effects on the developing brain by specific classes of nuclear receptors, presumed to modulate protein synthesis by altering genomic transcription (Beyer and Feder, 1987). The distribution of these receptor classes corresponds with sexually dimorphic areas in the brain, including those implicated in the regulation of sexual behavior, gonadotropin secretion, and other gender-specific social behavior (Baum, 1986; MacLusky et al., 1987). Testosterone implants in the female rat were associated with the marked growth and differentiation of neurons in the sexually dimorphic preoptic nucleus and spinal nucleus supplying the bulbocavernosus muscle, whereas castration of male rats at birth resulted in significant decreases in these areas. Further studies involving exposure of female rats to testosterone have shown that the growth and differentiation of the spinal nucleus supplying the bulbocavernosus is exquisitely sensitive to the timing of this exposure. Female rats exposed to testosterone on the two prenatal days when males are normally exposed to this surge (E18 and E19) showed a marked increase in cell number in this spinal nucleus. This increase was significantly greater than that seen in females exposed to testosterone just prior to or following these two specific days (Ward et al., 1996). Also, transplantation of the sexually dimorphic nucleus to the brains of castrated male rats restored mating behavior and gonadotropin regulation (Arushanyan and Borovkova, 1989). In addition to gender differences in gross volume of the brain, sexual dimorphism has been reported in the planum temporale, corpus callosum, amygdala, and cerebellum (Baum, 1986; Beyer and Feder, 1987; MacLusky et al., 1987). There is also a large amount of converging, although indirect, evidence that gonadal steroids directly influence the systematic sex differences in the degree of lateralization of the cerebral hemispheres (Wisniewski, 1998). The sexually dimorphic features of the human brain are summarized in Table 7.3.

Dimorphic Features	Sex Differences
Global characteristics	
Brain weight	M > F by 10%-15%
Brain volume	M > F by 10%-15%
Dendritic arborization	M > F at birth
Hypothalamus	
Sexually dimorphic nucleus	M > F
Suprachiasmatic nucleus	M > F
Thalamus	
Masa intermedia	Present in F > M
Cerebral cortex	
Heschl's gyrus	Different morphology in M/F
Anterior end of Sylvian fissure	Located more anterior in M
Planum temporale	L > R in M, L = R in F
Posterior frontal opercular sulcus	Different morphology in M/F
Corpus callosum	
Genus splenium	M > F
Isthmus	F > M

**Table 7.3. Sexual Dimorphism of the Human Brain**

Androgens and estrogens affect brain growth globally and neuronal differentiation in sexually dimorphic areas may be mediated either directly or secondary to their effects on glial cells. For example, exposure to estrogens stimulates astrocytes to participate in the remodeling of hypothalamic neurons that control pituitary function. Glial cells may modulate neuroendocrine actions by synthesizing and releasing trophic factors such as IGF-1 or transforming growth factor- $\beta$  (TGF- $\beta$ ), which may regulate the release of hypothalamic releasing factors (e.g., luteinizing hormone-releasing hormone, LHRH) directly, or by actions on other neurons or glial cells (Duenas et al., 1994). In the rat arcuate nucleus, gonadal steroids caused a marked up-regulation of IGF-1-like immunoreactivity in astrocytes and tanocytes, associated with permanent changes in the morphology of the arcuate nucleus (Duenas et al., 1994). Further studies to define the precise cellular changes produced by gonadal steroids in the developing brain, together with the genomic and nongenomic mechanisms of these effects, should be related to the gender-specific differences in male and female behavior. Only then will we understand the biological basis for developmental abnormalities in gender-derived social behavior.

### DEVELOPMENT OF THE PITUITARY GLAND

Anatomic origin of the pituitary occurs from the hypophyseal placode, a thickening of the midline somatic ectoderm, which is rostrally continuous with the neural crest (Schwind, 1928). With the closure of the neural tube and formation of the mouth, this hypophyseal placode comes to lie ventral to the floor of the forebrain vesicle in the region of the infundibulum and medial eminence, just rostral to the anterior end of the notochord (Schwind, 1928). The earliest molecular markers for the hypophyseal placode include the mRNAs for the  $\alpha$ -glycoprotein subunit of the gonadotropins and the  $\beta$ -thyroid-stimulating hormone subunit  $\beta$ -TSH, expressed on E11 when the anterior neuropore is just closing (Simmons et al., 1990). This is followed by evagination of the infundibulum from the floor of the developing hypothalamus and the formation of Rathke's pouch by E13. A day later,  $\beta$ -TSH mRNA are localized to the most anterior part of anterior lobe, with proopiomelanocortin (POMC) mRNA expressed in cells just caudally. By E17, ventrally located cells in the anterior lobe first express the mRNAs for luteinizing hormone (LH) and follicle-stimulating hormone (FSH), followed by the expression of GH and prolactin (PRL) transcripts by E18 (Swanson, 1992).

During the next 2 weeks of development, cells expressing GH mRNA proliferate much faster than those containing PRL, indicating a differential genetic regulation of these cell types. The expression of these hormones is preceded by the synthesis of Pit-1 mRNA and protein on E15, a specific transcription factor that up-regulates the transcription rates of both GH and PRL genes (Ingraham et al., 1988). Pit-1 is expressed in somatotropes, lactotropes, and thyrotropes and also serves as a growth factor for each of these cell types (Simmons et al., 1990). Another nuclear transcription factor belonging to the leucine zipper family, called thyrotroph embryonic factor (TEF) expressed on E13, increases the transcription rate of the  $\beta$ -TSH gene (Drolet et al., 1991). Thus, these transcription factors play an important role in the cell- and tissue-specific expression of the anterior pituitary hormones, and their spatiotemporal patterns correspond with the expression of the hormonal genes that they regulate.

### HYPOTHALAMIC-PITUITARY-ADRENOCORTICAL AXIS

#### Ontogeny of the Hypothalamic-Pituitary-Adrenal Axis

In the rat fetus, corticotropin-releasing factor (CRF)-immunoreactive nerve terminals can be detected in the anterior regions of the median eminence from E18 (Bugnon et al., 1982), followed by proliferation and growth of CRF-immunoreactive fibers and nerve terminals into the developing pituitary. This period is also associated with the proliferation of pituitary cells expressing the POMC gene, although it is unknown whether the maturing CRF-containing median eminence nerve terminals have any effect on the differentiation of these cells. CRF mRNA was detected in the ventral neuroepithelial lobe of the fetal hypothalamus on day 17 of gestation, prior to the formation of a morphologically distinct PVN (Grino et al., 1989b). Hypothalamic CRF mRNA levels increased markedly on E19 and E20, with simultaneous increases in POMC gene transcription and fetal circulating ACTH levels (Grino et al., 1989a,b). Following birth on E21, CRF immunostaining is temporarily absent from the hypothalamic median eminence, probably related to the stress of parturition, because CRF perikarya in the PVN- and CRF-containing fibers in the median eminence can be detected by 12 hours after birth (Bugnon et al., 1982). In newborn rats from P0 to P7, the hypothalamic CRF and pituitary ACTH

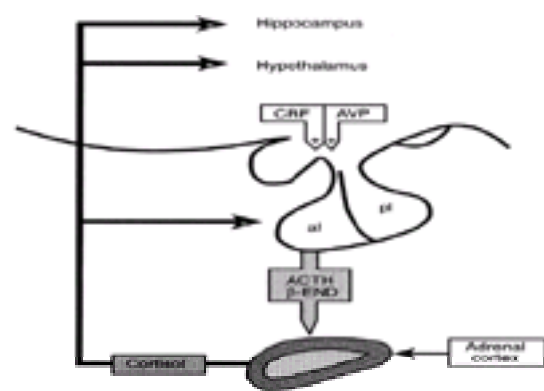

concentrations are approximately 10% of those in adult rats and increase progressively to adult concentrations by 45 days after birth ( Walker et al., 1986a). A targeted mutation in the CRF gene results in CRF-deficient mice, which manifested lung hypoplasia during fetal life. Despite severe glucocorticoid deficiency, these mice exhibited normal growth, fertility, and longevity in postnatal life ( Muglia et al., 1995).

### Corticotropin-Releasing Factor Regulation of the Hypothalamic-Pituitary-Adrenocortical Axis

Within minutes after exposure of pituitary cells to CRF *in vivo* or *in vitro*, a dose-dependent increase in the secretion of POMC-related pituitary hormones occurs, including adrenocorticotrophic hormone (ACTH) and b-endorphin ( Aguilera et al., 1986; Rivier and Plotsky, 1986). ACTH secretion following adrenalectomy or acute stress can be greatly decreased by intravenous injection of a-helical CRF<sub>9-41</sub>, a CRF<sub>1</sub> receptor antagonist, or neutralization with CRF-antiserum, or destruction of the paraventricular nucleus (PVN) of the hypothalamus ( Rivier and Plotsky, 1986; Rivier et al., 1982). These data, taken together with the CRF responses to stress, adrenalectomy, and corticosteroid replacement support the hypothesis that release of endogenous CRF from the paraventricular nucleus regulates the secretory activity of pituitary corticotropes ( Rivier and Plotsky, 1986). CRF may mediate the ACTH response to stressors with a more "psychological" component, whereas both CRF and vasopressin may be involved in the increased ACTH responses to physical stressors ( Mason, 1971; Pich et al., 1993). Both norepinephrine and epinephrine augment cyclic AMP production and the ACTH responses to CRF in pituitary cells ( Abou-Samra et al., 1986; Aguilera et al., 1986). A similar synergism occurs between CRF and vasopressin on ACTH release ( Aguilera et al., 1986). Thus, a variety of neuroendocrine factors have important roles in the regulation of ACTH secretion.

Control of ACTH secretion is mediated by the feedback inhibition of cortisol in primates (corticosterone in rodents). The removal of this feedback by adrenalectomy causes threefold increase in CRF mRNA expression and fourfold to sevenfold increase in arginine vasopressin (AVP) mRNA expression in PVN neurons ( Bradbury et al., 1994; Byer et al., 1988), together with large increases in the synthesis of ACTH ( Fig. 7.1). Feedback inhibition of ACTH release by corticosterone can be divided into rapid and delayed effects, which are partially reversed by exposing pituitary corticotropes to CRF, vasopressin, angiotensin II, and norepinephrine ( Abou-Samra et al., 1986; Levin et al., 1988). The rapid effects on ACTH secretion occur within minutes because of direct steroid effects on ACTH release mechanisms, and the delayed effects occur over hours and days mediated by the inhibition of CRF mRNA expression in the PVN, decreased CRF release from the median eminence, altered CRF receptor-mediated signal transduction, decreased POMC gene transcription, and ACTH synthesis in the pituitary ( Dallman et al., 1994). Chronic *in vivo* or *in vitro* exposure to high CRF concentrations desensitizes the secretory responses of pituitary corticotrophs by down-regulation of the CRF receptor ( Aguilera et al., 1987; Axelrod and Reisine, 1984). In addition to potentiating CRF-stimulated ACTH secretion, vasopressin may also modulate CRF-induced desensitization and down-regulation of CRF receptors in the anterior pituitary ( Aguilera et al., 1987). Occupancy of the high affinity (type I or mineralocorticoid, MR) receptors by low plasma concentrations of corticosterone decreases CRF and AVP expression in PVN cells and normalizes the basal ACTH secretion in the morning. However, occupancy of both MR and low affinity glucocorticoid receptors (GR) is required to reduce the peak ACTH secretion in the evening ( Bradbury et al., 1994; Byer et al., 1988; Kwak et al., 1993). Specific MR antagonists increase basal ACTH secretion, whereas both MR and GR antagonists increase ACTH secretion during the circadian peak or following stress ( Dodt et al., 1993; Ratka et al., 1989). Neurotransmitters other than the glucocorticoids and mineralocorticoids also have been demonstrated to regulate CRF release.

**Figure 7.1.** The hypothalamic-pituitary-adrenocortical axis. ACTH, adrenocorticotrophic hormone; al, anterior lobe of pituitary; AVP, arginine vasopressin; CRF, corticotropin-releasing factor; b-END, b-endorphin; pl, posterior lobe of pituitary. (Negative feedback inhibition is mediated by corticosterone in the rodent species and cortisol in the human species.)

Neurotransmitters that promote CRF release include norepinephrine, acetylcholine, serotonin, neuropeptide Y, interleukin-1B, angiotensin-II and estrogen, whereas inhibitory neurotransmitters include GABA, opioids, atrial natriuretic peptide, substance P, nitric oxide, progesterone, and leptin ( Grossman and Costa, 1993; Heiman et al., 1997; Roy et al., 1999). In addition to feedback inhibition from glucosteroids, CRF is bound by a binding protein that at least theoretically reduces its availability to act on CRF receptors (Reichlin, 1998). CRF binding protein gene transcription is positively regulated *in vivo* by cyclic AMP and CRF ( Cortright et al., 1997), and CRF binding protein mRNA levels are increased by restraint stress in the rat ( McClennen et al., 1998). This suggests that the CRF binding protein may provide an additional feedback mechanism on the HPA axis, although further studies on the ontogeny and precise function of this protein are certainly needed.

Urocortin, a second neuropeptide of the CRF family, also has been discovered recently ( Vaughan et al., 1995). Urocortin shares 45% sequence homology with CRF, but there appears to be limited overlap between urocortin and CRF expression in the rat brain ( Kozicz et al., 1998; Morin et al., 1999; Wong et al., 1998). This suggests that the two neuropeptides may serve different functions. This hypothesis is supported by recent evidence that, in contrast to CRF, urocortin does not significantly affect the release of ACTH from the anterior pituitary under basal conditions, after stress exposure, or adrenalectomy ( Masuzawa et al., 1999; Turnbull et al., 1999).

### Distribution of Corticotropin-Releasing Factor in the Brain

Although the main physiologic function of CRF is to act as the cephalic representative of the HPA axis, the biological role of the peptide involves widespread CNS effects on autonomic, immune, and behavioral functions. CRF immunoreactivity has been localized in hypothalamic and extrahypothalamic structures of the CNS ( Bloom et al., 1982; Swanson et al., 1983, 1986). In addition to CRF-containing cell bodies in the hypothalamic PVN, CRF-containing neurons and nerve terminals are localized in the central nucleus of the amygdala, parabrachial area and substantia innominata, bed nucleus of the stria terminalis, locus ceruleus and the olfactory bulb. Bipolar cerebrocortical cells containing CRF (presumably interneurons) also occur, mainly in layers III and IV of the neocortex ( Swanson et al., 1986). The very high density of CRF binding sites in the primate prefrontal, orbital, and insular cortices differentiates the pattern for CRF receptor distribution in the primate and rodent brain ( DeSouza et al., 1985; Millan et al., 1986; Wynn et al., 1984). These are phylogenetically mature brain regions and control higher cortical functions of primates.

Hypothalamic CRF neurons are present throughout the parvocellular division of the PVN, particularly in a dorsomedial cell condensation just ventral to the anterior commissure, and project to the median eminence. The magnocellular division contains few CRF-positive neurons, and these are functionally associated with vasopressinergic and oxytocinergic neurons ( Swanson et al., 1986). Good correspondence was noted between the distribution of CRF neurons, CRF binding sites, and *in situ* hybridization of CRF receptor mRNA ( DeSouza, 1987; Perrin et al., 1993). The abundance of CRF neurons in extrahypothalamic brain regions, together with its electrophysiologic effects, suggests a neurotransmitter role for CRF, which modulates affective behavior and visceral responses ( Menzaghi et al., 1994) (Table 7.4).

Major Effects of CRF	Major Effects of CRF Receptors in CRF Administration
Increased locomotor activity in familiar environments	Reversed stress and drug-induced anxiolysis
Increased exploration of unfamiliar environments	Attenuated stress-induced fighting
Decreased response to spatial conflict	Reversed defense withdrawal (induced by stress, drug, or genetic) and reduced aggression behavior
Enhanced stress-induced feeding	Attenuated stress-induced feeding
Decreased food intake	Blocked hypothermic state
Disrupted sexual behavior	Attenuated acquisition of conditioned emotional response
Enhanced acoustic startle response	Reduced defense burying
Conditioned fear and aversion	Reversed stress-induced analgesia
Disrupted sleep rhythms	
Increased frequency of grooming and defensive burying	
Reduced values of high doses	

**Table 7.4. Behavioral Effects of Corticotropin-Releasing Factor**

The analgesic properties of CRF have been demonstrated in several studies, and have been posited to be a major mediator for stress-induced analgesia (Chappell et al., 1986; Schafer et al., 1996, 1997). Several studies show that CRF mediates its analgesic actions at all levels of the neuraxis, as well as in the periphery (Lariviere and Melzack, 2000; Schafer et al., 1996, 1997). As previously suggested, the pituitary release of b-endorphin following CRF injection (via various routes: intravenous, intracerebroventricular, intracisternal, and intrathecal) does not explain CRF-induced analgesia, which is a specific CRF effect. From various experimental paradigms it appears that CRF-induced analgesia may be more potent in the setting of inflammatory and prolonged pain, and dysregulation of these mechanisms may play a significant role in the chronic pain syndromes associated with HPA axis abnormalities (Lariviere and Melzack, 2000).

In summary, hypothalamic CRF release triggers a cascade of hormonal events via stimulation of the anterior pituitary and sympathetic outflow, leading to ACTH release and adrenomedullary release of catecholamines. These responses significantly alter cardiovascular, gastrointestinal, metabolic, and immune function, depending on their magnitude and duration. In a complementary manner, the extra-hypothalamic release of CRF seems to mediate the appropriate behavioral and emotional responses to physical and psychological stressors.

### Regulation of Corticotropin-Releasing Factor Receptors

Previous studies using homogenate-binding assays and autoradiography techniques (DeSouza et al., 1985; Hauger et al., 1987, 1988a; Wynn et al., 1984) together with recent molecular approaches (Perrin et al., 1993) have allowed a characterization of the development, anatomic distribution, and regulation of CRF receptors. Activation of CRF receptors leads to the stimulation of adenylate cyclase activity and consequent increases in cyclic AMP levels (Aguilera et al., 1986) in pituitary cells, orbital and frontal cortical neurons, and the amygdala (Millan et al., 1986; Wynn et al., 1984).

Two CRF receptor subtypes, CRF<sub>1</sub> and CRF<sub>2</sub>, have been identified in the rodent (Chalmers et al., 1995; Lovenberg et al., 1995a,b; Potter et al., 1994) and human brains (Chen et al., 1993). These two subtypes have very different patterns of distribution in the brain (Primus et al., 1997). In the rat, the CRF receptor has two different splice variants, CRF<sub>2a</sub> and CRF<sub>2b</sub>. CRF<sub>2a</sub> is the major splice variant located at neuronal membranes, whereas CRF<sub>2b</sub> is found predominantly in nonneuronal elements. The primary endogenous ligand for CRF<sub>2a</sub> appears to be urocortin rather than CRF (Vaughan et al., 1995). Studies using CRF<sub>1</sub>-receptor knockout mice (Smith et al., 1998; Timpl et al., 1998) and studies using antisense oligodeoxynucleotides directed at CRF<sub>1</sub> and CRF<sub>2a</sub> (Heinrichs et al., 1997; Liebsch et al., 1999; Skutella et al., 1998) indicate that the CRF<sub>1</sub>-receptor appears to regulate angiogenesis. CRF<sub>2a</sub> appears to be involved primarily in regulation of feeding and possibly reproductive and defensive behaviors (Steckler and Holsboer, 1999).

The expression of pituitary CRF receptors is altered by physiologic variations in circulating glucocorticoid levels and associated with the delayed corticosteroid inhibition of ACTH transcription and release. Exogenous corticosterone administration produces a dose-dependent reduction in CRF receptor density (B<sub>max</sub>) in the anterior pituitary, thus contributing to the feedback inhibition of ACTH secretion (Hauger et al., 1987). Adrenalectomy causes a decrease in CRF-stimulated adenylate cyclase activity and a down-regulation of pituitary CRF receptors, which is prevented by corticosteroid replacement in adrenalectomized rats (Aguilera et al., 1986; Wynn et al., 1984). The hypersecretion of CRF from hypothalamic neurons results in a homologous, ligand-induced down-regulation of CRF receptors and desensitization of the remaining CRF receptors by uncoupling from adenylate cyclase-linked signal transduction. Nevertheless, CRF receptor regulation is dissociated from ACTH responsiveness following adrenalectomy based on the observation that *in vivo* and *in vitro* ACTH responses to CRF are greater following adrenalectomy, despite the loss of pituitary CRF receptors (Aguilera et al., 1986). In contrast to these changes in the pituitary, CRF receptors in other parts of the brain are unchanged following very high doses of corticosterone or adrenalectomy (Hauger et al., 1987). Release of ACTH and corticosteroids following acute stress does not alter CRF receptor density in the pituitary, although chronic stress causes a down-regulation of pituitary CRF receptors, which is temporally related to the progressive normalization of ACTH secretion during chronic stress (Hauger et al., 1988a). Pituitary ACTH responses to novel stressors or intravenous CRF injection were accentuated in chronically stressed animals, compared with the ACTH responses of nonstressed controls (Hauger et al., 1988a,b). *In vitro* CRF-stimulated cyclic AMP and ACTH release from pituitary cells is reduced following chronic stress, a discrepancy explained by the concomitant effects of vasopressin release *in vivo*, which reverses the desensitization of pituitary cells to resemble those of nonstressed controls (Hauger et al., 1988a). Thus, it appears that vasopressin, norepinephrine, and other neurotransmitters contribute to the *in vivo* sensitization of ACTH responses to novel stressors in chronically stressed animals.

### Hypothalamic-Pituitary-Adrenal Axis Responses to Stress

#### THE STRESS HYPORESPONSIVE PERIOD

ACTH release from fetal or neonatal pituitary glands can be demonstrated *in vitro* following CRF stimulation (Dupouy and Chatelain, 1983; Hary et al., 1984), although the HPA axis *in vivo* remains relatively hyporesponsive to stress for 7 to 10 days after birth in rats (Levine, 1970; Sapolsky and Meaney, 1986; Walker et al., 1986a,b). The threshold for pituitary-adrenal responsiveness is particularly high in the 24 hours after birth, with progressive decreases in the subsequent weeks. Following the increased transcription of hypothalamic CRF mRNA and pituitary POMC mRNA levels in rat fetuses from E17 to E20, CRF and POMC gene transcription decreases markedly during the perinatal period (Grino et al., 1989a,b). A progressive increase in POMC mRNA expression occurs in the rat neurointermediate lobe of the pituitary from P1 to P21, which is corticosteroid insensitive owing to an absence of glucocorticoid receptors. This implies a greater glucocorticoid negative feedback in the perinatal period, leading to secondary inhibition of the expression of CRF mRNA expression in PVN neurons (Grino et al., 1989a,b).

The hypothesis that the stress-hyporesponsive period results from increased corticosteroid inhibition of the HPA axis was supported by the demonstration of enhanced sensitivity to negative feedback, *in vivo* and *in vitro*, to CRF-induced pituitary ACTH release in neonatal rats (Walker et al., 1986a,b). Adrenalectomy of perinatal rat pups was associated with normal ACTH responses to ether stress, although the levels of POMC mRNA in the anterior pituitary after adrenalectomy were lower at P7 than at P14 (Grino et al., 1989a,b). Thus, the relative hyporesponsiveness of the anterior pituitary during the perinatal period may be explained by decreased sensitivity to CRF stimulation and increased sensitivity to corticosteroid negative feedback.

Previous data suggested that b-endorphin responses to CRF stimulation in pituitary cells were similar in 7- and 14-day-old rats (Grino et al., 1989a), although CRF mRNA expression in the PVN increases significantly in 14-day-old rats and remains unchanged in 7-day-old rats following adrenalectomy, an effect reversed by daily CRF injections (Grino et al., 1989a,b). Consequently, the stress hyporesponsive period may result from immature corticosteroid regulation of CRF gene expression in the hypothalamus, perhaps because of the immaturity of afferent inputs to CRF neurons in the neonatal PVN. The ontogeny of CRF receptors in the CNS does not explain the stress hyporesponsive period. Detectable numbers of CRF receptors (40% of receptor density in the adult rat) were measured in the E17 rat CNS (Insel et al., 1988). CRF receptor concentrations increased progressively in the brain until P8, when the receptor density was 312% of adult levels, and then declined to typical adult levels by P21 (Insel et al., 1988). The highest densities of fetal CRF receptors were found in the striatum, whereas after birth CRF binding increased progressively to reach its maximum in the cerebral cortex (Insel et al., 1988). Fetal CRF receptors are coupled to adenylate cyclase-linked signal transduction from E17, and postnatal development is characterized by progressive increases in the percentage of CRF receptors coupled via the stimulatory G-protein to the adenylate cyclase catalytic subunit, with maximum coupling noted in the CNS of adult rats (Insel et al., 1988). Maternal-infant interactions are also involved in the maintenance of the stress hyporesponsive period as outlined in the following.

In contrast, other reports have shown robust adrenocortical responses in neonatal rats soon after birth to physical stressors such as cold-separation stress, which occurred at P0, P9, and P15 (Baram et al., 1997). These studies suggest that careful sampling techniques are required to demonstrate HPA stress responsiveness in

the early postnatal period, which are related to the difficulties in obtaining nonstressed baseline values from neonatal rat pups. Similarly, recent studies showed the rapid transcription of heteronuclear (hnRNA) and messenger RNA (mRNA) for CRF in the hypothalamic paraventricular nucleus of infant rats following even mild aversive stimulation, such as a saline injection ([Dent et al., 2000](#)). Other studies showed the absence of a stress hypo-responsive period in response to an immune challenge (injection of endotoxin), demonstrated by neuronal activation in the hypothalamic PVN accompanied by CRF transcription in neonatal rats ([Dent et al., 1999](#)). Stress hypo-responsiveness of the HPA axis during the perinatal period has not been documented in the human neonate, although neurologic maturity of the newborn rat (at P0) corresponds to that of the premature infant at 24 weeks gestation (data summarized in [Table 7.1](#)).

### STRESS RESPONSES IN HUMAN NEONATES

The hormonal responses of human neonates to surgical operations performed under minimal or no anesthesia are characterized by substantial increases in plasma catecholamines, which return to preoperative values by 6 hours after surgery ([Anand et al., 1985a,b](#)). Responses of the HPA axis to surgical stress are observed with significant perioperative increases in plasma cortisol concentrations in term neonates and significant increases of the precursor steroid hormones (11-deoxycortisol, 11-deoxycorticosterone, 17-hydroxyprogesterone, and progesterone) in preterm neonates ([Anand et al., 1987, 1988](#)). The magnitude and duration of these responses are proportional to the degree of surgical stress, and may be correlated with postoperative clinical outcomes ([Anand, 1993; Anand and Aynsley-Green, 1988](#)). In term neonates subjected to unanesthetized circumcision, plasma cortisol values increase markedly during and after the procedure ([Gunnar et al., 1985](#)).

Fentanyl anesthesia in preterm babies undergoing thoracotomy produces a substantial reduction in the hormonal stress responses to surgery, as indicated by significant decreases in plasma epinephrine, norepinephrine, glucagon, aldosterone, corticosterone, and other steroid hormone responses. The hormonal stress responses of neonates receiving minimal anesthesia lead to significant metabolic derangements (increases in blood glucose, lactate, pyruvate, endogenous protein breakdown, and postoperative complications), which are prevented or diminished in neonates receiving opiates during and after surgery ([Anand et al., 1987, 1988; Anand and Hickey, 1992](#)).

In neonates undergoing cardiac surgery, anesthetic management with halothane and low-dose morphine is associated with substantial catecholamine, corticosteroid, b-endorphin, and glucagon responses during and after cardiac surgery; these responses are blunted in neonates given high-dose sufentanil anesthesia ([Anand and Hickey, 1992](#)). The incidence of metabolic, infectious, and cardiovascular complications postoperatively decreases, together with a significant reduction in postoperative mortality in neonates given sufentanil ([Anand and Hickey, 1992](#)). In addition to the stress of surgery, human neonates who have encountered stressful conditions during birth or unanesthetized circumcision just after birth, maintain an increased responsiveness of the HPA axis with increased salivary cortisol responses and increased pain behaviors when receiving routine vaccinations at 4 and 6 months of age ([Ramsay and Lewis, 1995; Taddio et al., 1997](#)).

### Effects of Early Handling and Maternal Deprivation

Several decades ago, Levine and colleagues noted that repeated handling of rat pups in the first week after birth (or for 21 days, in some studies) results in adult rats with decreased behavioral inhibition in novel environments and decreased HPA responses to a variety of stressors ([Ader and Grotta, 1969; Levine, 1957, 1962; Levine et al., 1967; Meaney et al., 1989](#)). Handled rats (H) had decreased ACTH and corticosterone responses as compared with nonhandled rats (NH) in response to a variety of stressors ([Hess et al., 1969; Meaney et al., 1989, 1991; Viau et al., 1993](#)). Lower peak plasma levels and a faster return to baseline in H rats led to substantial differences between the integrated plasma hormone responses of H and NH rats, and these differences persisted over the entire life of these animals ([Meaney et al., 1988, 1991](#)). These studies showed no differences between the H and NH groups in the adrenal sensitivity to ACTH, the pituitary sensitivity to CRF, the metabolic clearance of ACTH or corticosterone, the plasma levels of corticosterone-binding globulin, or in the basal ACTH or corticosterone levels at any point in the diurnal cycle. These data suggested that long-term effects of neonatal handling were related to neuroendocrine changes above the level of the pituitary. Subsequent studies demonstrated that differences in the HPA axis responses of H and NH rats resulted from increased negative-feedback inhibition in H rats, secondary to an increased expression of glucocorticoid receptors in the hippocampus and median prefrontal cortex of H compared with NH animals ([Meaney et al., 1985, 1987, 1989; O'Donnell et al., 1994; Sarrieu et al., 1988](#)). Chronic corticosteroid treatment (for 5 days) in H and NH rats reversed their differences in both the hippocampal glucocorticoid receptor density and the HPA axis responses to stress ([Meaney et al., 1985](#)). Thus, it appears that up-regulation of glucocorticoid receptors in the hippocampus is a critical determinant of the decreased HPA stress responses in the adult rat subjected to neonatal handling. This receptor up-regulation is dependent on increases in pituitary–thyroid activity and ascending serotonergic systems that act via increased cyclic AMP formation and activation of protein kinase A activity ([Meaney et al., 1987; Mitchell et al., 1990, 1992; Smythe et al., 1994](#)). Inhibitors of thyroid hormone synthesis and serotonin receptor antagonists block this effect ([Meaney et al., 2000](#)). Hippocampal lesions result in increased CRF and AVP mRNA expression in the hypothalamus and increased corticosterone responses to stress ([Herman et al., 1989; Jacobson and Sapolsky, 1991; Sapolsky et al., 1984](#)).

Prolonged separation from the mother during the neonatal period results in a loss of maternal care, which includes the maternal behaviors feeding, grooming, and licking. These maternal behaviors seem to increase cognitive ability during adulthood and maintain the stress hypo-responsiveness of the rat pup HPA axis ([Meaney et al., 2000; Suchecki et al., 1993](#)). An inverse relationship also has been found between time spent in these behaviors as a pup and subsequent adult HPA stress responsiveness ([Liu et al., 1997](#)). Recent studies suggest a vertical transmission of these maternal behaviors and their long-term effects, via either polygenetic determinants or through learned behavioral modes that have major impact on subsequent stress responsiveness as well ([Francis et al., 1999; Liu et al., 2000](#)). Rat pups separated from their mothers in the first 3 weeks after birth exhibit higher basal corticosterone levels and greater corticosterone responses to acute stress than nonseparated controls ([Thomas et al., 1968](#)). Rat pups separated from their mothers for 0, 15, 30, 60, 180, and 360 minutes each day from P2 to P14 showed markedly different HPA responses to stress during adulthood ([Plotsky and Meaney, 1993](#)). Rats separated for 0 and 15 minutes each day behaved like the NH and H rats, respectively, as described; rats separated for 180 to 360 minutes each day showed significantly increased ACTH and corticosterone responses compared with the H and NH groups. These adult rats (following 180 min/day neonatal separation) showed marked increases in CRF mRNA in paraventricular neurons in the hypothalamus and the central nucleus of the amygdala, increases in CRF peptide content in the median eminence, and nonsuppression in a dexamethasone suppression test. These data suggest increases in the hypothalamic mechanisms regulating the ACTH and corticosterone responses to stress ([Hsu et al., 1998; Makino et al., 1994; Plotsky and Meaney, 1993](#)). Following neonatal exposure to stress, glucocorticoid receptor density decreases in the hypothalamus, hippocampus, and frontal cortex and mineralocorticoid receptor density increases in the hippocampus, related to the decreased negative feedback sensitivity of the HPA axis during adulthood ([Ladd et al., 1998; Meaney et al., 1994](#)). The persistence of these effects is determined by the timing of neonatal stress during critical developmental windows. Thus, if prolonged maternal separation (24 hours) occurred on P3, it produced increased ACTH/corticosterone responses to stress on P20; whereas similar maternal separation on P11 produced blunted ACTH/corticosterone responses to stress on P20 ([van Oers et al., 1998; Workel et al., 1997](#)).

The excessive and prolonged HPA axis responses appear to damage hippocampal neurons because of the prolonged exposure to stress-induced elevations of plasma corticosterone concentrations via indirect glucocorticoid effects on NMDA receptor-dependent excitatory pathways ([Cameron et al., 1993, 1995; Gould et al., 1994](#)). In addition to their immunosuppressive and metabolic effects, high circulating levels of glucocorticoids accelerate the loss of hippocampal neurons, leading to cognitive and memory impairments, stress, and perhaps anxiety and mood disorders during adult life ([McEwen, 1994; Sapolsky et al., 1986](#)). Glucocorticoid hypersecretion was associated with the loss of type II glucocorticoid receptors in chronically stressed rats, aged rats, and AVP-deficient Brattleboro rats ([Sapolsky et al., 1986](#)). These long-term effects may result from the impaired feedback inhibition mediated by hippocampal neurons, leading to increased expression and release of CRF and AVP from hypothalamic neurons in response to acute stress, with consequently increased ACTH and corticosterone responses ([Dallman et al., 1993; Ladd et al., 2000; Meaney et al., 1993; Plotsky et al., 1986; Plotsky and Sawchenko, 1987](#)). The transition from low to high serum corticosterone concentrations within the range of physiologic circadian changes or from high basal to stressed values, increases the susceptibility of hippocampal neurons to excitotoxic damage (quantitated by increased neuron loss, spectrin proteolysis, and qualitative changes in neuronal and dendritic morphology) in the CA3 region of the hippocampus ([Meaney et al., 2000](#)). Postnatal handling increases glucocorticoid receptor expression in the rat hippocampus, thus altering the regulation of hypothalamic synthesis of CRF and the HPA response to stress. Recent findings suggest that postnatal handling might alter glucocorticoid receptor gene expression via cyclic AMP–PKA pathways involving the activation of NGFI-A and AP-2 ([Meaney et al., 2000](#)).

As summarized in [Table 7.4](#), central administration of CRF in nonhuman primates causes behavioral changes almost identical to those observed in primate models of depression involving the separation of neonatal monkeys from their mothers ([Kalin and Takahashi, 1988](#)). Several lines of evidence suggest that the hypothalamic hypersecretion of CRF may result from maternal deprivation and predispose to the development of depression in adulthood ([Gold et al., 1988](#)). Evidence for this phenomenon has been found from both rodent and nonhuman primate studies ([Coplan et al., 1996; Owens et al., 1994](#)). Prolonged increases were noted in the cerebrospinal fluid (CSF) concentrations of CRF in young adult monkeys following maternal stress as infants owing to variable foraging conditions ([Coplan et al., 1996](#)). Interestingly, chronic treatment with the antidepressants paroxetine and mirtazapine seem to normalize the behavioral and endocrine stress responses in maternally separated rats ([Ladd et al., 1997; Plotsky et al., 1996](#)). Clinical correlates of these experiments are being obtained from victims of sexual or physical abuse, poor parenting, or exposure to other stressful life events ([Goodyear, 1994; Heim et al., 1998, 2000; Kaufman et al., 1997; Mullen et al., 1993](#)), although the mechanisms mediating such changes in the neonatal brain have remained largely unexplored. One possibility is that lack of  $\text{N-methyl-D-aspartate}$  (NMDA) receptor activity from maternal separation and sensory isolation leads to increased apoptosis in multiple areas of the immature brain ([Ikonomidou et al., 1999](#)). On the other hand, exposure to repetitive pain may cause excessive NMDA/excitatory amino acid activation, resulting in excitotoxic damage to developing neurons. These changes

promote two distinct behavioral phenotypes characterized by increased anxiety, altered pain sensitivity, stress disorders, hyperactivity/attention deficit disorder, leading to impaired social skills and patterns of self-destructive behavior ( [Anand and Scalzo, 2000](#)).

## ALTERATIONS IN CHILDHOOD PSYCHIATRIC AND BEHAVIORAL DISORDERS

### Childhood Shyness

Shyness was defined by [Kagan and coworkers \(1988\)](#) as an initial avoidance of and/or prolonged behavioral restraint to an unfamiliar event. Although some shyness may be expected within the range of normal childhood behaviors, excessive shyness in young children has been correlated with excessive anxiety, social avoidance and isolation, and panic and mood disorders during adulthood, leading to severe psychological impairment. In pathologically shy children, hypothalamic and amygdala-mediated responses to novel situations are hyperreactive. Increased sympathetic nervous system activity was documented in shy and inhibited children exposed to unfamiliar events, by their increased heart rate, pupillary dilation, and peripheral norepinephrine responses, also correlated with high morning levels of salivary cortisol ( [Kagan, 1982](#); [Kagan et al., 1988](#)).

It is likely that shyness results from the diathesis of an abnormally low threshold for limbic–hypothalamic responsivity to novel stimuli or stress. Because CRF is a primary regulator of limbic sites stimulating the sympathoadrenomedullary axis and the HPA axis, CRF may be involved in the pathogenesis of severe childhood shyness. CRF hypersecretion may cause behavioral inhibition and enhanced pituitary–adrenal, catecholamine, and cardiovascular responses in shy children. CRF overdrive in the CNS may be a common pathogenetic mechanism for childhood shyness and major depression in adults ( [Gold et al., 1988](#)).

### Major Depressive Disorder

Chronic hyperactivity of the HPA axis occurs in adults with a major depressive disorder (MDD), which is owing to CRF hypersecretion, at least in part. Pathophysiologic alterations of the HPA axis in depression during the acute phase of illness include hypersecretion of cortisol, increased amplitude of each cortisol secretory episode, and an early onset (i.e., phase-advance) of the nocturnal quiescent period and the subsequent increase toward the morning peak for ACTH/cortisol circadian rhythms. Alterations in corticosteroid feedback, as evidenced by nonsuppression of plasma cortisol levels in response to the synthetic glucocorticoid dexamethasone, decreased ACTH responses to intravenously administered CRF, and increased CSF concentrations of CRF occur, together with down-regulation of the number of CRF receptor sites in the frontal cortex of depressed suicidal patients ( [Francis et al., 1999](#); [Gold et al., 1988](#); [Hauger et al., 1989](#); [Nemeroff et al., 1988](#)). Although some of these HPA axis abnormalities are not unique to depression, their presence in acutely depressed patients suggests that CRF hypersecretion at hypothalamic and extrahypothalamic levels may contribute to the pathogenesis of depression. This overactivity of the HPA axis is a reversible, state-dependent secretory disturbance, which normalizes following recovery from depression. Therefore, these neuroendocrine changes are indicative of a state of stress maladaptation, supporting the hypothesis that pathologic stress responses contribute to the pathogenesis of depression ( [Anisman, 1984](#)).

There is currently considerable debate over the issue of whether the HPA axis of prepubertal children and adolescents with MDD resembles the overactive HPA axis of adult patients with depression. A preliminary study suggested that cortisol hypersecretion could occur in prepubertal children with endogenous depression ( [Puig-Antich et al., 1979](#)), although this was not confirmed in subsequent studies of children and adolescents with MDD ( [Casat and Powell, 1988](#); [Dahl et al., 1989](#); [Kutcher et al., 1991](#); [Puig-Antich et al., 1989](#)). Cortisol hypersecretion occurs in severely depressed and suicidal children and adolescents requiring hospitalization ( [Evans et al., 1987](#); [Dahl et al., 1991](#); [Pfeffer et al., 1991](#)), and during the recurrence of major depressive episodes ( [Rao et al., 1996](#)), although dexamethasone suppression occurs infrequently in childhood and adolescent MDD ( [Dahl et al., 1992](#)). This overall lack of cortisol hyperresponsiveness may be related to a more sensitive plasma cortisol feedback mechanism occurring in all but the most severely depressed children and may represent a developmental stage of the adult syndrome ( [DeBellis et al., 1996](#)). It is possible the progressive changes in the regulation of hypothalamic CRF secretion during childhood may finally manifest in the full-blown adult disorder ( [Liu et al., 1997](#)).

### Posttraumatic Stress Disorder

As seen in major depression, there is some degree of uncertainty as to the continuity of HPA axis findings between children and adolescents and adults in posttraumatic stress disorder (PTSD). Adult PTSD patients demonstrate increased CRF levels in the CSF and blunted ACTH responses, and yet they exhibit a normal cortisol response to exogenously administered CRF ( [Bremner et al., 1993](#); [Smith et al., 1989](#)). Adults demonstrate low urinary cortisol levels, suppression to low doses of dexamethasone, and increased glucocorticoid receptors on lymphocytes ( [Heim et al., 1996](#); [Yehuda et al., 1991, 1995](#)). Adult combat veterans also exhibit elevated urinary levels of catecholamines ( [Yehuda et al., 1992](#)). Although adult PTSD patients exhibit hypocortisolemia, there have been findings of hippocampal atrophy in combat veterans with PTSD ( [Bremner et al., 1995](#); [Gurvits et al., 1996](#)) and adult survivors of childhood abuse ( [Bremner et al., 1997](#); [Stein et al., 1997](#)).

Increased urinary catecholamines were reported in recent studies of children and adolescents with PTSD, similar to the adult studies ( [DeBellis et al., 1994b, 1999](#); [DeBellis and Putnam, 1994](#); [Queiroz et al., 1991](#)). This finding is associated, however, with increased, rather than decreased, urinary cortisol levels ( [DeBellis et al., 1994a, 1999](#)). It has been hypothesized that this difference in cortisol levels may be the result of either a maturational effect or a long-term adaptation of the HPA axis to stress ( [DeBellis et al., 1994a, 1999](#)).

### Childhood Autism

Autism is a developmental neuropsychiatric syndrome characterized by the early childhood onset of severe disturbances in language, cognitive development, absence of object relatedness, social withdrawal, idiosyncratic affective states, motoric stereotypies, and increased locomotor behavior. In an often-cited study, [Schain and Freedman \(1961\)](#) demonstrated that circulating levels of serotonin (5-HT) were markedly elevated in autistic children. Further investigations revealed that blood 5-HT concentrations were elevated in 30% of children with clinically defined (Diagnostic and Statistical Manual-III [DSM-III] criteria) autism. Several mechanisms may account for this finding, ranging from abnormal metabolism of serotonin in the gut, to the properties of platelets that transport serotonin, to CNS mechanisms that control these processes. Systematic studies of peripheral serotonin production, gut motility, and blood flow; platelet numbers, size, storage capacity, and half-life; hormones or other endogenous mediators that may alter the serotonin transporter on platelet membranes; or the central dysregulation of serotonergic pathways are necessary because all could contribute to defining the etiopathogenesis of autism. However, in most studies published subsequently, the patient populations were not defined by hyperserotoninemia but by the clinical features of autism. A great deal of research that focused on defining the abnormal serotonergic mechanisms in autism did not even measure blood serotonin concentrations. This is important because only 30% of clinically defined autistic children have hyperserotoninemia, and the percentage in any subpopulation may range from 0% to 100%. Therefore, separate studies measuring a variable relevant to the mechanism of hyperserotoninemia will differ quantitatively in accordance with the unknown proportion of hyperserotoninemic subjects in the study population, leading to different, or even opposing, conclusions. Two additional potential confounds in this area that have been recently examined are ethnicity and pubertal status. Ethnicity was found to have a greater effect than diagnosis when platelet serotonin levels were compared among prepubertal autistic children, nonautistic mentally retarded prepubertal children, and normal controls of the same age. Ethnicity and diagnosis were both nonsignificant in postpubertal groups and platelet serotonin levels were significantly lowered in postpubertal versus prepubertal subjects ( [McBride et al., 1998](#)). Much of the confusion in this area might be avoided if study populations were defined by their etiologic diagnosis rather than their clinical diagnosis ( [Yuwiler, 1995](#)).

Fenfluramine given in low doses acutely increased central 5-HT neurotransmission via stimulation of 5-HT release, inhibition of presynaptic 5-HT reuptake, and interaction at certain postsynaptic 5-HT receptors as a weak agonist ( [Costa et al., 1971](#)). High-dose or chronic fenfluramine administration exerts neurotoxic effects on presynaptic 5-HT nerve terminals, with a sustained depletion of neuronal 5-HT stores ( [Costa et al., 1971](#); [Garrattini et al., 1975](#)). Fenfluramine therapy in autistic children (administered in studies prior to its withdrawal from the market by the FDA) resulted in significant clinical improvement and was correlated with 50% reduction in blood serotonin levels ( [Ritvo et al., 1984](#)), although these findings were not replicated in subsequent studies. Fenfluramine-induced changes in pituitary prolactin secretion were used to measure serotonergic responsivity in male autistic children ( [McBride et al., 1989](#)). Prolactin responses to fenfluramine were blunted in autistic patients, together with a marked reduction in the magnitude of 5-HT–amplified platelet aggregation and decreased numbers of 5-HT<sub>2</sub> receptors in the platelets of autistic children ( [McBride et al., 1989](#)). It is plausible that hyperserotoninemia and the desensitization of brain serotonergic systems to 5-HT agonists may characterize autism. Decreased activity in serotonergic pathways in autistic patients may explain a number of their clinical findings and suggests that drugs augmenting central serotonergic neurotransmission may have therapeutic effects. Concordance between serotonergic mechanisms in peripheral blood platelets and the CNS has not been proven conclusively, although it is frequently assumed in mechanistic and therapeutic studies.

Stress responses of the HPA axis may be abnormal in autistic children. Cortisol secretion in response to insulin-induced hypoglycemia is elevated and prolonged in autistic children as compared with normal controls ( [Maher et al., 1975](#)). Because the regulation of hypothalamic CRF release involves stimulatory input from serotonergic neurons (via 5-HT<sub>2</sub> receptors), the abnormal cortisol responses to hypoglycemia may reflect abnormalities in central serotonergic neurotransmission

([Calogero et al., 1989](#)). Fenfluramine administration reduces hypothalamic CRF concentrations, presumably by stimulating CRF release, and increases CRF concentrations in the hippocampus, midbrain, and spinal cord ([DeSouza et al., 1989](#)). The clinical improvement noted with fenfluramine therapy in autistic children could be partially related to the normalization of CRF-mediated mechanisms essential for stress adaptation.

Some of the behavioral and motoric symptoms in autism suggest abnormalities in dopamine (DA) neurotransmission. Increased CSF concentrations of the principal DA metabolite homovanillic acid ([Cohen et al., 1977](#)) and decreased GH responses to L-dopa were documented in autistic children ([Deutsch et al., 1985](#)), suggesting that dopaminergic mechanisms influencing GH release may be desensitized in autism. Conversely, the GH responses to insulin-induced hypoglycemia, mediated via the catecholaminergic, serotonergic, and glucoreceptor stimulation of PVN neurons, were prolonged in autism ([Deutsch et al., 1986](#)). There are no data demonstrating alterations in endogenous opioid neuropeptides in autism and no therapeutic effects have been demonstrated with the use of opioid agonists or antagonists in this disorder ([Gillberg and Coleman, 1992](#)).

A number of animal studies show that oxytocin plays a role in social behavior and communication ([Insel et al., 1999](#)). A recent human study showed that plasma oxytocin concentrations in autistic children were half those of normal controls. In these autistic subjects, their age and lack of interpersonal skills were correlated with a failure of the developmental increases in oxytocin levels ([Modahl et al., 1998](#)), although oxytocin levels in the CSF of autistic subjects have not been measured. These disparate neuroendocrine manifestations of childhood autism indicate the need for much greater precision in neurobiologic studies investigating the mechanisms of this neuropsychiatric disorder, with particular focus on regulation of the HPA axis and somatotrophic axis. Certainly brain-imaging studies, both structural and functional, could play a pivotal role in elucidating the pathophysiology of this devastating disorder.

## THE SOMATOTROPHIC AXIS

### Ontogeny of the Somatotrophic Axis

Growth hormone-releasing factor (GHRF) immunoreactivity can be measured in the infundibular nucleus of the hypothalamus from 18-week-old human fetuses ([Bresson et al., 1984](#)); however, GHRF neurons in the arcuate nucleus cannot be detected until 29 weeks of gestation ([Bloch et al., 1984](#)). Consequently, fetal GH regulation may not involve GHRF until mid- to late gestation. In the feline CNS, GHRF terminals are sparse in the median eminence at 15 days postpartum, followed by their rapid proliferation in the first month after birth ([Bugnon et al., 1983](#)). Fetal sheep have higher circulating concentrations of GH as compared with neonatal sheep, associated with the maximum GH responses to GHRF in fetal sheep from 71 to 135 days of gestation ([Gluckman, 1984](#); [Ohmura et al., 1984](#)). In the human species, GH responses to GHRF are fairly constant throughout puberty and adulthood. The sensitivity of the pituitary somatotroph to GHRF does not change after early childhood. The gradual reduction of GH secretion with age is secondary to increasing sensitivity of the pituitary to somatostatin and may be related to the increased production of the somatostatin<sub>2</sub> receptor subtype with age, as recently demonstrated in the rat brain ([Reed et al., 1999](#)).

### Distribution of Growth Hormone-Releasing Factor in the Brain

After [Vale and colleagues \(1981\)](#) reported the isolation, sequencing, and synthesis of a 41-amino acid ovine hypothalamic peptide CRF that stimulated pituitary ACTH and endorphin secretion ([Vale et al., 1981](#)), the same group ([Rivier et al., 1982](#)) and another group ([Guillemin et al., 1982](#)) independently identified and sequenced GHRF from tissue extracts of pancreatic islet cell tumors from two patients with acromegaly ([Guillemin et al., 1982](#); [Rivier et al., 1982](#)). Further research has characterized the distribution of hypothalamic neurons containing these peptides, together with the localization of receptor sites for these regulatory factors in the pituitary gland and other parts of the brain.

Although CRF, somatostatin, and thyrotropin-releasing hormone (TRH) are widely distributed in the mammalian brain, GHRF has a much more limited localization in the human, nonhuman primate, and rodent brains ([Bloch et al., 1983](#); [Merchenthaler et al., 1984](#)). GHRF-immunoreactive cell bodies are primarily located in the arcuate and ventromedial nuclei of the hypothalamus and project GHRF-containing nerve terminals to the median eminence. Other tissues that express GHRF-like peptides include the placenta and parts of the gastrointestinal tract (e.g., in the gastric antrum and upper intestinal tract it is colocalized with the peptide gastrin).

The only nonhypophysial behavioral effect thus far identified for GHRF injected intracerebroventricularly (ICV) is its ability to stimulate food intake ([Vaccarino et al., 1985](#)) and induce sleep ([Frieboes et al., 1995](#)). The intravenous administration of GHRF releases GH without stimulating feeding behavior ([Vaccarino et al., 1985](#)). The regulation of appetite is a central action of GHRF that may facilitate GH-induced somatic growth in children and adolescents.

### Regulation of GHRF Receptors

Specific high-affinity receptor sites for GHRF were demonstrated in the anterior pituitary and other organs, including the exocrine pancreas, where GHRF stimulates pancreatic enzyme secretion ([Seifert et al., 1985](#)). Although GHRF receptors in the pituitary are specific for GHRF, other endogenous mediators such as vasoactive intestinal peptide (VIP) also demonstrate a high affinity binding to pancreatic GHRF receptors ([Pandol et al., 1984](#); [Seifert et al., 1985](#)). The GHRF receptor is a G protein-coupled receptor, which activates cyclic AMP by binding to a stimulatory G protein, which activates adenylate cyclase, increases intracellular free calcium, releases preformed GH, and stimulates GH mRNA transcription and synthesis of new GH ([Barinaga et al., 1983](#); [Cronin and Thorner, 1995](#)).

The HPA axis modulates the somatotrophic axis by multiple mechanisms, largely via the central effects of adrenocortical hormones. *In vitro* experiments have shown that glucocorticoids increase GH gene transcription, increase GH content and release, and enhance GH responses to GHRF from pituitary somatotrophs. *In vivo*, corticosteroids suppress somatic growth and GH responses to various stimuli ([Evans et al., 1982](#); [Gelato and Merriam, 1986](#); [Wehrenberg et al., 1983](#)). The GHRF-binding capacity of the anterior pituitary is decreased by adrenalectomy, and dexamethasone administration substantially increases the number of pituitary GHRF receptors in adrenalectomized rats ([Seifert et al., 1985](#)). The physiologic role of this interaction was substantiated by a similar increase in GHRF-binding capacity in animals with intact adrenal glands, suggesting that the HPA axis is part of a larger hypothalamic neural network that mediates feeding, growth, and energy balance ([Dallman et al., 1994](#); [Seifert et al., 1985](#)). Within this network, corticosteroids may enhance the responsiveness of pituitary somatotrophs by up-regulating GHRF receptors. Stress-mediated glucocorticoid release may exert a negative effect on GH secretion, in order to inhibit feeding and other restorative behaviors. The stress-related or baseline secretion of glucocorticoids may also modulate the central actions of GHRF, such as the stimulation of food intake.

Similar to other transmitter systems, prolonged exposure to hypothalamic releasing factors results in a desensitization of their secretory responses and is associated with a concurrent down-regulation of their specific receptors ([Catt et al., 1979](#)). Thus, prolonged exposure to GHRF stimulation *in vivo* or *in vitro* leads to a significant blunting of the resulting GH responses, associated with GHRF receptor down-regulation ([Bilezikjian et al., 1986](#); [Ceda and Hoffman, 1985](#); [Wehrenberg et al., 1986](#)). The *in vitro* desensitization of GH secretory responses during prolonged exposure to increased GHRF levels does not correspond with the loss of pituitary GHRF receptors ([Bilezikjian et al., 1986](#)). Pituitary somatotrophs become less sensitive to GHRF owing to the depletion of GHRF-sensitive intracellular GH pools. Such desensitized pituitary somatotrophs can respond to very high levels of GHRF, indicating that chronic GHRF infusions may have a therapeutic role in disorders of growth ([Bilezikjian et al., 1986](#)).

### Regulation of Growth Hormone Secretion

#### SOMATOSTATIN

The oscillatory interactions between GHRF and somatostatin are primarily responsible for the regulation of GH release ([Fig. 7.2](#)), although a number of neural factors also influence GH release. GH itself and IGF-1, whose release from the liver is stimulated by GH, both also provide negative feedback inhibition of GH release. The pulsatile secretion of GH results from GHRF pulses released by hypothalamic GHRF neurons, whereas the intermittent secretion of hypothalamic somatostatin causes the variability in the magnitude of GH pulses secreted in response to GHRF. The peaks of GH secretion result from the coincidence of a GHRF peak and a somatostatin nadir from the hypothalamus, and the troughs of serum GH concentrations correlate with the peaks of somatostatin release from the hypothalamus ([Gelato and Merriam, 1986](#); [Hartman et al., 1993](#)). This regulation is illustrated by a sustained increase in GH secretion for several hours in response to a continuous infusion of GHRF during immunoneutralization of somatostatin. In the absence of pretreatment with the somatostatin antiserum, the same GHRF infusion results in pulsatile GH release ([Wehrenberg et al., 1986](#)). Neural influences on GH release include stimulation of GH release by dopamine ([Boyd et al., 1970](#)), norepinephrine, serotonin, acetylcholine,  $\alpha$ -adrenergic receptor stimulation, VIP, nitrous oxide ([Reichlin, 1998](#)), galanin ([Davis et al., 1987](#)), and opioids ([Grossman, 1983](#)). GH secretion is inhibited by TRH under normal physiologic conditions ([Chiara et al., 1977](#)) and  $\beta$ -adrenergic receptor stimulation ([Reichlin, 1998](#)). Somatostatin release is inhibited by GABA and can be stimulated by acetylcholine, substance P, or VIP ([Reichlin, 1998](#)). GH release is also modified by endogenous sleep rhythms, stress, exercise, and the metabolic state ([Reichlin, 1998](#)). The influence of metabolic state may be mediated at least partially by the recently discovered adipose cell

hormone leptin, which stimulates GH secretion ([Tannenbaum et al., 1998](#)).

**Figure 7.2.** The somatotrophic axis. al, anterior lobe of pituitary; GH, growth hormone; GHRH, growth hormone-releasing hormone; IGF-1, insulin-like growth factor-1; pl, posterior lobe of pituitary; SRIF, somatostatin.

Somatostatin acts by the binding of the somatostatin receptor to inhibitory G proteins, which, in turn, lower cyclic AMP and reduce intracellular free calcium through effects on the voltage-sensitive calcium ion channel ([Kleuss, 1995](#); [Schonbrunn, 1990](#)). The effects of lowered cyclic AMP appear to only partially account for the effects of somatostatin, however. Changes in calcium concentration are likely a crucial step in the process, probably acting via increased potassium ion conductance and resultant membrane hyperpolarization ([Patel et al., 1995](#)).

#### EFFECTS OF CORTICOTROPIN-RELEASING FACTOR

Somatostatin can centrally inhibit CRF release and prevent stress-induced ACTH and epinephrine secretion ([Brown et al., 1984](#)). Activation of somatostatin receptors on pituitary cells may decrease ACTH responses to CRF ([Axelrod and Reisine, 1984](#)). Alternatively, high circulating levels of glucocorticoids in depressed patients decrease somatostatin release in the brain, leading to disinhibition of the HPA axis. The nonsuppression of plasma cortisol levels after dexamethasone in depressed patients was correlated with low CSF somatostatin concentrations ([Rubinow, 1986](#)). These data substantiate a pathophysiologic relationship between somatostatin and the HPA axis in depressed patients.

CRF directly stimulates somatostatin secretion from cultured fetal brain cells ([Peterfreund and Vale, 1983](#)). Although CRF has no direct inhibitory effects on pituitary GH secretion, the ICV injection of CRF suppresses basal GH secretion, morphine-stimulated GHRF release, and GH responses to intravenous GHRF ([Rivier and Vale, 1985](#)). Immunoneutralization of endogenous somatostatin abolishes CRF-induced suppression of basal and dynamic GH secretion, whereas the ICV administration of a CRF-receptor antagonist (a-helical CRF<sub>9-41</sub>) abolishes the inhibition of GH secretion after acute stress ([Rivier and Vale, 1985](#)). Therefore, central CRF hypersecretion in pathophysiologic states may alter the regulation of GH secretion by GHRF by stimulating the release of somatostatin. Hyperglycemia in normal human subjects can result in GH hyposecretion and also inhibit pituitary GH responses to GHRF ([Gelato and Merriam, 1986](#)). Hyperglycemia may stimulate hypothalamic somatostatin release, thus altering the responsiveness of pituitary somatotrophs. These interactions further substantiate the view that the HPA axis and somatotrophic axis are embedded within a larger hypothalamic neural network controlling growth, metabolism, and energy balance.

#### Disorders of the Somatotrophic Axis During Childhood

##### GROWTH HORMONE DEFICIENCY

Monosodium glutamate treatment of neonatal rats results in the destruction of GHRF-producing neurons in the arcuate nucleus, leading to GH hyposecretion and growth failure, which are reversible by exogenous GHRF administration ([Millard et al., 1982](#); [Nemeroff et al., 1977](#); [Wehrenberg et al., 1984](#)). Exogenous GHRF does not stimulate cyclic AMP production or GH secretion from pituitary cells of the "lit/lit" dwarf mouse, an animal model of pituitary GH deficiency ([Jansson et al., 1986](#)). The somatotrophs of lit/lit mice were unresponsive to GHRF, although dibutyryl cyclic AMP, forskolin, and cholera toxin stimulated *in vitro* pituitary GH release. These data suggest that the catalytic and regulatory subunits ( $G_s$ ) of adenylate cyclase and the GH release pathway distal to adenylate cyclase can be activated in pituitary somatotrophs from the lit/lit mouse ([Jansson et al., 1986](#)). The GHRF challenge test is being utilized to distinguish GH deficiency states owing to hypothalamic versus pituitary defects. For example, a functional GH response to an injection of GHRF in patients with growth impairment would indicate a hypothalamic defect in the somatotrophic axis ([Gelato and Merriam, 1986](#)). If an intrinsic pituitary defect is excluded, treatment with exogenous GHRF potentially could be used to restore normal growth.

##### PSYCHOSOCIAL DWARFISM

Psychosocial dwarfism is defined as a syndrome of reversible growth failure and developmental delay characterized by reduced growth and hyposecretion of GH ([Powell et al., 1967a,b](#)). The diagnostic criteria proposed for psychosocial dwarfism include: (a) onset between 2 to 3 years of age; (b) delayed bone age and linear growth retardation (<third percentile) without signs of malnutrition; (c) decreased basal secretion of GH and somatomedin; (d) blunted GH responses to secretory stimuli; (e) behavioral changes such as bizarre patterns of food intake, sleep disorders, temper tantrums, withdrawal, delayed cognitive development, and so on; and (f) parental deprivation secondary to psychiatrically disturbed and abusive parents ([Green et al., 1987](#)).

Endocrinologic studies of these patients demonstrated pathologically low fasting GH levels, and reduced GH responses to insulin-induced hypoglycemia, arginine infusion, or exercise, when the patients were in the deprived environment ([Green et al., 1987](#); [Money et al., 1976](#); [Powell et al., 1967a,b](#)). Sleep studies in children suffering from psychosocial dwarfism showed increased stage I sleep, a large reduction in slow-wave sleep (SWS) owing to the absence of stage IV sleep, and a decrease in the total sleep period ([Guilhaume et al., 1982](#)). The SWS phase of sleep is primarily associated with nocturnal GH secretion; therefore, growth failure occurs from the lack of this physiologic stimulus for GH secretion. This SWS-induced GH release is mediated by serotonergic fibers ([Reichlin, 1998](#)). The regulation of GH secretion in psychosocial dwarfism is very sensitive to the child's environment. For example, during a hospital admission or when the child is placed in a beneficial nurturing environment, basal GH secretion and dynamic GH responses normalize rapidly, with initiation of bone growth. If the child returns to the socially deprived environment, GH hyposecretion recurs ([Powell et al., 1967a,b](#)). Normalization of the diminished circulating levels of serum somatomedins occurs in children with psychosocial dwarfism after hospitalization ([D'Ercole et al., 1977](#)).

Maternal deprivation by physical separation or maternal anesthesia was used to develop an animal model of psychosocial dwarfism in preweaning rat pups. The relative lack of active tactile interaction between the rat pups and their mothers decreased the circulating serum GH concentrations, metabolic activity of brain and peripheral tissue, and ornithine decarboxylase (ODC) activity, an index of organ growth and differentiation. These changes were rapidly reversed when the pups were returned to their mother ([Kuhn et al., 1978](#)). Because maternal deprivation did not alter serum concentrations of corticosterone or prolactin, it is unlikely that hyposecretion of GH resulted largely from the effects of stress. Exogenous GH or placental lactogen, combined with normal feeding of these pups, did not reverse the reduced brain and peripheral ODC levels in the absence of the mother. Conversely, vigorous stroking of the separated rat pups or the presence of an awake mother who cannot nourish because of ligated nipples was found to restore growth and maturation ([Kuhn et al., 1979](#)). This maternal tactile stimulation appears to stimulate secretion of GH via serotonergic and noradrenergic effects on GHRF and somatostatin ([Katz et al., 1996](#)). [Kuhn and colleagues \(1990\)](#) have further reported that prolonged periods of maternal separation (>2 hours) result in a suppression of plasma GH, whereas brief periods of separation (i.e., 15 minutes) or handling lead to increases in plasma GH concentrations. Thus, differential environmental conditions during early life may have widely different neuroendocrine effects; there is some evidence that these neuroendocrine changes persist for the entire life of the individual ([Meaney et al., 1994](#)).

GH hyposecretion and subsequent tissue insensitivity to GH in human psychosocial dwarfism may result from the psychogenic suppression of GHRF secretion in the CNS and/or the excessive release of brain somatostatin in the absence of active mothering behavior. This hypothesis was originally proposed by Powell and associates when they stated, "the emotional disturbance in these children may have had an adverse effect upon release of pituitary trophic hormone via the central nervous system." A state-dependent decrease in the basal secretion of corticosteroids is present in children with psychosocial dwarfism, which can be reversed by exogenous ACTH administration ([Powell et al., 1967a,b](#)). Although ACTH secretion may be deficient, adrenocortical sensitivity to ACTH is intact in psychosocial

dwarfism. Early maternal separation leads to marked and long-term increases in the sensitivity of the HPA axis to mild or moderate stressors, secondary to decreased feedback inhibition of PVN neurons expressing CRF and AVP ([Meaney et al., 1994](#)) and to CNS CRF neurons as well ([Coplan et al., 1996](#)), as described.

## MAJOR DEPRESSIVE DISORDER

Diurnal hypersecretion of GH occurs in adult patients with endogenous depression, with a phase-advanced circadian timing of GH secretion ([Linkowski et al., 1987](#); [Mendelwicz et al., 1985](#)). This abnormality persists despite a therapeutic response to antidepressants or following complete recovery in remitted patients who are off antidepressants ([Jarrett et al., 1990](#)). The GH responses to insulin-induced hypoglycemia, clonidine, desmethylimipramine (DMI), and zimelidine (but not to the dopamine agonists amphetamine, L-Dopa, or apomorphine) have been consistently shown to reduce during depression. In adult patients with MDD, the blunting of GH responsiveness to these stimuli persists despite clinical remission and response to therapy ([Amsterdam et al., 1987](#); [Charney et al., 1982](#); [Siever and Uhde, 1984](#)).

Further, some (but not all) investigators have reported that GH responses to GHRF are significantly reduced in adult patients with MDD as compared with those in healthy controls ([Krishnan et al., 1987](#); [Lesh et al., 1987](#); [Risch et al., 1988](#)); the blunting of GH responses to GHRF may persist for years after recovery from depression ([Risch and Hauger, 1988](#)). Decreased GH secretion in major depression may either result from desensitization of pituitary somatotrophs by excessive release of GHRF, or from somatostatin hypersecretion in the depressive state. Based on preclinical studies, CRF hypersecretion in depression could suppress basal GH secretion and dynamic GH responses by stimulating the excessive release of somatostatin from extrahypothalamic and hypothalamic sites. However, other studies indicated that GH responses to GHRF are not decreased and may actually be increased in depression ([Krishnan et al., 1987](#)). This conflicting finding and the observation that major depression is associated with an episodic daytime hypersecretion of GH would suggest that hypothalamic somatostatin secretion is reduced, a hypothesis consistent with the measurement of low CSF somatostatin concentrations in depressed patients ([Rubinow et al., 1983](#)).

Prepubertal children and adolescents with major depression also demonstrate abnormalities in GH secretion. In contrast to depressed adults, prepubertal children secrete excessive GH during the total sleep period in the acute episode of endogenous depression and during remission ([Puig-Antich, 1987](#); [Puig-Antich et al., 1984a,b,c,d](#)). Similar excessive GH secretion during sleep was noted in two studies comparing adolescents to matched controls ([Kutcher et al., 1988, 1991](#)), but these findings were not replicated in two similar more recent studies of depressed adolescents ([Dahl et al., 1992](#); [DeBellis et al., 1996](#)). In one of these more recent studies, dividing the MDD group into those patients with and those without suicidality revealed significant blunting of nocturnal GH in the suicidal group, similar to findings in adults ([Dahl et al., 1992](#)). However, this finding in the suicidal MDD subgroup was not replicated in a second recent study ([DeBellis et al., 1996](#)). Abnormal regulation of GH secretion in MDD is supported by the reduced GH responses to insulin-induced hypoglycemia and DMI in depressed prepubertal children and adolescents; these changes persist during remission ([Puig-Antich, 1987](#); [Puig-Antich et al., 1984a,b,c,d](#); [Ryan et al., 1988, 1994](#)). Clonidine challenge did not produce statistically significant changes in GH response in one study ([Ryan et al., 1994](#)). Deficient GH responses were not correlated with the severity or other features of MDD, although the maximum reduction of GH responses to DMI were measured in adolescents who had made a suicide attempt or had prominent suicidal ideation ([Ryan et al., 1988](#)). Clinical application of these data suggests that trait dysregulation of GH secretion may identify depressed adolescents at risk for suicide. State-dependent abnormalities in the HPA axis of adult patients with depression were also associated with increased suicidality ([Arato et al., 1988](#); [Nemeroff et al., 1988](#)). Despite numerous studies in this area, it remains unclear whether alterations in the somatotrophic axis play any precise role in the etiology or pathophysiology of MDD.

## HYPOTHALAMIC-PITUITARY-THYROID AXIS

The effects of thyroid hormones on the development of the brain were described in the first part of this chapter and are summarized in [Table 7.2](#). This section examines the ontogeny of the hypothalamic-pituitary-thyroid (HPT) axis and describes the neuroendocrine regulation of thyroid function under basal conditions and during acute stress, as well as discusses some of the psychiatric correlates of abnormal thyroid function ([Fig. 7.3](#)).

**Figure 7.3.** The hypothalamic-pituitary-thyroid axis. al, anterior lobe of pituitary; pl, posterior lobe of pituitary; SOM, somatostatin; T<sub>3</sub>, triiodothyronine; T<sub>4</sub>, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

### Regulation of the Hypothalamic-Pituitary-Thyroid Axis

The major thyroid gland hormones are T<sub>3</sub> and T<sub>4</sub>, both of which are released from the thyroid gland. However, about 90% of plasma T<sub>3</sub> is derived from the deiodination of T<sub>4</sub> in the CNS and peripheral tissues. The biological activity of T<sub>3</sub> is much greater than T<sub>4</sub>, and more than 99% of both hormones are bound in serum to proteins such as thyroxine-binding globulin (TBG), albumin, and prealbumin; thus, less than 1% of the circulating concentrations of these hormones are unbound and biologically active. The biological activity of these hormones in the brain is closely regulated by uptake across the blood-brain barrier ([Schreiber et al., 1990](#)), and the activity of the enzyme 5 $\alpha$ -deiodinase-II, which converts T<sub>4</sub> to T<sub>3</sub> in neuronal and glial cells ([Leonard, 1990](#)).

Biosynthesis and release of T<sub>3</sub> and T<sub>4</sub> are controlled by thyroid-stimulating hormone (TSH) secreted from the anterior pituitary, and the biosynthesis and release of TSH is regulated by TRH secreted from nerve terminals in the median eminence into the hypothalamo-hypophysial portal venous system. Dopamine ([Kaptein et al., 1980](#)) and somatostatin ([Ferland et al., 1976](#)) are potent inhibitors of TSH synthesis and release and blunt the pituitary responses to TRH with consequent decreases in serum T<sub>3</sub> and T<sub>4</sub>. Thyroid hormone in turn inhibits the release of somatostatin ([Berelowitz et al., 1980](#)). Homeostatic control within the HPT axis is maintained by the feedback inhibition of TSH biosynthesis and release, mediated mostly by the biologically active circulating concentrations of T<sub>3</sub> and to a lesser extent T<sub>4</sub>. T<sub>4</sub> in the blood gains access to TRH-secreting neurons in the hypothalamus by way of the CSF. The hormone is taken up by epithelial cells of the choroid plexus of the lateral ventricle, bound within the cell to locally produced transthyretin, and then secreted across the blood-brain barrier ([Schreiber et al., 1995](#)). Within the brain, T<sub>4</sub> is converted to T<sub>3</sub>, which selectively reduces TRH biosynthesis in the PVN ([Segerson et al., 1987a,b](#)) by interacting with thyroid hormone receptor subtypes TR-a-1, TR-b-1, and TR-b-2 ([Lechan et al., 1994](#)). This provides another means for homeostatic control of the HPT axis. The secretion of TSH and TRH is under complex control and can be modified by alterations in the activity of several neurotransmitter systems ([Jacobowitz, 1988](#); [Morley, 1981](#)).

Effects of T<sub>3</sub> and T<sub>4</sub> in the brain are controlled by 5 $\alpha$ -deiodinase-II activity, which has been localized only in the brain, pituitary, brown adipose tissue, and placenta. 5 $\alpha$ -Deiodinase-II activity in the brain increases threefold to fivefold within 24 hours of thyroidectomy and decreases by 80% to 90% within a few hours after injection of a saturating dose of T<sub>3</sub>, suggesting that the enzyme is responsible for a homeostatic mechanism by which intracellular T<sub>3</sub> levels are maintained within narrow limits ([Leonard, 1990](#)). Thyroid hormone-related changes in enzyme activity are owing to changes in the half-life of the enzyme and do not depend on changes in the rates of transcription or translation ([Leonard, 1990](#)). Thus, it is reasonable to expect that thyroid hormones play important roles in the normal development and functioning of the intact brain. The impact of thyroid function on brain development has been described in the preceding, and support for the effects of T<sub>3</sub> and T<sub>4</sub> on brain function is obtained from significant changes in the electroencephalogram (EEG) and evoked potentials ([Pohunkova et al., 1989](#); [Sulc et al., 1990](#)), the observation of specific behavioral changes during thyroid disease, and reports of alterations in the HPT axis in certain psychiatric disorders.

### Ontogeny of the Pituitary-Thyroid Axis

With its expression on E11, the mRNA for b-TSH forms one of the earliest molecular markers for the developing hypophyseal placode ( [Simmons et al., 1990](#)). By E14, the mRNA for b-TSH is localized in the anterior-most cells of the developing anterior pituitary. The TEF, expressed on E13, specifically increases the transcription rate of the b-TSH gene in these cells ( [Drolet et al., 1991](#)). The mRNA for TRH is first detected in the hypothalamus on E14 and is localized in parvocellular neurons of the PVN and other hypothalamic neurons by E16 ( [Burgunder and Taylor, 1989](#); [Segerson et al., 1987a](#)). The expression of TRH mRNA reaches an adult pattern of distribution in hypothalamic and extrahypothalamic sites by P21 in the rat ( [Burgunder and Taylor, 1989](#)). Exposure of immature and adult rats to hypothermia up-regulates TRH mRNA expression in the PVN; however, this effect is not seen at the circadian peak of TRH mRNA levels at the onset of darkness ( [Zoeller et al., 1990](#)).

### Effects and Regulation of Thyrotropin-Releasing Hormone Secretion

Regulation of TRH secretion by parvocellular neurons in the PVN occurs by negative feedback inhibition. The mechanisms for feedback inhibition mediated by  $T_3$  and  $T_4$  develop and mature between E20 and P7 in the neonatal rat ( [Taylor et al., 1990](#)). High levels of TRH mRNA in the PVN were noted in animals that were chemically thyroidectomized and reverted to baseline after treatment with  $T_3$  ( [Koller et al., 1987](#); [Segerson et al., 1987b](#)). Regulation of TRH expression is primarily controlled by the direct action of  $T_3$  in PVN neurons and is independent of TSH, other pituitary hormones, and catecholamine input to the hypothalamus ( [Dyess et al., 1988](#); [Zoeller et al., 1988](#)). Support for the primary role of  $T_3$  in feedback inhibition of TRH is provided by transcripts encoding for the  $\alpha_1$ - and  $\beta_1$ -thyroid hormone receptor genes in parvocellular neurons of the PVN ( [Bradley et al., 1989](#)).

TRH is the primary regulator of TSH secretion from the anterior pituitary, and it also stimulates prolactin release. The concentrations of TRH are highest in the median eminence, although substantial concentrations of TRH are localized in extrahypothalamic brain areas including the brain stem, midbrain, preoptic area, septum, basal ganglia and the cerebral cortex, where TRH apparently functions as a neurotransmitter and neuromodulator ( [Timiras and Nzekwe, 1989](#)). TRH effects on anterior pituitary cells are mediated via the phosphoinositol second messenger system; other forms of signal transduction may be involved in the nonpituitary effects of TRH. The neurotransmitter role for TRH is thought to explain widespread changes in behavior and brain functions, such as the antagonism of hibernation and the sedation and hypothermia induced by centrally acting depressants (e.g., barbiturates, ethanol, and anesthetics). In addition, TRH increases body temperature, reduces food intake, stimulates locomotor activity, increases blood pressure and respiratory rate, causes arousal and EEG activation, increases gastric motility, and has antinociceptive effects. These effects may be produced directly or by interaction with a variety of monoamine and peptide neurotransmitters ( [Griffith, 1985](#); [Nemeroff et al., 1984](#); [Timiras and Nzekwe, 1989](#); [Vaccari, 1988](#)). In human subjects, TRH appears to increase the sense of well-being, motivation, relaxation, and coping capacity. These effects were noted in normal subjects and patients with neurologic (Parkinson's disease) or psychiatric disorders (depression, schizophrenia, autism) ( [Loosen, 1988a,b](#); [Loosen and Prange, 1984](#); [Prange et al., 1979](#)), although it is often difficult to separate the direct behavioral effects of TRH from its endocrine effects, leading to secondary changes in behavior, as well as its interactions with various other neurotransmitter systems ( [Griffith, 1985](#); [Nemeroff et al., 1984](#)).

### Thyroid Hormone Receptors

A specific class of intracellular nuclear receptors, found on both neuronal and glial cells, mediates the effects of thyroid hormones ( $T_3$  and  $T_4$ ) on the developing and adult brain ( [Evans, 1988](#)). Although both  $T_3$  and  $T_4$  bind to the nuclear thyroid receptor, most of the biological activity results from  $T_3$  and 80% of the  $T_3$  is derived from the b-deiodination of  $T_4$  in the neuronal cell ( [Dussault and Ruel, 1987](#)). The homology between steroid and thyroid receptors suggests that these belong to a superfamily of nuclear receptors containing three functional domains that mediate hormone binding, DNA binding, and transcription ( [Evans, 1988](#); [Evans and Arriza, 1989](#); [Samuels et al., 1989](#)). The binding affinity of these receptors for  $T_3$  is about 10 times their affinity for  $T_4$ , a factor that roughly parallels the *in vivo* potency ratio for these two hormones ( [Komisaruk et al., 1986](#)).

The expression of thyroid hormone receptors in the human brain precedes the prenatal increase in serum  $T_3$  levels and the peak growth spurt in neuronal differentiation and glial replication ( [Komisaruk et al., 1986](#); [Kuhn and Schanberg, 1984](#)). High densities of thyroid receptors are expressed in the developing brain from early gestation, with preferential localization on neurons rather than glial cells. Specific  $T_3$ -binding sites were barely detectable at 10 weeks gestation and increased tenfold by 16 weeks gestation in the human fetus. Similar increases occurred around birth in rat pups and reach peak levels at P9 ( [Dussault and Ruel, 1987](#); [Komisaruk et al., 1986](#); [Kuhn and Schanberg, 1984](#)). The abundant expression of thyroid hormone receptors in early gestation underlines the important role of  $T_3$  and  $T_4$  in controlling the normal development of the immature mammalian brain.

### Hypothalamic-Pituitary-Thyroid Axis Responses to Stress

Acute stress in the form of critical illness, surgical operation, starvation, burns, or severe systemic diseases produces the "euthyroid sick syndrome" in all age groups. This includes decreased plasma concentrations of  $T_3$ , low or normal total and free  $T_4$ , normal TSH, and significantly increased plasma reverse  $T_3$  concentrations ( [Brandt et al., 1976](#); [Fisher, 1990](#); [Weissman, 1990](#)). Serum TSH responses to exogenous TRH appeared normal after surgical stress, but the maximal TRH-induced increase in TSH and the integrated TSH responses were reduced in critically ill postoperative patients ( [Zaloga et al., 1985](#)). Pituitary hyporesponsiveness to TRH stimulation was directly correlated with serum dopamine concentrations, and with clinical outcome following critical illness ( [McLarty et al., 1975](#); [Philips et al., 1984](#); [Silberman et al., 1988](#)). These findings were confirmed in a recent study, in which the plasma concentrations of cortisol,  $T_3$  and TSH were found to be the most accurate predictors of mortality following critical illness ( [Rothwell and Lawler, 1995](#)). These findings indicate that pathologic alterations in the HPT axis and thyroid function in response to acute stress are associated with marked increases in illness severity and poor outcome.

### Behavioral Manifestations of Thyroid Dysfunction

#### HYPOTHYROIDISM

Infants with untreated congenital hypothyroidism show profound mental retardation with specific motor and sensory abnormalities, in addition to the physical stigmata and metabolic characteristics of cretinism ( [Fisher, 1986](#)). Severe deficits in IQ occur in more than 80% of hypothyroid infants who received delayed treatment, and only 15% of infants who received early treatment with thyroxine ( [Klein et al., 1972](#)). The degree of thyroid deficiency and the age of the patient at the time treatment is begun determine the intellectual prognosis and effectiveness of therapy ( [Dussault, 1986](#); [New England Congenital Hypothyroidism Collaborative Study, 1981](#)). Even in patients with normal or near normal intellectual development, impaired brain development may be manifested in the form of clumsiness (33%), behavior disorders (23%), speech disorders (20%), learning deficits (26%), and poor motor coordination in the majority of children ( [MacFaul et al., 1978](#)). Older children and adolescents may show a variable deterioration in school performance ( [Fisher, 1986](#)).

Acquired hypothyroidism in adults is manifested primarily by impaired cognition, often associated with depression, fatigue, and anxiety, and occasionally the development of psychosis ( [Reitan, 1963](#); [Schon et al., 1961](#); [Whybrow et al., 1969](#)). In some patients, the overt psychiatric disorders may precede the onset of hypothyroid signs and symptoms and may go unrecognized until the failure of therapy with psychopharmacologic intervention ( [Reed and Bland, 1977](#)).

An association has been reported between attention deficit hyperactivity disorder (ADHD) and the rare thyroid disease called generalized resistance to thyroid hormone (GRTH). The occurrence of symptoms consistent with a diagnosis of ADHD was noted in a significantly higher number of adults and children with GRTH than unaffected family members ( [Hauser et al., 1993](#)). These symptoms were consistent with the Hyperactive/Impulsive but not Inattentive DSM-IV subtypes of ADHD ( [Hauser et al., 1997](#)). A subsequent study of 132 children and adolescents with ADHD, however, failed to find evidence of GRTH in any subjects and also found only minor abnormalities in thyroid function tests that occurred at the same rate reported for populations of normal children in the literature ( [Spencer et al., 1995](#)).

#### HYPERTHYROIDISM

The behavioral manifestations of hyperthyroidism may include cognitive changes ranging from subtle defects in attention and concentration (potentially mistaken for ADHD) to overt delirium. Depression may also be seen in hyperthyroidism and is its most common psychiatric manifestation ( [Anfinson et al., 1998](#)). Anxiety also may be seen and manifestations of mania, hypomania, and psychosis may occur rarely ( [Anfinson et al., 1998](#)).

### Thyroid Function in Major Depressive Disorder

The HPT axis is as important for the maintenance of normal affective state and behavior as it is for cognition. As noted, depression occurs commonly in patients with

both hypothyroidism and not uncommonly in hyperthyroidism. Conversely, approximately 30% of euthyroid-depressed patients show a decreased TSH secretory response to TRH administration (Gold et al., 1981; Loosen, 1992). Antithyroid antibodies were found in 20% of psychiatric inpatients with prominent depressive symptoms (Nemeroff et al., 1985) and 9% of patients with unipolar depression (Joffe et al., 1987), evidence of incipient hypothyroidism. Additionally, an inverse relationship between peripheral TSH and regional cerebral blood flow and cerebral glucose metabolism was shown in a PET study of adults with major depression and bipolar disorder (Marangell et al., 1997). Although the endocrine effects of treatment with antidepressants cannot be separated, most studies have shown a significant improvement in thyroid function with remission in depressed patients (Loosen, 1992). This was first suggested by Whybrow and associates (1972), who found that improved thyroid function before treatment in depressed patients was positively correlated with a rapid response to treatment with imipramine. Decreased thyroid function noted in patients with rapid cycling bipolar disorder has been associated with a clinical response to treatment with high-dose T<sub>4</sub> in a pilot study (Bauer and Whybrow, 1990). The few studies evaluating thyroid function in adolescent major depression, however, have produced conflicting results. This is exemplified by three different studies comparing free T<sub>4</sub> levels in depressed adolescents and normal controls. One study found reduced free T<sub>4</sub> (Dorn et al., 1996), one elevated free T<sub>4</sub> (Carstens et al., 1990), and one no change (Sokolov et al., 1994). It should be noted that there were significant methodologic differences among the studies.

Decreased TSH responses to TRH in depressed patients were not correlated with their age or somatic measures, the severity of depression or treatment history, or levels of thyroid hormones, corticosteroids, somatostatin, or dopamine. Decreased TSH responses were not correlated with clinical factors such as primary or secondary depression, unipolar or bipolar subgroups, and patients who were acutely ill or in remission. However, the primary clinical importance of decreased TRH-induced TSH responses derives from their association with a history of violent suicidal behavior and an increased risk of suicide (Loosen, 1988a,b). Repeated TRH tests may be useful for prognostic purposes, although these data have not been validated and require cautious interpretation (Loosen, 1992). The data begin to suggest some similarities between the endocrine correlates of critical physical illness (see the preceding) and severe psychiatric disorders, a concept that may generate a host of interesting hypotheses for future research.

## HYPOTHALAMIC-PITUITARY-GONADAL AXIS

### Ontogeny of the Pituitary-Gonadal Axis

Neurons expressing gonadotropin-releasing hormone (GnRH) first develop anteriorly in the olfactory placode and migrate posteriorly to reach the median basal hypothalamus by 9 to 11 weeks of gestation in the human fetus. The development and migration of these neurons are altered in patients with Kallman's syndrome (hypogonadotropic hypogonadism and hyposmia) associated with a Xp22.3 deletion of the X chromosome (Handelin et al., 1993; Schwanzel-Fukuda et al., 1989). In the normal human fetus, GnRH mRNA is expressed in the fetal hypothalamus from about 10 weeks gestation, and the developing pituitary gland contains b-FSH from 10 to 15 weeks of gestation. The mRNA for the  $\alpha$ -glycoprotein subunit of gonadotropins forms one of the earliest molecular markers for the hypophyseal placode, expressed on E11 in the rat fetus, when the anterior neuropore is just closing (Simmons et al., 1990). By E17 in rats, ventrally located cells in the anterior lobe first express the mRNAs for luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Swanson, 1992). The hypothalamic-hypophyseal portal circulation develops at about midgestation in most species, leading to a marked increase in gonadotropin secretion (Gluckman et al., 1981). The increased concentration of gonadotropins in peripheral plasma is responsible for the testicular and ovarian maturation that occurs after midgestation. Sheep fetuses exposed to a long-acting GnRH agonist in the latter half of gestation showed the absence of pituitary gonadotrophs and reduced testicular growth at birth (Thomas et al., 1994). Steroidogenic factor 1 (SF-1), an orphan nuclear receptor, regulates the development of gonadotrophs in the pituitary, as well as the enzymes that synthesize sex steroids in the adrenal gland and gonads. In SF-1 knockout mice, pituitary cells lacked the expression of gonadotroph-specific factors, including LH-b, FSH-b, and the GnRH receptor (Ingraham et al., 1994).

During the third trimester, the expression of steroid receptors in the hypothalamus is associated with the onset of feedback inhibition and a resulting decrease in the secretion of gonadotropins. At birth, the fetal hypothalamus is released from the control of high maternal plasma estrogen concentrations, and gonadotropin secretion increases substantially within 2 to 4 days after birth. Episodic peaks of gonadotropin secretion can be detected for 2 to 4 years after birth, often associated with the secretion of gonadal steroid hormones in the pubertal range (Stein, 1992).

### Neuroendocrine Regulation of Puberty

Puberty is a sequence of events characterized by the secretion of pituitary and gonadal hormones leading to the development of secondary sexual characteristics, gametogenesis, reproductive function, and transformation of the child's appearance to the dimorphic adult state. Regulation of the onset of this epochal life event involves the complex interaction of several neuroendocrine mechanisms, many of which are susceptible to modulation by genetic, psychological, behavioral, dietary, and environmental factors. Some of these regulatory neuroendocrine mechanisms include: (a) changes in the sensitivity of the hypothalamus to inhibitory steroid feedback, (b) synchronization of the GnRH secreting hypothalamic neurons leading to a summation of the stimuli producing the secretion of gonadotropins (FSH, LH) from the pituitary, (c) development of the secretory capacity of pituitary gonadotrophs, (d) removal of inhibitory influences of nongonadal origin (e.g., melatonin), and (e) proposed decreases of the inhibitory influences from higher brain centers. Other somatic and endocrine factors include the amount and distribution of body fat mass (de Ridder et al., 1992), the levels of sex-hormone binding globulin (SHBG) (Mendel, 1989; Sitteri et al., 1972), ovarian estrogen secretion in response to LH (Garibaldi et al., 1993), and the effects of other pituitary hormones and cytokines (Chrandrashekar et al., 1988; Hall et al., 1992).

### CONTROL OF GONADOTROPIN SECRETION

Stimulation of the pituitary gonadotrophs by the hypothalamic decapeptide GnRH released into the hypophyseal portal system leads to the characteristic secretion of FSH and LH pulses as measured in peripheral plasma (Apter et al., 1993) (Fig. 7.4). The pulsatile secretion of GnRH most likely results from intrinsic mechanisms within the network of GnRH-secreting neurons (Mellon et al., 1990), although the frequency of GnRH pulses and synchronization of individual GnRH neurons may depend on other hypothalamic and extrahypothalamic factors (Styne, 1994). In normal children, increased gonadotropin secretion occurs for a period of 2 to 4 years after birth followed by a period of quiescence, which is known as the juvenile phase. At the onset of puberty, the GnRH secretion increases again with marked accentuation of the magnitude and duration of gonadotropic hormone pulses (Grumbach and Styne, 1998). Other pituitary hormones may also alter the secretion of gonadotropins. Studies in transgenic mice overexpressing the human GH gene suggested that GH altered the pituitary sensitivity to GnRH and/or increased pituitary gonadotropin synthesis and secretion (Chrandrashekar et al., 1988, 1989). Decreased body weight, testicular weight, and development following thymectomy in animals were related to the stimulation of hypothalamic GnRH secretion and pituitary LH release by thymosin-b4 (Comsa, 1973; Hall et al., 1992). Conversely, the blockade of GnRH receptors in neonatal rats (P1 to P5) permanently impaired the development of the thymus and maturation of T lymphocytes and inhibited normal sexual maturation (Morale et al., 1991).

**Figure 7.4.** The hypothalamic-pituitary-gonadal axis. al, anterior lobe of pituitary; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; pl, posterior lobe of pituitary.

Inhibition of gonadotropin secretion results from feedback inhibition of sex steroid hormones and inhibin (which suppresses FSH secretion only), and control from higher brain centers. In patients without gonads (e.g., patients with Turner's syndrome, agenesis of the ovary) or in castrated animals, the pattern of gonadotropin secretion during infancy and childhood is qualitatively similar to that of normal children, but the baseline and peak serum levels of gonadotropin pulses are increased significantly (Conte et al., 1975). The absence of gonads does not alter the qualitative pattern of increased gonadotropin secretion during infancy or puberty and the

quiescent phase during childhood, but the quantitative increases in the magnitude of gonadotropin secretion implicate the inhibitory feedback of gonadal steroid hormones ([Grumbach and Styne, 1998](#)). Increased plasma cortisol also decreases the pulsatile secretion of LH and GnRH, implying its role in stress-associated menstrual disturbances ([Saketos et al., 1993](#)).

Inhibitory control from higher brain centers is thought to be responsible for mediating the juvenile phase, which occurs in a steroid-independent manner. Although the exact mechanisms and precise loci mediating this control of gonadotropin secretion are presently unknown, a significant amount of evidence primarily from primate studies indicates a significant role for GABA in the inhibition of the GnRH pulse generator by higher brain centers ([Grumbach and Styne, 1998](#)). Loss of this control is demonstrated in patients who develop chronic increases in intracranial pressure (e.g., secondary to hydrocephalus or subarachnoid cysts) with the onset of central precocious puberty (CPP), which is reversed by surgical procedures (e.g., ventriculoperitoneal shunt placement) that normalize the intracranial pressure. Rare patients with hamartomas of the tuber cinereum, which often contain ectopic GnRH-secreting neurons, also present with central precocious puberty because these ectopic neurons do not receive the descending inhibitory control from higher brain centers ([Grumbach and Styne, 1992](#)). Thus, the onset of CPP may be related to the disinhibition of hypothalamic GnRH neurons resulting from the absence of control from higher brain centers.

Both of the gonadotropins, LH and FSH, can be measured by specific radioimmunoassays, although recent interest in measuring the biologically active component of LH (by testosterone production in rat Leydig cells) and FSH (by aromatase activity in rat Sertoli cells) has demonstrated different patterns of changes from those of the immunoreactive hormones ([Beitins and Padmanabhan, 1991](#); [Kletter et al., 1993](#)). These data revealed that plasma concentrations of biologically active LH may increase manyfold and were not associated with corresponding changes in immunoreactive LH concentrations. Comparison of biologically active and immunoreactive FSH concentrations in serum did not show such striking differences ([Kletter et al., 1993](#)). The role of bioactive gonadotropins in the regulation of the normal and abnormal HPG axis remains speculative.

#### ONSET OF PUBERTY

The amplitude and frequency of nocturnal GnRH pulses from the hypothalamus increase gradually and progressively well before the onset of pubertal development ([Apter et al., 1993](#)). These changes are associated with increased production of pituitary gonadotropins and episodic increases in estrogen and testosterone secretion from the immature gonads. In prepubertal boys, early morning testosterone levels of >0.7 nmol/L were accurate predictors of the onset of puberty within 12 to 15 months ([Wu et al., 1993](#)). Another predictor of pubertal onset was the magnitude of LH secretion in response to exogenous GnRH (100 mg intravenously). Although significant increases in serum LH concentrations were predictive of pubertal onset within 6 to 12 months, the wide variability of individual responses was associated with a number of false-positive and -negative results ([Crowley and Jameson, 1992](#)). Longer-acting and more potent analogs of GnRH activity may be more accurate in determining the onset of puberty ([Cuttler et al., 1993](#)).

Normal pubertal development is characterized by a complex interaction of gonadal steroids, gonadotropins, SHBG, and body mass composition ([de Ridder et al., 1990](#); [Frisancho and Flegel, 1982](#)). The amplitude of nocturnal GnRH pulses is markedly accentuated at the onset of puberty, leading to significant increases in the magnitude and duration of gonadotropic hormone pulses, developmental changes in the gonads, and the production of gonadal steroids. Initially, the GnRH and gonadotropic pulses occur at the onset of sleep and progressively increase to cover the entire night ([Grumbach and Styne, 1992](#); [Morales et al., 1992](#)). Developmental changes in monopolar and bipolar GnRH-immunoreactive neurons located in the medial septal-preoptic area and the diagonal band of Broca in male syrian hamsters were related to the onset of puberty ([Urbanski et al., 1992](#)), although the mechanisms mediating these morphologic changes remain unknown. In normal girls, control of the onset of puberty and the maturation of negative feedback control of the HPG axis are partially independent, thus allowing "catch up" pubertal maturation in girls with a late onset of puberty ([de Ridder et al., 1992](#)).

The change in GH secretion during the pubertal growth spurt is closely associated with the stages of puberty. Plasma concentrations of both LH and GH measured in normal boys and girls (7.2 to 14.6 years age) showed increases in the amplitude and frequency of nocturnal pulses with the progression of puberty ([Bourouignon, 1991](#)). The coordination of the pubertal growth spurt and pubertal development may occur via neuroendocrine mechanisms at the hypothalamus and/or pituitary. Little is known of these mechanisms apart from GH effects on the pituitary sensitivity to GnRH and/or increased pituitary gonadotropin secretion (Chandrashekar et al., 1988, 1989). The role of endocrine and paracrine factors *other than gonadotropins* in regulating the production of gonadal estrogens was suggested in a recent study of early central precocious puberty in girls ([Garibaldi et al., 1993](#)). For example, interleukin-1 (IL-1) altered the expression of LH receptors in the rat ovary, and interferon- $\alpha$  was capable of suppressing estrogen and progesterone release ([Hall et al., 1992](#)). These data indicate that a complete understanding of the mechanisms controlling the onset of puberty is not presently available.

After the onset of puberty, gonadotropin secretion during the daytime increases associated with progressive decreases in the nocturnal gonadotropin secretion that is characteristic of early puberty. The later stages of puberty are identified by the lack of diurnal variation in gonadotropin secretion and development of positive feedback between ovarian estrogen secretion and pituitary LH release to stimulate normal ovulation at the peak of the LH surge ([Morales et al., 1992](#)).

#### Disorders of Hypothalamic-Pituitary-Gonadal Function

##### ANOREXIA NERVOSA AND BULIMIA

Anorexia nervosa is behaviorally defined as weight loss of more than 15% below expected body weight, associated with an intense fear of weight gain, an abnormal body image, and amenorrhea. Bulimia is characterized by recurrent episodes of binge eating followed by purging behavior such as self-induced vomiting, use of laxatives, diuretics, strict dieting, or vigorous exercise ([Kennedy and Garfinkel, 1987](#)). These two disorders have considerable overlap: They first appear during adolescence and young adulthood, are often accompanied by major depression, and have characteristic abnormalities in neuroendocrine function ([Bruch, 1973](#); [Kennedy and Garfinkel, 1987](#)). The etiology of anorexia nervosa and bulimia most likely involves complex interactions between the endocrine system, CNS, and psychological and social factors. A great deal of recent research has examined the hypothesis that primary hypothalamic abnormalities may lead or predispose to the combination of behavioral disorders and neuroendocrine pathophysiology that characterize anorexia nervosa and bulimia. Their neuroendocrinology may be comparable because both cause similar behavioral and psychological disturbances (such as a morbid fear of obesity, distorted body image, poor impulse control, anxiety, and depression).

The weight loss in anorexia nervosa is preceded by amenorrhea, a clinical finding also noted in underweight bulimic patients, but not in those of normal weight ([Boyar et al., 1974](#); [Halmi and Sherman, 1975](#); [Marshall and Kelch, 1979](#)). The amenorrhea in both disorders is attributed to hypothalamic hypogonadism and it may or may not be reversed by the restoration of weight gain. Basal circadian levels of LH and FSH are decreased in pubertal women with anorexia nervosa to plasma levels typical of the prepubertal period ([Boyar et al., 1974](#); [Halmi and Sherman, 1975](#); [Marshall and Kelch, 1979](#)). Exogenous administration of GnRH results in the normal release of LH and FSH, suggesting that the pituitary is intact and that the abnormality exists at the level of the hypothalamus. The hypothesis that the site of the neuroendocrine dysfunction is at or above the hypothalamus, however, does not confirm whether weight loss, protein-calorie malnutrition, or a primary CNS defect results in amenorrhea. CRF hypersecretion may contribute to the hyposecretion of gonadotropins ([Olster and Ferin, 1987](#); [Rivier and Vale, 1984](#)). For example, intracerebroventricular (ICV) administration of CRF produces a dose-dependent decrease in pituitary LH secretion (without any effects on FSH secretion) ([Rivier and Vale, 1984](#)). The stress-induced suppression of LH secretion can be abolished by the central administration of CRF antagonists ([Rivier et al., 1986](#)). Therefore, intrahypothalamic CRF hypersecretion may inhibit GnRH neurons in the arcuate nucleus, via mechanisms that remain obscure.

The neuropeptides neuropeptide Y (NPY) and peptide YY (PYY) may also play a role in the neuroendocrine pathophysiology of eating disorders. NPY is secreted by the hypothalamic arcuate nucleus and then acts on the hypothalamic paraventricular nucleus to mediate increased eating and decreased energy expenditure ([Kaye et al., 1998](#)). ICV administration of NPY to experimental animals produces several physiologic and behavioral changes similar to anorexia nervosa. These changes include gonadal steroid mediated effects on LH secretion ([Kalra et al., 1986](#)), suppression of sexual activity ([Clark et al., 1985](#)), increased CRF release in the hypothalamus ([Haas and George, 1987](#)), and hypotension ([Fuxe et al., 1983](#)). Underweight anorexics have been found to have significantly elevated concentrations of CSF NPY compared to normal volunteers that normalized with recovery (although amenorrheic anorexics continued to show some degree of CSF NPY elevation) ([Kaye et al., 1990](#)). This elevated NPY is clearly not effective in stimulating eating in underweight anorexics but may possibly play a role in the obsessive and paradoxical food interests shown by many anorexics ([Kaye et al., 1998](#)).

CSF PYY concentrations in anorexics were not different from controls ([Kaye et al., 1990](#)), but PYY may play a role in bulimia nervosa. ICV injection of PYY into rats caused massive food ingestion to which tolerance did not develop ([Morley et al., 1985](#)). CSF PYY in normal weight bulimics who were actively bingeing and vomiting were similar to controls, but CSF levels after 1 month of abstinence from bingeing and purging were significantly elevated in bulimics ([Kaye et al., 1990](#)). It is possible that increased CSF PYY early in recovery from bulimia nervosa may contribute to the drive to binge and contribute to the risk for relapse in this disorder.

The recently discovered adipose hormone leptin has also been studied in eating disorders. Leptin changes in anorexia nervosa thus far appear to be consistent with normal physiologic reactions to weight loss ([Kaye et al., 1998](#)). Leptin signaling may play a role in the suppression of reproductive function seen in anorexia nervosa ([Kopp et al., 1997](#)). Leptin also does inhibit the starvation related elevation of NPY in the hypothalamus ([Stephens et al., 1995](#)). The role of leptin in eating disorders continues to be the subject of investigation.

The HPA axis is hyperactive in anorexia nervosa, based on the observations of elevated basal cortisol secretion, increased cortisol responses to stress, an increased number of cortisol secretory episodes per day, and decreased feedback inhibition (based on abnormal dexamethasone suppression test). As patients gain weight, the rate of cortisol secretion normalizes and feedback inhibition is restored, suggesting this defect is state-dependent ([Kennedy and Garfinkel, 1987](#)). Abnormal dexamethasone suppression tests are also characteristic of depression, bulimia without weight loss, late-stage Alzheimer's disease, and protein-calorie malnutrition. Increased plasma cortisol concentrations may reflect both a decreased metabolism and increased HPA axis activity, the latter further suggested by increased CSF levels of CRF in underweight patients ([Kaye et al., 1987](#)). Increased plasma cortisol levels also occur in starved human subjects who do not have anorexia nervosa or depression ([Fichter and Pirke, 1986](#); [Pahl et al., 1985](#)). A generalized reduction in metabolic rate occurs as a physiologic adaptation to protein-calorie malnutrition and cachexia. Anorexia nervosa, bulimia, and MDD share neuroendocrine abnormalities, anorexia, amenorrhea, decreased libido, hyperactivity, agitation, and depression. Thus, it is likely that hypercortisolism, an abnormal dexamethasone suppression test, and hypersecretion of CRF in various neuropsychiatric syndromes reflect a common CRF-mediated stress pathophysiology rather than being etiologic factors unique to any particular disorder.

Patients with anorexia nervosa have increased GH levels; these are restored to normal with increased caloric intake ([Kennedy and Garfinkel, 1987](#)). Increased secretion of GH occurs in protein-calorie malnutrition with chronic hypoglycemia, thereby further supporting the hypothesis that neuroendocrine abnormalities in these two conditions are related to reduced caloric intake. Diminished GH responses to insulin-induced hypoglycemia and L-Dopa, and increased GH responses to GHRF (but not clonidine), occur in anorexic patients ([Brambilla et al., 1989](#)).

Other neuroendocrine disturbances in eating disorders do not suggest that their etiology is related to central neuroendocrine dysfunction ([Kennedy and Garfinkel, 1987](#)). Thyroid function is characterized by a reduction in peripheral T<sub>3</sub> concentrations and increased concentrations of the inactive reverse T<sub>3</sub> in the face of normal circulating levels of TSH and T<sub>4</sub>. These changes in thyroid hormones result from the decreased hepatic deiodination of T<sub>4</sub> to T<sub>3</sub>, typical of catabolic states. The low T<sub>3</sub> decreases the metabolic degradation of cortisol because T<sub>3</sub> replacement in anorexic patients results in a shorter half-life for cortisol. The TSH response to TRH is also blunted in bulimia, similar to the responses seen in MDD, while anorexic patients exhibit a delayed but not blunted TSH response.

Patients with anorexia nervosa exhibit defects in urinary dilution and concentration that result from abnormal secretion of AVP ([Gold et al., 1983](#); [Nishita et al., 1989](#)). Cold intolerance is characteristic of anorexia nervosa and may be related to a central defect in temperature regulation in the hypothalamus. Anorexic patients also manifest various abnormalities of monoamine secretion ([Kennedy and Garfinkel, 1987](#)). Decreased CNS noradrenergic activity and turnover may be a trait marker for anorexia nervosa, as suggested by decreased urinary, plasma, and CSF concentrations of 3-methoxy-4-hydroxy-phenylglycol (MHPG), the norepinephrine metabolite; low CSF levels of norepinephrine; decreased CSF and urinary homovanillic acid (HVA)—which remain unchanged with long-term recovery. Decreased CSF and urinary concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the serotonin metabolite, which normalize with weight gain, suggest state-associated disturbances of serotonin metabolism, in contrast to the state-independent changes in norepinephrine metabolism. Bulimic patients also have decreased central norepinephrine and serotonin function, which can precede, accompany, or follow behavioral changes. Their role in the etiology of eating disorders remains uncertain because similar changes in neurotransmitter metabolism may result from caloric deprivation or weight loss per se. However, it is of interest that several of the selective serotonin reuptake inhibitor antidepressants such as fluoxetine have been demonstrated, in double blind, placebo-controlled clinical trials, to be efficacious in the treatment of bulimia.

#### *HYPOTHALAMIC OBESITY*

A number of endocrine and genetic causes can lead to hypothalamic obesity, including Cushing's disease, polycystic ovary syndrome, castration, and Prader-Willi syndrome, to name a few. Although hypothalamic obesity was described over 100 years ago ([Bray and Gallagher, 1975](#)), studies using stereotaxic lesions have shown that small lesions in the paraventricular nucleus ([Fukushima et al., 1987](#)) or the ventromedial nucleus (VMN) of the hypothalamus ([Parkinson and Weingarten, 1990](#)) can produce hypothalamic obesity. Lesions in the PVN produce hyperphagia leading to obesity (prevented by limiting caloric intake), whereas VMN lesions cause obesity by complex alterations in autonomic function (increased parasympathetic activity and decreased sympathetic activity) ([Bray, 1992](#)). Following a VMN lesion, vagal efferent activity increases acutely (with increased insulin secretion), the thermogenic component of sympathetic activity decreases ([Bray et al., 1990](#); [Sakaguchi et al., 1988](#)), and GH secretion decreases because of injury to GHRH-producing cells ([Bernardis and Frohman, 1970](#)). These neuroendocrine changes lead to decreased energy expenditure for growth or temperature regulation and increased retention of ingested calories as fat. In humans, hypothalamic obesity is often associated with impaired diurnal rhythms, somnolence, and abnormalities in temperature control ([Bray, 1992](#)). Prader-Willi syndrome, characterized by hypogonadism, central obesity, delayed puberty, hypotonia, and mild mental retardation, is associated with deletions or translocations on chromosome 15 or with a normal karyotype. Obesity in these patients is related to a remarkable hyperphagia and hypoactivity. Behavioral difficulties also include cognitive and language problems, temper tantrums in infancy, and poor relationships with peers ([Butler, 1990](#); [Cassidy and Ledbetter, 1989](#)). Thus, central or peripheral abnormalities in the HPG axis may lead to altered caloric intake and metabolism and should be considered in obese patients with behavioral and psychiatric illnesses.

#### *PRECOCIOUS PUBERTY*

Pubertal development before the age of 8 years is defined as precocious puberty. The etiology of precocious puberty can be classified into peripheral, central, and combined causes. Central precocious puberty results from the premature activation of the HPG axis by GnRH or gonadotropins. Peripheral precocious puberty is a gonadotropin-independent process that results from the excessive production of adrenal or gonadal steroids or from ingestion of exogenous sex steroids. Combined precocious puberty involves activation of the HPG axis following abnormal production of sex steroids in the adrenal glands or gonads. The diagnosis and treatment of precocious puberty is not discussed any further here; the interested reader may refer to several recent reviews ([Breyer et al., 1993](#); [Pescovitz, 1990](#); [Reichlin, 1998](#); [Stein, 1992](#)).

Behavioral disturbances, development of breasts and pubic hair, and accelerated growth with premature epiphyseal closure are common early manifestations of precocious puberty. Children with precocious puberty often have poor self-esteem and difficulty with peer and parental relationships ([Jackson and Ott, 1990](#)) and may be at high risk for sexual abuse because of their cognitive and emotional immaturity.

#### *TRANSSEXUALITY AND HOMOSEXUALITY*

The neurobiologic basis for sexual and behavioral orientations has been investigated for several decades. Sex hormones are thought to be the major biological determinants of sexual orientation because of their well-known effects on somatic sexual differences and the development of sexual dimorphism in the brain ([Witelson, 1991](#)). Despite recent advances in neurobiology and behavior, the relative importance of biological and psychosocial factors, and their complex interactions in the development of sexual orientation are poorly understood. Studies associating sexual orientation with systemic sex hormone levels during adolescence and adulthood yielded largely negative results, especially in men (Meyer-Bahlberg, 1984, 1991). Psychoneuroendocrine research on transsexuality and homosexuality is therefore focused on the role of prenatal or perinatal sex hormones on the development of structural sex differences in the brain and on the gender-specific repertoires of reproductive and nonreproductive behaviors ([Gerall et al., 1992](#); [MacLusky and Naftolin, 1981](#); [Tallal and McEwen, 1991](#)).

In many species, the hypothalamus and adjacent areas of the brain undergo sexual differentiation following exposure to sex steroids at a species-specific sensitive interval during the perinatal period ([MacLusky and Naftolin, 1981](#)). Sex differences noted in the human brain are listed in [Table 7.3](#). The sexually dimorphic nucleus (SDN), located in the preoptic area of the hypothalamus, has been posited to be involved in sexual orientation and gender identity; its size is reportedly 2.5 times greater in men and contains twice as many neurons as compared to the number in women ([Gorski, 1985](#)). The size, number, and morphology of neurons in the SDN are determined by exposure to sex hormones in the perinatal period ([Gorski et al., 1978](#)). Small-sized SDNs were found in the brains of transsexuals as compared to heterosexual men ([Swaab and Hofman, 1988](#)), suggesting a role for this nucleus in male homosexuality.

Some of these structural sexual differences in the brain can be produced by exposure of the female fetus or newborn to androgenic hormones. Postnatal treatment of female gerbils with testosterone (or diethylstilbestrol, DES) increased the relative sizes of the SDN and suprachiasmatic nucleus (SCN), whereas similar treatment during adulthood had no effect. Increase in the size of the left SDN was associated with male-type courtship vocalizations ([Holman and Hutchison, 1991](#)). The effects of testosterone are located in sexually dimorphic areas of the hypothalamus and limbic areas associated with reproductive functions ([Wozniak et al., 1992](#)). Administration of testosterone with an aromatase cytochrome P-450 inhibitor or an estrogen antagonist abolishes the effects of testosterone on sexual behavior. The

mechanism of action of testosterone and other androgens therefore appears to depend on their *in situ* aromatization in these areas (Hutchison and Beyer, 1994). Further, the expression of aromatase mRNA in the mouse diencephalon was significantly increased by testosterone via transcriptional control (Yamada et al., 1993). This mechanism may also explain why prenatal exposure to DES, an estrogen, has behavioral and morphologic consequences similar to those of androgen exposure (Herbst, 1981). The control of reproductive behaviors by neuroendocrine mechanisms remains under active investigation.

The importance of these findings results from the exposure of human fetuses to DES, which is thought to be related to altered sexual behavior and the development of homosexual orientation (Meyer-Bahlburg et al., 1995). Human females exposed to prenatal androgens because of congenital adrenal hyperplasia or DES were more masculine in their childhood behavior than their own sisters or unrelated control subjects. These females also showed increased physical activity; increased preference for rough-and-tumble and pursuit play and male-typical toys and activities; and a decreased preference for parental doll play, and female-typical toys and activities. These girls were also more likely to emphasize careers over childbearing in their fantasies about adult life (Berenbaum and Snyder, 1995; Ehrhart and Baker, 1974; Money and Ehrhardt, 1972). Many of these changes in behavior and interest have been shown to persist into adolescence in patients with congenital adrenal hyperplasia (Berenbaum, 1999). However, DES exposure was not shown to produce significant changes in neuropsychological tasks that commonly show gender differences in performance, when DES-exposed women were compared to their nonexposed sisters (Hines and Sandberg, 1996).

Atypical gender role behavior during childhood was documented by history in about two-thirds of homosexual men and women, interpreted as having crossed the line into the other gender's role-play and identity during childhood (Bell et al., 1981; Whitman and Mathy, 1986). To some extent, the neuropsychological differences between homosexual and heterosexual men resemble those found between heterosexual men and women (McCormick and Witelson, 1991). Hormonal studies in transsexuals have been inconsistent thus far (Bosinski et al., 1997).

We must emphasize that, even if a neuroendocrine basis for sexual orientation is confirmed, this may apply to only a percentage, currently unknown, of homosexual men and women, and that the importance of learning, psychosocial role models, and other cultural factors is not diminished by these hypotheses or supporting data.

## FUTURE DIRECTIONS AND DEVELOPMENTAL PSYCHONEUROENDOCRINOLOGY

The past decade has witnessed remarkable advances in neuroscience in general, and in molecular neurobiology and structural and functional brain imaging in particular. All of these approaches can be applied to developmental psychoneuroendocrinology, both basic and clinical, with the resultant incremental advance in our knowledge of developmental neuroscience, a discipline that has always lagged behind the rest of neuroscience because essentially the CNS, particularly the brain, develops differently virtually on a daily basis. As such, neuroanatomists, neurochemists, and behaviorists have to some extent steered clear from this complicated and difficult to untangle area because the CNS substrate changes so rapidly. Indeed, we still do not have at our disposal a high-resolution developmental brain atlas for most mammals, including humans.

Further measurement of the expression of various genes encoding for neurotransmitters, neurotransmitter-linked enzymes, and neurotransmitter receptors and their regulation in development is needed. This will undoubtedly help understanding of complex phenomena such as the timing of puberty, maturation of the stress response, and the pathophysiology of a variety of important clinical disorders, such as anorexia nervosa, precocious puberty, and even complex behavioral alterations such as sexual preference.

Perhaps the greatest promise for clinical studies to help us elucidate the pathophysiology of childhood disorders, such as autism, affective disorders, anxiety disorders, eating disorders, and ADHD, lies with functional brain imaging. Techniques that do not involve radiation exposure show promise for safely studying brain activity in children and adolescents. These methods, combined with structural brain imaging, will undoubtedly point to particular brain regions that need to be further scrutinized in these devastating disorders. In addition, reproducible abnormalities established using functional brain imaging in symptomatic patients then could be followed after treatments for these disorders to determine whether markers for such disorders can be identified. There is great promise that the next decade will bring continued advancements in this area, far beyond what we might have hoped for in the past.

The boundary between biology and behavior is arbitrary and changing. It has been imposed not by the natural contours of the disciplines but by lack of knowledge ([Kandel, 1991a](#)).

It is not the purpose of this chapter to review in detail the nature of brain structure and function, nor behavior minutely dissected, both of which are covered in other sections of this volume and in specialized reviews and texts such as [Kandel and colleagues \(2000a\)](#). Rather, discussion is restricted to a broad-brushed canvas of the relationship between brain and behavior (used in its widest meaning), concentrating on the principles that are germane to child and adolescent psychiatry. In so doing, certain points must be borne in mind:

First, child and adolescent psychiatry is, above all, concerned with developing behavior and biology, which although continuing throughout the life span, will not again do so at such a fast pace until the last of the Seven Ages of Man (this time negatively). Put another way, it is not that development is irrelevant to mature life; it is just that the pace is slow enough for it to be conveniently ignored, whereas with children and youth, the fact is obtrusive and inescapable.

Second, scientific knowledge applicable to brain and behavior is now so vast and developing so rapidly that no one person can hope to grasp more than an inkling of their interrelationship. Nevertheless, although knowledge (especially in molecular biology and neuroimaging) is expanding rapidly, there is still a remarkable continuity of knowledge over time in neuroscience, as revealed by scholarly texts that have a sense of history such as [Kandel and colleagues \(2000a\)](#). Thus, what was learned in medical school or residency training is far from totally obsolete or useless in understanding brain and behavior today and puts the fundamental principles within the grasp of any child psychiatrist or mental health professional with training in human biology. Particularly compelling is a slow but significant and escalating change in child psychiatry over time. There has been a rediscovery of the idea that many psychiatric disorders once considered psychogenic have primarily biological causes (for example, autism); genetic and bioenvironmental contributions to the development or expression of psychiatric disorders is becoming clearer; and the concept of neurodevelopment in the etiology of some psychiatric disorders such as schizophrenia ( [Weinberger 1987](#), [Weinberger 1995](#) ) has increasingly shown that child psychiatry will assume a key role in the definitive prevention of these adult disorders (see the following).

Third, bear in mind that, despite all the advances, there is still a yawning gap between the laboratory and clinical practice. Most clinical decisions must be made with an imperfectly garnered, largely pragmatic data set that at best touches only lightly on brain–behavior functions. This knowledge gap often produces two extreme positions—those who crudely crash it and see a disordered brain behind everything clinical, and those who, apart from an occasional perfunctory genuflection to the brain, act as if all behavior is determined solely by intrapsychic, interpersonal, or (nowadays) intrafamilial processes. In fact, a good grasp of brain–behavior relationships is one of the unique things that psychiatrists bring to the multidisciplinary team and is a way to command respect for this complex area of science without overvaluing its role in clinical decisions.

However, looking at the development of biological psychiatry since 1950, it is not hard to see that in some areas etiologic breakthroughs that will radically affect clinical practice are imminent. Most of these will affect the major psychiatric disorders (such as attention deficit hyperactivity disorder, obsessive-compulsive disorder (OCD), schizophrenia, and Tourette's disorder), which form an increasing part of child and adolescent psychiatry. Perhaps more important in terms of its larger clinical applicability, better understanding will come too of the genetic and molecular biological basis of human variability ( [Chapter 1](#), [Chapter 2](#), [Chapter 3](#), [Chapter 4](#), [Chapter 5](#), [Chapter 6](#) and [Chapter 7](#) ) and how its derived macrofunctions, such as temperament, cognition, and other developmental abilities, interact with experience to create psychopathology ([Lewis, 1992](#); [Shaw and Bell, 1993](#); [Taylor, 1991](#)). From this knowledge, it is but one step to biologically based modifications, some therapeutic, but most excitingly, some preventive, in a true pediatric psychopharmacology. For this, if no other reason, the child and adolescent psychiatrist must try to stay abreast of developments in brain–behavior relationships.

### GENERAL PRINCIPLES

#### Concepts of Brain–Behavior Relationships

The best way to introduce fundamental concepts is by way of a historical review. The notion that the brain influences behavior is fairly recent, appearing significantly only with 19th century phrenology ([Kandel, 2000a](#)). Before that, humoral (i.e., endocrinologic) theories, derived from Greek medicine, seem to have predominated and gave such words as sanguine, melancholy, and choleric. Hippocrates (460 to 377 BC) summarized the humoral theory of “diseases,” which were conceptualized as imbalance between fluids (“humors”), and there was no dichotomy between disorders of the body and disorders of the “soul.” Descartes (1596 to 1650) established the landmark for the “Cartesian dualism” of body and mind, with the belief that it was impossible that mental and physical interact.

Some of the basic ideas about how the brain influences behavior (and vice versa) arose over 150 years ago.

#### Localization Versus Equivalence

The phrenologists who mapped 35 higher brain functions, such as benevolence, hope, conjugality, and secretiveness, to specific bumps on the skull were the first exponents of one of the two recurring themes: neurobehavioral theory and localization of function. According to [Kandel \(2000a\)](#), the phrenologists were debunked by Flourens, who removed parts of the brains of animals and, finding no site-specific change in behavior, simultaneously created the other evergreen theme, equivalence, which holds all parts of the brain to be capable of performing any function. The reader should note these two themes of localization and equivalence well because they still continue to leapfrog each other in popularity, especially in the area of higher functions such as cognition and emotion. It appears that we are well into another localization era, derived from developments in pharmacology, neurotransmitter physiology, and brain imaging, but it was not always so.

The prime example of a persistent equivalence view in child psychopathology is that of minimal brain damage/dysfunction, in which it is the amount of brain damage, not its site, that is believed to determine the syndrome. As positron emission tomography (PET) scans have shown, both views are correct and complementary—many functions are localized but their learning, execution, or integration with others requires most of the brain to be involved.

The newest themes popularized by neuroimaging researchers are functional anatomy (structures with specific functions) and connectivity (patterns of flow of information between brain areas forming a functional “network” or “circuit”).

### Hard and Soft Effects

Many years ago [Teuber \(1960\)](#) drew attention to another important concept associated particularly with abnormal brain function, that of the hard, or deterministic, view in which the brain is seen as totally determining observed behavior. This view was popular in the eugenics era around the turn of the 19th century and, in child psychiatry, after the encephalitis pandemic of the 1920s in what we now call conduct disorder. A more modern example is seen among those who explain behavior in children, especially younger ones, entirely on the basis of temperament via such concepts as “the difficult child syndrome” without reference to the flow-on effects of interactions between parent and difficult infant, infant and difficult parent, or both ( [Shaw and Bell, 1993](#)) ([Chapter 14](#) and [Chapter 15](#)).

The opposite of the hard is the soft view, in which the brain is seen as irrelevant before the much more powerful influence of experience, a view that seems to have dominated much of child psychopathology research between 1940 and 1970 and is today seen in the thinking of far too many child mental health professionals in (unwitting) parent-blaming.

In fact hard and soft views are less categorical than extreme poles of a single axis, so that intermediate views ( [Eisenberg, 1957](#); [Lewis, 1992](#); [Lewis et al., 1989](#); [Shaw and Bell, 1993](#)) emphasize that behavior is a downstream endpoint in the interaction between brain function and experience. The explosion of molecular genetics and functional neuroimaging research endorses this longer-held view. Concepts of genetic determination soften as the role of experience on genetic coding becomes more apparent, and the plasticity of the neural machinery is revealed in an ebullient new field of neuroscience. This interactive view between biology and experience then seems both the most sensible and valid one. It might suggest that, as indeed it seems at times to do, in view of the enormous variation in human experience and the transactional effect of development, detection of any meaningful relationships between brain function and behavior in children will be impossible—that is, each child is unique. Science does not accept this pessimistic view and seeks to reduce experience to a manageable number of types, as indeed do most developmental theories, whatever their theoretical orientation, for example, attachment or social learning ( [Shaw and Bell, 1993](#)).

## THE BRAIN

### How the Brain Works

As detailed in the previous chapters of this section, the brain consists of billions of cells and their processes—neuronal, which do the work of the brain, and glial, which support, nourish, and clean up the neurons. The principles of neuronal function and synaptic transmission have already been described in previous chapters in this section and/or are too well known to need detailing. More important for the purposes of this chapter is how these individual cells are organized to do the work of the brain. There are two main ways of operating: point-to-point or one-way traffic, rather like telegraph or fax systems. The other is more like the telephone, in which communication goes back and forth between sender and receiver, although in the brain, two electrically separate cables are used. The back-and-forth telephone model is much more characteristic of most brain function than the telegraph model. What were formerly thought of as unidirectional way stations like the thalamus or basal ganglia are now known to transmit, receive, and modulate in a perpetual dialog. Because axonal and synaptic transmission is so ultrarapid, it is clear that some kind of way of keeping things alive and active is needed for slower processes such as memory, thinking, worrying, and the like. This is achieved by reverberating circuits, some of which (e.g., the Papez or emotional/memory circuit) are very extended. Individual neurons and their processes become organized partly by genetic programming and partly by experience, into units called cell assemblies ( [Hebb, 1949](#)), which are very like integrated circuits or chips. These become the functional units in much of the brain's actions, although they do have connections in parallel and series outside these assemblies, very importantly, allowing for cross talk.

### Development of the Brain

This is discussed in detail in this book ( [Chapter 3](#)) and elsewhere ( [Casaer, 1993](#); [Ebels, 1980](#); [Jacobson, 1991](#); [Kandel et al., 2000](#)). Life begins as a single cell, yet the billions of neurons are created, basically differentiated, and crudely in place by birth and by and large are nonreplaceable. However, from later fetal life on, the process shifts from skeletal construction to one of embellishment or differentiation and fine-tuning. Modern developmental neurobiology holds that most of the fundamental organization and architecture of the brain, differentiation of neurons, and axonal development is preprogrammed and uninfluenced by anything but adverse and physical environmental experiences, yet it is also estimated that there are sufficient genes to program only a fifth of the brain's neurons, leaving huge areas of flexibility on which experience can work and that form the basis of learning.

Postnatally, the most significant developments in the brain are: (a) the development of interconnections shown microscopically by an enormous proliferation of dendritic and axonal processes and (b) myelination of axons, which greatly enhances the speed and efficiency of nerve conduction ( [Ebels, 1980](#)). Although approximately 75% of brain growth (as shown by weight) occurs by the age of 2 years ( [Carmichael, 1990](#)), these two processes of differentiation continue ( [Casaer, 1993](#)), although at a decelerating rate, until adulthood. Even thereafter, increase in myelin density ( [Kolb and Whishaw, 1980](#)) and axonal and dendritic growth continue throughout life until final senescence. This means that at the level of cell assembly organization or complex circuitry the brain is actually in a constant state of change, and this is probably one mechanism by which learning occurs.

### Disruptions in Brain Development

As can be seen from previous chapters, the initial process of neurogenesis and development of brain architecture is a highly complex and surprisingly rapid process. It is obvious that brain development should be most susceptible to disruption during the most rapid phase of neurogenesis and organization, when any disruptions may have gross and catastrophic results, such as congenital malformations and severe mental retardation. As pointed out in [Chapter 3](#), there are two major types of disruptions of normal development—pathogenic “software” owing to abnormal genes/chromosomes and errors in execution of the genetic programming induced by subtle changes in the intrauterine environment, such as those induced by viral infections or biochemical abnormalities, for example, from alcohol, tobacco, and drug abuse, maternal malnutrition, placental dysfunction, maternal vomiting, and even stress ( [Leckman et al., 1990](#); [Taylor, 1991](#)) ([Chapter 7](#)). Being highly specialized in function, neurons are exquisitely sensitive to such changes in the biochemical environment—its acidity, ionic composition, and supply of essential nutrients, particularly oxygen and glucose. Both of the latter are vulnerable to marked change in blood levels (e.g., during abnormalities of pregnancy and delivery) and in demand according to the brain activity, which is never zero, because a mature neuron maintains a basal tonic level of readiness for action that is essential to normal function.

As knowledge grows about the surprisingly early and critical role in initial brain organization of neurotropic messengers, most of which are normal biochemical substances that will later fulfill endocrine, such as androgens ( [Peterson et al., 1992](#)) ([Chapter 6](#) and [Chapter 34](#)), and neurotransmitter ( [Casaer, 1993](#)) function, concern must mount about the possibilities of subtle brain disruptions. For example, [Casaer \(1993\)](#) points out that receptors in the cerebellum become sensitive to g-aminobutyric acid (GABA) before its actual productive and, more importantly, inactivation mechanisms develop. He argues that benzodiazepines given to the mother, therefore, might have powerful effects in fetal life. The same may be true for the effect of nicotine *in utero*, because the cholinergic receptors and enzymes are present in the brain very early in life ( [Ernst et al., in press](#)).

Injury and local brain disease can also result in direct loss of nervous tissue, so that after these prenatal pathogens, the most dangerous point is often assumed to be birth. However, the most destructive force at this time is not direct injury to the brain, but that induced by anoxia and hypoglycemia, especially when combined with prematurity ( [Werry, 1986](#)). Modern advances in obstetric and neonatal care have greatly reduced the frequency of this kind of brain disruption, and it is possible that

postnatal head injury is now more of a threat to brain development in children.

Much of the controversy about brain and behavior ([Kreusi, 1990](#); [Rutter, 1982](#); [Taylor, 1991](#); [Werry, 1986](#)) does not involve gross and obvious abnormalities of development usually resulting in one or more of the neurologic “big three” (mental retardation, cerebral palsy, and epilepsy), but rather focuses on the role, compared with that of the social environment, of minor congenital abnormalities or prenatal, perinatal, and postnatal insults to the brain ([Taylor, 1991](#)) in the production of extreme temperamental types such as the “difficult child” or psychiatric disorders such as attention deficit hyperactive disorder (ADHD), developmental learning, tic and OCDs ([Leckman et al., 1990](#)), and schizophrenia ([Werry and Taylor, 1994](#)). For example, there is a close association between social advantage and school performance, but how much actual physical brain development directly contributes to this is unclear ([Madge and Tizard, 1980](#)). One study of children who had marasmus showed that malnutrition and, presumptively, the resultant brain maldevelopment have some effect independent of social environment. The effect on IQ was small, but there were much larger effects on more subtle cognitive functions such as attention and also on emotional stability ([Galler et al., 1983a](#), [Galler et al., 1983b](#), [1985](#)). This along with other evidence suggests that effects may be there but less obvious ([Taylor, 1991](#)). Increasing overpopulation and putative climatic change leading to famines in the horn of Africa and other Third World areas stress the potential devastating importance of this pathogenic process.

## Recovery from Brain Disruptions

### GENERAL PRINCIPLES

Despite the preceding litany of risk factors, one thing is clear about most brain disruptions—there is no simple relationship between brain insult and brain development ([Taylor, 1991](#)). For one thing, there is both a high threshold to injury ([Taylor, 1991](#)) and a strong tendency to recovery or increasing attenuation ([Kreusi, 1990](#)). The basis of this is disputed and probably multifactorial. One factor could be surplus neurons because, as noted, there is a large redundancy of neurons (as high as 50%) gradually lost by adulthood through neuronal death owing to disuse ([Casaer, 1993](#)). Some is owing to cleanup of the products of inflammation, necrosis, trauma, bleeding, and so on. Loss of neurons may be compensated to some degree by development of more dendritic processes, thus getting a bigger bang for the neuronal buck, as it were. Such development, however, is an active process that requires stimulation and so lends plausibility to the hypothesis that active rehabilitation and learning programs should have a role to play in repairing brain insults. But probably the most important factor is that of parallel functions: When one way is obstructed, there is always another. In the brain, this parallelism is derived in part from the fact that chains of neurons are probably connected in series and in parallel. But it is not only neurons that exhibit parallelism; so too do the elementary subfunctions of higher information processing, so that “neural processing for a given function is distributed within the brain and handled at several sites” ([Kandel, 2000a](#)). However, this principle is limited and least true of, for instance, motor or sensory ones, functions that are simple or highly specific and sharply topographically localized with point-to-point representation.

### AGE AND RECOVERY

It is often held that brain injury occurring early in life has a better prospect of recovery because of the putative increased neuronal plasticity, belief that stemmed from the Kennard principle that posits that the earlier the lesion, the better the outcome. This principle is based on the work of Margaret Kennard on the effects of age a lesion onset in primates where cortical lesions made on young animals had less effect on behavior than have similar lesions in adults ([Kennard, 1938](#), [Kennard, 1940](#)). Certainly, all the prospective studies of putatively brain-damaging prenatal and perinatal situations have shown that many initial effects are often largely undetectable by the start of school ([Kreusi, 1990](#); [Rutter, 1981](#); [Werry, 1986](#)). The counter view is that of critical periods, well demonstrated in the area of the development of vision, where early disruption (e.g., strabismus) can lead to functional blindness (amblyopia, [Chapter 3](#)). In a review of the empirical evidence, [Fletcher and Satz \(1983\)](#) concluded that the only thing that makes early damage look less disabling is the increased length of time between assessment of function and damage, or, in short, that time after injury, not age, may be the critical determinant of recovery. In fact, they concluded that there is some evidence that early damage may be more serious than later damage. [Taylor \(1991\)](#) also points out that regrowth and reconnection may not always be beneficial, but may produce new anomalies and that the early consequences (notably motor problems) may be different from the late one (cognitive) and require more subtle detection methods.

Nevertheless, some degree of recovery continuing for a long time is almost inevitable and may give intensive rehabilitative treatments a credibility that they do not deserve.

## Experience and the Brain

So far the emphasis has been on disruptions in the brain, but what evidence is there that experience may influence brain development? Animal experiments have shown that the weight of the brain, complexity of dendrites, and synaptic size are all significantly greater in animals exposed to an enriched environment and that these morphologic changes are matched by improved performance. The increases are greatest if stimulation is given early in life but are still apparent even if applied later ([Kolb and Whishaw, 1980](#), [1995](#)). [Kandel \(2000a\)](#) summarizes the process of brain development: Synapse formation is largely under genetic control, but when in place, synapses require appropriate environmental stimulation for their activation and fine-tuning. Some of this activation may have a critical time frame (e.g., the development of binocular vision, affection bonds, or fluency in a language). After the laying down of synapses, experience works throughout the life span primarily by influencing the effectiveness of these synapses—downgrading some (unlearning) and upgrading others (learning). This view of synaptic strength, which is attributable to [Hebb \(1949\)](#), has much experimental support but does not take account of the fact that the neuronal processes are actually in a constant state of growth, with synapses disappearing and reorganizing. It seems likely that the concept of synaptic strength is conceptually correct but anatomically incorrect. However, it matters little for our purposes; the important and obvious thing is that experience alters the brain.

## Methods of Studying Brain Function

No attempt will be made to cover these in detail. For more detail see other sections and chapters of this book ([Chapter 9](#)), and [Ernst and Rumsey \(2000\)](#), [Rutter \(1981, 1982\)](#), [Taylor \(1991\)](#), and [Werry \(1986\)](#). In humans, because of obvious ethical constraints, natural clinical states such as disease, injury, malformation, and so on must be utilized. Unless the patient dies, the full extent of the abnormality is rarely known, and the child psychiatry literature is full of methodologically pitiful studies that have aggregated “brain-injured” children when there is good reason to suspect that the site, extent, and nature of the brain damage differed widely. Even in disorders of similar etiology such as head injury ([Chapter 33](#)), the variation in brain damage can be enormous, not only because of differences in the site and force of the impact, but also because of variable disseminated or far-distant effects such as deceleration, contrecoup, shearing, and torsion effects. Add to all this, the variation in postinjury experience, and the situation can be seen to be most complex. Only large single effects are likely to be detectable in the usual-size sample of considerably fewer than 100 subjects.

### CLINICAL METHODS (HISTORY AND EXAMINATION)

These are the most popular, yet among the poorest because they are often unreliable, of unknown validity, only lightly correlated with brain damage, and subject to errors of detection, especially for areas of the brain that are of most interest in psychopathology. Much of the study of brain function in child psychiatry before 1980 falls in this category and is quite error-prone ([Rutter, 1981](#); [Werry, 1986](#)).

### PSYCHOPHYSIOLOGY

In more recent years, the crude and largely noncontributory technique of electroencephalography (EEG) has been replaced by more functionally oriented methods such as evoked potentials and other techniques ([Chapter 9](#)), many of which have attained great sophistication through computer averaging, mathematical analysis like power spectral analysis, and a general growth in knowledge about each of the components of the characteristic waveform. In general, evoked potentials ([Chapter 9](#)) are most suited to studies of general brain states such as arousal and vigilance or gross intactness of the sensory apparatus and brain as a whole. However, they have also offered some useful if very technical information on the development of certain brain processes such as attention ([Lincoln et al., 1990](#)) and for the functional analysis of pharmacological effects such as that of the stimulants ([Coons et al., 1987](#)). The combination of EEG and magnetic field techniques has given rise to the new if still complex and costly magnetoencephalography imaging (MEG) based on surface electrical recording ([Rojas et al., 2000](#)). MEG signal represents a direct index of neural activity, which is not the case for most other functional neuroimaging methods such as functional magnetic resonance imaging (fMRI), which measures changes in cerebral blood oxygenation and cerebral blood flow (i.e., indirect indices of neuronal activity).

### ANATOMIC AND FUNCTIONAL PATHOLOGY

These methods are largely limited to postmortem studies, and death is a rare event in most children with psychiatric disorders. It is of interest that good autopsy reports of disorders such as autism are only just emerging. The increasing problem of teenage suicide offers an unfortunate window of opportunity by making

postmortem studies of this population more common. Two recent contributions bear mention: Pandey (1997, 1999) measured two rather novel enzymes involved in signal transduction linked to receptors such as 5-HT 2a. This shows that even anatomic pathology is moving away from the relatively simple measurement of structure and quantification of receptors toward more refined functions such as second messengers.

## BRAIN IMAGING

Brain imaging methods are discussed in more detail in [Chapter 9](#).

Traditional methods, such as ventriculography, of very limited (gross anatomic pathology) and somewhat dangerous nature, have now given way to exciting developments even beyond computed tomography (CT) and magnetic resonance imaging (MRI). New tools that test brain function rather than inform about anatomic structures are revolutionizing the research on brain and behavior ([Chapter 9](#)). These new tools include functional MRI (fMRI) ([Eden and Zeffiro, 2000](#)), MRI ([Yurgelun-Todd and Renshaw, 2000](#)), MEG ([Rojas et al., 2000](#)), and the much more cumbersome PET ([Kuperman et al., 1990](#); [Herscovitch and Ernst, 2000](#); [Martin and Brust, 1991](#)) and single photon emission computed tomography (SPECT) ([Herscovitch and Ernst, 2000](#)). More emergent techniques include optical imaging ([Frostig et al., 1990](#)) and transcranial magnetic stimulation (TMS) ([Pascual-Leone et al., 1999](#)).

All these new methods are beginning to be used in an organized and logical fashion that offers promise in unveiling neural mechanisms mediating psychopathology. However, many challenges still need to be overcome, encompassing technical limitations, adequate theoretical models, and most important in research in children, ethical issues ([Arnold et al., 2000](#); [Ernst, 1999](#)). Despite all these new methods of studying the human brain, so far the clinical yield in child psychiatry has not been too impressive, except: (a) what it has ruled out as causes, (b) in demonstrating the role of neurodevelopment in the expression and changes over time of psychiatric symptoms, and (c) for clear indications that the role of brain factors in etiology of psychopathology is probably much more extensive than formerly believed ([Berthier et al., 1993](#); [Ernst and Rumsey 2000a](#); [Hendren et al., 1991](#); [Kuperman et al., 1990](#); [Leckman et al., 1992](#)).

## NEUROPSYCHOLOGY

Child psychiatry has had a long association with neuropsychology, since at least the days of [Strauss and Lehtinen \(1947\)](#). There is good reason for this, namely, the close relationship between school and clinic and the common association of behavioral and learning problems. Neuropsychology is now an advanced science typified in texts such as [Hynd and Obrzut \(1981\)](#), [Kolb and Whishaw \(1980\)](#), and [Lezak \(1995\)](#), to name but a few. Although such tests are extremely helpful in the assessment of major neurologic brain disorder, their role in most of the problems seen in child and adolescent psychopathology have been controversial at best ([Feagans, 1983](#); [Taylor, 1991](#); [Werry, 1986](#)). Much of the problem lay in the unknown reliability and validity of the tests in the detection and localization of brain disorders. Often they seem to have acquired a quasineurologic status that they may not deserve, especially in the area of learning disabilities ([Feagans, 1983](#); [Werry, 1986](#)).

However, with the advent of functional neuroimaging and techniques of cognitive activation, the neural substrates of many of the classical neuropsychological tests are now being better delineated. Impaired performance on these tests can now more clearly suggest dysfunction in specific brain regions or neural networks. In fact, neuropsychological testing paired with functional neuroimaging is becoming one of the more powerful strategies to study and understand the neural substrates of cognitive and emotional processes in health and disease.

This is not the way they are used in most clinical practices—yet. A recent review ([Halperin and McKay, 1998](#)), for example, points out that there is a common misconception, that large differences in verbal and performance IQ are pathological, whereas more than half the children in the standardization of the sample for the Wechsler Intelligence Scale for Children III (WISC III) had discrepancies greater than 9 points and about 25% greater than 14 points ([Wechsler, 1991](#)).

Projective testing (e.g., Rorschach) has undergone a resurgence of interest too because of supportive reliability and validity studies and the development of systematic ways of administration and scoring the Exner Comprehensive System.

In summary, neuropsychological testing remains an important adjunctive source of information for clinicians and researchers, but caution is needed in using these as indicators of brain function, especially localized brain function.

## BIOCHEMICAL AND PHARMACOLOGIC STUDIES

Again, this is a rapidly developing area. The past tendency to rely primarily on the passive analysis of blood, cerebrospinal fluid, and other body fluids has been improved by the use of active chemical probes of function analogous to the increasing use of evoked potentials in the electrophysiology field. The most useful instruments for this probe are pharmacologic substances, ever-increasing in number and specificity. This is well illustrated in modern theories of schizophrenia and major depression and in child psychiatry, of autism, Tourette's disorder, and ADHD ([Zametkin and Rapoport, 1987](#)) ([Chapter 4](#)).

However, there are limitations to this approach: Few drugs or their target receptors are specific to one functional area or system. The complex interactive nature of brain function, with the convergence of many different pathways at the effector level, may result in confusion of downstream or compensatory effects for the primary disturbance. Some of these may be responsible for the fact that the biochemical theories of schizophrenia and depression do not seem to have advanced much because the cellular actions of the drugs used in their management became known more than 30 years ago. Currently, the use of pharmacologic challenges has fallen somewhat out of favor as the newer neuroimaging techniques (e.g., MRS, PET, SPECT) permit direct probing of biochemical processes in the brain.

## GENETIC STUDIES

Good summaries of this area can be found in reviews by [Kreusi \(1990\)](#), [Propping and Hebebrand \(1990\)](#), [Shields \(1980\)](#), and [Chapter 1](#). The most important methods are family pedigree studies, twin studies, and naturally occurring experiments such as chromosomal abnormalities. The finding of some genetic role in the etiology of behavior cognitive disorders such as autism ([Propping and Hebebrand, 1990](#)), ADHD ([Goodman and Stevenson, 1989b](#)), or Tourette's disorder ([Leckman et al., 1992](#)) permits an inference that the brain is affected either directly or indirectly.

In the last few years tremendous strides in molecular biology have opened up the possibility of converting these assumptions into direct causative relationships. The best example of this is Huntington's disease, where the genetic location has been established, although not the precise biochemical mechanism. However, the past 10 years have been most notable for conceptual advances as opposed to such actual breakthroughs in the localization of genes that specifically account for syndromes or behavior.

The initial enthusiasm for molecular genetic approaches has now been tempered by the growing realization that most of the neuropsychiatric syndromes in child and adolescent psychiatry will be the result of multiple genetic effects as opposed to single genes, by risk factors rather than direct effects and nonshared environmental influences. Fortunately, exciting, complex new methodologies will facilitate such study.

## Summary

Methods of studying brain function and critical influences on it are developing rapidly and to most of us, dauntingly and bewilderingly. They show great promises but, although individually often alluring and sophisticated, still have a long way to go before they can help in pinpointing any role brain function might have in understanding and treating the complex dysfunctions seen clinically. Additionally, there are specific issues relating to children. Many of the indicators of brain dysfunction so useful in adults represent loss of function, whereas in children, the problem is one of failure to develop a function (e.g., enuresis) or, more commonly, slower or imperfect development (e.g., motor incoordination or dysphasia). Put another way, abnormality is often developmental or chronological and quantitative rather than qualitative. In this context it is hard to know whether the "abnormality" is merely a lag in development, a developmental variation (that can have experiential as well as physical causes), or a true abnormality. For example, it is said that both Einstein and Churchill began to talk very late, yet clearly, they had very good brain function. Or again, many of the so-called soft neurologic signs, such as sensorimotor incoordination, are, in fact, merely the kinds of function seen in somewhat younger children (or immaturities), and their status as true neurologic indicators is unclear ([Tupper, 1987](#)) ([Chapter 44](#)).

## BEHAVIOR

## Classification of Behavior

So far the talk has been largely of the brain. Now discussion moves to behavior, defined in the broad way of child psychiatry to encompass all activity of the organism beyond simple physiologic functions necessary to sustain life. There are certain conventions in classifying brain functions that offer a point of convergence with the behavior side of the brain–behavior equation. The neurologic view, derived largely from the study of disease and the ability to detect these diseases with simple clinical examinations, has typically been input (sensation/perception), output (motor), and in between (association). The latter, being much more complex and less reachable, has remained more elusive to study, yet this is the area of greatest interest to psychiatry. Neuropsychiatry has therefore developed somewhat different classifications, which are more dissected, more functional, less topographic, and more oriented to psychological theory, although compatible with the neurologic view. One of these taxonomies of behavior is as follows ([Lezak, 1995](#)).

1. Information processing or intellectual function, further subdivided into receptive function (acquisition, processing, classification, and integration of information); memory and learning (storing and recall of information); thinking (organization and reorganization of information); and expressive functions (communication and enacting of information). Mental activity, although closely allied to intellectual function, is not considered a basic function because it has no clear behavioral end product but is concerned with the efficiency of intellectual function, including attention, level of consciousness, and activity rate or speed.
2. Emotionality (feelings, motivation). This is one of the traditional domains of psychiatry, although some of the previously popular theories, such as Freud's, still require scientific validation.
3. Executive and control functions. These are capacities that enable a person to engage in independent, purposive, self-serving behavior successfully ([Lezak, 1995](#)). A survey of these three areas shows how germane they all are to child and adolescent psychiatry and how artificial are divisions among child psychiatry, pediatric neurology, and neuropsychology. If psychiatry can claim any particular specialization within this area, it must be to whole organism function, but even that is an artifact of poor medical practice, which has aimed to separate patient from illness, mind from body. However, it would be idle to claim that this classification of behavior is complete or satisfactory for much that concerns child psychiatry because it is essentially intraorganismic and pays little credence to the context in which behavior occurs, the stimuli that elicit it, or its social interactive, systemic, or developmental properties ([Shaw and Bell, 1993](#)).

## Development of Behavior

In view of extensive coverage in Section C of this volume, it is unnecessary to do other than summarize the main principles of child development here. If one tried to isolate the main themes in development, they would include the following:

### *LOSS OF STEREOTYPED REFLEXIVE BEHAVIOR*

The neonate and young infant have a series of preprogrammed behaviors, many necessary for survival, such as the rooting and sucking reflexes, which are lost in a few months. Other studies, particularly by ethologists (e.g., Bowlby), have identified other reflexes, such as stranger and separation anxiety, that prevent the newly mobile immature organism from straying from protecting caretakers, or the smiling reflex, and have shown how these initially automatic reflexes become the basis of socialization as they lose their automaticity. Compared with most other species, the human baby has relatively few of these automatic behaviors, and it is thought that this is because this places fewer obstacles in the way of the rapid development of complex and flexible behaviors, such as most intellectual and social function.

However, there is still considerable debate as to precisely how much of behavior, especially in infants and younger children, is deterministic; for example, the exact role of temperament and gender differences ([Chapter 14](#), [Chapter 15](#)).

### *DIFFERENTIATION OF BEHAVIOR*

Throughout development, there is a movement away from gross, poorly targeted behavior involving most of the organism toward highly specialized, focused activities. Examples of this progression can be seen in motor behavior, from the whole body, flailing behavior of the infant to the finely coordinated activities of the watchmaker or musician. But this is equally true of every subcategory of intellectual, executive, and emotional behavior, although perhaps least striking in the latter.

### *INTERNALIZATION OF BEHAVIOR*

Impulsive gross motor or emotional reactions to stimuli decrease in frequency because more and more behavior occurs unseen, as incoming and self-generated information is processed internally by thinking, as developmental epistemologists such as Piaget have described. But this is also seen in the gradual reduction in motor activity level (and hence of hyperactivity) throughout childhood.

### *HIGHER-ORDER CONTINGENCIES*

More and more, behavior becomes governed by a set of complex rewards and punishments—problem solving, intellectual/aesthetic satisfaction, and, above all, social responses—and less and less by primary self-survival needs. Both behaviorists and psychoanalysts, among others, have described this process in their developmental theories. The pace of this development varies with the function. For example, the acquisition of language and vocabulary between the ages of 1 and 3 years is truly astounding ([Howlin, 1980](#)), as is the acquisition of reading skills at the start of school, whereas the process of intellectual development outlined by Piaget occurs more gradually. As a general rule, the more complex the function (e.g., social behavior; very finely coordinated motor skills, as in violin playing), the longer the process as such is likely to be. Of course, too, the pace begins to decelerate and ultimately even reverse as adult life proceeds to its inevitable conclusion.

It is also apparent that many primitive or immature levels of behavior do not disappear completely. It is not only the infant who has temper tantrums or who will ignore any rights of others in egocentric pursuit, but also these would be expected to emerge in most adults only in disaster situations or when the power of the brain is diminished because of such influences as alcohol intoxication or dementia.

## BRAIN AND BEHAVIOR

Having described both brain and behavior, now it is time to try to relate the two to each other and look at their interaction.

### **Brain Anatomy and Behavior**

One approach to the question, “How do we know the brain affects behavior and in what way?” is to look at the relationship between brain anatomy and behavior. Much of the knowledge applicable to humans in this area is understandably derived from disease or other abnormal states, for the very good reasons that animal work has limited extrapolation, and studies of normal function are more difficult to relate precisely to brain function. The problem is even more difficult with children and adolescents whose brains are still immature, and the ways of relating any deviations in development to brain states are handicapped by the lack of good information about exactly what is truly abnormal and what is simply within normal variation.

### *GENERAL PRINCIPLES*

Comparative anatomic studies show that the amount and complexity of brain development, especially in the cerebral cortex, is closely related to the complexity of behavior, both reaching their highest development in the human species. There are strong parallels between the developmental state of the brain and the development of behavior in humans, especially in early childhood. At birth, the cerebral cortex consists of small, underdeveloped neurons, with few dendrites, especially in the newer parts of the brain ([Casaer, 1993](#)). The process of dendrite differentiation and axonal myelination occurs rapidly during the first few years, although it continues to a diminishing degree into adult life. The brain and certain specific behaviors can be seen to be topographically linked in animal experiments, and in humans, not only in disease states but also in normal development. For example, the smiling response in infants coincides with the myelination of the visual cortex ([Casaer, 1993](#)). The linkage is closest for simple input and output functions. Complex functions such as thinking involve many parts of the brain and, further, are subject to the principle of parallelism of functions discussed in the preceding. This means that topography is less well defined in these behaviors in development and disease states, although still discernible at times. For example, recent brain imaging studies in children have shown that anatomic development generally matches what would be expected from known child development. For example, there is a rapid growth up to puberty in areas subserving highest functions: frontal networks (executive planning), corpus callosum (communication between hemispheres), and association and language areas with loss of some tissue in more

primitive areas such as subcortical gray matter. This rapid development, nonetheless, is not even throughout the brain and continues later in some areas (temporal lobes subserving memory and emotion, and occipital cortex concerned with vision). Much function is asymmetrical, and this asymmetry is reflected in anatomic asymmetry ([Davidson and Hugdahl, 1994](#)). For example, the left hemisphere, which subserves much language function, is heavier than the right in most individuals, especially males, with those areas concerned specifically with language being larger in the dominant hemisphere than in the nondominant hemisphere. On the other hand, areas concerned with visuospatial function, subserved largely in the nondominant hemisphere, are larger there than in the dominant hemisphere ([Lezak, 1995](#)).

### **Brain Topography and Behavioral Function**

The precise relationship between specific brain areas and behavior is now reviewed. Much of what follows is set out in [Lezak \(1995\)](#), Lishman ([1987](#), 2000). In child psychopathology, the reviews by Lewis ([1992](#)) and Taylor ([1991](#)) are among the most germane in trying to relate topography to behavior. Only those areas concerned with higher functions are discussed. A word of warning is needed though. Most of the data come either from animal studies or, in humans, brain disorders in adults when differentiation of function is long established. It is not clear how true the findings are of children, especially when the damage occurs very early in life when there is greater opportunity for utilization of alternative pathways and also development of alternative adaptational behaviors ([Taylor, 1991](#)). However, data from neuroimaging research is rapidly updating the knowledge gained through animal and human studies. Although research in children using these new techniques is still lagging behind research in adults, it is increasing and will give a much better understanding of brain and behavior in child development and psychopathology.

#### *DIENCEPHALON*

This is the only midline structure to be discussed and includes the thalamus and hypothalamus. The thalamus is the Grand Central Station of sensation, through which sensory information passes on its way to the cortex and allied nuclei, but there are also important return circuits. It is involved in sensory processing (crossed), local sensorimotor integration, memory, emotion, attention, and alerting. Deficits associated with thalamic lesions are less absolute than are subtle but important impairments, such as a decrease in verbal fluency (left-sided deficits) and difficulty with pattern recognition (right-sided deficits). As is well known, the hypothalamus is concerned with autonomic and endocrine functions and thus is intimately involved in the expression of emotion (including stereotyped responses such as rage) and motivational states such as sexual drive and aggression ([Lewis, 1992](#)).

#### *CEREBELLUM*

In the past 5 years, not only has much been uncovered about the function of this large area of the brain by technical advances in neuroscience, but also there has been a conceptual shift away from earlier more narrowly focused views of the cerebellum as an organ primarily involved with posture and voluntary movement ([Middleton and Strick, 1998](#)). The cerebellum is intimately involved in such diverse activities as motor learning, adaptive plasticity, central timing (the ability of an organism to measure time, for example, in delay responding) motor and nonmotor aspects of behavior, especially context-dependent and adaptive responses and even cognitive processes such as working memory, learning, and language now appear to be involved ([Middleton and Strick 1998](#); Thach, 1996; Thompson, 1986).

#### *BASAL GANGLIA*

These modulate motor and some autonomic functions by varying tone and producing synchrony of movement but are also involved in intellectual functions too, especially the maintenance of attention. Their function is probably better described as one of generally maintaining and regulating motor and information flow and cerebral activity through reverberating circuits between cortex (especially the frontal region) and basal ganglia. Indeed, the basal ganglia has been shown to play a role in a variety of neuropsychiatric conditions involving motor and attentional dysfunctions ([Mega and Cummings, 1994](#); [Peterson et al., 1998](#); [Rauch and Savage, 1997](#)). These diverse functions are proposed to be subserved by five functionally interconnected subcortical regions: caudate nucleus, putamen, globus pallidus, subthalamic nucleus, and the ventral mesencephalic dopamine system. In addition, as many as five parallel basal ganglia thalamocortical circuits have been proposed ([Alexander et al., 1986](#), [Alexander et al., 1990](#)) to convey the output of these subregions through specific thalamic zones to different parts of the frontal cortex. Impairments here are most easily demonstrated in the classical movement disorders of parkinsonism, athetosis, chorea, and dystonias, but disorders of intellectual function are also seen in basal ganglion disorders. In parkinsonism, there is rigidity of attention and inflexibility of cognition, qualitatively rather similar to the motor disorder ([Lezak, 1995](#)). Perhaps of more interest to child and adolescent psychiatrists (apart from drug-induced parkinsonism) is OCD. Although ordinarily thought of as an anxiety disorder, OCD has strong cognitive components that exhibit some of the same kind of rigidity seen in parkinsonism, except that in this case the rigidity is not one of tone but of a circularity or positive feedback loop of thinking. But just as parkinsonism has both motor and cognitive components, so has OCD at times, in the well-known concurrence of obsessive thinking in Tourette's disorder and postencephalitic parkinsonism ([Leckman et al., 1993](#); [Rapoport, 1988](#)). It is therefore not surprising that recent research suggests that in OCD there may be an abnormality of the circuit between the frontal lobes, basal ganglia, and thalamus ([Cohen and Leckman, 1994](#); [Rapoport, 1988](#)). Recent findings suggest that even ADHD, which equally is characterized by both motor and cognitive impairments, may involve primary dysfunction of the basal ganglia ([Ernst et al., 1998](#)).

#### *THE AMYGDALA*

These are bilaterally paired nuclei deep within the cerebral hemispheres and in close relationship with the older olfactory brain. Not surprisingly, their strongest topographical link is to fear-provoked aggression ([Lewis, 1992](#)). But, as with the basal ganglia, lesions of the amygdala have more widespread effects—disturbances of control, spontaneity, and flexibility of affect and cognition. Its importance in child psychiatric disorders is not well recognized, despite its role in disorders of reward mechanisms, such as substance abuse and eating disorders, and probably in anxiety disorders.

#### *WHITE CEREBRAL MATTER (LARGELY FIBERS)*

This consists primarily of three types of fibers: association fibers, linking parts of the cortex together; commissure fibers, connecting the hemispheres; and projection fibers, linking cortex to distant parts. The effects of disorders of association fibers depend on the tightness of the fiber organization, the specificity of the function, and the extent of the lesion. For example, lesions of the tightly bound left arcuate fasciculus linking Broca's area (frontal) and Wernicke's area (parietal) produce construction aphasia in which the patient understands and expresses language well, but cannot repeat phrases accurately and tends to use inappropriate words ([Kandel, 2000a](#)). In most instances, however, damage to the association areas results in subtle defects of integration of higher function between the areas affected and, as a consequence, a more general, less specific type of impairment ([Lezak, 1995](#)). Abnormalities and lesions of the corpus callosum are often surprisingly silent ([Taylor, 1991](#)), perhaps because of alternative and possibly more usual vertical interconnections through the thalamus. However, neuropsychological tests show that slowing and some impairment of tasks that rely on integration of functions between hemispheres is often present. On the other hand, projection fiber lesions such as those of the internal capsule are likely to have predictable and obvious results, such as hemiplegia, because most are involved in highly specific point-to-point representation.

#### *Cerebral Cortex*

Lezak ([1995](#)) points out that cortical functions can be thought of as roughly organized along two dimensions: lateral (left/right) and frontal/posterior. However, it is important to state early on that this oversimplified topography becomes inaccurate when the function concerned involves much of the brain as PET scans have shown is often the case, especially in any complex or novel task ([Martin and Brust, 1991](#)). Currently, the most frequently used taxonomy of brain function is that of Brodmann, which identifies regions by their functional organization rather than their anatomic localization ([Talairach and Tournoux, 1988](#)).

### **Asymmetric Functions**

In addition to similar but crossed primary sensory and motor functions, both hemispheres have specialization of function. In general, the left or dominant hemisphere is concerned with verbal and language functions, and this includes the storage of such information in the memory systems of the temporal lobes. The right hemisphere is concerned with nonverbal, including spatial, information. But these distinctions are not absolute, and the idea of dominance itself is misleading because specialization of function in each hemisphere is more accurate ([Taylor, 1991](#)). For example, the "poor relation" right hemisphere may actually be the one that enriches brain function and experience in general. For example, much of the melody of speech, humor, lateral or intuitive thinking, imagination, artistry, and music, and the visuospatial aspects of mathematics may be quite dependent on the nondominant or right hemisphere, as may attention itself. There are gender differences in right and left hemispheric organization, primarily, in females, later developing and less marked laterality (e.g., of language functions) that is accompanied by less marked morphologic differences in the two hemispheres ([Kelly, 1991](#); [Lezak, 1995](#)). At a functional level these differences are also matched by differences in the cognitive styles of men and women—men are better at advanced mathematics, less verbally fluent, and better visuospatially, although these anatomic, organizational, and functional differences are relative, and there are large areas of overlap between the two sexes ([Lezak, 1995](#)). How these gender differences arise is still a mystery.

The politically fashionable view is that these are the result of socialization; but there is now clear evidence that there are gender differences in endocrine secretion beginning early in fetal life ([Peterson et al., 1992](#)) when the brain is first developing and that these are related to sexual dimorphism in the brain ([Lewis, 1992](#)) although what relationship these have to nonsexual behavior is unclear. In child psychiatry, one of the more durable areas involving asymmetry of function is that of learning disorders, where failure to develop asymmetry is posited to lie behind some cases of dyslexia ([Duane, 1989](#)), although considerable skepticism about this rather durable theory is needed because reading is a most complex process ([Snowling, 1991](#)). Proof of this lies in recent studies examining morphology in this disorder with MRI and autopsy that suggest unilateral changes in the insula and surrounding areas with less interest in the asymmetry. (The insular cortex is lateral to the globus pallidus but deep to the temporal cortex [[Kandel, 2000b](#)].)

#### *Frontal/Posterior Dimension*

The frontal lobes are most concerned with motor and executive functions such as speaking, organizing, and planning complex activities. Defects lead to aphasias, certain kinds of apraxias (inability to plan and execute sequences of movements such as dressing), deficits of attention, and the planning and execution of complex behavior ([Lezak, 1995](#); [Rothenberger, 1990](#)). The parietal, occipital, and parts of the temporal lobes have largely sensory functions, including complex interpretations of sensory data in light of experience and integration of these data across modalities. Deficits here lead to agnosias and receptive aphasias.

#### *Temporal Lobes and the Limbic System*

These are of special interest in psychiatry because of their well-demonstrated emotional and memory function, but they also have sensory functions associated with visceral sensations, olfaction, hearing, and speech. Organizationally, they have close links to midline structures concerned with emotional expression (e.g., the hypothalamus) and memory (e.g., the nucleus basalis of Meynert) ([Cote, 1991](#)), as well as to the cortex as a whole. Stimulation of this region during surgery or by an irritable focus can produce schizophrenic-like positive symptoms such as déjà vu and visceral or other hallucinations, giving strength to the postulate that dysfunction of the left temporal lobe is involved in schizophrenia ([Crowe, 1990](#)). Destructive lesions can result in negative symptoms or deficits (e.g., amnesias) and agnosias (e.g., impaired sound discrimination, amusia, and receptive dysphasias). Emotional disturbances of blandness similar to the negative states of schizophrenia or of poor regulation (e.g., irritability, panics, anxiety, obsessions) are also characteristic.

#### *LONGITUDINAL SYSTEMS*

The most important one for psychiatry is the reticular system of the more rostral brain stem, which has projections throughout the cortex. This system is much more complicated than originally thought, containing homeostatic, postural, activating (noradrenergic), and incoming information-modulating (serotonergic and dopaminergic) sections ([Kelly, 1991](#)).

#### **Factors Affecting Brain and Behavior**

More detailed discussions appropriate to each disorder and brain damage syndromes in general can be found elsewhere in this book and in other reviews ([Gudex and Werry, 1990](#); [Kreusi, 1990](#); [Rutter, 1981](#), [Rutter, 1982](#); [Taylor, 1991](#); [Werry, 1986](#)). Here, discussion is restricted to factors that have general effects on brain-behavior relationships or that illustrate particular points. Much of what follows relates to major brain abnormalities and hence should be applied with caution to lesser or more uncertain lesions or normal states. The caveat about the validity of these largely adult-derived data in children also applies.

#### **Localized Versus Generalized Damage**

Lipowski ([Gudex and Werry, 1990](#)) has classified brain-behavior syndromes as partial (or localized) and generalized, and this typology has been applied to organic brain disorders in children ([Gudex and Werry, 1990](#)). The amnesic disorders and some types of personality change owing to a general medical condition (e.g., frontal or temporal lobe syndromes) are examples of partial disorders, whereas dementia and delirium are examples of generalized syndromes.

#### **Partial Syndromes**

In child psychiatry those of particular interest are the so-called “temporal lobe” syndromes of explosive, aggressive behavior said to be associated with temporal lobe epilepsy or inferred to represent temporal lobe dysfunction from the behavior itself or its putative response to anticonvulsants ([Kandel, 2000a](#)). The validity of this syndrome is still disputed, especially in children ([Hermann and Whitman, 1984](#); [Kreusi, 1990](#); [Lewis et al., 1989](#); [Rutter, 1981](#)), and although there were allusions to it in Diagnostic and Statistical Manual (DSM)-III in the text, it does not appear in DSM-IV, where classifications of personality change owing to medical conditions are defined strictly behaviorally rather than etiologically. However, the idea is not such as likely to die so easily. (See [Taylor, 1991](#).) A number of psychiatric disorders, such as developmental language (right temporal lobe), learning and motor skills disorders ([Duane, 1989](#); [Feagans, 1983](#); [Silver, 1989](#); [Taylor, 1991](#); [Werry et al., 1990](#)), and ADHD ([Rothenberger, 1990](#); [Taylor, 1991](#); [Zametkin and Rapoport, 1987](#)) can be considered localized or partial syndromes. For example, brain imaging techniques suggest a dysfunction of frontobasal ganglia circuits in ADHD ([Castellanos, 1997](#); [Schweitzer et al., 2000](#)), OCD and Tourette’s disorder ([Cohen and Leckman, 1994](#); [Peterson et al., 1998](#); [Rapoport, 1988](#)), and of the temporal lobe in panic disorder ([Kandel, 2000a](#)), whereas schizophrenia seems to have both temporal and frontal lobe deficits ([Weinberger, 1995](#); [Werry and Taylor, 1994](#)). So far, these are only isolated findings, and conclusive evidence of localized or partial syndromes in child psychiatry remains elusive, although newer neuroimaging research in general is supportive of defined functional neural networks and areas.

#### **Generalized Syndromes**

In contrast to syndromes in adults, generalized syndromes such as dementia and delirium, so topical in adult psychiatry, are little studied in children ([Gudex and Werry, 1990](#); [Volkmar, 1992](#)). In adults, generalized brain disorders are marked by decline in all higher functions, although the precise pattern depends on how much and which parts of the brain and which localized functions are affected as well ([Albert, 1981](#)). In child and adolescent psychiatry, degenerative disorders are rare, and greater interest centers on mental retardation, the effects of anoxia at birth, and postnatal head injury. It seems logical to expect that, as in dementia, there should be a general reduction in the overall number of neurons. In Down syndrome, brain size is reduced by about 25% (although interestingly this is not true until ages 3 to 5, suggesting a failure of the brain to develop), and there is also a reduction in the complexity of convolutions so essential to accommodate the increased number of neurons and processes in the human cerebral cortex. At a microscopic level, there appears to be little localization of pathology ([Propping and Hebebrand, 1990](#)); all this suggests that severe mental retardation can be viewed as a generalized syndrome. Whereas gross brain damage/disorder occurring prenatally or perinatally can result in mental retardation, long-term follow-up studies suggest that the effects of the much commoner milder degrees of anoxia are difficult to detect after the first few years of life, when the compensatory effect of a felicitous environment seems to override the more obvious effects of generalized brain damage ([Rutter, 1981](#); [Werry, 1986](#)). More subtle, difficult to detect effects such as attentional and learning disorders remain a strong possibility ([Feagans, 1983](#); [Taylor, 1991](#)); most such learning disorders would be localized, not generalized, syndromes ([Duane, 1989](#)). Head injuries ([Chapter 33](#)) ([Guthrie et al., 1999](#); [Homer and Kleinman, 1999](#); [Lam and MacKersie, 1999](#)) in children and adolescents are frequent—40,000 in the United Kingdom in 1985 ([Middleton, 1989](#)), and approximately 2 million in the United States as of the early 1990s, with 56,000 deaths at all ages ([Kraus and McArthur, 1996](#)). Individuals with head injury provide opportunities to study brain-behavior relationships in a generalized context because, in addition to local and contrecoup lesions, head injury often produces widespread permanent microscopic effects ([Lezak, 1995](#); [Taylor, 1991](#)) as a result of acceleration and torsion effects. Such generalized effects in adults are well described and can be summarized as a decline in mental efficiency affecting attention, speed of mental processes, cognitive efficiency, and, when severe, high-level intellectual functions such as abstract reasoning. In turn, this often is accompanied by irritability, fatigability, and loss of initiative ([Lezak, 1995](#)). In children, in addition, there is evidence that the risk of development of any psychiatric disorder is increased, suggestive of some general effect ([Taylor, 1991](#)) ([Chapter 33](#)). Data on children are less extensive, although Mittenberg and associates (1997) showed that when assessed in a similar manner to adults, postconcussion syndrome is equally similar. Fortunately, severe injury is infrequent in children and adolescents, most of the injuries are mild, and better treatment of the behavioral and neuropsychological problems is appearing. Although [Middleton \(1989\)](#) criticized the widespread belief that mild injuries are without long-term sequelae, recent reviews ([Lord-Maes and Obrzut, 1996](#); [Satz et al., 1997](#)) are more optimistic in that most better studies showing no abnormal findings. However, it is best to keep an open mind for the moment. Much of the more recent work in adults has shown that the postconcussional changes are detectable for several months after even a mild concussion ([Middleton, 1989](#)), suggesting a significant immediate impact. In children the effects are similar but development of the brain continues into adolescence, and there is a change in the relative importance of areas of the brain toward those concerned with higher levels of cognitive function. Thus there may well be “sleeper,” or delayed, effects that become apparent only later. In summary, then, generalized brain disorder probably results in generalized cognitive and behavioral changes, of a degree and permanence depending on the amount involved. However, the brain seems to have some capacity for recovery, especially in the long term. Much more controversial are other possible generalized (or localized) brain-behavior syndromes that are not owing to frank brain pathology but to normal variations such as temperament and certain behavioral traits such as high activity or sociability. Much of the research in this area depends for its biological underpinnings on genetic studies, especially of twins ([Garrison and Earls, 1987](#)). For example, the studies by [Goodman and Stevenson \(1989b\)](#) suggest that activity level has a strong genetic base (50% of the variance) and that even

anxiety/withdrawal and somatizing traits may also have some hereditary base ([Goodman and Stevenson, 1989b](#)). In the end, genes operate through specific cellular effects, and the brain seems the most logical vehicle if temperamental and personality trait variations are biologically influenced.

## Age

Age is of critical interest in child and adolescent psychiatry. One of the more durable beliefs about brain–behavior relationships is that of plasticity; the effects of any abnormalities of brain structure or function are said to be less serious the younger they occur. But there is an equally durable but opposite view that there are critical periods for the development of normal function, which, if missed or impaired, result in permanent disabilities. This is best illustrated by strabismus, which, if not corrected in the first few years of life, results in amblyopia. There is evidence to suggest that the popular idea that younger age reduces the risk of severity or durability of disability may well be false ([Fletcher and Satz, 1983](#); [Middleton, 1989](#)). Further, the notion of sleeper, or delayed, effects emerging only later as a function of development of more complex cognitive and other brain functions must be borne in mind. In his review, [Taylor \(1991\)](#) expresses concern about the failure of neurologists, child psychiatrists, developmental psychologists, and others to get together on this issue, pointing out, for example, that most of the best studies of head injury were done more than 20 years ago and before modern brain imaging techniques could pinpoint the amount and location of damage so critical to meaningful study.

## Gender

Nearly all the putative brain–behavior syndromes in children, such as ADHD, learning and developmental language disorders, autism, schizophrenia, and Tourette's disorder, have appeared markedly in excess in boys. This may well reflect the sexual dimorphism of brain anatomy and development ([Peterson et al., 1992](#)) discussed in the preceding under Asymmetrical Functions, such as, in females, later and less complete development of dominance, lesser differences in size between right and left hemispheres, and/or in males, greater vulnerability to damage ([Kelly, 1991](#)). Also interesting is animal and clinical research on disorders such as Turner's syndrome and on androgen sensitivity in the development of sexual preference and gender identity ([Zucker et al., 1999](#) and [Chapter 58](#)), and developmental research on other kinds of behavior, such as aggressiveness or activity level, that are observed to be different in the two sexes ([Goodman and Stevenson, 1989a](#); [Lewis, 1992](#)), even early in life ([Garrison and Earls, 1987](#)). Research into gender identity, sex-typed behavior, and sexual preference in animals and humans with chromosomal or endocrine anomalies such as Turner's syndrome or androgen insensitivity suggests that brain factors are influential, especially in the prenatal period ([Garrison and Earls, 1987](#); [Kelly, 1991](#); [Rutter, 1980](#)), but so are environmental factors, as shown in the controversial studies of “intersex” children (those with indeterminate anatomic gender at birth) ([Kelly, 1991](#); [Rutter, 1980](#); [Zucker et al., 1999](#) and [Chapter 58](#)). Nevertheless, the very early demonstration of sexual dimorphism (e.g., in androgen levels) in the fetus when the brain is first developing ([Peterson et al., 1992](#)) and clear differences in behavior (e.g., in activity level) in male and female infants suggest that brain–behavior relationships get off to a somewhat different start in the two sexes. How much they then diverge further or converge on the basis of experience is a most important and quite complex question that unfortunately seems to attract oversimplified polarization ([Zucker et al., 1999](#) and [Chapter 58](#)).

## Etiology

Although different etiologies produce different brain–behavior effects—for example, those of trisomy 21, head injury, and disorders of the temporal lobe all differ—there is good reason to posit that these differences will in the end be better explained by precise knowledge of the regions and functions of the brain affected and the pace and durability of any pathologic changes ([Rutter, 1980](#), [Rutter, 1981](#); [Werry, 1986](#)). Quite apart from the needs of treatment, it thus makes good sense to identify etiology as an important defining variable in brain–behavior relationships and to utilize what is known about the general and anatomic pathology (e.g., amount of extravasation, toxicity, and regional vulnerability of the brain) to generate hypotheses about brain–behavior relationships, and then to relate these to clinical facts. This is one of the main approaches in current neuropsychology, which increasingly eschews such global concepts as “brain damage,” dementia, intelligence, and so on ([Albert, 1981](#); [Lezak, 1995](#)); instead, etiology is seen as often having strong functional implications. However, [Taylor's \(1991\)](#) extensive critical review of etiology shows that in children this is full of methodologic complexities, few of which have characterized past studies, such as accurate delineation of areas of dysfunction (many of which are biochemical, not anatomic), precise and comprehensive measures of psychological function, and controlling for environmental and developmental effects

## Experience

It is probably unnecessary in child psychiatry to highlight the role of experience in shaping and modifying brain–behavior relationships. This review and others have given instances in which the outcome of any brain state or dysfunction has been demonstrated to be influenced by experience; for example, limbic dysfunction and violent behavior ([Lewis, 1992](#); [Lewis et al., 1989](#)), sexual preference and the reassigning of gender ([Kelly, 1991](#)) ([Zucker et al., 1999](#)), and the attenuation of long-term effects of perinatal anoxia ([Rutter, 1980](#), [Rutter, 1981](#); [Werry, 1986](#)). There is also no doubt that experience can produce permanent change in normal brain structure and function; that is what learning and long-term memory must be. For example, although the postcentral gyrus sensory map of the brain is basically similar in all humans, animal experiments have shown that this map can be changed quite significantly by immobilizing some fingers and exercising the others, or by sectioning a nerve ([Kandel, 2000b](#)). This process of “reassigning” brain areas seems to be a general property of the nervous system. At a cellular level, reassignment, learning, and memory are thought to be achieved to a significant degree by alteration of synaptic transmission—increasing or decreasing the sensitivity or effective number of active presynaptic release sites or postsynaptic receptors ([Kandel, 2000b](#)). The way that this is brought about is probably complex and not necessarily homogeneous. For example, the elaboration of dendritic processes would increase the number of receptors, whereas biochemical changes at any one synapse could result in changes in the ratio of active to inactive receptors. Considerable progress is being made in moving these conjectures toward fact, particularly in learning associated with emotion. For example, increased presynaptic neurotransmitter release following long-term potentiation (LTP) in the amygdala has been demonstrated. Even more intriguing, the basis for this LTP is owing to a gene and transgenic mice that overexpress the gene exhibit neither LTP nor fear conditioning. This has important implications for brain–behavior relationships, understanding why some children are temperamentally more timid and anxious than others, and for the interaction between brain and environment in the genesis of anxiety disorders. At a macroanatomic level, new brain imaging techniques are identifying those parts of the brain involved in memory and learning. Although some of this has confirmed the role of traditional structures such as the hippocampus and temporal lobes, they have also emphasized the role of other structures such as the prefrontal cortex and amygdala. They are also showing that there are many different kinds of learning and memory depending on the type, cues, and context and that different parts of the brain are associated with each.

As more is learned about the biological basis of learning and memory, especially emotionally laden memory, this may lead to innovative approaches to the core deficits seen in mental retardation as well as the milder more circumscribed learning disabilities. However, it would be naive to go as far as Flourens or Lashley (see “Concepts of Brain–Behavior Relationships” and [Kandel, 2000a](#)), or too many professionals working with children, to think that experience or retraining programs can overcome any or all brain dysfunctions ([Taylor, 1991](#)). It seems likely that certain regions of the brain where localization is well developed and not replicated and/or the amount of residual brain left after damage will limit the extent and scope of experience ([Taylor, 1991](#)).

## A Clinical Example

The clinical cogency of brain–behavior relationships and the principles outlined in the preceding are illustrated now with one brief example, Tourette's disorder, largely because it has some of the most elegant hypotheses of brain–behavior interactions among child and adolescent disorders. What follows is described in more detail later in this volume ([Chapter 59](#)) and elsewhere ([Cohen and Leckman, 1994](#); [Leckman et al., 1990](#), [Leckman et al., 1992](#), [Leckman et al., 1993](#); [Peterson et al., 1992](#)). Here the emphasis is on illustrating clinical relevance of principles, rather than the disorder itself.

The behavior that brings the patient with Tourette's disorder to the clinician is unwanted, involuntary, repetitive, purposeless, stereotyped motor and vocal acts (tics), which may take quite complex forms in severe cases and can be socially disabling. These acts are often preceded by premonitory urges ([Leckman et al., 1993](#)). The disorder is often accompanied by other behavioral difficulties of a disinhibited, impulsive, or obsessive-compulsive kind ([Chapter 59](#)).

Pedigree and twin studies have suggested that Tourette's disorder is the product of a single major autosomal gene, but that the frequency in identical twins is only 50% ([Hyde et al., 1992](#); [Leckman et al., 1990](#)). Also, the disorder is more common in boys, its severity varies across and within individuals, and there is an increased frequency of other disorders, notably OCD and ADHD in relatives.

These mostly clinical observations raise a number of questions that epitomize the nature of brain–behavior relationships in child psychopathology: What is the action of Tourette's disorder genes on the developing brain? Where do they act? What makes males more susceptible? What are the risk and protective factors determining whether or not, how severely, and which of the interrelated disorders appear clinically? How do these protective/risk factors operate on the brain? What is it that influences the day-to-day and minute-to-minute frequency of the symptoms in any one individual? Why does it take several years before the disorder emerges?

Although no definitive answers are yet available to any of these questions, there are some promising hypotheses and leads.

Simplistically, tic disorders (and OCD) seem to reflect neuronal circuits that reverberate instead of switching off—a failure to self-inhibit ( [Leckman et al., 1993](#)). Genes lay down the fundamental anatomic organization of the brain, and minor variations in this could lead to the propensity of some microcircuits to be driven by some ectopic or rogue pacemaker and/or to be over-readily excited by incidental brain activity. Research suggests that the anatomic substrate may lie in the cortico-striato-cortico-thalamic system that regulates the planning and performance of motor behavior ( [Leckman et al., 1993](#)). This could explain why the disorder manifests both cognitive (premonitory urges) and complex motor (tics) symptoms and also why there may be a particular somatic distribution to both ( [Leckman et al., 1993](#)).

The increased frequency in males is of interest because it is characteristic of a number of psychiatric (and physical) disorders and is intimately related to the controversial question of sexual dimorphism of the brain discussed in the preceding. There is now evidence that testicular hormones begin to be secreted as early as the eighth week of fetal life, at a time when the brain is undergoing its major initial development, and are thought to play a major part in sensitizing certain regions to sex hormones ( [Peterson et al., 1992](#)). The way in which this could predispose males to Tourette's disorder and induce it in childhood and adolescence as androgen secretion increases is outlined with supporting evidence in [Peterson and colleagues \(1992\)](#). The delays in onset of the disorder can be explained, in part, by this rise in secretion, but also by maturation and/or experiential realigning of brain architecture, which as already noted is most active during early life but continues at a negatively decelerating rate until death.

The development of the brain is also dependent on a continued optimum biochemical environment and this is vulnerable to disruption. Two such disruptive factors, maternal vomiting during the first trimester and maternal stress, were shown in one study to influence the severity of tics in those with established Tourette's disorder ( [Leckman et al., 1990](#)). Another risk factor, observed in identical twins, is lower birth weight ( [Hyde et al., 1992](#)), suggesting that the power of one twin to get a better share of placental nutrients is a factor in the impact of genes on brain development. Maternal drug, tobacco, and alcohol use are universal ambients also known to alter the fetal environment and fetal development, although their role in Tourette's disorder awaits clarification ( [Leckman et al., 1992](#)).

The influence of psychosocial variables in Tourette's disorder in postnatal life is widely assumed, but as in many other disorders, study of these variables would benefit from the same degree of rigor that now typifies biological studies—*anxiety and/or stress may precipitate or make tics worse and they may be suppressed for variable periods with effort and are more prominent in relaxed or drowsy states (Chapter 59)*. How these might work at a psychophysiological level needs clarification, although one obvious mechanism is through concomitant variations in neurotransmitters such as noradrenalin, dopamine, and serotonin (5-hydroxytryptamine [5-HT]) and neuropeptides, all of which have modulating actions on brain activity additional to any specific transmitter actions ( [Chapter 4](#)). In summary, Tourette's disorder illustrates how genes, gender, maternal stress, and uterine environment might alter brain microstructure and microorganization, making some individuals vulnerable to develop the disorder. The trigger for the emergence of the disorder might be the maturation of “capable” pathways, the rise of sex hormones, and as posited by Weinberger ( [1987, 1995](#)) for schizophrenia, development-specific stresses that activate at risk pathways. Temperamental variables that increase anxiety-proneness may also make individuals more vulnerable. Once the disorder is established, its severity is influenced by variations in levels in arousal, which in turn are influenced by what is happening to the child or adolescent on a moment-to-moment basis. The content of vocal tics reflects the child's learned vocabulary, and educational, supportive, and behavioral programs, suggesting that even presumptively biogenic mechanisms can be influenced to some degree by purely psychosocial variables. In the end, all factors—biogenic or psychogenic—operate through a final common brain pathway to express the disorder as clinicians recognize it.

Tourette's disorder illustrates the power of the biological substrate in this equation, but other disorders could have been chosen equally to illustrate the power of the environment. It is, however, not either/or, but a question of variation in the mix of these two factors and where current knowledge indicates therapeutic intervention may best be made. There is, however, a need in research on psychosocial variables to move beyond correlational studies, be cast more precisely, and be tied functionally to variations in brain function; otherwise, their credibility in this equation may be diminished, which would be most unfortunate.

## CONCLUSIONS

This chapter shows that the brain is an inordinately complex and wondrous mechanism. Its functions are both sharply localized and generalized, depending on the complexity of the function and the number of different regions of the brain necessary to that function. In a way, however, even the generalized functions seem composed of parallel or interacting localized functions so complex that they only seem generalized. Sharply localized functions such as speech or fine motor movements are vulnerable to disruption in disease states, but parallel function protects a lot of higher functions from greater devastation from disease or injury.

Development is a major variable, of relevance in terms of both brain morphology and the unveiling of complex functions. It also protects the brain before and during birth in that the undeveloped state of the cortex particularly makes it more resistant to pressure and anoxia ( [Werry, 1986](#)). Although much of the process of brain development is preprogrammed, inexorable, and with clear limits, experience plays a vital role, especially in more subtle aspects of morphologic and biochemical differentiation, shaping, and reshaping. The behavioral analog of this we call learning, which is a lifelong process, not confined to childhood or adolescence. Although there is now a large body of knowledge linking brain function and topography to behavior, much of this is derived from adults, animals, and disease states of little relevance to child and adolescent psychiatry. It does, however, enable hypotheses to be made about possible relationships and indicate meaningful lines of research.

As [Kandel \(2000b\)](#) points out, the separation of brain and behavior reflected in the divorce of neurology and psychiatry in the mid-20th century was owing largely to the limitations of our knowledge and becomes increasingly obsolete. Rapid developments in molecular biology, neuropsychology, and other neurologic and behavioral sciences are closing this gap, although this may be more apparent at a research and theoretic than at a clinical level. However, such is the pace of development of new knowledge that it is not too fanciful to predict that presumptively major brain disorders such as autism, OCD and Tourette's disorder, and schizophrenia will yield their secrets and cause a major shift in the focus and thinking in much of child and adolescent psychiatry because many of these disorders are neurodevelopmental, with origins in childhood or even fetal life. But this will be but part of the shift. Soon to be revealed too will be the biological (especially the polygenetic) basis of a major preoccupation of child psychiatry, variations of normal behavior/personality such as temperament, hyperactivity, anxiety threshold, and so on. Then doctors will surely be asked to change this or that characteristic in children, probably through pharmacologic or molecular biological means. Trained as they are in human biology in health and disease and steeped in the ethical traditions of medicine, child psychiatrists must accept the responsibility to serve as a bridge to knowledge about brain and behavior so that the clinical picture of the child may be fuller and richer, yet keeping the treatment always in the child's best interests as a unique human being.

The close of the last millennium witnessed the development and extraordinary growth of brain imaging studies in childhood neuropsychiatric disorders. Although initially lagging behind studies of adult disorders because of caution in applying new methodologies to the study of children, imaging studies of childhood disorders now have made tremendous strides in defining the neurobiological basis of these childhood illnesses. Imaging studies, in fact, arguably offer the greatest promise of improving our understanding of normal brain development and the neural bases of these complicated syndromes *in vivo*. This chapter first presents an introduction to contemporary imaging modalities and their contribution to our understanding of brain development in normal children. It then presents summaries of findings across a broad range of conditions, including preterm birth, autism, fragile X, velocardiofacial syndrome (VCFS), childhood-onset schizophrenia, attention deficit/hyperactivity disorder, obsessive-compulsive disorder (OCD), Tourette's syndrome, pediatric autoimmune neuropsychiatric disorders (PANDAS), mood and anxiety disorders, posttraumatic stress disorder (PTSD), and dyslexia.

## IMAGING MODALITIES

### Computed Tomography

The development and widespread application in the mid-1970s of axial computed tomography (CT) first heralded the advent of neuroimaging in neuropsychiatric disorders. It permitted noninvasive images of the brain and cerebrospinal fluid (CSF) tissues *in vivo* for the first time. Computed tomography scanning utilizes x-radiation, however, which has limited the use of CT in the research of childhood disorders.

In the acquisition of a CT image, an x-radiation source is physically rotated many times around the subject's head. The varying strength of the x-radiation that passes through the head, which is determined by characteristics of the tissue through which it passes, is then measured multiple times and at multiple angles through the cranium. Computer processing methods then reconstruct the image through calculation of attenuation coefficients for each portion of the brain, and those coefficients are then assigned intensity values, which produces light and dark areas (contrast) in the brain image. Contrast is the main determinant of our ability to discriminate different tissue types in an image. Tissue contrast is vastly inferior to that of magnetic resonance imaging (MRI), which accounts for the favored use of MRI in

neuroimaging studies. Computed tomography scan resolution is approximately 1 mm, although the imaging plane is limited to axial sections.

## Magnetic Resonance Imaging

Structural (or anatomic) magnetic resonance imaging (MRI) allows visualization of the size and shape of various brain regions, in fine detail and with exceptional contrast. Structural MRI scanning has been widely available clinically since the early 1980s, although the remarkable “resonance” property of certain nuclei when placed in magnetic fields had been known for decades prior to the first acquisition of MR images ( [Smith, 1998](#)). Hydrogen is among the nuclei that share this remarkable property, and the fact that it is the most common nucleus in biological tissues is what makes the imaging of brain tissue possible.

This is what is meant by the “resonance” of the hydrogen nucleus. Normally, the hydrogen nucleus spins at a particular frequency with its axis of spin pointed randomly in any direction. When placed in a strong magnetic field, however, this nucleus orients its axis parallel to the external magnetic field. In addition to its usual nuclear spin, the nucleus now also has another motion, that of precession around an axis parallel to the magnetic field, similar to a spinning top or gyroscope ( [Fig. 9.1](#)). While the strong magnetic field is maintained, a very brief radiofrequency magnetic pulse is then emitted from a coil apparatus around the subject's head. The frequency of the applied pulse is carefully chosen to be precisely the frequency that is most efficiently absorbed by the nucleus, its “resonance” frequency. This happens to match the frequency of precession of the nucleus; therefore, “resonance” refers to the absorption of radiofrequency energy by the nucleus at its particular precessional frequency.

**Figure 9.1.** Precession of nuclei occurs when certain spinning nuclei are placed in an external magnetic field. The precession occurs around an axis parallel to the lines of force of the magnetic field. When an appropriate external radiofrequency pulse is applied to the precessing nuclei, the magnitude of the precession increases, effectively tipping the nuclear spin axis toward the transverse plane perpendicular to the precessional axis and the lines of force of the external magnetic field. (Figure courtesy of Brad Peterson.)

Absorption of the resonant energy tips the spin axis toward a plane perpendicular to the precessional axis, in effect increasing the amplitude of the precessing motion. This “excited” nucleus then begins to tip its spin axis back toward the precessional axis, while continuing to precess because of the continued presence of the external magnetic field. The rate at which the nucleus realigns itself with the precessional axis is determined in part by its immediate physical environment, the nuclei surrounding it. The nuclear spin creates a small magnetic field in the nucleus that generates a small radiofrequency signal as the nucleus precesses. Thus, the scanner's radiofrequency pulse excites and tips a precessing nucleus, which produces a radiofrequency signal and which carries information about its unique physical environment in its rate of return toward its precessional axis. In effect, each precessing nucleus becomes a radio transmitter whose broadcasted signal specifies the location of the nucleus and nature of its immediate physical environment.

Highly specialized signal processing techniques are needed to discern this newly emitted signal and decode the information it contains about the excited, resonating nuclei. It is the development and application of these image reconstruction and processing techniques that made MR imaging possible and useful for quantitative studies. Image reconstruction techniques rely on Fourier analysis of the signal to transform into spatial coordinates—the many complex radiofrequency waveforms emitted by the excited nuclei. In addition to providing spatial coordinates of nuclei, these reconstruction methods must also provide signal intensity information that differentiates one nucleus from another. Without this information, spatial localization would simply provide a visually uniform map of hydrogen nucleus localization. Magnetic resonance images also provide intensity information, and hence intensity contrast between different portions of the image, based on the differing tissue environments experienced by the nuclei.

Magnetic resonance imaging techniques provide this information of tissue environment by measuring separately the spin component that is parallel to the precessional axis of the nucleus (and the external magnetic field), and another component that lies in the transverse plane perpendicular to that axis. These components vary in time as the excited, precessing nucleus returns toward its precessional axis, a process called “relaxation.” The time constant for relaxation along the axis parallel to the magnetic field is called “ $T_1$ ” and that within the transverse plane perpendicular to this axis is called “ $T_2$ .” These relaxation times vary according to the tissue characteristics in which the nucleus resides. The intensity value of each picture element (pixel) in an image depends on the timing of the MR measurement relative to the relaxation time constants. Hence,  $T_1$  and  $T_2$  are the major determinants of tissue contrast in MR images.

Because the tissue characteristics determine  $T_1$  and  $T_2$  relaxation times, different tissue characteristics can be emphasized on an MR image simply by varying the intensity values assigned to each combination of  $T_1$  and  $T_2$  times. Thus, the water content of CSF or the fat content of white matter myelin can be varyingly emphasized or deemphasized, depending on the clinical or investigative need. The excellent tissue contrast that MRI produces, its excellent in-plane and between-plane resolution (now approximately 1 mm), and its safety make MRI a useful clinical and research tool.

## Positron Emission Tomography

Positron emission tomography (PET) involves the imaging of radiolabeled tracers that emit positrons. When the tracers are injected or inhaled, the positrons emitted from the tracers soon (within a 3-mm distance from the tracer molecule) collide with electrons. The colliding positrons and electrons annihilate one another, producing two gamma rays that are emitted at 180-degree trajectories from one another. These two gamma rays then pass out of the tissue and are recorded by detectors in the axial plane surrounding the subject. The precise localization of the origination of the gamma rays can be determined by noting which detections occur simultaneously at 180-degree orientations ( [Rebe, 1993](#)).

This site of gamma ray origination varies depending on the pharmacologic properties of the particular radiotracer used. Some tracers, for instance, are primarily confined to intravascular space, and the localization of gamma ray origination can be assumed to reflect the distribution of blood vessels. Other tracers, such as 2-deoxyglucose, are taken up by neurons and phosphorylated. Because the phosphorylated deoxyglucose cannot be metabolized further, the accumulating tracer reflects the degree of activity of the neurons containing them, which is then measured in the amount of radioactivity detected in that particular brain region. Additional tracer types include ligands for specific neurotransmitter receptors. Raclopride, for instance, is a  $D_2$  receptor ligand. The isotopes that are incorporated into the various tracers have short half-lives: that for  $^{15}\text{O}$  (incorporated in water for blood flow studies) is 2 minutes,  $^{11}\text{C}$  (incorporated, for instance, into raclopride for dopamine  $D_2$  receptor studies) is 20 minutes, and  $^{18}\text{F}$  (incorporated into deoxyglucose for metabolic studies) is 110 minutes. In-plane resolution of the newer PET scanners is approximately 3 mm for  $^{18}\text{F}$ -labeled tracers, and 8 mm for  $^{15}\text{O}$ -labeled ones, the difference being caused by differences in the distance between origination and annihilation of the positrons from each of the isotopes in their differing tissue compartments.

## Single Photon Emission Computed Tomography

Single photon emission computed tomography (SPECT) imaging is functionally similar to PET, the primary differences between the two being spatial resolutions and kinds of tracers employed. Whereas PET tracers emit positrons that then produce gamma rays, SPECT tracers emit photons of characteristic energies. Each photon is emitted in a manner that is directionally random and temporally independent of any other photon release, thus accounting for the “single photon emission” portion of the SPECT acronym. Specifics of the photon detection system are the primary determinants of resolution of any particular SPECT scanner. Currently, the spatial resolution of SPECT, although rapidly improving, is still (at approximately 6 mm) inferior to that of PET. Single photon emission computed tomography ligands,

however, typically incorporate long-lived isotopes of technetium and iodine, which, unlike PET ligands, do not need to be synthesized on-site in a large and expensive cyclotron. This is a major cost-saving advantage of SPECT. In addition, the development of new, pharmacologically specific SPECT tracers makes the future of SPECT imaging quite promising.

Although new radiotracers may be developed whose pharmacologic properties and half-life offer the potential of reducing the radiation exposure for children who might undergo PET or SPECT imaging in the future, the need for radiation exposure in these imaging modalities will never be eliminated entirely. Reducing total radiation exposure sufficiently reduces the risks associated with PET and SPECT, so that the techniques might be justifiable for the clinical investigation of children who have severe neuropsychiatric illnesses. Nevertheless, the persistence of radiation exposure, no matter how minimal, is also likely to make the recruitment of normal control children for research protocols prohibitively difficult. The development of novel experimental designs that would contrast various disease groups could make the combination of clinical and research protocols possible in the future, however.

### Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) studies permit the identification of the brain regions that are engaged in processing various types of information or in solving various types of problems. The first reports characterizing changes on MR images during specific cognitive tasks appeared in 1991 ( [Belliveau et al., 1991](#)). The changes on the MRI scans, which consist of subtle regional intensity changes during task activation, are now believed to track blood flow-related phenomena. The regional image intensity changes appear to derive from changes in the contents of oxyhemoglobin and deoxyhemoglobin present during the task, compared with their contents during the control state. Decreases in deoxyhemoglobin concentration during task performance increases the strength of the radiofrequency signal emitted by the underlying tissue, producing a locally increased intensity in the image. Images acquired during task activation can be compared with appropriate control images to determine which pixel intensities (and where in the brain local oxyhemoglobin levels) have changed during the task.

It also appears that the spatial and temporal resolutions of fMRI surpass conventional PET and SPECT imaging capabilities. fMRI can provide in-plane resolution of 1 mm or less, which compares favorably with the current in-plane resolution of the best PET cameras, which is 2 to 3 mm. Functional magnetic resonance imaging's temporal resolution of approximately 1 second is comparable to that of PET but inferior to that of the electroencephalogram (EEG), which has a temporal resolution in the tens of milliseconds—similar to the time scale of neural events. It is doubtful whether fMRI will ever be able to achieve the temporal resolution necessary to resolve discrete neural processes. Nevertheless, its relative safety (especially in children), good spatial and fair temporal resolution, the ability to scan subjects on multiple occasions, and low cost compared with PET or SPECT make fMRI an attractive functional imaging modality and accounts for the vast number of fMRI studies that are now appearing in the literature.

### Diffusion Tensor Imaging

Diffusion tensor imaging (DTI) is a unique and relatively recent application of MRI technology that provides, among other things, detailed information about the orientation of fiber tracts within the brain, especially information about the orientation and integrity of white matter tracts. It provides this information primarily by tracking the nonrandom diffusion of water through those fiber tracts, as follows.

Magnetic resonance images based on T1 and T2 relaxation times provide information on the molecular environment of water molecules. Extravascular water diffuses more or less randomly in tissues, but its movement is influenced by cell membranes (and cytoskeletal structures), which act as barriers to free motion. The first major clinical application of diffusion imaging was in stroke diagnosis. It was shown that the technique demonstrated contrast changes minutes after an insult, whereas conventional T<sub>2</sub>-weighted imaging showed changes only after about 24 hours ( [Moseley et al., 1990](#)). It was later found that diffusion is not isotropic (i.e., the same in all directions) in white matter, which is interpreted as a reflection of the coherent orientation of axons in white matter fibers. According to this model, diffusion is relatively rapid parallel to axons because fewer membranes are encountered moving in this direction than in the perpendicular direction. Therefore, finding the direction of rapid diffusion determines the orientation of axons represented in a pixel or volume element (voxel) of an image. Fibers can be tracked from one voxel to the next by combining this orientation information from neighboring voxels. Continuing this procedure, the paths of fibers can be reconstructed from one region of the brain to another ( [Fig. 9.2](#)). Magnetic resonance fiber tracking can be used to visualize individual axon fascicles in the brain, and provide information on neuronal connectivity. It is thought, although not yet proven, that measurements of fascicle diameter reflect the number of constituent axons and that the rate of water diffusion perpendicular to a fiber depends on axon density.

**Figure 9.2.** Fibers tracked through the internal capsule project to different areas of the cortex. Fibers are shown (in a three-dimensional view) in relation to one of the axial diffusion weighted images from which they are calculated. The head is viewed from the front (along the midline) and somewhat lower than the image slice. (Figure courtesy of Adam Anderson.) See [color plate](#).

Clinical applications of DTI have focused on the integrity of white matter tracts, as measured by the local anisotropy of diffusion (the more highly organized an axon bundle, the less isotropic will be the diffusion). For example, DTI has been used to show loss of white matter structure in multiple sclerosis ( [Werring et al., 1999](#)), schizophrenia ( [Buchsbaum et al., 1998](#); [Foong et al., 2000](#); [Lim et al., 1999](#)), dyslexia ( [Klingberg et al., 2000](#)), and preterm birth ( [Hüppi et al., 1998](#)). It is likely that this imaging method will find many other applications in neuroimaging because it opens an entirely new window on brain structure.

### Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) directly measures the concentrations of certain chemical compounds in the brain. It can be used to measure, for instance, compounds such as *N*-acetyl aspartate, which is thought to be an index of neuron number or integrity ( [Birken and Oldendorf, 1989](#)). It can also measure compounds involved in membrane phospholipid metabolism, pH, lactate, and concentrations of certain neurotransmitters, such as glutamate and  $\gamma$ -amino butyric acid (GABA).

The principles of MRS are similar to those of MRI. Instead of imaging primarily hydrogen nuclei, however, MRS can also image other nuclei that exhibit MR. Magnetic resonance depends on having a net nuclear spin, which entails that only nuclei having odd-numbered protons or neutrons will demonstrate MR. These nuclei include <sup>1</sup>H, <sup>13</sup>C, <sup>19</sup>F, <sup>23</sup>Na, and <sup>31</sup>P. Each of these nuclei has unique resonant frequencies in any given magnetic field because they vary in atomic weight; thus, the MR scanner's excitatory radiofrequency pulse can selectively excite any one of these nuclei simply by applying the radiofrequency pulse of the appropriate frequency. As the excited nuclei relax, the radiofrequency signal that they, in turn, emit is, like that emitted in MR imaging, in part determined by the physical environments immediately surrounding those nuclei. The frequency of the signal is altered slightly, producing a "chemical shift" fingerprint. This fingerprint is characteristic of the specific molecules in which the resonant nuclei are incorporated. The areas under specific spectral peaks then reflect the concentrations of the specific molecules generating the peaks.

In addition to the nuclei that are selectively excited, another difference of MRS from MRI is the importance of using stronger and more homogenous magnetic fields in MRS studies because they allow the preservation and discrimination of the subtle radiofrequency chemical shifts. Imaging in MRS also typically requires the use of surface coils, which localizes the region of interest to a volume of tissue near the cortical surface, although newer image processing methods make the imaging of larger regions of interest possible. Obtaining spectra from structures deep within the brain is very difficult with MRS because of their distance from the radiofrequency

coils and the iron deposits in basal ganglia and brain stem nuclei that disturb the magnetic field locally within those tissues.

Although all potential uses of MRS are still unknown, the technique promises to provide detailed information on regional brain metabolism of high-energy phosphates such as adenosine triphosphate (ATP), regional membrane phospholipid metabolism, electrolyte balance, and the metabolism of carbohydrates, amino acids, and lipids. The numerous current limitations of MRS include poor spatial and temporal resolution (although this is rapidly improving with the development of scanners with stronger magnetic fields), poor chemical detection sensitivity, and the limited number of biologically relevant nuclei that can be imaged.

## NORMAL DEVELOPMENT

We must first identify the normal patterns of brain development if we are to test the widely held belief that many childhood neuropsychiatric disorders are manifestations of subtle deviations in normal brain development. Recent findings indicate that although total brain size attains 95% of its adult size already by age 5, various brain subcomponents continue to change considerably throughout childhood and adolescence.

### Cortical Gray

Frontal gray matter increases during childhood, reaching a peak at about 11 years in girls and 12 years in boys. Frontal gray matter then decreases during adolescence. Gray matter in the parietal lobe follows a similar developmental trajectory, although temporal lobe gray matter does not reach its maximum thickness until age 16. Occipital gray matter increases mildly throughout the childhood and adolescent years ( [Fig. 9.3](#)). These differing rates of gray matter development seem to be uniquely human ( [Giedd et al., 1999a](#)).

**Figure 9.3.** Age-related changes in selected brain regions. Total cerebral volume for males (blue) and females (red) are shown in ( A). Each line represents one subject. ( B) and ( C) figures show predicted size of total white matter and frontal gray matter with 95% confidence intervals for 243 scans from 89 unrelated males and 56 unrelated females, ages 4 to 22 years. (Figure courtesy of Jay Giedd.) See [color plate](#).

The extent to which the buildup and pruning down phase are influenced by psychiatric illness, genetics, hormones, diet, activity, or other environmental factors is an active area of research. Studies of identical and nonidentical twins, children with neuropsychiatric disorders, and people with anomalous sex chromosomes (e.g., XXY, XYY, XXYY) or hormonal abnormalities (e.g., congenital adrenal hyperplasia) will help to sort out some of the relative influences of these determinants on brain development.

### White Matter

As opposed to the regionally specific, curvilinear developmental trajectories of gray matter volume, white matter volumes tend to increase linearly and at roughly similar rates in the frontal, parietal, temporal, and occipital lobes; however, the corpus callosum (the massive white matter pathway connecting the cerebral hemispheres) increases in size more posteriorly than anteriorly during childhood and adolescence ( [Giedd et al., 1999b](#)). Newer methods to track white matter changes precisely in an individual child over time reveal robust changes in corpus callosum morphology over time intervals as short as 1 year ( [Thompson et al., 2000](#)). White matter density also has been shown to increase with age in speech-related, corticospinal, and frontotemporal pathways (Paul et al., 1999).

### Basal Ganglia

The basal ganglia are subcortical gray matter structures comprised of the caudate nucleus, putamen, globus pallidus, subthalamic nucleus, and substantia nigra. These structures not only are well known to influence movement and muscle tone, but they are also integral components of circuits mediating higher cognitive functions, attention, and affective states. Of the basal ganglia components, only the caudate, putamen, and globus pallidus currently are large enough to be readily quantifiable by MRI. The growth of these structures follows a developmental course similar to the frontal cortical gray matter ( [Giedd et al., 1996b](#)).

### Sex Differences

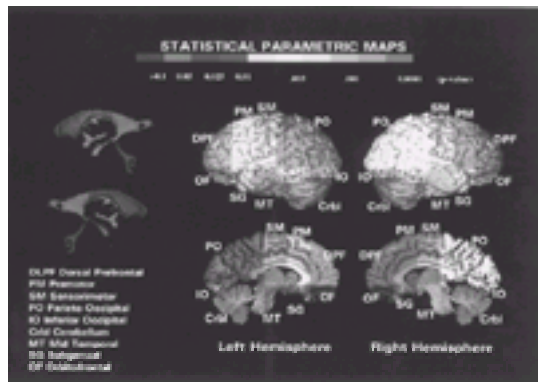

Many brain regions develop differently between boys and girls ( [Giedd et al., 1997](#)). These sex differences may be particularly relevant for child psychiatry because nearly all childhood-onset neuropsychiatric disorders have different ages of onset, prevalence, and symptomatology between the sexes. One example of sexually dimorphic brain development is the amygdala, which increases more robustly in volume in adolescent boys than girls ( [Giedd et al., 1996c](#)). Another is the hippocampus, which increases significantly more in volume in adolescent girls. These sex differences in the amygdala and hippocampus are consistent with the amygdala having a predominance of androgen receptors and the hippocampus having a predominance of estrogen receptors. The temporal lobes, amygdala, and hippocampus subserve functions of language, emotion, and memory, which are known to change dramatically from ages 4 to 18 years. The sizes of these brain structures are highly variable, even in well-screened healthy control groups ( [Lange et al., 1997](#)), thus emphasizing the need in imaging studies for large sample sizes and longitudinal studies to accurately characterize developmental curves.

## PRETERM BIRTH

Infants weighing less than 1,500 g (3.3 lbs) at birth account for 1.5% of all live births in the United States ( [Guyer et al., 1999](#)). Survival rates of these infants currently approach 85%. The prevalence of major neurodevelopmental disturbances in these children range from 12% to 32% and are a growing public health concern ( [Hack et al., 1996](#); [Whitaker et al., 1997](#)). Preterm infants, even those who have uncomplicated neonatal courses, frequently experience serious cognitive and educational difficulties ( [Sykes et al., 1997](#)). IQ scores are nearly one standard deviation (15 points) below the population mean ( [Wolke, 1991](#)), more than half of these children require special assistance in school, and nearly 20% repeat a grade in school by the age of 8 years ( [McCormick et al., 1996](#)). The prevalence of mood and anxiety disorders, as well as attention deficit/hyperactivity disorder, is markedly elevated over the rates reported in community-based samples ( [Whitaker et al., 1997](#)).

Prior quantitative MRI studies of preterm infants have suggested the presence of reduced cortical gray and white matter volumes, as well as increased CSF in preterm infants studied at term ( [Hüppi et al., 1996](#), 1998; [Inder et al., 1999](#)). Anatomic abnormalities seem to persist through later childhood and have been noted in qualitative studies of school-aged preterm children, including enlargement of the occipital horns ( [Olsén et al., 1998](#)), white matter damage ( [Olsén et al., 1998](#); [Stewart et al., 1999](#)), and thinning of the posterior corpus callosum ( [Cooke and Abernethy, 1999](#); [Stewart et al., 1999](#)). A recent quantitative study of 25 preterm and 39 term control children studied at 8 years of age supported the findings from these qualitative studies and further documented large volume reductions in sensorimotor, premotor, midtemporal, parieto-occipital, and subgenual cortices bilaterally, as well in the basal ganglia, amygdala, hippocampus, and corpus callosum ( [Peterson et al., 2000](#)). Volumes of the cerebral ventricles were two to four times larger in the occipital and temporal horns of the preterm children. Volumes of sensorimotor and temporal cortices were associated positively with full scale, verbal, and performance IQ scores (the smaller and more abnormal the volume, the lower the IQ). Gestational age at birth was associated positively with volumes of premotor, sensorimotor, and temporal cortices. Frontal volumes were relatively preserved in the preterm children ( [Fig. 9.4](#)). These findings suggest that preterm birth is associated with regionally specific, long-term reductions in brain volume and that those morphologic abnormalities are in turn associated with poorer cognitive outcome. They dramatically emphasize the importance of perinatal and developmental

influences on long-term brain development ( [Fig. 9.5](#)).

**Figure 9.4.** Differences between preterm and term children in regional brain volumes: statistical parametric map. Differences in brain volume between preterm and term children are color-coded and displayed on a subdivided brain and ventricular system. The medial views are located slightly lateral to the interhemispheric fissure to allow visualization of hemispheric tissue. (Figure courtesy of Brad Peterson.) See [color plate](#).

**Figure 9.5.** Imaging of infant brains. The scalp, brain, and ventricular system of an infant is volume-rendered to demonstrate the ability of imaging technologies to measure these small structures in living neonates. The subdivision of these structures is the same as in [Fig. 9.4](#). (Figure courtesy of Brad Peterson.) See [color plate](#).

## AUTISM

Autism is a severe developmental disorder of communication, reciprocal social interaction, and repetitive, rigid, and odd behaviors ( [DSM-IV, 1994](#)). Evidence for a biological basis for autism is substantial ( [Schultz et al., 2000](#)), but there are as yet only a few well-replicated findings from which to begin building a model of pathophysiology. Progress has been slowed by changing diagnostic standards during the past two decades and by a clinical heterogeneity that may well be inherent to the disorder. Current conceptualizations of the pathophysiology of autism emphasize the likely existence of a broader autism phenotype that includes Asperger's syndrome and other syndromic variants. The highly overlapping symptoms of these autism spectrum conditions suggest that they may share common biological foundations, perhaps some kind of “final common pathway” to illness. Converging findings from recent postmortem studies, *in vivo* neuroimaging investigations, and human and animal lesion data suggest that the common biological foundations of autism spectrum disorders may involve abnormalities in overall brain growth, as well as more regionally specific abnormalities in structure and function of the temporal lobe, amygdala, and medial and orbital subdivisions of the frontal lobe.

### Brain Size

One of the more intriguing recent findings is that overall brain size may be increased in autism. Evidence comes from measurement of exterior head circumference ( [Lainhart et al., 1997](#)) and from direct measurement of brain volume in postmortem examinations and *in vivo* neuroimaging studies ( [Piven et al., 1996](#)). It is not yet clear whether all systems are equally affected by the volume expansion, nor is it clear what the functional significance of the expansion may be. One study has reported a selective enlargement of occipital, parietal, and temporal lobes, but not frontal cortex ( [Piven et al., 1996](#)). Increased brain size could come at the expense of the integrity of the interconnections among specialized neural systems, giving rise to a more fragmented processing structure ( [Schultz et al., 2000](#)). This disrupted integration of neural systems could contribute to a lack of “central coherence,” a processing style that makes integration of parts into wholes problematic and that may contribute to the quality of autistic symptoms ( [Frith, 1989](#)).

The timing of the origin of the abnormalities in brain growth is unknown. Some studies suggest that the growth abnormality may be postnatal ( [Lainhart et al., 1997](#)), and others suggest that it may be prenatal ( [Woodhouse et al., 1996](#)). Specifying the point in brain development when the rate of growth is most abnormal in autism would help to identify the underlying cellular mechanisms that are producing the abnormality ( [Schultz et al., 2000](#)). An origin at particular times of fetal brain development could suggest disturbances in the regulation of neuronal or glial cell proliferation, neuronal migration, or apoptosis, for instance.

Prenatal origins of disturbed brain development have been suggested by reports of increased frequencies of abnormalities in morphology of the cerebral cortex in autistic individuals ( [Bailey et al., 1998](#); [Berthier et al., 1992](#); [Piven et al., 1990](#); [Schifter et al., 1994](#)). One study found, for example, that seven of 13 subjects with autism had cortical abnormalities, including polymicrogyria in five, schizencephaly and macrogyria in one, and macrogyria in another subject, compared with no abnormalities in 13 control subjects ( [Piven et al., 1990](#)). The cortical abnormalities are thought to derive from disturbances in neuronal migration during fetal brain development.

### Temporal Lobe

The limbic-temporal cortex forms a functional system ( [Amaral and Price, 1984](#)) that mediates social–emotional processes ( [Adolphs et al., 1994](#); [Kling and Brothers, 1992](#)). The amygdala, in particular, plays a critical role in emotional arousal, assigning significance to environmental stimuli and mediating emotional learning ( [Gaffan et al., 1988](#); [Geschwind, 1965](#); [LeDoux, 1996](#)). Persons with autism perform poorly on measures of face recognition ( [Boucher and Lewis, 1992](#); [Klin et al., 1999](#); [Langdell, 1978](#)), emotional perception and comprehension ( [Fein et al., 1992](#); [Hobson, 1986](#)), and imitating emotional expressions ( [Macdonald et al., 1989](#)). The social–emotional dysfunction found in autism may arise from functional disturbances in this temporo-limbic system ( [Baron-Cohen et al., 2000](#); [Schultz et al., 2000](#)).

Regions of the temporal lobe specialized in normal individuals for interpreting facial expressions and identifying facial identity have been mapped with fMRI, PET, and lesion data ( [Fig. 9.6](#)). Functional magnetic resonance imaging studies in autism have reported that a specific region on the ventral surface of the temporal cortex, the fusiform gyrus, fails to respond fully to the human face during perceptual tasks ( [Critchley et al., 2000](#); [Schultz et al., 2000](#)). Thus, deficits in face recognition have a clear functional correlate in higher-order perceptual systems of the ventral temporal lobe in autistic subjects. These functional disturbances could be a primary deficit in autistic individuals, an acquired (secondary) deficit caused by failed emotional learning during critical periods of early social development ( [Schultz et al., 2000](#)), or a nonspecific finding that reflects generalized disturbances in cognitive functioning in autistic individuals. Postmortem findings of abnormalities in size, density, and dendritic arborization of neurons in the amygdala, hippocampus, and entorhinal cortex are consistent with these findings of abnormal temporo-limbic functioning ( [Bauman and Kemper, 1985, 1994](#)).

**Figure 9.6.** Functional magnetic resonance image (fMRI) t-maps of the brain during face perception. The fusiform face area is shown in red or yellow (arrows) in: (A) a young adult with Williams syndrome (WS) and (B) a matched normal control. In both persons, there is a clear focus of face-related activation bilaterally in the fusiform gyrus along the ventral surface of the temporal lobe. Images are in a coronal orientation, with right and left hemisphere reversed by convention. Functional data are superimposed on anatomic images for localization. Note the normal intensity and size of the fusiform face area in WS referenced to the control subject. For contrast, (C) note the lack of activation in the fusiform gyrus in a young adult with autism. fMRI data are from a blocked experiment comparing (D) face perception to (E) nonface object perception during a “same/different” discrimination task on a 1.5 Tesla system, the threshold for displaying activations is set at  $T = 1.5$ . Regions of the brain that activate specifically to objects are shown in blue on the fMRI maps. (Figure courtesy of Robert Schultz.) See [color plate](#).

Other evidence implicating the temporal system in autism include case studies of patients with temporal lobe lesions and autisticlike behaviors ( [Gillberg, 1991](#); [Hoon and Reiss, 1992](#)) and reduced functional activity in the temporal lobes on SPECT scans in autistic subjects ( [Mountz et al., 1995](#)). Furthermore, an association between tuberous sclerosis and autism has long been recognized, and a specific association of the location of the tubers in the temporal lobe with autism has been reported ( [Bolton and Griffiths, 1997](#)).

### Amygdala

Animal models suggest that developmental abnormalities in the amygdala may play a particularly important role in the development of autistic symptoms ( [Bachevalier, 1994](#)). Bilateral damage of the amygdala shortly after birth in monkeys can produce patterns of behavior similar to those of autism, such as social isolation, lack of eye contact, impaired facial expression, and motor stereotypies. Similar lesions in adulthood fail to produce these behaviors. The early postnatal lesions do not immediately produce the signs characteristic of autism spectrum disorders ( [Bachevalier, 1994](#); [Thompson, 1981](#)). Rather, the deficits emerge during early development. These findings are consistent with the hypothesis that autistic symptoms are, in part, a function of faulty early emotional learning mediated by limbic system pathology. Furthermore, monkeys with early lesions to the amygdala and surrounding entorhinal cortex later in adulthood exhibit abnormalities in the frontal cortex on MRS, and the regulation of dopaminergic activity in frontal cortex and the basal ganglia is abnormal ( [Bertolino et al., 1997](#); [Saunders et al., 1998](#)).

Accurate measurement of the amygdala with MRI is difficult. Findings from two studies of amygdala volume have produced opposite findings. Amygdala volumes were significantly smaller in 14 autistic adolescents and adults without mental retardation when compared with 14 age- and IQ-matched male controls ( [Aylward et al., 1999](#)). The size of the hippocampus was smaller only when considered relative to volume of the entire brain, which was enlarged, as expected. Larger volumes of the amygdala were reported, however, in a second study using a very different measurement approach in 15 persons with autism compared with matched controls ( [Abell et al., 1999](#)).

### Frontal Lobe

A  $P^{31}$  MRS study found alterations in phospholipid metabolism and evidence of enhanced membrane degradation in the dorsal prefrontal cortex (PFC) of autistic individuals ( [Minschew et al., 1993](#)). This early study suggested that the dorsal PFC of high-functioning autistic subjects is hypermetabolic. More widespread decreases in frontal lobe perfusion subsequently have been suggested by two SPECT studies ( [George et al., 1992](#); [Zilbovicius et al., 1995](#)).

Functional imaging studies suggest that dorsomedial prefrontal cortex (primarily Brodmann's area 9) is the critical substrate for “social cognition,” that is, for thinking about other's thoughts, feelings, and intentions ( [Baron-Cohen et al., 1994](#); [Goel et al., 1995](#)), and that the ventromedial PFC is involved in processing normal affects ( [Lane et al., 1997a,b](#); [Reiman et al., 1997](#)). Function of these prefrontal cortices seems to be disturbed in persons with autism spectrum conditions. A PET study, for instance, reported reduced dopaminergic activity in the medial prefrontal cortex of autistic subjects ( [Ernst et al., 1997](#)). Reduced glucose metabolism also has been reported in a subdivision of the anterior cingulate gyrus (right Brodmann's area 24) in persons with autism engaged in a verbal memory task ( [Haznedar et al., 1997](#)). A pilot PET study of Asperger's syndrome using a theory of mind task showed specific engagement of the medial PFC, except that the center of activation was displaced below and anterior in patients compared with controls ( [Happé et al., 1996](#)).

### Posterior Fossa

Considerable excitement in the study of autism followed initial MRI reports of reduced volumes of portions of the cerebellum (vermian lobules VI and VII). The initial study reported a 19% reduction in size of these regions in 18 autistic and 12 normal control subjects ( [Courchesne et al., 1988](#)). These initial MRI findings were viewed as consistent with small postmortem studies of persons with autism that revealed a variety of abnormalities, including a significant decrease in the number of Purkinje cells and a variable decrease in granule cells throughout the cerebellar hemispheres ( [Arin et al., 1991](#); [Bauman and Kemper, 1985, 1994](#)). The postmortem comparisons, however, showed that the reduction in Purkinje cell numbers was confined to the cerebellar hemispheres and not observed in the vermis ( [Bauman and Kemper, 1996](#)).

Subsequent studies, some with sizable samples, had trouble replicating the initial findings of cerebellar hypoplasia, particularly when controlling for subject characteristics such as age, sex, and IQ ( [Hashimoto et al., 1992](#); [Kleiman et al., 1992](#); [Piven et al., 1992](#); [Ritvo and Garber, 1988](#)). Subsequently, a reanalysis of data from previous work ( [Courchesne et al., 1988, 1994](#); [Kleiman et al., 1992](#); [Piven et al., 1992](#)) suggested the presence of a bimodal distribution in the sizes of vermian lobules VI and VII in autistic subjects compared with a unimodal distribution in the control subjects ( [Courchesne et al., 1994](#)). This bimodal distribution argued for the existence of hypoplastic and hyperplastic subtypes of vermian size in autistic subjects. Significant IQ differences between autistic and control groups call into question the validity of this finding, however, because IQ seems to be associated with hypoplasia of the cerebellar vermis ( [Piven et al., 1992](#)). These difficulties underscore the importance of rigorously controlled studies in the study of autism.

## FRAGILE X SYNDROME

Fragile X syndrome, one of the leading causes of inherited mental retardation, is caused by a single gene mutation, altering brain development and producing a distinctive physical, cognitive, and neuropsychiatric phenotype. Occurring in one out of every 2,000 to 4,000 live births, the fragile X mutation affects males and females differently, as would be expected in an X-linked disorder. In boys, fragile X is associated with mental retardation, difficulties in visuospatial and memory function, hyperactivity, gaze avoidance, autisticlike features, and poor social communication. In girls who are heterozygous for the fragile X full mutation, the syndrome is associated with variable intellectual functioning (ranging from mild mental retardation to normal cognition), math difficulties, attentional deficits, anxiety, and poor social communication ( [Reiss et al., 2000](#)).

Disruption of the expression of the fragile X gene (FMR1) produces lower levels of the fragile X mental retardation protein (FMRP) and abnormal dendritic spine morphology, which has been observed in human neuropathologic studies of individuals with fragile X ( [Hinton et al., 1991](#)) and studies of fragile X knockout mice ( [Comery et al., 1997](#)). Early studies reported that FMRP normally is most abundantly expressed in neurons of the hippocampus, nucleus basalis, and cerebellum ( [Devys et al., 1993](#); [Hinds et al., 1993](#)). This prompted initial neuroimaging studies to focus on those (and other subcortical) regions in fragile X ( [Reiss et al., 1991a,b, 1994, 1995](#)).

### The Posterior Fossa

When compared to age- and IQ-matched individuals with developmental disabilities and to age-matched controls with normal IQs, 14 males with fragile X were noted to have reductions in the areas of lobules VI and VII of the cerebellar vermis, as well as increases in size of the adjacent fourth ventricle ( [Reiss et al., 1991a](#)). In a complementary study ([Reiss et al., 1991b](#)), females with fragile X also had a reduced size of vermal lobules VI and VII and increases in volume of the fourth ventricles, although these abnormalities in females were not as pronounced as those in males with fragile X. This “intermediate gene dosage effect” of the mutation in heterozygote females is consistent with the sex differences expected in an X-linked disorder.

Hypoplasia of the cerebellar vermis was associated with behavioral and cognitive dysfunction in fragile X syndrome in two studies of school-age girls. In one of those studies, a significant negative correlation of the area of lobules VI and VII with parental ratings of autisticlike behaviors was observed, particularly with measures of social communication and stereotypic behaviors ( [Mazzocco et al., 1997](#)). In the second study, posterior vermis size correlated significantly with Full-Scale, Verbal, and Performance IQ scores, and with measures of executive functioning ( [Mostofsky et al., 1998](#)). The cerebellar vermis is thought to play a role in modulating sensory stimulation and mediating higher-order cognitive functions. This supports the hypothesis that the vermis may be a component of a circuit underlying the behavioral difficulties and cognitive dysfunction observed in individuals who have fragile X syndrome.

That the size of the vermis is reduced in individuals who have fragile X but not those who have nonspecific developmental delays suggests that these findings have some degree of specificity for the fragile X syndrome. The presence of cerebellar hypoplasia in children with autism and the association of cerebellar hypoplasia with autisticlike symptoms in children with fragile X has led some researchers to suggest that fragile X can be viewed as an etiologically homogeneous model for understanding the pathophysiology of autism ( [Reiss et al., 2000](#)).

### **Temporal Lobe**

The presence of deficits in learning and memory in individuals with fragile X syndrome has motivated study of the temporal lobe in this disorder. Although two studies reported a 10% to 20% enlargement of hippocampal volumes in individuals with fragile X ( [Kates et al., 1997](#); [Reiss et al., 1994](#)), a third study was unable to confirm these findings ( [Jakala et al., 1997](#)). Larger sample sizes are needed to settle these discrepancies.

One cross-sectional study also reported that hippocampal volumes were positively associated with age and that superior temporal gyrus (STG) volumes were negatively associated with age in subjects with fragile X ( [Reiss et al., 1994](#)). These associations of age with volume in the hippocampus and STG, combined with the known age-related decline in intellectual functioning in fragile X boys, suggests that the fragile X mutation may continue to exert a detrimental effect on brain development even into later childhood. Longitudinal, prospective studies are needed to test this hypothesis directly ( [Kraemer et al., 2000](#)).

### **Caudate and Thalamus**

One study compared 31 females and 18 males with fragile X to samples of IQ-matched controls and normal controls ( [Reiss et al., 1995](#)). The volumes of the caudate nucleus were increased in both genders with fragile X, lateral ventricle volumes were increased in fragile X males, and thalamic volumes were increased in fragile X females.

### **Frontal and Parietal Lobes**

Although deficits in higher-order cognitive functions (e.g., executive function and working memory) that are putatively mediated by frontal and parietal cortices have been reported in patients with fragile X, morphologic imaging studies of the frontal and parietal lobes have not yet been reported. However, recent functional studies have advanced our understanding of the relation among gene dosage, cortical activation, and behavior in this disorder. An fMRI study, for example, reported reduced activity in frontal-subcortical circuits in individuals with fragile X ( [Hjalgrim et al., 1999](#)). The prefrontal-caudate circuits are associated with the regulation of impulses and attention, and lesions of these circuits have previously been associated with hyperactivity, inattention, and perseveration—all features of the fragile X behavioral phenotype. In addition, a significant association has been reported between FMRP levels and brain activation in the right inferior frontal, left and right middle frontal, and supramarginal gyri during a working memory task in 10 females with fragile X ( [Menon et al., 2000](#)).

### **Conclusions**

Taken together, these findings suggest that the disruption of FMR1 gene expression affects FMRP levels across various cortical and subcortical regions of the brain in fragile X patients, consistent with the recent finding that FMRP is widely distributed throughout the mammalian brain ( [Feng et al., 1997](#)). Nevertheless, we do not fully understand the neural circuits through which FMR1 gene expression disrupts cognitive and emotional functions throughout childhood. Longitudinal studies of brain morphology and function therefore are needed in patients with fragile X. Of particular importance is defining the relation of FMRP protein levels with brain structure, function, and behavior.

## **VELOCARDIOFACIAL SYNDROME**

Velocardiofacial syndrome (VCFS) (also known as the 22q11 deletion syndrome) is caused by a microdeletion on chromosome 22q11.2. It has a variable phenotype that includes congenital anomalies, language delays, learning disabilities, and disorders of attention, affect, and anxiety. Approximately 30% of individuals with VCFS develop schizophrenia in late adolescence or young adulthood. This has stimulated interest in defining the anatomic and functional anomalies of the central nervous system (CNS) that are associated with this specific genetic mutation and that may be associated with the development of severe psychiatric illness.

### **Qualitative Studies**

Initial MRI studies were qualitative and based on clinically acquired scans. White matter hyperintensities, small cerebellar vermis, and cysts adjacent to the anterior horns of the lateral ventricles were reported in a sample of 11 children with VCFS ( [Mitnick et al., 1994](#)). In a study of 11 adults who had both VCFS and schizophrenia ( [Chow et al., 1999](#)), 90% had white matter hyperintensities, 45% midline anomalies, 54% cerebral atrophy or enlargement of the lateral ventricles, and 36% cerebellar hypoplasia.

### **Cerebral Cortex**

Initial quantitative MRI studies of children with VCFS have focused on abnormalities of the cerebral cortex. Two separate studies of the cerebral cortex that used the same measurement methodologies have been reported. The first compared 15 children with VCFS ( [Eliez et al., 2000](#)), and the second compared 10 children with VCFS ( [Kates et al., 2001](#)) to age- and sex-matched control samples. Both studies found total brain volume to be reduced by nearly 11% in children with VCFS. White matter was reduced (most notably in nonfrontal regions of the cortex) more than gray matter in subjects with VCFS. Both studies also found disproportionate reductions in the left parietal lobe of children with VCFS. One study found the reductions limited to parietal gray matter ( [Eliez et al., 2000](#)), whereas the other study found the reductions limited to parietal white matter ( [Kates et al., 2001](#)). Reductions in parietal tissue are consistent with the VCFS neuropsychological phenotype, which includes deficits in visual perception and spatial working memory.

### **Posterior Fossa**

Preliminary studies suggest that regions of the posterior fossa are aberrant in children and adolescents with VCFS ( [Eliez et al., 2000](#)). Both the pons and lobules VI to VII of the cerebellar vermis appear to be significantly reduced in children with VCFS.

### **Temporal Lobe**

Initial quantitative studies suggest the presence of temporal lobe abnormalities in VCFS patients. Although brain-corrected volumetric differences in temporal lobe regions have not been reported between VCFS patients and controls, a cross-sectional study suggested possible age-related reductions in volumes of the temporal lobe and left hippocampus. If this latter finding is replicated, it would provide an additional link between the neuroanatomic anomalies found VCFS and those found in schizophrenia because temporal lobe abnormalities are probably the most robust abnormalities noted in adults who have schizophrenia.

## Conclusions

Neuroanatomic studies of individuals with VCFS are just beginning. Replication of the initial findings is needed. Imaging modalities such as DTI and MRS may prove useful for investigating and understanding the pathophysiology of the white matter reductions that have been reported in the cerebral cortex. Finally, longitudinal studies are needed to help identify the neuroanatomic abnormalities (as well as neurocognitive and behavioral features) that place children with VCFS at the greatest risk for developing severe psychiatric illness in adulthood.

## CHILDHOOD ONSET SCHIZOPHRENIA

Childhood onset schizophrenia is a rare, clinically severe form of schizophrenia associated with the premorbid disruption of cognitive, linguistic, and social development ([Jacobsen and Rapoport, 1998](#)). Although the disorder is rare, understanding the brain changes that mediate the emergence of schizophrenic symptoms at an unusually early age may improve our understanding of the developmental abnormalities that trigger the later onset of schizophrenia and that determine the severity and course of symptoms.

Imaging studies thus far have focused on brain morphology using MRI. Fewer studies have examined indices of brain neuronal integrity using MRS or brain function using PET or SPECT. Studies of brain function in this population have been limited by the severe positive and negative symptoms that these patients experience and their consequent inability during scanning to be still and perform cognitive tasks.

### Brain Volumes

Perhaps the most consistent finding across studies of brain morphology in childhood onset schizophrenia is that these children have smaller brains and enlarged ventricles ([Hendren et al., 2000](#); [Sowell et al., 2000](#)). Longitudinal studies have shown that children with schizophrenia undergo a fourfold greater decrease in cortical gray matter than do controls during adolescence, and that this decrease is most prominent in frontal and temporal regions ([Rapoport et al., 1999](#)). This results in a more rapid decrease in total brain and hippocampal volume and a more marked increase in ventricular volume during this period in patients than controls ([Giedd et al., 1999](#); [Jacobsen et al., 1998](#)). Decline in volume of the right posterior superior temporal gyrus during this adolescent period has been found to predict the severity of positive symptoms of psychosis at follow-up ([Jacobsen et al., 1998](#)). The rate of decline in gray matter volume attenuates by early adulthood, possibly explaining why longitudinal studies of adults with schizophrenia have generally not found progressive age-related changes in brain volume ([Giedd et al., 1999](#)).

Cross-sectional and longitudinal studies of children and adolescents with childhood onset schizophrenia have also documented the presence of a reduced size of the thalamus in the midsagittal plane as well as enlarged basal ganglia structures in patients receiving typical neuroleptic medication ([Hendren et al., 2000](#)). Basal ganglia volumes were found to decrease to normal levels after 2 years of therapy with the atypical antipsychotic medication, clozapine ([Frazier et al., 1996](#)). This reversible enlargement of basal ganglia structures associated with typical neuroleptic therapy has also been observed in adults with schizophrenia. Although the mechanism of this enlargement is unknown, it may stem from depletion of striatal dopamine ([Jacobsen et al., 2001](#)).

### Neurochemical Studies

Magnetic resonance spectroscopy was used to measure the ratio of  $N$ -acetyl-aspartate to creatine (NAA:Cr), an index of neuronal number and integrity, in two samples of patients with childhood onset schizophrenia and in one sample of children with schizophrenia spectrum disorders. All three studies found lower NAA:Cr ratios in the frontal lobes of children with schizophreniform disorders ([Bertolino et al., 1998](#); [Brooks et al., 1998](#); [Sowell et al., 2000](#)). One study in addition observed decreased NAA:Cr ratios in the hippocampus bilaterally ([Bertolino et al., 1998](#)). These findings are similar to the findings of altered brain NAA:Cr ratios in adult onset schizophrenia.

### Functional Imaging Studies

One small study of blood flow using xenon-133 inhalation showed significant hypofrontality in a sample of 10 neuroleptic-naïve adolescents with schizophrenia compared with age- and sex-matched controls ([Chabrol et al., 1986](#)). A second study examined cerebral glucose metabolism using PET in adolescent subjects with childhood onset schizophrenia and healthy adolescent controls ([Jacobsen et al., 1997](#)) during an auditory continuous performance task. Global cerebral glucose metabolism did not differ between groups. A significantly increased metabolic rate was observed, however, in the supramarginal gyrus, inferior frontal gyrus, and insular cortex of the schizophrenia group, and a decreased metabolic rate was observed in the middle and superior frontal gyri.

## Conclusions

Brain imaging studies of patients with childhood onset schizophrenia have demonstrated a consistent pattern of abnormalities similar to those observed in adult onset schizophrenia. The accelerated loss of cortical and subcortical gray matter tissue in these patients, however, may represent a distinct pathologic process that is confined to adolescence. The rate of this accelerated loss of gray matter in certain regions may influence clinical outcome. A critical question to address in future research is whether this accelerated loss of gray matter is unique to childhood onset forms of schizophrenia or whether it is also present premorbidly in individuals who develop schizophrenia as adults. Addressing this question will require longitudinal brain imaging studies of high-risk or prodromal patients.

## ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Early imaging studies of attention deficit/hyperactivity disorder (ADHD) were hampered by the absence of explicitly formulated diagnostic criteria and by the poor ability of CT scans to differentiate between gray and white matter. For the past decade, an increasing number of investigators have applied anatomic and functional MRI, as well as PET or SPECT, to the study of individuals with ADHD. Although many unsettled questions remain, a relatively coherent picture of the neuroanatomic basis of ADHD is beginning to emerge.

### Fronto-Striatal Circuits

A well-known PET study performed in adults with ADHD ([Zametkin et al., 1990](#)) reported decreased cerebral metabolism throughout the brain, particularly in frontal regions. Unfortunately, attempts to replicate and extend this approach to adolescents yielded mostly conflicting and unconvincing results. A number of groups began concurrently to explore anatomic MRI in children with ADHD. Initial studies used small samples and relatively primitive measurement techniques, but they provided further evidence for abnormalities in frontal, as well as in striatal brain regions ([Giedd et al., 1994](#); [Hynd et al., 1990, 1991, 1993](#)). The pattern of fronto-striatal abnormalities, particularly volume reductions in the right hemisphere, was confirmed in the largest anatomic MRI study of boys with ADHD ([Castellanos et al., 1996](#)). Other groups have generally supported those findings, although not always with regard to laterality ([Aylward et al., 1996](#); [Filipek et al., 1997](#)).

### Cerebellum

Numerous functional imaging studies and basic science research have suggested the importance of the interplay between prefronto-striatal circuits and the cerebellum, particularly in the regulation of attention ([Middleton and Strick, 1994](#)). These considerations motivated an examination of the cerebellum in ADHD. One small and well-delineated region, the posterior-inferior vermis, subsequently, was found to be smaller in three independent samples of children with ADHD ([Berquin et al., 1998](#); [Castellanos et al., 2001](#); [Mostofsky et al., 1998](#)). Although the functional significance of a smaller volume in this small region is unclear, it may be relevant that this particular region is unique in that it is one of the very few cerebellar tissues to receive dopaminergic innervation ([Melchitzky and Lewis, 2000](#)).

### Dopaminergic Systems

Although nature is rarely so simple, the longstanding theme of dopamine-linked abnormalities in ADHD continues to accumulate supporting evidence from neuroimaging investigations. Besides the modest but replicated associations between ADHD and a pair of dopaminergic genes ([Swanson et al., 2000](#)), fMRI studies have found abnormalities in dopamine-influenced regions of the brain, such as the striatum ([Rubia et al., 1999](#); [Vaidya et al., 1998](#)), prefrontal cortex ([Rubia et al., 1999](#)) and the anterior cingulate cortex ([Bush et al., 1999](#)). Two ligand-based SPECT studies of the dopamine transporter system in adults with ADHD demonstrated a significant and robust elevation of dopamine transporter levels in the ADHD subjects ([Dougherty et al., 1999](#); [Krause et al., 2000](#)). In one of these studies ([Krause et](#)

al., 2000), all 10 patients were medication-naïve at the time of their initial scan. In addition, all underwent a second scan after 4 weeks of treatment with 15 mg methylphenidate daily. This low-dose treatment resulted in a 30% decrease in dopamine transporter binding to levels somewhat below those of normal controls. If confirmed, these results suggest a relatively straightforward model of adult ADHD pathophysiology in which an excess of dopamine transporters produces a deficit in striatal dopamine functioning owing to excessive reuptake. Whether this abnormality represents the basic genetic “lesion” or whether it reflects a compensatory overproduction of dopamine transporters, however, is unclear. This question will not be answered easily because of the practical impossibility of studying normal control children with even small doses of radiation (required for SPECT or PET) and because even the best PET cameras and ligands are currently unable to quantify dopamine transporter levels *in vivo* outside of the striatum, such as in frontal cortex or cerebellum.

Ongoing anatomic MRI studies in ADHD subjects are examining the role of stimulant treatments in producing deleterious anatomic brain changes, as has been charged by some critics. These studies are also examining the possible abnormalities in brain development associated with ADHD.

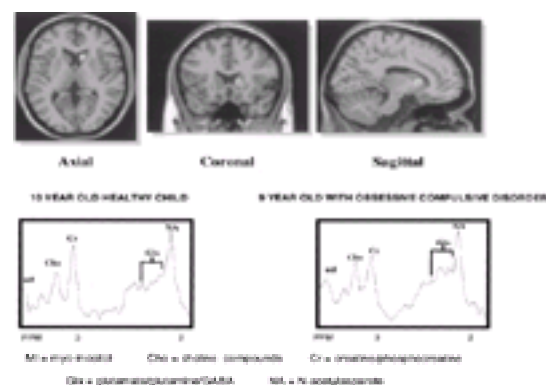

## OBSESSIVE-COMPULSIVE DISORDER

Investigations of childhood OCD have tended to focus on patients near the onset of their illness. This approach minimizes potentially confounding factors that include illness duration and exposure to CNS-active medications.

### Striatum

The striatum is believed to be a primary locus of abnormality in OCD (Rauch et al., 1998). MRI and CT studies of striatal volumes in OCD adults, however, have been highly variable in their findings. Volumetric studies in children with OCD have been more consistent in identifying abnormalities of the striatum. One early CT study reported reduced caudate volumes in adolescent and young adult male OCD patients (Luxenberg et al., 1988). A later MRI study of younger OCD patients, 7 to 17 years of age, also reported smaller striatal volumes (Rosenberg et al., 1997a). Striatal volumes correlated inversely with OCD symptom severity, but they did not correlate with illness duration, suggesting that decreased striatal volumes may be a central abnormality in pediatric-onset OCD.

Elevated glutamate concentrations have also been observed in MRS studies of the caudate nucleus but not in the occipital lobe of treatment-naïve pediatric OCD patients (Rosenberg et al., 2000a) (Fig. 9.7), suggesting that the glutamate abnormalities may be localized to specific striatum-based brain circuits in children with OCD. Glutamate concentrations in the caudate decreased significantly to normal levels after 12 weeks of treatment with paroxetine. Changes in caudate glutamate concentrations correlated positively with changes in OCD symptom severity during treatment, indicating that elevated pretreatment glutamate concentrations in the caudate predicted a better symptomatic response to paroxetine. In contrast, caudate glutamate concentrations did not decrease in pediatric OCD patients after cognitive behavioral therapy (Benazon et al., 2000). Thus, normalization of caudate glutamate concentrations during SSRI treatment in pediatric OCD demonstrates some specificity to treatment modality—it is not simply a generalized treatment effect.

**Figure 9.7.** Illustration of voxel placement in the left caudate nucleus. Proton magnetic resonance spectroscopy of an 0.7-mL volume of interest centered in the left caudate in a 10-year-old healthy control and a 9-year-old treatment-naïve patient with obsessive-compulsive disorder as shown on the T1-weighted magnetic resonance images. (From Rosenberg DR, Keshavan MS, Dick EL, et al.: Corpus callosal morphology in treatment-naïve pediatric obsessive compulsive disorder. *Progr Neuro-Psychopharmacol Biol Psychiatry* 21:1269–1283, 1997a.) (Figure courtesy of David Rosenberg.)

### Prefrontal Cortex

The prefrontal cortex is the major “decision-making” center of the brain. It subserves executive-type cognitive and behavioral processes that include abstraction, inhibiting inappropriate impulses and desires, and delaying responses (Fuster, 1997). An initial study of prefrontal cortical volume in pediatric OCD patients did not reveal significant differences from control patients (Rosenberg et al., 1997a).

A subsequent investigation demonstrated the presence of a significantly larger genu of the corpus callosum in 21 psychotropic-naïve children with OCD compared with healthy controls (Rosenberg et al., 1997b). Because the genu is the region of the corpus callosum that interconnects the ventral portions of the prefrontal cortex in each hemisphere (de Lacoste-Utamsing et al., 1985; Seltzer and Pandya, 1986), the finding of a larger genu in OCD children suggests the involvement of ventral prefrontal cortex in the pathophysiology of OCD. Other investigators have recently reported increased corpus callosal signal intensity localized to the region of the genu and have hypothesized that this may be owing to increased myelin sheath thickness (MacMaster et al., 1999).

These findings prompted examination of subregions of the prefrontal cortex in OCD children (Rosenberg and Keshavan, 1998). Increased anterior cingulate volumes but not in dorsolateral prefrontal or posterior cingulate cortices were observed in OCD children. Increased anterior cingulate volumes in turn correlated positively with severity of OCD symptoms but not illness duration.

### Thalamus

The thalamus is a major motor and sensory relay station, and it is the final subcortical input to the frontal lobe. It stimulates cortical output when released from the inhibitory tonic influence of the striatum (Baxter et al., 1996). Increased thalamic volumes have been reported in OCD children (Gilbert et al., 2000). After 12 weeks of therapy with paroxetine, thalamic volume decreased significantly in these same OCD children to control levels. The change in volume correlated positively with the reduction in OCD symptom severity after the paroxetine treatment. This finding may be specific to SSRI therapy, as no significant change in thalamic volume was observed in treatment-naïve pediatric OCD patients treated for 12 weeks with cognitive behavioral therapy (Rosenberg et al., 2000b). Furthermore, paroxetine-induced reduction in thalamic volumes seems to be localized to medial thalamic regions (Nolan et al., personal communication, January 2001).

These findings are intriguing in view of recent findings in which MRS localized neurochemical marker abnormalities in pediatric OCD patients to the medial but not the lateral thalamus (Fitzgerald et al., 2000). This marker (*N*-acetyl-aspartate) is believed to be a reliable indicator of neuronal viability (Birkin and Oldendorf, 1989). After 12 weeks of effective paroxetine therapy, concentrations of this marker increased in the OCD patients (Amponsah et al., 2000). Longitudinal studies are needed to measure changes in the concentrations of this marker during the course of illness.

## Conclusions

These studies suggest that pediatric OCD may be associated with a reversible glutamate-mediated dysfunction of a ventral prefrontal-striatal-thalamic system. Glutamate concentration may be a marker of illness and a predictor of treatment response. Various brain patterns detected by brain imaging studies, for example, may predict response (or lack, thereof) to a particular treatment (e.g., medication versus cognitive behavioral therapy).

## TOURETTE'S SYNDROME

Similar to theories of the pathogenesis of OCD and ADHD, the etiology of Tourette's syndrome (TS) is thought to involve disturbances in cortical-subcortical circuitry involved in the regulation of cognition, affect, and movement. The common involvement of these circuits across these disorders may account in part for their common co-occurrence in clinical populations ( [Peterson et al., 1998](#)).

## Basal Ganglia

Reduced volumes of the basal ganglia have been reported in both adults and children with TS, particularly in the putamen and globus pallidus ( [Peterson et al., 1993](#); [Singer et al., 1993](#)) (Fig. 9.8). These studies also found some evidence for the presence of reduced asymmetry in these regional volumes and for abnormalities in basal ganglia tissue characteristics ( [Peterson et al., 1994](#)). A subsequent study of monozygotic (MZ) twin pairs with TS reported reduced volumes of the caudate nucleus in members of the twin pairs who had more severe tics ( [Hyde et al., 1995](#)). Because the twins were genetically identical, reduced volumes of the right caudate nucleus were presumably caused by nonshared environmental determinants and not the effects of TS vulnerability genes. These anatomic findings are consistent with reports of natural lesions in the basal ganglia that seem to have produced or worsened tic symptoms ( [Liu et al., 1999](#); [Peterson et al., 1996](#)).

**Figure 9.8.** Basal ganglia definitions. The basal ganglia are important in the pathophysiology of several childhood disorders, including attention deficit/hyperactivity disorder, obsessive-compulsive disorder, and Tourette's syndrome. In the top row are presented varying views of the basal ganglia in a high-resolution MRI scan: axial (*left*), coronal (*middle*), and sagittal (*right*). The caudates are red or light blue, the putamen are green or purple, and the globus pallidus nuclei are blue or yellow. In the bottom row are oblique frontal views of three-dimensional volume rendered basal ganglia nuclei, rotated around the anterior-posterior axis successively by 180 degrees from left to right in the row. (Figure courtesy of Brad Peterson.) See [color plate](#).

A host of functional imaging studies have suggested that basal ganglia are dysfunctional in TS subjects. Reduced resting metabolism and blood flow to these regions has been consistently reported ( [Braun et al., 1993](#); [Chase et al., 1986](#); [Hall et al., 1990](#); [Moriarty et al., 1995](#); [Riddle et al., 1992](#)). Many of the early PET and SPECT studies, however, actually did not have adequate resolution to distinguish clearly metabolism and blood flow abnormalities within the basal ganglia regions or between the basal ganglia and nearby cortical regions. Because of ethical concerns about the use of PET and SPECT in children, metabolism and blood flow studies were of symptomatic TS adults, so that generalizing their findings to children is problematic ( [Peterson, 2000](#); [Peterson and Thomas, 2000](#)).

One fMRI study examined the changes in brain activity associated with the voluntary suppression of tics in TS adults ( [Peterson et al., 1998](#)). These subjects alternated between allowing themselves to tic freely and suppressing their tics completely. Tic suppression was associated with increased activity of the ventral portion of the right caudate nucleus and in numerous cortical regions, especially prefrontal and temporal cortices. Tic suppression was also associated with decreased activity of the ventral globus pallidus, putamen, and thalamus bilaterally. The severity of tic symptoms correlated with the change in activity of the basal ganglia and thalamus regions and suggested that as symptom severity increased, the changes in subcortical activity during tic suppression decreased. These findings suggest that the increases in neural activity of subcortical regions—increases in the right caudate and decreases in the rest of the subcortex—participate in the suppression of tics, and that when these cortical-subcortical braking mechanisms fail, tics may be progressively more likely to escape the inhibitory influences of these circuits on motor behavior.

Other functional studies have imaged the dopamine neurotransmitter system in the striatum of TS adults. Several early studies failed to detect abnormalities in the D<sub>2</sub>-receptor system ( [Brooks et al., 1992](#); [Singer et al., 1992](#); [Turjanski et al., 1994](#)). A subsequent preliminary SPECT study suggested the presence of elevated presynaptic dopamine transporter levels in TS subjects ( [Malison et al., 1995](#)), but this finding was not replicated in a larger TS SPECT study ( [Heinz et al., 1998](#)). Another SPECT study of five adult TS MZ twin pairs reported an increased availability of the D<sub>2</sub>-receptor in the caudate nucleus of all five of the more severely affected cotwins ( [Wolf et al., 1996](#)), and differences between cotwins in receptor availability correlated significantly with the differences between twins in tic symptom severity. D<sub>2</sub>-like receptors, however, were reported to be normal in two subsequent PET studies ( [Wong et al., 1997](#)), emphasizing the need to replicate the findings from the MZ twins. Finally, a PET study reported higher F-DOPA accumulation in the left caudate nucleus and right midbrain of 11 TS adolescents compared with 10 sex-matched normal controls ( [Ernst et al., 1999](#)). The results if replicated suggest the presence of increased DOPA decarboxylase enzyme activity in these regions, which would suggest the presence of either a larger number of dopaminergic synapses or enzyme up-regulation in the caudate and midbrain. Clearly, more research is needed to define the role of the dopamine system in TS.

## Corpus Callosum

The apparent abnormalities in structural lateralization of the basal ganglia in TS prompted the search for abnormalities in other structurally lateralizing neural systems, including the corpus callosum. This structure was found to be smaller throughout all of its subregions in TS adults ( [Peterson et al., 1994](#)). A subsequent study in children, however, found the structure to be larger in children who had "pure" TS (i.e., without OCD or ADHD), with abnormalities confined to the anterior portions of the structure. These seemingly contradictory findings could reflect chance findings owing to methodologic differences, or they could reflect real morphologic differences in the callosum of TS children compared with adults. The latter possibility is strengthened by recent age-specific findings in the cortices of TS children and adults (see the following).

## Cortical Regions

A large anatomic imaging study examined regional cortical and ventricular volumes in 155 TS and 131 healthy children and adults ( [Peterson et al., 2001](#)). The most prominent regional effect in TS subjects was a larger volume of dorsal prefrontal cortex. This effect, however, derived primarily from larger volumes in TS children. Group differences were less prominent in older children owing to an inverse association of age with prefrontal volumes in the TS group. In fact, by adulthood, the TS subjects had smaller dorsal prefrontal volumes. Similar effects that were specific to age group were observed in the parieto-occipital region, where volumes were larger in younger TS children but negligibly larger by late adolescence. In adults, parieto-occipital volumes were still significantly larger in TS men but were significantly smaller in TS women. Group differences were nearly identical in inferior occipital regions, except that volumes were not significantly different for TS men. Because tic symptoms typically attenuate through adolescence, smaller prefrontal volumes in symptomatic TS adults could have contributed to the relatively unusual persistence of their symptoms into adulthood, and then to the subsequent clinical identification and inclusion of those adults in the imaging study.

Prominent sex differences were observed in normal individuals but not in TS subjects in the parieto-occipital region. The finding was strongest in adult subjects. This difference between groups was owing to relatively larger volumes in TS males and smaller volumes in TS females. This finding is consistent with a previously hypothesized involvement of sexually dimorphic brain regions in the pathophysiology of TS ( [Peterson et al., 1992](#)) and may account in part for the predilection of TS to affect males more often than females.

Regional cerebral volumes were significantly associated with the severity of tic symptoms in orbitofrontal and parieto-occipital regions, suggesting that smaller volumes in these regions may provide insufficient inhibitory reserve to help suppress tics. Larger prefrontal volumes in the TS subjects may represent an activity-dependent structural plasticity that could help to suppress tics, consistent with numerous preclinical and clinical studies suggesting that the orbitofrontal region plays an important role in inhibitory control ( [Diamond and Goldman-Rakic, 1989](#); [Divac et al., 1967](#); [Drewe, 1975](#); [Fuster, 1997](#); [Goldman-Rakic, 1987](#); [Iverson and Mishkin, 1970](#); [Luria, 1980](#); [Mishkin and Manning, 1978](#); [Rosvold and Mishkin, 1961](#)). The presence of larger prefrontal volumes that correlate with symptom severity

is also consistent with the prior finding that prefrontal activation is required by TS subjects to suppress their tics ( [Peterson et al., 1998](#)). The larger premotor regions in men compared with smaller volumes in TS boys, in contrast, were hypothesized to represent long-term, activity-dependent effects in the motor system associated with the presence of tics. Longitudinal imaging studies are required to understand better the age-associations seen in TS imaging studies, particularly whether age-related findings represent central deficits or compensatory responses to the longstanding presence of tics and related symptoms.

## PEDIATRIC AUTOIMMUNE NEUROPSYCHIATRIC DISORDERS

Exacerbations of tic and OCD symptoms associated with group A beta-hemolytic *Streptococcus* (GABHS) infections are now typically referred to as pediatric autoimmune neuropsychiatric disorders (PANDAS) ( [Swedo et al., 1998](#)). Recent imaging investigations of PANDAS have reported enlarged basal ganglia volumes ( [Giedd et al., 1995, 2000](#)). Other investigators recently extended this finding and reported that chronic or recurrent GABHS infections were associated with increased basal ganglia volume in OCD and ADHD patients ( [Peterson et al., 2000c](#)). They also observed correlations between antibody titers and basal ganglia volumes. Moreover, at least some forms of immunotherapy (e.g., plasmapheresis) seem to attenuate GABHS-related OCD symptoms ( [Allen et al., 1995](#)), and normalization of basal ganglia volumes may accompany the improvement in OCD symptoms ( [Giedd et al., 1996a](#)). In at least one study, however, the associations between antibody titers and basal ganglia volumes were most prominent in children with ADHD ( [Peterson et al., 2000c](#)), suggesting that basal ganglia enlargement may not be specific to autoimmune subtypes of OCD and tic disorders.

Both increased and decreased basal ganglia volumes therefore have been associated with pediatric OCD and ADHD. This may suggest that nonspecific volumetric disturbances in the striatum may be more relevant for striatal function than any particular direction of change. It may also suggest the existence of distinct neurobiological subtypes of pediatric OCD and ADHD—namely, those that are and those that are not associated with recent GABHS infection.

## MOOD AND ANXIETY DISORDERS

Compared with other areas of pediatric brain imaging, relatively few neuroimaging studies have contributed to the neurobiological understanding of pediatric mood or anxiety disorders, with the exception of research on OCD. In fact, as of this writing, only four published studies and a handful of other unpublished reports have compared brain structure or function between healthy and ill children using modern neuroimaging methods. Two of these studies examined major depression, and one each examined bipolar disorder or generalized anxiety disorder.

The two studies of major depression used structural MRI and MRS to examine brain volumes and neurochemistry in depressed children ( [Steingard et al., 1996, 2000](#)). The volumetric study compared frontal lobe volumes between depressed and healthy subjects ( [Steingard et al., 1996](#)), based on extensive research implicating the frontal lobes in various forms of psychopathology, including major depression ( [Drevets, 2000](#)). This study found reduced frontal lobe volumes in pediatric depression. Of note, this initial study employed relatively older morphometric techniques, and recent studies of depression among adults suggest that structural abnormalities may vary as a function of family history or particular components of the frontal lobes. For example, familial forms of major depression show particularly consistent associations with abnormalities in ventral frontal regions, in the vicinity of the subgenual cingulate gyrus ( [Drevets, 2000](#)). In unpublished work among adolescent twins ( [Botteron, 1999](#)), an association seems to exist between major depression and subgenual cingulate abnormalities.

Consistent with this focus on frontal lobe pathology, the MRS study of depressed children compared choline-to-creatinine levels in the orbitofrontal cortex of depressed and healthy adolescents ( [Steingard et al., 2000](#)). Studies among adults have noted an association between brain choline levels and depression, although associations vary by brain region and disorder ( [Renshaw et al., 1997](#)). The childhood study found evidence of increased brain choline in depressed adolescents. In addition to these studies of unipolar depression, high rates of T<sub>2</sub>-hyperintensities on structural MRI have been observed in bipolar children, consistent with data in bipolar adults ( [Botteron et al., 1995](#)).

The only study of pediatric generalized anxiety disorder reported enlarged volumes of the right amygdala ( [De Bellis et al., 2000](#)). It is worth noting that enlarged amygdala volumes have been reported in studies of adults with bipolar disorder ( [Altshuler et al., 2000](#)) but not in studies of adults with anxiety disorders. Such structural findings have stimulated functional MRI studies of amygdala activity. A relationship between anxiety levels and the degree of amygdala activation has been noted in children during face viewing, a task that normally increases amygdala activity in both children and adults ( [Thomas et al., 2000](#)).

Two areas appear particularly promising for future study in children with mood or anxiety disorders. First, depressed or anxious adults seem to have both structural and functional abnormalities in limbic brain regions involved in memory and attention ( [Drevets, 2000](#)), consistent with neuropsychological studies of attention and memory in mood and anxiety disorders ( [McNally, 1996](#); [Mineka and Sutton, 1992](#); [Moog and Bradley, 1998](#)). Despite evidence from two studies relating mood or anxiety in children to mnemonic dysfunction ( [Moradi et al., 1999](#); [Pine et al., 1999](#)), evidence from other studies suggest that this association may only be found in subsets of depressed or anxious children ( [Frost et al., 1989](#); [McClure et al., 1997](#); [McGee et al., 1986](#)). This might include children with severe, persistent, or comorbid forms of depressive or anxiety disorders. Further neuroimaging studies of limbic structure and function in these children are needed. Second, abnormalities in lateralized brain functions using quantitative EEG and dichotic listening tests have been documented in adults with mood or anxiety disorders ( [Kayser et al., 2000](#)). Similar abnormalities have recently been reported in depressed or anxious children and adolescents (Kentgen et al., in press; [Pine et al., 2000](#)), suggesting that future neuroimaging studies should investigate lateralized neural systems in these disorders.

## POSTTRAUMATIC STRESS DISORDER

The majority of neuroimaging studies of posttraumatic stress disorder (PTSD) have been conducted in adults. Functional imaging studies using PET and SPECT have characterized changes in brain activity associated with exposure to pictures or scripts that recall past traumatic events. These studies suggest that PTSD is associated with changes in key cortical (e.g., prefrontal, cingulate, orbitofrontal) and subcortical (e.g., hippocampus, amygdala) structures known to be involved in the regulation of the stress response and control of memory functions ( [Newport and Nemeroff, 2000](#)). Specifically, when exposed to these trauma-related stimuli, adults with PTSD show increased regional cerebral blood flow (rCBF) in orbitofrontal cortex ( [Rauch and Shin, 1997](#); [Shin et al., 1999](#)), posterior cingulate cortex ( [Bremner et al., 1999a,b](#)), or the amygdala ( [Liberzon et al., 1999](#); [Rauch et al., 2000](#); [Shin et al., 1997](#)). Decreased rCBF is seen in the medial prefrontal cortex of subcallosal gyrus ( [Bremner et al., 1999a,b](#)), anterior cingulate ( [Bremner et al., 1999b](#); [Shin et al., 1999](#)), or hippocampus ( [Bremner et al., 1999a](#)). The relatively small number of subjects included in these studies has contributed to the variability in these findings. Nevertheless, when significant changes in rCBF have been reported in a given brain region, the direction of change has been consistent across studies, and each of the preceding changes in rCBF have been replicated at least once.

The most consistent finding across several structural MRI studies of adults with PTSD has been reduced hippocampal volume ( [Bremner et al., 1995, 1997](#); [Gurvits et al., 1996](#); [Stein et al., 1997](#)). These reduced volumes may represent local tissue atrophy, possibly a toxic consequence of stress-induced elevations in circulating glucocorticoids (e.g., cortisol) and excitatory neurotransmitters (glutamate). No consistent changes in amygdala volume have yet been documented in these structural imaging studies ( [Bremner et al., 1997](#); [Gurvits et al., 1996](#)), despite consistent findings of functional abnormalities in these regions in PTSD.

Only two neuroimaging studies have yet been reported in children and adolescents with PTSD. One was a pilot MRS study of 11 maltreated children with PTSD and 11 healthy, nontraumatized controls ( [De Bellis et al., 2000](#)). Concentrations of *N*-acetyl-aspartate (NAA) were measured in the anterior cingulate gyrus ( [De Bellis et al., 2000](#)), based on findings from adult studies of anterior cingulate dysfunction in PTSD ( [Bremner et al., 1999a](#); [Shin et al., 1999](#)). Reduced NAA concentrations were detected in the maltreated children, suggesting the presence of reduced integrity of anterior cingulate neurons in children with PTSD.

The other was a morphometric study that attempted to replicate the association between PTSD and reduced hippocampal volumes previously reported in adults ( [Bremner et al., 1997](#); [Gurvits et al., 1996](#); [Stein et al., 1997](#)) and in preclinical studies of early stress effects on hippocampal structure ( [Sapolsky, 2000](#)). Regional brain volumes were examined in 44 maltreated children with PTSD and 61 matched controls ( [De Bellis et al., 1999](#)). Unlike the findings from adult studies, hippocampal volumes were normal in children with PTSD. This study did report, however, an overall reduction in brain volume in pediatric PTSD that correlated with various indices of environmental stress ( [De Bellis et al., 1999](#)). Children with PTSD also had smaller medial and posterior portions of the corpus callosum, and volumes of the right and left lateral ventricles were significantly increased over control values.

Relevant to these findings in children with PTSD is an MRI study that examined the effects of early stress on brain structure in prepubescent nonhuman primates ( [Sanchez et al., 1998](#)). Most preclinical studies of early stress have examined the long-term impact of these experiences on brain development in adult animals. In contrast to findings in adult animals, this study of young primates failed to detect hippocampal atrophy. Instead, reduced size of the medial and caudal portions of the midbody of the corpus callosum was detected, consistent with the findings from structural imaging studies of maltreated children ( [De Bellis et al., 1999](#); [Teicher et al., 2000](#)). A recent abstract has reported that psychiatric inpatients with a history of maltreatment had a similarly reduced size of the medial and caudal portions of the corpus callosum compared with controls without a history of early childhood trauma ( [Teicher et al., 2000](#)). The significance of these corpus callosum findings, if they

are replicated, is not clear. Several of the regions that are interconnected through these portions of the corpus callosum are also connected with prefrontal cortical areas that mediate the processing of emotional stimuli and various memory functions that comprise the core disturbances in PTSD ( [Pandya and Seltzer, 1986](#)). If corpus callosum abnormalities contribute to the pathophysiology of PTSD, they may do so via downstream effects on these prefrontal regions. Clearly, more research is needed to understand the neural underpinnings of PTSD in children, especially because the neuroanatomic and functional abnormalities associated with PTSD may differ between children and adults.

## DYSLEXIA

Reading disability is characterized by the failure to develop age-appropriate reading skills despite normal intelligence and adequate reading instruction. Behaviorally, deficits are most evident at the level of single word and pseudoword reading, in which reading disabled (RD) performance is both slow and inaccurate relative to nonimpaired (NI) readers. Many lines of evidence converge on the conclusion that the difficulties with word and pseudoword reading in developmental dyslexia, to a large extent, are manifestations of more basic deficits at the level of rapidly assembling the phonologic code represented by a token letter string ( [Bradley and Bryant, 1983](#); [Lieberman et al., 1989](#)). Given this behavioral literature, the studies selected for discussion here will involve a comparison of RD and NI reading groups on word and pseudoword reading tasks that stress phonologic processing. For a discussion of functional neuroimaging studies that have examined sensory-level processing deficits in developmental dyslexia ( [Demb et al., 1998](#); [Eden et al., 1996](#)) the reader is referred to [Eden and Zeffiro \(1998\)](#). For reviews of research examining differences in brain structure between RD and NI groups, please see [Filipek \(1995\)](#) and Galaburda (1992).

When contrasting the functional organization of the brain in nonimpaired and reading disabled populations, we must turn first to the literature on the neurobiology of skilled reading. Converging findings from a number of laboratories using several imaging technologies fMRI, PET, and magnetoencephalography (MEG) indicates that printed word and pseudoword reading is based in a left hemispheric, posterior reading system consisting of two components, a ventral and dorsal component. The *ventral circuit* includes lateral extrastriate areas and a left inferior occipito-temporal area, where functional imaging studies show robust and early (i.e., 150 to 180 msec) activity as subjects perform word and pseudoword reading tasks ( [Fiez and Peterson, 1998](#); [Frackowiak et al., 1997](#); [Henderson, 1986](#); [Nobre et al., 1994](#); [Puce et al., 1996](#); [Salmelin et al., 1996](#)). The more *dorsal circuit* includes the angular gyrus and supramarginal gyrus in the inferior parietal lobule, as well as the posterior aspect of the superior temporal gyrus (Wernicke's area). This latter temporo-parietal circuit has long been implicated in reading. A large literature associates the acquired inability to read (alexia), for example, with neuroanatomic lesions that are centered most prominently about the angular gyrus ( [Damasio and Damasio, 1983](#); [Dejerine, 1891](#); [Henderson, 1986](#)), a region considered pivotal in carrying out the cross-modal integration of sensory stimuli that is necessary for reading (i.e., the mapping of the visual percept of printed letters onto the phonologic structure of language) ( [Benson, 1994](#); [Black and Behrmann, 1994](#); [Geschwind, 1979](#)). An *anterior circuit* centered in and around Broca's area in the inferior frontal gyrus appears to be associated with, among other things, the sequencing and control of speech-gestural articulatory recoding. This circuit is also involved in silent reading and naming ( [Fiez and Petersen, 1998](#); [Frackowiak et al., 1997](#); [Pugh et al., 1996, 1997](#); [Shaywitz et al., 1998](#)).

Neuroimaging studies of skilled readers reveal task-dependent differences in activity of the dorsal and ventral regions in the posterior left hemisphere reading system ( [Frackowiak et al., 1997](#); [Pugh et al., 2000](#)). These differences prompt speculation about the distinctive roles of these circuits in word and pseudoword reading. The dorsal circuit may play a critical role in extracting the predictable mappings among the orthographic, phonologic, and morphologic forms of words with the lexical-semantic properties of words, binding these properties into integrated mental representations. This circuit may be necessary for rule-based, algorithmic, learning. By contrast, the ventral occipito-temporal area, the point of contact between the ventral visual stream and the middle to inferior temporal lobe, may constitute a linguistically structured, memory-based, fast word identification system (i.e., a template-like device for recognizing word-forms). Research on a large sample of children at different ages suggests that the ventral word form area likely plays an increasingly important role in word identification in NI readers as they develop skill ( [Shaywitz et al., 2000](#)). That work also suggests that the development of this ventral circuit with increasing age and skill depends on the integrity of the dorsal circuit's analytic processing.

### Posterior and Anterior Circuits in Reading Disability

NI and RD readers clearly differ with regard to task-related activity in these dorsal, ventral, and anterior portions of reading circuitry. Functional imaging studies of phonologic processing in RD readers, for example, have repeatedly shown dysfunction of the left posterior hemisphere system in both the dorsal and ventral sites ( [Brunswick et al., 1999](#); [Helenius et al., 1999](#); [Horwitz et al., 1998](#); [Pugh et al., 2000](#); [Rumsey et al., 1997](#); [Salmelin et al., 1996](#); [Shaywitz et al., 1998, 2000](#); [Simos et al., 2000](#)). This disruption is reflected both by a relative under-engagement of these circuits, as well as a reduced functional connectivity between them, specifically when the phonologic decoding of words and pseudowords is required. Dysfunction in the activity of these regions and the associations among them is consistent with a recent anatomic study using diffusion weighted imaging that reported the presence of structural anomalies in white matter tracts within the temporo-parietal region of the left hemisphere (Klingsberg et al., 2000). In a recent examination of children ( [Shaywitz et al., 2000](#)), abnormal activation was observed in RD readers at both dorsal and ventral left hemisphere sites during word and pseudoword reading tasks, confirming that similar abnormalities observed previously in adults are also present in children ( [Rumsey et al., 1997](#); [Shaywitz et al., 1998](#)). This posterior anomaly was confined to tasks of word and pseudoword reading (demonstrating the linguistic specificity of the finding), and it was seen in both adults and children.

In several studies, some of the differences between RD and NI groups in brain activity appears to be compensatory for deficits elsewhere ( [Shaywitz et al., 1998, 2000](#)). On tasks that make explicit demands on phonologic processing (pseudoword and word tasks), for example, RD readers showed a disproportionately greater engagement of inferior frontal gyrus and prefrontal dorsolateral sites than did NI readers ( [Brunswick et al., 1999](#); [Richards et al., 1999](#); [Rumsey et al., 1997](#); [Salmelin et al., 1996](#)).

Evidence of a second apparent compensatory shift (in this case, to the posterior right hemisphere), comes from several findings. In one study ( [Shaywitz et al., 1998](#)), greater right than left hemisphere activation was observed in RD readers, whereas greater left than right hemisphere activation was detected in NI readers ( [Barnea et al., 1994](#)). Additionally, in these same reading tasks, the major posterior circuits in the left hemisphere of RD readers did not correlate with one another as they did in NI readers, suggesting a problem with the connectivity of these circuits. In contrast, RD readers displayed strong correlations at homologs of these sites in the right hemisphere that were more robust than the correlations among these regions in NI readers ( [Pugh et al., 2000](#)). Right hemisphere activation seems to correlate with standard measures of reading performance only in children and adult RD readers ( [Rumsey et al., 1999](#); [Shaywitz et al., 2000](#)), suggesting a compensatory function for the shift to the right hemisphere.

### Summary

Posterior reading circuits including both dorsal (temporo-parietal) and ventral (occipito-temporal) components are disrupted in people who are reading disabled, as indicated by reduced activation as well as disrupted functional connectivity among these areas. Additionally, there appear to be two characteristic compensatory patterns in response to this posterior left hemisphere anomaly: (a) increased reliance on inferior frontal gyrus during reading and (b) an increased tendency to rely on the RH homologs of the dysfunctional left hemisphere posterior circuits.

The studies of children suggest the following model. In the normally developing NI reader, the development of the posterior left hemisphere reading circuits, particularly the ventral occipito-temporal area, is dependent on an organized integration of phonologic, morphologic, and lexical-semantic processing of words within highly overlapping neural circuits. This integration presumably relies initially on the intactness of processing in the temporo-parietal circuit. Deficient dorsal function will fail to support appropriate ventral development. Thus, in the RD reader, temporo-parietal difficulties disrupt the normal developmental trajectory of the occipito-temporal circuits. The shift to inferior frontal sites in the RD child reflects a compensatory reliance on these circuits to support articulatory recoding (covert pronunciation) in an attempt to cope with a problematic phonologic analysis of printed words. A second compensatory shift, from posterior left hemisphere to posterior RH, likely reflects the development of an additional word recognition process that is essentially visual-perceptual—graphemic patterns in the printed word are associated directly with entries in the RD reader's mental lexicon. Thus, these visual patterns do not code the phonologic or morphologic information that the NI reader perceives within the printed word but instead represent the printed word as a nonlinguistic visuo-semantic icon.

## FUTURE DIRECTIONS OF NEUROIMAGING IN DEVELOPMENTAL NEUROPSYCHIATRIC DISORDERS

### Imaging Technologies

The immediate and intermediate future of brain imaging in childhood disorders will be dominated by investigations that employ MRI because of its safety in cross-sectional and longitudinal studies. The use of PET and SPECT will be limited because of their dependence on radioactive ligands and tracers that are

problematic in children, especially normal control children.

Technological advances have intensively driven brain imaging, like most of science. These advances dictate the kinds of scientific questions we are able to ask in our studies. Technological innovations that will affect MRI studies include the application of scanners with higher magnetic field strength, which provide greatly improved resolution and signal-to-noise in the images. MRS and DTI will be applied increasingly to the study of chemical compounds and fiber tract tracing studies, particularly as magnetic field strengths increase to improve the information available from these imaging modalities.

### **Broadening the Scope of the Disorders Studied**

Despite the high prevalence and morbidity of many childhood developmental neuropsychiatric disorders, such as depression, conduct disorder, anxiety disorders, and pervasive developmental disorders, and despite the known importance of biological, environmental, and developmental determinants in each, remarkably few imaging studies of these disorders in children have been reported. These are currently areas of increasingly intense focus, however, and we will soon learn much about the pathophysiology of these childhood conditions.

### **Studying Pathophysiologic Determinants**

Aside from technical advances, new directions in the imaging of childhood disorders will involve the novel application of more standard clinical investigative tools to help delineate through imaging studies the genetic and nongenetic determinants of the neurobiological substrate of childhood disorders. Stratifying subjects with respect to the degree of genetic risk (using family-genetic data or genetic markers) and degree of exposure to known nongenetic risks (such as prenatal and obstetric complications) will permit the ascertainment of the effects of genetic and nongenetic factors on the neurobiological substrate of these disorders.

The effects of these factors will likely be most evident in their interactions for the vast majority of complex neuropsychiatric disorders. A given nongenetic risk factor may exert its effect on neurobiologic substrate, for instance, only in the context of some threshold of genetic risk or vulnerability to developing the disorder. Conversely, nongenetic determinants appear to have varying degrees of importance in the pathophysiology of childhood neuropsychiatric disorders. Exposure to a nongenetic risk factor during a period of developmental vulnerability alone may be sufficient to produce a specific disorder and its corresponding substrate; alternatively, an environmental exposure may predispose to any number of disorders, in which case the child's specific genetic and other constitutional endowments will determine which particular disorder is manifested. Only careful clinical and biological characterization will permit the kind of dissection of pathophysiology that will discern the effects of these numerous determinants on neurobiological substrate and disease phenotype. These studies necessarily also will involve a large number of subjects to permit these associations and interactions to be detected reliably.

### **Longitudinal Studies**

Finally, perhaps the most important scientific information to be obtained in imaging childhood neuropsychiatric disorders will derive increasingly from longitudinal studies of brain structure and function in normal and pathologic development. The importance of studying developmental changes in brain structure and function in normal children for the improved understanding of pathologic brain development cannot be overemphasized. Longitudinal imaging studies are understandably less feasible than simple cross-sectional studies, given the potential difficulties inherent in longitudinal research with patient compliance and current concerns about radiation exposure with PET and SPECT that limit the possibilities of repeated examinations within subjects. Nonetheless, longitudinal imaging studies are necessary to determine whether individual and group differences seen in disease states are a cause or consequence of the disease. Longitudinal studies also are necessary to begin discerning the effects that normal CNS maturation has on the unfolding of the clinical expression of a disease at characteristic times and in characteristic manners at varying stages of development. Sizable longitudinal studies, combined with careful clinical and biological characterization of subjects, thus will permit the beginning elucidation of the mechanisms whereby genetic and environmental risk, in the context of normal and pathologic CNS maturation, interacts to produce a particular neurobiological substrate and subsequently unique clinical phenotype.

A useful theory of child and adolescent development should provide a guiding framework for organizing and conceptualizing information about thoughts, feelings, and behavior. Recently, models that have integrated concepts from different theories offer promising backdrops for understanding the course of human development (Kendall, 2000b). One of these integrative approaches, the cognitive-behavioral model, combines features of learning theory with aspects of human information processing to explain both adaptive and maladaptive behavior during childhood and adolescence. Instead of considering it an exotic, new theoretical model, the cognitive-behavioral approach can be viewed as an evolving theoretical orientation—one that attempts to preserve concepts of behavior therapy (within a less doctrinaire context), while incorporating the cognitive activities of the individual (Kendall and Hollon, 1979). In this chapter, we briefly review the evolution of a cognitive-behavioral approach by: (a) presenting the general principles of the behavioral and cognitive models, (b) discussing how the combination of these concepts contributes to the development of cognitive-behavioral interventions, and (c) considering how the integrative techniques are best applied to the treatment of psychopathology during childhood and adolescence.

Our first section begins with a discussion of the behavioral approach, a framework that conceptualizes human actions in terms of overt behavior, whenever possible. The next section presents the principles of the cognitive model, a perspective that emphasizes the contribution of people's beliefs, expectancies, and other cognitive activities for producing and understanding thoughts, feelings, and behavior. The ideas of the behavioral and cognitive models are combined into an integrative theoretical perspective with the introduction of the cognitive-behavioral model in the third section. To discuss the theoretical orientation of the cognitive-behavioral approach in greater detail, the remainder of the chapter considers the application of cognitive-behavioral therapy (CBT) to human problems. This discussion considers the key elements of CBT including treatment goals and strategies, the role of the therapist, and the conceptualization of therapeutic change.

## PRINCIPLES OF THE BEHAVIORAL MODEL

The behavioral model focuses on the manner in which human behavior is learned or acquired, and encompasses principles, assumptions, and techniques rooted in learning theory. Consistent with this model, behavior therapy, or behavior modification as it is often called, deals with the assessment, evaluation, and alteration of human behavior. It underscores the observable behavior of the individual and the environmental factors that maintain a particular action. Because behavior is thought to occur as a consequence of its having been learned in the past, behaviorally oriented psychologists stress the role of a person's learning history and reinforcement (pleasant events), as well as the role of the current interpersonal and social environment, as factors that contribute to both adaptive and maladaptive behavior.

A behavioral model rests on the primary assumption that behavior develops and is maintained according to the principles of learning (Herbert, 1988; Johnson et al., 1986). As such, the model argues that when other influencing factors are constant (e.g., biology), the differences that exist among people's behavior are the result of learning. Within this perspective, changes in the environmental influences are thought to have a profound effect on the alteration of both normal and abnormal behavior patterns (O'Leary and Wilson, 1987). Interestingly, although researchers during the first half of the 20th century (Pavlov, 1927; Thorndike, 1911; Watson, 1913) pointed to the importance of behavioral principles in shaping human behavior, it was not until the 1950s that mental health professionals began to apply behavioral techniques on a wider scale to the treatment of mental disorders. To date, the techniques embraced by behavior modification have been used for different populations showing a range of maladaptive behaviors and clinical disorders (e.g., affective, developmental, anxiety, conduct, or oppositional-defiant). In addition, the techniques have been used to alter maladaptive behavior or improve the quality of life of individuals outside of the clinical setting; these efforts have included increasing prosocial interactions among children and their peers, helping individuals adhere to medical regimens, and promoting healthy lifestyles involving exercise and nutritious diets (Bellack et al., 1990; Hersen et al., 1994).

Although applicable to a variety of concerns, behavior therapy also has been useful for different types of individuals. These populations include children, adolescents, and adults in everyday surroundings (e.g., school, work, and home), and also specific groups like individuals in psychiatric settings. Given that behavior modification can be applied to a wide range of problems and populations, it is important to note that this approach does not refer to one specific form of treatment. Instead, behavioral techniques have come to embrace several theories about the development and maintenance of maladaptive behavior. As a result, proponents of behavioral techniques do not all offer the same explanation of behavior. With respect to describing behavior, some behaviorists, for example, stress the importance of processes that result from events in the environment (e.g., consequences of behavior, cues, and feedback). In contrast, other behaviorists emphasize the role of processes within the individual (e.g., perceptions, thoughts).

Although behavior modification encompasses a variety of populations, treatment techniques, clinical concerns, and theoretical perspectives, the approach consistently focuses on the development of adaptive functioning in life. Three forms of learning—the roots of behavior modification—have made significant contributions to our current understanding of how behavior patterns develop: classical conditioning, operant conditioning, and observational learning. Given that each form of learning plays a role in the development of later cognitive-behavioral interventions, we now turn our attention to presenting each form in greater detail.

### Classical Conditioning

Among the many influences on behavior modification is the significant work of Russian physiologist Ivan Pavlov (1849 to 1936). Pavlov's seminal research involved the study of reflex responses with animals, specifically dogs. After using food to stimulate different parts of an animal's digestive system, Pavlov found that animals would begin to secrete gastric juices when they merely saw food or heard food being prepared. This finding was significant because it demonstrated that digestive processes could be elicited in the absence of any physical stimulation. Pavlov continued his work using other environmental stimuli, such as sounds and sights, showing that various environmental incentives could elicit reflex reactions such as salivation (Pavlov, 1906, 1927). He argued that the connections between the environmental stimuli and the animals' reactions were the result of learning that took place in the laboratory. This type of learning is now referred to as classical or respondent conditioning.

In general, classical conditioning is interested in stimuli that evoke responses. The process involves a once, neutral stimulus (e.g., light, noise) that comes to elicit involuntary unconditioned responses or reflex reactions (referred to as respondents). The respondents are often considered automatic responses because they are not under the individual's control. In this way, the association between the neutral, unconditioned stimulus and the response is one that is *not* learned. It is possible, however, for reflex behavior to occur in response to a stimulus that would not automatically evoke the response; in this situation, the behavior is considered one that is

learned. To illustrate the difference between an automatic and learned response, suppose that you find yourself stuck in a dangerous location, such as on the center lines dividing traffic on a major highway. In this situation, your reflex reaction to feel frightened would be perfectly normal and adaptive. When, however, people learn to be afraid of certain things and situations when it may not be adaptive or normal to feel frightened, classical conditioning can help explain the development of these types of fears.

To begin, a realistically dangerous situation produces fear without prior learning or conditioning. Because this fear occurs without learning or conditioning, the dangerous situation is called an *unconditioned stimulus* (UCS), and the reaction, fear, is the *unconditioned response* (UCR). They occur naturally. A neutral stimulus does not itself produce a response; however, a neutral stimulus that is repeatedly paired with a dangerous situation becomes a conditioned stimulus (CS) and can itself lead to the UCR, fear. When the neutral situation itself becomes capable of producing fear, the fear it produces is called a conditioned response (CR). It is the conditioned (learned) responses that are of particular interest in psychopathology. For example, a specific piece of music paired repeatedly in a dangerous situation becomes itself capable of producing fear. Consider the two-note theme from the movie *Jaws*. The music becomes a CS because it has acquired the fear-producing properties via conditioning, and the fear it produces is a CR. Thus, through classical conditioning, a stimulus that was once neutral can gain the power to elicit a reflex response or respondent behavior.

Pavlov's work was significant because his findings offered one explanation for how behaviors can be learned. His specific findings, as well as his tightly controlled methods of laboratory investigation, made important contributions to the study of behavior and launched further examinations of learning processes. In one of the seminal investigations of learned behavior, [Watson and Rayner \(1920\)](#) studied an 11-month-old boy named Albert. In their work, Watson and Rayner provided a significant example of how a fear reaction can be elicited via classical conditioning. The investigators paired an originally neutral stimulus (white animal) with a loud noise (unconditioned stimulus) that produced a startle or fear response (unconditioned response). After pairing the white animal with the noise only seven times during the period of 1 week, the investigators could eventually make Albert respond simply by showing him the white animal. Thus, after 1 week, the conditioned stimulus (animal) was able to elicit the conditioned response (fear). In a related line of research, one of Watson's students, Jones (1924a), reported the case of a 34-month-old boy named Peter. As with Albert, a neutral stimulus was repeatedly paired with an unconditioned stimulus, so that that the neutral stimulus—in this case, a rabbit—would elicit a fear response. After the link between the conditioned stimulus and response was successfully established, the association was systematically deconditioned via gradual pairings of the feared object with positive reactions. Through the process of deconditioning, Peter was able to overcome his fear of rabbits. Collectively, the work of Watson, Rayner, and Jones demonstrated that fears could be both conditioned and deconditioned via the principles of classical conditioning, two findings that exerted a significant impact on the study of behavior.

Another contemporary extension of classical conditioning that is of historical significance is the work of Joseph Wolpe. [Wolpe \(1958\)](#) examined an experimentally induced state, experimental neurosis, in which cats showed disruption of behavior, irritation, agitation, and other symptoms akin to anxiety in humans. In an attempt to decrease the anxiety experienced by the cats, Wolpe gradually exposed the animals to situations and cues that elicited decreased amounts of anxiety. He also encouraged the animals to engage in other activities (e.g., playing or eating) while experiencing states of decreased arousal. Based on his observations, he reasoned that anxiety could gradually be overcome if an animal engaged in competing responses while exposed to anxiety-provoking situations. Eventually, Wolpe applied his research findings to human participants and developed a treatment referred to as systematic desensitization for human anxiety. In this procedure, individuals were exposed to a series of situations, either imaginary or real-life, that provoked increasing levels of anxiety. Wolpe trained his clients to engage in deep relaxation so that the representation of situations would only produce mild forms of anxiety. Relaxation would be paired with the anxiety-provoking situations, and over time, the individual would be able to use relaxation to overcome situations with increasing levels of anxiety. Eventually, the client would not be anxious in response to the stimulus that originally produced anxiety because the conditioned relaxation response was incompatible with the fear.

## Operant Conditioning

An alternate form of learning that was under investigation was concerned, not with examining reflex responses, but with evaluating the impact of different consequences on developing new behavior ([Kazdin, 1978](#)). This separate line of inquiry led to what is now known as operant conditioning—the probability that a response will be increased or decreased when followed by reinforcement or punishment ([Thorndike, 1911](#)). According to the principles of operant conditioning, responses are strengthened and more likely to occur in the future when they lead to satisfying consequences. In contrast, responses are not strengthened and are less likely to occur again in the future if they lead to unsatisfying consequences. Edward Thorndike (1874 to 1949), who was interested specifically in how new behaviors were learned, was most responsible for developing the behavioral principles of operant conditioning. In his well-known puzzle-box experiments with cats, he discovered that rewards (e.g., food for the cat after escape) provided consequences that increased learning of the behavior (e.g., successful exit from the puzzle-box). From his careful experimentation and observations, he formulated principles or laws of behavior, the most significant being the Law of Effect (consequences that follow behavior help learning) ([Thorndike, 1932](#)).

BF Skinner, who was influenced by the work of Pavlov and Thorndike, further developed the theory of behavioral consequences. He was interested in the impact of consequences on behavior and used the principle of reinforcement to describe how behavioral consequences can strengthen the probability of a behavior recurring. He pointed out that many behaviors are performed spontaneously (not as reflex responses) and are controlled primarily by their consequences (not by eliciting stimuli). Skinner referred to these behaviors as operants because the responses operated or demonstrated some type of influence on the environment. Examples of everyday operant behaviors include smiling, laughing, talking, walking, or any other response that is influenced or controlled by its consequences (Skinner, 1953). Operant conditioning, then, is the process of learning operant behavior, and operant behaviors increase or decrease as a function of the events that follow them.

[Skinner \(1938\)](#) outlined four major principles to demonstrate how operant behavior can develop and undergo change. The principles describe the relations between overt behavior and environmental consequences and include: (a) reinforcement, (b) punishment, (c) extinction, and (d) stimulus control. The first principle, reinforcement, refers to an increase in the frequency of a response owing to the presentation or removal of an event after the response. For example, when positive consequences follow a behavior, the behavior is positively reinforced or rewarded, and the behavior is more likely to occur again in the future. Indeed, maladaptive behavior, as well as desired patterns of behavior, can be acquired through their consequences. For example, when a child is polite in the presence of houseguests, she may be rewarded with a snack for her good behavior; however, a child who screams or throws a temper tantrum may also get a snack (reward) simply because the parent wants to calm the child down. Because both types of behavior are rewarded, they are both more likely to occur again.

Given that human existence does not proceed from a sequence of one simple behavior after another, it must be the case that not all behavior has to be directly reinforced to be learned. For example, in the case of complex behavior, the process of rewarding successive approximations (i.e., shaping) does not require the learner to produce an entire new response pattern to receive reinforcement. The shaping process is gradual and the reinforcement is provided for several intermediate steps. As the learner masters each successive step, reinforcement shifts so that it is provided only after the new last step in the sequence is established. Thus, a child's disruptive behavior in the classroom may be the result of a shaping process that has taken years to complete, rather than a behavior that was learned all at once. The fact that maladaptive patterns of behavior can be shaped over time has significant implications for child development ([Gewirtz and Pelaez-Nogueras, 1992](#)) and for understanding and treating ([Mash, 1998](#)) disorders.

Another type of reinforcement is negative reinforcement. With negative reinforcement (which is not the same as punishment), the likelihood of a response increases by the removal of a negative or unpleasant stimulus or situation. For example, if you politely ask a roommate to turn off the television so you can study, and your roommate does so immediately, the likelihood of your making a similar polite request in the future is increased. The polite request was reinforced by the removal of the unwanted (aversive) television distraction. A different but related situation characterized by negative reinforcement involves avoidance and escape responses. For example, if a child is continuously teased by her peers, she may try to avoid interacting with her classmates or escape from situations that may lead to uncomfortable scenarios. Eventually, staying away from peer interactions can become associated with anxiety reduction—an avoidance response that prevents the unwanted or aversive emotions, but also has unwanted effects in terms of reduced socialization.

Skinner's other principles of behavior also describe the relations between overt behaviors and environmental consequences. Punishment, for example, refers to a decrease in the frequency of a response owing to the presentation or removal of an event after the response. Thus, if a child is scolded for misbehaving in front of guests (i.e., a negative outcome), the likelihood that the unwanted behavior (i.e., the misbehavior) will occur in the future is reduced. Extinction, the third principle of behavior, refers to a decrease in the frequency of a previously reinforced response owing to the removal of the reinforcing event after the response. For example, a parent may try to extinguish the occurrence of temper tantrums by removing what was once used as a reinforcer (e.g., snack). The act of removing the reinforcing event may work to decrease the unwanted behavior. Skinner's fourth and final principle, stimulus control, refers to a procedure in which a response is reinforced in the presence of one stimulus but not another. This process works to increase the frequency of the response in the presence of the former stimulus, while decreasing the frequency of the response in the presence of the latter stimulus.

As with classical conditioning, the principles of operant conditioning have extended beyond the experimental laboratories from which the laws of behavior originated. Specifically, the application of operant conditioning principles have benefited children and adolescents who demonstrate speech or language delays ([Drash and](#)

[Tudor, 1990](#); [Lovaas, 1977](#)), exhibit social skills deficits ([Elliott and Gresham, 1993](#)), are about to undergo medical procedures ([Horne et al., 1994](#)), and who have been diagnosed with clinical disorders such as autism ([Harris and Weiss, 1998](#)), attention deficit hyperactivity disorder ([Pelham et al., 1993](#)), and obesity ([Williams et al., 1993](#)). Although this portion of the chapter could provide only a sketch of certain learning principles and how they can be applied to human problems, we later address the importance of behavioral principles with respect to assessing, understanding, and treating psychological concerns. For now, it is important to note that the early investigations on conditioning principles sparked researchers to apply principles of learning to a variety of concerns within child clinical populations ([Ullman and Krasner, 1965](#)).

## Observational Learning

Observational learning or modeling is a type of learning in which behaviors are learned by observing others ([Bandura, 1969](#)). Modeling is a primary factor in social learning theory (also known as social cognitive theory) ([Bandura, 1977, 1986; Bandura and Wilson, 1963](#)), a theory that proposes that behavior is the product of both external stimulus events and internal cognitive processes. Social learning theory tries to expand on the cause–effect type of relations described by the aforementioned conditioning principles; it does this by combining the two conditioning perspectives with an understanding of cognitive processes. According to [Bandura \(1977\)](#), three types of regulatory processes govern learned behavior: (a) paired stimulus–response events (as in classical conditioning), (b) environmental consequences (as in operant conditioning), and (c) symbolic cognitive processes. The most significant of the three components are cognitive processes, and specifically those that involve observational learning—the hallmark of social learning theory. For example, a child who views another child being rewarded for talking politely in class will be more likely to engage in similar behavior. In this way, an individual's social context is important because it provides several opportunities for behavior to be observed and eventually imitated.

Two additional features of social learning theory underscore the theory's departure from the more deterministic, cause–effect view of human nature as described by the classical and operant conditioning theories. One concept is the notion that behavior is determined by the interaction of three factors: cognitive, behavioral, and other environmental factors ([Bandura, 1986](#)). This interplay, referred to as “triadic reciprocity,” stresses the importance of all three components for determining behavior. Another distinguishing feature of social learning theory is its emphasis on the capacity for self-directed change (i.e., self-efficacy) ([Bandura, 1977](#)). This notion, which reaffirms the concept of “triadic reciprocity,” carries significant import with respect to understanding the development of behavior patterns and the treatment of maladaptive functioning. Both the ideas of self-directed change and “triadic reciprocity” reappear later in this chapter as important components of cognitive-behavioral theories and interventions. We now turn our attention to presenting the next step in the evolution of the cognitive-behavioral theoretical orientation—a description of the cognitive model.

## PRINCIPLES OF THE COGNITIVE MODEL

From a behavioral perspective, observable phenomena play an essential role in how human dysfunction is assessed and understood. Although individuals' thoughts and feelings may not be completely ignored with respect to clinical problems, emphasis is placed on what a person does, or how a person behaves. Thus, human problems are conceptualized in terms of overt behavior whenever possible. In contrast, cognitive perspectives ([Beck, 1964; Ellis, 1962; Meichenbaum, 1977](#)) assert that people's beliefs, attitudes, expectancies, attributions, and other cognitive activities are central to producing, understanding, and predicting behavior, especially psychopathologic behavior. [Ellis' \(1962\)](#) rational-emotive theory, [Beck's \(1963, 1976\)](#) cognitive theory, and [Meichenbaum's \(1985\)](#) cognitive analysis have played significant roles in generating acceptance of such cognitive phenomena. Theoretical advances of learning theorists, such as [Kanfer's \(1970\)](#) notion of self-regulation and [Bandura's \(1977\)](#) theory of self-efficacy, have also helped legitimize the importance of covert cognitive processes. Cognitive theorists, then, assert that individuals are active participants in their environments, judging and evaluating stimuli, interpreting events and sensations, and appraising their own responses ([Beck and Weishaar, 1995](#)).

Cognitive models argue that cognitive functioning contributes to emotional and behavioral distress. How human beings recognize, perceive, reason, and judge information has come to play an important role in attempts to understand the development of different disorders. According to [Beck \(1967\)](#), the individual develops a schema, or frame of reference, from which each individual uniquely views himself or herself, others, and the environment. This schema, then, affects what an individual perceives, recalls, and prioritizes as important. Beck argues that it is through schemas that an individual interprets the world and derives meaning accordingly. When emotional psychopathology is present, it is hypothesized that the activated schemas are maladaptive in nature. As a result, a person may show systematic biases in information processing, such that he may overgeneralize, selectively attend to, magnify or minimize, personalize, or make arbitrary references about information ([Beck, 1967, 1976](#)). For example, a tendency to blame oneself for mistakes, misperceive interpersonal situations, or think negatively about circumstances without sufficient data, are all examples of dysfunctional cognitive processing often limited to depression.

Cognitive theorists suggest that clinical disorders have specific cognitive profiles as evident in dysfunctional schemas, automatic thoughts, and biased interpretations. For a cognitive therapist, then, psychological interventions focus on the cognitive schemas thought to contribute to the development and maintenance of a particular disorder. In contrast, a behavioral approach underscores observable behavior and environmental factors. It is the combination of the two approaches that provides the foundation for a cognitive-behavioral orientation. This perspective stresses the importance of overt behavior and covert cognition, along with the interaction between the two, for explaining the development and maintenance of emotional and behavioral distress.

## THE COGNITIVE-BEHAVIORAL APPROACH

The cognitive-behavioral approach integrates the two more traditional approaches—the behavioral and the cognitive. It is an integration of the methodologically rigorous and performance-oriented behavioral techniques with the evaluation and treatment of cognitive-mediational phenomena ([Craighead et al., 1994; Kendall and Hollon, 1979](#)). In this way, the cognitive-behavioral model is essentially a two-process approach combining behavioral models with a cognitively mediated model. The model places greatest emphasis on the learning process and the influence of contingencies and models in the environment, while stressing the centrality of the individual's mediating/information-processing style in the development and remediation of psychological distress ([Kendall, 2000a](#)). Thus, the cognitive-behavioral model represents an integrationist perspective ([Meichenbaum, 1977](#)) and considers both children's internal and external environments. The hyphenated “cognitive-behavioral” term represents an integration of cognitive, behavioral, emotion-focused, and social aspects of change. Without a singular allegiance to a behavioral or cognitive model, the cognitive-behavioral perspective includes the associations of behavior and cognition to the emotional state and functioning of the organism in the larger social context.

When considering a cognitive-behavioral approach, it is important to recognize how the term cognition is used and understood within this particular perspective. Although some mental health professionals have viewed cognition as inaccessible, cognitive-behavioral theorists have promoted the notion that cognition can be subdivided for access and understanding. For instance, it has been suggested ([Ingram and Kendall, 1986; Kendall and Ingram, 1989](#)) that cognition is a complex system that includes cognitive content (events), processes, products, and structures that can be distinguished.

### Considering Cognition

Cognitive structures, which can also be referred to as cognitive schemata ([Beck, 1976](#)), refer to memory, specifically information that is internally represented in memory. The notion of a cognitive structure can be viewed as a template that filters certain cognitive processes. With more rigid schemas, children's perceptions become more filtered and potentially more dysfunctional ([Lochman and Dodge, 1998](#)).

Cognitive content refers to the information that is actually represented: the contents of the cognitive structures. Cognitive content may be referred to as one's self-talk or internal speech ([Kendall and Hollon, 1981; Meichenbaum, 1977](#)): comments in which the audience is primarily the person himself or herself, and not just those comments in which the individual is the object of the statement.

Cognitive processes are the procedures by which the cognitive system operates: how we go about perceiving and interpreting experiences. Cognitive products (attributions) are the resulting cognition that emerges from the interaction of information, cognitive structures, content, and processes. After several real or imagined experiences, a person can come to have a characteristic way of making sense of events. Attributions about the event and its outcomes reflect the influence of the preexisting structure. In this model, psychopathology can be related to any problem in each or all of these areas, and effective therapy includes consideration of these factors for each individual client.

Children and adolescents are in the process of developing ways to view their world. Cognitive-behavioral treatments seek to provide educational experiences that attend to cognitive content, process, and product (paying attention to the child's self-talk, processing style, and attributional preferences) to help the child/adolescent build a cognitive structure that will have a positive influence on future experiences. For example, the cognitive schema for the anxious child is threat—threat of loss,

criticism, or harm. The child brings this anxiety-prone structure to an experience and processes the experience accordingly. Cognitive-behavioral interventions provide the arena to challenge the youth's preexisting anxious structure (Kendall et al., 2000d). In-session role-playing experiences and exposure experiences are valuable opportunities for learning in such cases.

For the purposes of applying cognitive-behavioral interventions, it is important to understand the nature of the cognitive dysfunction. Because not all cognitive dysfunction is the same, knowing the nature of the dysfunction associated with specific psychological disorders has important implications for treatment ( Kendall, 1993).

### The Nature of Cognitive Dysfunction

Not all cognitive dysfunction is the same. A distinction can be made between cognitive deficiency (lacking careful informational processing where it would be beneficial) in processing and cognitive distortion (dysfunctional thinking processes) in processing ( Kendall, 1981, 2000a), which can help design interventions that direct themselves appropriately to the area of concern.

Distorted information processing has been implicated in anxiety and depression, in which individuals tend to misconstrue or misperceive their social and interpersonal environment. In these cases, there is active information processing, but it is distorted (irrational, illogical, or crooked). For example, in a series of studies with depressed youngsters, the depressed children perceived themselves to be less capable on several dimensions than their nondepressed classmates when, in fact, teachers reported that the nondepressed and depressed children were indistinguishable on the same dimensions that the depressed children saw themselves lacking (Kendall et al., 1990). Thus, it was the depressed children who evidenced distorted thinking via the underestimation or misperception of their competencies. Additional studies have demonstrated that anxious and depressed youth tend to misperceive threats and danger, misperceive demands of the environment, and make attributional errors (anxiety: Daleiden et al., 1996; depression: Hammen and Zupan, 1984).

In contrast to anxious and/or depressed children, impulsive and hyperactive children tend to evidence processing deficiencies in the form of acting without thinking or performing poorly on a task because of a lack of planning or forethought. Children with deficiencies in processing do not engage in careful information processing and their performance suffers as a result. Their difficulties emerge from failing to stop and think before acting, as opposed to distorted processing of information. Studies have shown that aggressive (Dodge, 1985) and impulsive acting-out behavior is in part related to a lack of self-control, a lack of social perspective-taking, and a failure to employ verbal mediational skills ( Kendall and MacDonald, 1993). Interestingly, research has shown that aggressive youth evidence both cognitive distortions and deficiencies. An example of a deficiency is the limited ability to generate alternative, nonaggressive solutions to interpersonal conflicts ( Edens et al., 1999; Lochman and Dodge, 1998; Nelson and Finch, 2000). An example of a processing distortion of an aggressive youth is the child's tendency to misattribute the intentionality of others' behavior (e.g., construing an ambiguous situation as intentional) ( Dodge, 1985).

Cognitive-behavioral treatment strategies are modified to account for whether the youth acts without thinking or partakes in action with misguided thinking. Therapy for youth with cognitive deficiencies requires stopping nonthoughtful activity and developing and deploying skills in thoughtful problem solving. Helping youth with cognitive distortions involves the identification of faulty thinking and correction of distorted processing. Recognition of this distinction and the use of interventions that direct themselves appropriately to the needed arena have benefits for participating youth.

### A Temporal Model: Developing Coping Over Time

Empirical investigation continues to document the role of cognitive concepts such as expectations, attributions, self-statements, beliefs, and schemata in the development of both adaptive and maladaptive behavior patterns and the process of behavior change, yet the interrelations of these and other cognitive factors themselves need further clarification.

A model that can be useful in elucidating these relationships is one built along a temporal dimension. The model must take into account and be able to reflect the cognition associated with behavior across time (e.g., cognitions that occur before, during, and after events). Because events do not occur in a vacuum and behavior is determined by multiple factors, the model must allow for feedback that results from multiple, sequential behavioral events. This implies that the cognition before an event varies and the variation is owing to outcomes of previous events. The model must allow for variations in the pre-event cognition associated with the different outcomes (e.g., successful, unsuccessful) of prior events. Furthermore, the model must emphasize the development of more regularized cognitive processing (e.g., cognitive structures, cognitive styles) because repetitions of cognitive-event sequences result in some consistency in cognition.

The proposed model (Fig. 10.1) illustrates the flow of cognition across behavioral events of different emotional intensity. The starting point (on the left) is the initial behavioral event, which ultimately leads to cognitive consistency (on the right) after much repetition. Attributions are the cognitive concepts that are important after the behavioral event. How do children disambiguate the causes of their behavior once it has occurred? In other words, of all possible explanations that can be proposed, how do youth explain their own and others' behavior to themselves? Attributions are temporally brief in that they occur at the termination of the event. It is possible to assess an attribution long after an event, although many factors (e.g., memory recall) may interfere with accurate recall. Typically, the assessment of attributions occurs soon after the behavioral event took place.

**Figure 10.1.** A temporal model of the flow of cognition across behavioral events of different emotional intensity. Self-statements and images occur at any point and can be studied at various points in the temporal flow. Problem-solving processes also occur at various points, especially where conflicts arise.

Repeated behavioral events and the related cognitive processing result in some degree of consistency in both behavior and cognition. The figure illustrates that cognitive consistency (i.e., beliefs, and attributional style, or a cognitive structure) results from multiple events. These cognitive variables (consistencies over time) are more stable than a single attribution. More stable cognitive style variables may be more predictive in a general sense but are less predictive in specific situations than the actual cognition at the time of the specific behavioral event.

When there is an accumulation of behavioral events and event outcomes, the youth experiences more precise anticipatory cognition (i.e., expectancies). Bandura (1977) described expectancies as outcome expectancies and self-efficacy expectancies. Intentions, plans, and commitments are also anticipatory cognition, which may be more stable and consistent over time than situationally specific expectancies. The generalized expectancy is transitional in nature and can be viewed as an attributional style. For example, the generalized expectancy of an external locus of control can be present both before (expectancy) and after (attribution) an event. Preceding the event, the person's external orientation can lead to the anticipation of having a minimal effect: "Why bother to speak up? No one listens to me." After the event, when a decision has been made without the child's input, the event can be attributed to powerful others: "See? The big mouths always get their way."

Emotional intensity is represented vertically in Fig. 10.1. The higher the elevation of the bar indicating a behavioral event, the more emotionally intense the behavioral event. The greater the emotional intensity is, the more intense the experience is; thus, the greater the impact on the development of cognitive structure (schema). Events that are less emotionally intense may have less influence on attributions, future expectations, and memory, whereas emotionally significant events have greater impact on the development of schema and future thinking. Early negative experiences can result in future dysfunctional thinking. Thus, therapy should be emotionally positive and involve experience, leading to coping and adaptive cognitive processing. Effective cognitive-behavioral interventions for youth capitalize on

creating behavioral experiences with intense emotional involvement, while recognizing and addressing the participant's cognition.

## COGNITIVE-BEHAVIORAL THERAPY

The cognitive-behavioral approach to therapy can be defined as a rational amalgam: a purposeful attempt to preserve the demonstrated positive effects of behavioral therapy within a less doctrinaire context and to incorporate the cognitive activities of the client into the efforts to produce therapeutic change ( Kendall, 1993). According to the model outlined by Kendall (1985), CBT: (a) emphasizes both the learning process and the influence of the contingencies and models in the environment, while it (b) underscores the centrality of mediating information processing factors. As such, this integrative therapeutic approach combines the principles of early learning perspectives with aspects of the cognitive model. When treating children and adolescents, cognitive-behavioral strategies include both performance-based procedures and cognitive interventions to produce positive changes in thinking, feeling, and behavior.

Cognitive-behavioral therapy with children, as in work with adults, emphasizes the effects of maladaptive beliefs and attitudes on current behavior. The assumption is made that a child's reaction to an event is influenced by the meanings he or she has attached to the event. Or, in other words, emotional and behavioral responses to events in one's life are a function of how these events are perceived and recalled, in that the events affect one's self-perceptions and the pursuit of one's goals. In turn, these cognitive processes are influenced by underlying beliefs that individuals maintain about themselves, the world, and the future ( Hammen and Goodman-Brown, 1990). Accordingly, the treatment goal is for children to develop a new cognitive structure or a modified existing structure through which he or she can function adaptively in the world ( Kendall, 2000a). In the next section, we describe the key elements of CBT, including treatment goals and strategies, the role of the therapist, and the conceptualization of therapeutic change.

### Treatment Goal: Building a Coping Template

The notion of the schemata (Beck, 1976) or cognitive structure refers to the template through which an individual perceives and makes sense of the world. Cognitive-behavioral theorists have promoted the notion that this template influences what the individual perceives and how the information is processed and understood.

As children and adolescents develop, their style of processing the world changes. The goal of CBT, then, is to build new "coping" templates through education experiences and therapist-coached reconceptualizations of problems. New experiences, with guided processing of the experiences, are thought to help correct detrimental thinking.

What is being suggested is that the existing cognitive structure is not erased but that new skills and means of construing the world are built, and these new constructions come to serve as new templates for making sense of future experiences. Therapy does not provide a surgical removal of unwanted cognitive structures but offers to help to build new schemata with new strategies that can be employed in place of the earlier dysfunctional ones. Existing cognitive structures are incorporated into the new schemas providing the child with response alternatives. Consequently, the therapy helps to discourage the maintenance of dysfunctional schemas.

An effective program is one that intentionally plans and capitalizes on creating behavioral experiences with intense positive emotional involvement, while paying attention to the anticipatory and after-the-fact cognitive activities of the participants. The therapist guides both the child's attributions about prior behavior and his or her expectations for future behavior. Thus, the child can acquire a cognitive structure for future events (a coping template) that includes the adaptive skills and healthy cognition associated with adaptive functioning. Therapy aims to help a child change dysfunctional schemata into new schemata so that the child can identify and solve problems. The child either develops a new cognitive structure or modifies an existing structure, through which he or she can view a formerly distressing event.

### Elements of the Coping Template

Building a cognitive coping template entails the identification and modification of maladaptive self-statements, along with the building of a new way to view situations—a new structure that is based on coping. Cognitive-behavioral interventions promote the development of skills that are necessary for effective coping. Though several types of skill training techniques have been developed ( Table 10.1) (Kendall, 2000c), we focus mainly on a few procedures that have been most often used and studied. The following is an overview of these skill-building procedures, along with strategies that facilitate the child's acquisition of these skills.

Strategy	Specific intention
Coping modeling	Use of coping modeling, with therapist as role model rather than modeling model; the therapist models coping (into problem, behavior, strategy to deal with problem, eventual success); the coping model "thinks" out loud
Building coping template	Changing client's self-talk, reframing of problems, use of schemas as problems to be solved rather than as personal weaknesses
Rehearsal	Use of different contingencies, given the nature of the disorder being treated; modeling the frequency and intensity of self-evaluation, depending on the disorder
Rehearsal—practice procedures	Role-play exercises Multiple opportunities to practice Exposure to realistic experiences Simulated experiences
Effective education	Learning about feelings, self and others
Learning tools	Problem tools (e.g., worksheets) Homework (out-of-session) assignments

**Table 10.1. General Treatment Strategies Used in Cognitive-Behavioral Therapies with Youth**

## RELAXATION

As part of the treatment of psychological distress, cognitive-behavioral therapies offer exercises and opportunities to build skills in the area of relaxation. Relaxation training aims to teach children to develop awareness and control over their own physiologic and muscular responses. In this procedure major muscle groups of the body are progressively relaxed through systematic tension-releasing exercises ( King et al., 1988). By tensing and relaxing various muscle groups, the individual learns to perceive sensations of bodily tension and to use these sensations as the stimuli to relax.

When teaching these techniques, relaxation-training scripts are often incorporated ( Ollendick and Cerny, 1981). For example, a child is taught to tense and relax her stomach by imagining that she is squeezing through a fence or tensing and relaxing her hand muscles by pretending to squeeze the juice out of a lemon. There are substantial data supporting the beneficial results of teaching relaxation skills to children and adolescents ( Ollendick and Cerny, 1981; Koeppen, 1974).

## CORRECTING MALADAPTIVE SELF-TALK

Cognitively oriented therapies work from the assumption that maladaptive thinking is related to maladaptive behavior. By changing faulty cognitive functioning, thoughts can be restructured, so they can help the client function more effectively, rather than contribute to the client's dysfunction. Addressing the self-talk of children during stressful situations can have positive effects on their performance. Although they engage in some positive thought, they also engage in a detrimentally large amount of negative thought that detracts from and undermines their positive thinking. Data from research on young adults demonstrate that clients who are suffering from undue distress benefit from a reduction in their negative thinking ( Kendall, 1985; Treadwell and Kendall, 1996).

## PROBLEM SOLVING

Another component of the cognitive-behavioral approach is problem solving. Problems occur in the lives of all children and adolescents. The ability to solve problems is necessary for adequate adjustment in childhood. The overall goal of teaching problem solving is training children to develop confidence in their own ability to help themselves meet daily challenges. D'Zurilla and Goldfried (1971) have outlined a five-stage problem-solving sequence ( D'Zurilla and Nezu, 1999; Spivack and Shure, 1974). In the first stage, the therapist focuses on helping the child understand that problems are a part of everyday life and inhibit his or her initial impulses (e.g.,

avoidance behavior). In the second stage, the child works to formulate the problem into a workable problem with goals. The third stage involves generating alternative solutions, the core of which lies in brainstorming. Here, both practical and outlandish ideas should be generated. In the fourth stage of problem solving, the child evaluates each alternative, choosing the most appropriate solution, and then puts the action into effect. The fifth and final stage involves verifying the merit of the chosen solution. Training the child to ask himself or herself questions may help the child orient himself or herself in a problem-solving mind set. (Which solution do I think will work best?) In the end, problem solving helps the child become adept at generating alternatives in what may at first appear like hopeless situations.

Children's ability to generate alternatives to a problem and to competently evaluate each option is important for overall psychological health. In the domain of problem solving, it is important to recognize that: (a) children at different developmental levels face different challenges and (b) children vary in their ability to recognize a problem in need of a solution.

In therapy, children practice new skills while receiving encouragement and feedback, which leads to further refinement of those new skills. In addition, appropriate contingencies are established to shape involvement, to promote intrinsic interest, or to motivate clients who would otherwise be disinterested.

We have described a variety of skills typically referred to as "coping skills"—methods to cope with situations and events that would otherwise produce distress. The question remains, how best to transmit these skills to those children who need them most. In the next section, we describe several strategies that facilitate client acquisition of the coping skills. For instance, we discuss features of the therapeutic relationship that foster coping, as well as specific strategies including coping modeling, rehearsal (role-plays), and exposure.

## Treatment Strategies

Several treatment strategies have been developed to maximize the effective communication of the coping skills described earlier. We briefly describe the strategies that are most commonly considered essential in cognitive-behavioral therapies: coping modeling, behavioral rehearsal (role-plays), and exposure.

### COPING MODELING

Modeling derives its conceptual roots from social learning paradigm ( [Bandura, 1969, 1986](#)). The consistent finding that behavior can be acquired, facilitated, reduced, or eliminated through the process of observing others' behavior, and the effects of their behavior, has direct treatment implications. When perceived as a reasonable individual—respected, liked, and possibly even admired (and occasionally associated with positive reward)—the therapist can be a powerful model for nondistorted thinking, careful reasoning, and adaptive behavior.

Modeling is a valuable opportunity for children and adolescents to observe and learn; the therapist plans demonstrations that are focused on the child's specific behavioral and cognitive needs. The therapist can serve as a model for effective coping, not by behaving in an error-free manner (mastery-modeling), but also by exhibiting misbehavior, lack of attention, and cognitive misperception, while displaying strategies to correct these difficulties (coping modeling).

### REHEARSAL: ROLE-PLAYS

Practice is an essential strategy for enhancing learning and coping skills. Role-plays let both the therapist and child experience how it feels to utilize each of the alternative problem solutions that have been generated for a specific problem. These role-plays provide opportunities for the therapist to guide the experience and reinforce progress; this guided and reinforced practice is important in the remediation of cognitive, behavioral, and emotional difficulties. Role-playing can start with minimally stressful situations and, as the child masters the skills, move on to progressively more challenging situations. The therapist can begin with imaginal scenes and then move to real-life sessions that can be arranged in the office, home, school, or community.

### EXPOSURE

Exposure entails placing the child in a fear-provoking experience, either imaginably or *in vivo*, to help him or her acclimate to the distressing situation and to provide opportunities for the child to practice coping skills within simulated or real-life situations ( [Francis and Beidel, 1995](#); [Marks, 1975](#)). Exposure in one form or another has been the basis of treatment of several anxiety disorders for some time. Historically, variants of exposure include implosion and flooding. <sup>1</sup> Flooding involves exposing the client to the actual anxiety-provoking stimuli. Some treatment research has shown that flooding is helpful in the treatment of the more complex anxiety disorders such as agoraphobia and obsessive-compulsive disorders. In CBT, preparation for the exposure task, the exposure task itself, and postexposure discussions provide opportunities to address coping skills. Youths with anxiety, for example, can learn via exposure tasks that their predictions or fears are not always accurate, that they can experience and survive anxiety, and that they then have data to use to challenge anxious thoughts in the future.

Although we have described specific strategies for promoting change, CBTs are neither monolithic nor narrow-minded ( [Mahoney, 1977](#)). Quite the opposite is true: There are treatment strategies that appear in therapies for the various disorders; however, there are no rules carved in stone, and the emphasis on cognitive information processing within a context that uses social rewards and behavioral procedures to modify maladaptive methods of adjusting is intentionally flexible.

To assume that there is a simple monolithic "right" way to think, behave, and feel is to make a fatal error. In fact, quite the contrary is true ( [Kendall, 1992](#)). The human experience, including childhood and adolescence, is replete with opportunities for a diversity of thoughts, feelings, and actions. The definition of what is "normal" is broad and inclusive: Thoughts, feelings, and actions are abnormal only when they are maladaptive for the individual or interfering or destructive for others. Interventions are not designed to make the child conform to a single-minded definition of appropriate childhood behavior. Rather, interventions are designed to remove detrimental cognitive, affective, or behavioral styles that children may be developing and to offer—at an early point in life—valuable educational experience that can modify unwanted features of their developmental trajectory.

Interventions with youth are perhaps best when they mesh effectively with the normal developmental trajectory. In the target years of development, the move toward autonomy and independence is a central developmental challenge. A decided strength of the cognitive-behavioral strategy is that it works in a collaborative problem-solving fashion with the youth and, correspondingly, fosters independent development and prosocial behavior change. These intervention strategies are used to maximize the effective communication of the coping skills described earlier. Aside from specific strategies, the therapeutic relationship is critical in fostering the effective communication of these skills.

## Therapeutic Posture

The "posture" (referring to one's mental attitude) of the cognitive-behavioral therapist working with youth can be described using the terms "consultant," "diagnostician," and "educator." As a consultant, the therapist is a person who does not have all the answers but has some ideas worthy of trying out and some ways to examine whether or not the ideas have value for the individual youth. The consultant therapist helps create behavioral experiments to test some of the dysfunctional beliefs of the client. Telling a child or adolescent exactly what to do is not the idea: rather, the therapist gives the client an opportunity to try something and helps him or her to make sense of the experience. The therapist, as a consultant-collaborator, strives to develop skills in the client that include thinking on his or her own and moving toward independent, mature problem solving. The youngster and therapist interact in a collaborative, problem-solving manner.

As a diagnostician, the therapist integrates data, and, judging against a background of knowledge of psychopathology, normal development, and psychologically healthy environments, makes meaningful decisions. The posture associated with "diagnostician" is one of being confident to go beyond the verbal report and/or behavior of the client and his or her significant others. The cognitive-behavioral therapist serves as a diagnostician by taking into account the various sources of information (e.g., child, parent, school) and, judging against the background of knowledge, describes the nature of the problem and an optimal strategy for its intervention.

As an educator, the therapist is involved in teaching interventions for learning behavior control, cognitive skills, and emotional development in determining the optimal ways to communicate to help young people to learn. A good therapist, like a good educator, stimulates youths to think for themselves. A good educator observes the student, helps to maximize strengths and to reduce hindrances, and accepts that individuals can and should do things differently.

The posture of the cognitive-behavioral therapist working with children and adolescents is one that has a collaborative quality (therapist as consultant), integrates and decodes social information (therapist as diagnostician), and teaches through experiences with involvement (therapist as educator). A high-quality intervention is one

that alters how the child makes sense of experiences and the way the child will behave in the future.

## Developmental Considerations

The exact intervention method that is most effective is not necessarily the same for all children. When treating adolescents and children it is essential to be aware that they are not homogeneous groups. Children are developing organisms, which implies that they are ephemeral and evanescent beings. They are not stable, consistent, or unchanging. Numerous features of each child are not necessarily stable from pretreatment to posttreatment. Change over time owing to maturation alone is one aspect of the “developmental uniformity myth.” A second aspect of this myth is the assumption that children of different ages with the same behavioral problems are alike ([Kendall, 1984](#)). Clinicians need to be aware of the error in assumptions, and clinical interventions should be adjusted accordingly for different developmental levels. Furthermore, the same behavioral problems at various developmental levels may have varying effects on the child's social and interpersonal world.

The following example emphasizes the importance of considering developmental level in clinical interventions used with children. Systematic desensitization ([Wolpe, 1969](#)), a forerunner of more modern approaches, involves having the client experience deep muscle relaxation in the presence of gradually increasing exposure to feared stimuli. Muscle relaxation is an important part of the intervention. Interestingly, outcome literature of systematic desensitization with children has been unclear ([Hatzenbuehler and Schroeder, 1978](#)). It is possible that muscle tension is not uniformly associated with anxiety across various developmental levels. [Katz and colleagues \(1980\)](#) demonstrated that children between the ages of 10 and 18 experience muscle tension but that children under the age of 6 years do not. Thus, age may be considered a moderator in systematic desensitization.

Cognitive-behavioral interventions are designed with developmental considerations in mind. For example, a young cognitively immature child might benefit less from long, didactic sessions and would be better served by brief, active sessions, often with the cognitive content of the session occurring *in vivo*. Another important developmental consideration is sensitivity to the context of the developmental challenges facing the child. Therefore, a cognitive-behavioral therapist seeing a child with separation anxiety at 9 years of age intervenes within the appropriate developmental challenge, such as issues of autonomy. With older children, other themes (e.g., peer-related, achievement related) present themselves as more appropriate for intervention ([Southam-Gerow et al., 1997](#)).

## Parental Role

The cognitive-behavioral perspective considers the importance of the social context because behavioral patterns in the external world and cognitive interpretations in the internal world pertain to social and interpersonal contexts. The social context for children includes both family and peers. Satisfactory relations with peers are a crucial part of children's adjustment. Thus, an understanding of the role of peer relationships within a child's environment is necessary for meaningful assessment and treatment. Children learn about rules and roles for social interaction within the family context, making the family a powerful socialization agent.

The importance of parents in therapy for children and adolescents is clear. Increasingly, clinicians and researchers are focusing on the role of families in the treatment of childhood disorders ([Faubert and Long, 1991](#); [Sanders, 1996](#)). Adding a family management component to individual cognitive-behavioral therapy for children can be helpful ([Barrett et al., 1996](#); [Kazdin et al., 1992](#)). A family management component encompasses contingency management strategies to support and encourage courageous behavior and extinguish maladaptive behavior. Helping parents become more aware of their own emotions, teaching problem-solving skills, conflict-resolution training, and encouraging listening skills are some of the techniques used to help parents become more involved in their child's treatment and progress. Parents can serve as consultants by providing valuable information about the nature of their child's psychological problems and they can also help assist in the implementation of program requirements. In addition, parents' own maladaptive behavior and cognition can contribute to the child's distress. Changes in the family system are implemented in conjunction with promoting the child's skill building.

## Conceptualization of Change

Children and adolescents with behavioral and emotional difficulties have associated maladaptive qualities in cognitive information processing. Modifications in cognitive processing are in order for the depressed adolescent who is misattributing negative outcomes to internal-global-stable features, as well the impulsive or hyperactive child who is active in behavior but deficient in planned forethought. How might we conceptualize the needed changes?

Some cognitive distortions, as noted, require modification. New experiences, with guided processing of the experiences, help reduce distorted thinking. Thus, the existing cognitive structure is not being erased, but new skills and means of construing the world are built, and these new constructions come to serve as new templates for making sense of future experiences. For example, in the case of an aggressive child with a tendency to misinterpret the intentionality of others' behaviors, being bumped may be interpreted as being pushed maliciously by another child. With new skills such as enhanced problem-solving abilities, corrective of self-talk, and improved inhibition of maladaptive responses, the child can learn to adjust his or her interpretation and reaction (e.g., “maybe he tripped and lost his balance” or “stop and think before reacting”).

Therapy offers exposure to multiple behavioral events with concurrent cognitive processing, such that new cognitive structures can be built over time. Future experiences are construed differently as these new conceptions are incorporated into the child's overarching view of the world and his or her place in it. Using newly acquired skills and constructed schemata, the individual moves forward to face and confront new challenges in ways that manage former maladaptive tendencies.

## CONCLUSION

We have outlined a cognitive-behavioral theory in which behavioral events, associated anticipatory expectations and postevent attributions, ongoing cognitive information processing, and emotional states combine to influence behavior change. Relatedly, the theory adapts to the different challenges facing different levels of development. The theory is problem-solving oriented, deals directly with cognitive information processing, incorporates emotional and social/interpersonal domains, employs structured and manual-based procedures, and emphasizes performance-based interventions. Cognitive-behavioral therapy places greatest emphasis on helping youth advance their cognitive information processing in social contexts by using structured, behaviorally oriented practice, while concurrently paying attention to the participant youth's emotional state and involvement in the treatment.

The cognitive-behavioral model includes the relationships of cognition and behavior to the affective state of the organism and the functioning of the organism in the larger social context. Social/interpersonal factors play a crucial role in the design of and outcomes from therapy. Acknowledgments of peer and family contributions to child and adolescent psychopathology, however, far outweigh the currently available research database; the need for further inquiry into these areas cannot be overemphasized.

Cognitive-behavioral approaches to interventions for children and adolescents have been applied to a wide range of topics ([Kendall, 2000c](#); [Meyers and Craighead, 1984](#)), including anger ([Lochman et al., 2000](#)), attention deficit hyperactivity disorder ([Braswell and Bloomquist, 1991](#); [Hinshaw and Erhardt, 1991](#)), anxiety disorders ([Kendall, 1994](#)), medical and dental stress ([Melamed et al., 1984](#); [Varni et al., 2000](#)), depression ([Stark et al., 1991](#)), and impulsivity ([Kendall and Braswell, 1985](#)). Cognitive-behavioral approaches also have been used with children with chronic illness ([Walco and Varni, 1991](#)), depression ([Stark et al., 2000](#)), and learning disabilities ([Keogh and Hall, 1984](#); [Wong et al., 1991](#)). Inclusion of the parents ([Braswell, 1991](#); [Braswell and Bloomquist, 1991](#)) and families ([Barrett et al., 1996](#)) of youth has also been undertaken from the cognitive-behavioral perspective.

Cognitive-behavioral therapy with children and adolescents is promising in that it explicitly recognizes the importance of cognitive, behavioral, affective, and socioenvironmental variables in the etiology and maintenance of emotional disorders. Moreover, it is consistent with contemporary integrative models of behavioral change and maintains the objective, empirical focus that has served as the foundation of both behavioral psychotherapy and child psychiatry.

<sup>1</sup>In implosion, the therapist and child attempt to create feared images that are dramatic and exaggerated. As this imaginal exposure is prolonged, it is expected that extinction of the fear would occur. There is only limited research to support this approach, and its overall effectiveness has been questioned, especially with children (Rimm and Masters, 1979).

Freud described the mother–infant relationship as “unique, without parallel, established unalterably for a whole lifetime as . . . the prototype of all later love relations” (1940, p. 45). But he was not the first to describe how important the mother–infant relationship is for psychosocial growth. For centuries parents have recognized their special place in the lives of young children, and because infants are so vulnerable and dependent, philosophers, practitioners, and (later) psychologists have been concerned with the quality of parental care that provides a secure foundation for healthy psychological development. It is only in the past two to three decades, however, that their ideas have been systematically tested by developmental scientists, and the interesting and provocative findings from their studies have contributed to making attachment theory one of the most exciting fields of contemporary developmental study, addressing enduring questions concerning infant–parent relationships. Moreover, the applications of attachment research to understanding and treating conditions of developmental psychopathology, and describing the relational needs of children, adolescents, and adults in our society underscore the practical as well as theoretical value of this literature. In a sense, attachment theory and research have provided developmental scholars with an unprecedented opportunity to empirically evaluate theoretic views of the importance of parental care for early psychological development, and explore diverse important applications of this research.

Attachment can be defined as an enduring emotional bond uniting one person (or animal) with another, and attachments are commonly manifested in efforts to seek proximity and contact to the attachment figure, especially when the individual is under stress. Theories of attachment underscore its evolutionary origins to promote the protection and nurturance of the young and, thus, contribute to species survival. Applied to human behavior, attachment is also regarded as an important psychological catalyst for the early emergence of trust in others and understanding of self, and as the basis for risk for psychosocial difficulty if attachments are disorganized or dysfunctional. As a consequence, attachment theory unites interests in evolutionary biology, developmental psychology, and clinical concerns in understanding early parent–offspring bonding.

In succinctly summarizing this exciting field, my purpose is to provide an orienting introduction to the theoretical views, research methodologies and findings, ongoing controversies, applications, and emergent trends that characterize contemporary attachment theory and research. (The reader is also directed to major papers and current review sources for further information.) In so doing, my goal is to highlight both what we do and do not know about the origins, correlates, and sequelae of attachment relationships in early childhood, and their relevance to applied problems of early psychological development. The emerging literature on attachment in adolescents and adults is also profiled. Much has been learned about the nature and importance of early attachment relationships and, combined with the provocative conceptual views from attachment theory, there are many exciting ideas to guide current applications and future research. At the same time, recent research has also shown that when we consider seriously the mutual influences of the quality of parental care, child's characteristics, ecology of early development, and consistency of caregiving influences over time, attachment processes are far more complex than traditional theoretical views might portray. It is this complexity and the research agenda it provides that make this field of research both exciting and compelling.

## THE THEORETICAL LEGACY: DEVELOPMENTAL PSYCHOLOGY, EVOLUTIONARY BIOLOGY, AND OBJECT RELATIONS THEORY

Attachment theory has roots in the psychoanalytic emphasis on the enduring significance of the early mother–infant relationship, together with subsequent studies showing that this affectional bond does not necessarily depend on the provision of food, warmth, or other physical necessities (Harlow, 1958), and the insights of developmental psychology (Karen, 1994). To create a new conceptual synthesis, John Bowlby (1969/1983, 1973) borrowed from evolutionary theory to argue that infant–mother attachment develops not only because of the mother's satisfaction of physical needs but also species-typical behavioral patterns that evolved to promote infant survival. In the Savannah grasslands of human evolution, Bowlby reasoned, there would have been survival advantages for vulnerable and defenseless human young to seek the protective proximity of responsive conspecific adults, especially when they were distressed, alarmed, or in danger. Such adults function as a “secure base” for the infant, and processes of evolutionary adaptation may, thus, account for why infants develop emotional attachments to responsive adults that motivate such proximity and contact-seeking efforts. Young who are motivated to stay close to such adults in these circumstances are less likely to fall victim to predators, become lost, starve, or suffer other calamities that, in the end, will undermine reproductive success, and thus it is normative for infants to develop attachments to their caregivers in species-typical rearing conditions. In a sense, Bowlby proposed that infants are predisposed virtually from birth to respond socially to social partners as part of this survival-enhancing motivational system, and he borrowed ideas from engineering control systems theory (updating the hydraulic energy model of psychoanalysis) to explain the dynamic functioning of this system. Finally, Bowlby provided a developmental perspective to his analysis by using insights from developmental psychology (especially Piaget's cognitive theory) to explain the growth of the baby's discrimination of and emotional investment in the parent, the increasing sophistication of the infant's attachment behavioral repertoire, and the child's developing understanding of the relationship with the parent.

Bowlby's theoretical insights are consistent with research evidence concerning the development of attachments in the first year of life. Emotional attachments to familiar caregivers become apparent between 6 and 12 months of age as infants gradually construct expectations for the behavior of other people and are becoming socially and behaviorally more competent (Thompson, 1998). As a consequence, well before the first birthday, infants are showing their preferences for adults to whom they have developed attachment relationships. These attachment figures include mothers and fathers, of course, but they also include regular baby sitters, grandparents, day care teachers, and others who assume a frequent role in the child's nurturance. Bowlby's theory is also consistent with research evidence showing that virtually all infants normatively develop attachments to their caregivers. The innate impetus toward emotional attachments is poignantly evident in some young children who have been raised in extremely deprived or abusive conditions, but afterwards manage to quickly develop close bonds to the nurturing adults who subsequently care for them, although the quality of their attachments may be disordered (Chisholm, 1998).

Individual differences in the child's perception of the parent as a “secure base” are also important and as a clinician, Bowlby was concerned with the long-term consequences of variations in the quality of infant–parent attachment. He and another early attachment theorist, Mary Ainsworth (1973), argued that the quality of these attachment relationships varies on a dimension of security, and that infants develop security in their caregivers based on their prior experiences of sensitive, helpful, responsive care (cf. Erikson's [1963] concept of “basic trust”). The secure attachment that results is adaptive—in both an evolutionary and psychological sense—because it derives from the infant's confidence that his or her help-seeking signals will receive a prompt and appropriate adult response. If infants experience sensitive care only inconsistently or sporadically, or if their care is regularly insensitive or unresponsive, they develop insecure attachments. An insecure attachment is *not* the same thing as having no attachment at all to a caregiver, however, because a young child who is uncertain, even doubtful, about the caregiver's helpfulness nevertheless derives important emotional support from the caregiver's presence that would not be derived from the company of someone to whom the child had no attachment at all. This underscores how important it is to respect children's emotional attachments to caregivers, even caregivers who are insensitive, because of the emotional resources such attachments provide to young children.

Bowlby (1973) believed, nevertheless, that many adult psychological disorders could be traced to the early development of insecure attachment. Indeed, in his view, an important part of the therapeutic process is to assist the client in developing secure attachments (such as to the therapist) while examining the contemporary ramifications of earlier, insecure attachment relationships. Such a view recently has been revived in current studies of adults' representations of their early experiences of childhood care (Dozier et al., 1999; Main, 1991).

The formulations of object relations theory thus can be found in Bowlby's portrayal of the sequelae of early attachments, and attachment researchers have sought to understand both the behavioral and representational outcomes of attachment security in early childhood. According to current theorists ( [Bretherton and Munholland, 1999](#); [Thompson, 1998](#)), attachment relationships exist not only as a behavioral system characterizing infant–parent relationships but also as a conceptual system governing significant social ties throughout the life span, with the emotions and expectations (secure or insecure) arising out of infant–parent relationships forming the basis for rudimentary conceptual representations of self and others in the years that follow. These “working models” or “states of mind” ( [Bowlby, 1973](#); [Bretherton and Munholland, 1999](#); [Main, 1991](#)) of self and significant caregivers are portrayed by theorists as interpretive filters through which self-understanding and understanding of important relationships are processed, while operating generally out of conscious awareness. Because of this, they are thought to be relatively stable over time, and individual differences in working models may foster consistent, long-term characteristics in parent–child relationships and, as they are maintained, also intergenerational continuities in caregiving tendencies as offspring internalize roles of caregiver and care recipient ( [Sroufe and Fleeson, 1986](#)). Such a view is also consistent with the notion that psychosocial development is characterized by continuity in adaptation in which a child's success in meeting early developmental challenges (such as forming a secure attachment) provides a strong or weak foundation for subsequent developmental challenges ( [Sroufe, 1996](#)). In each case, a secure attachment in infancy provides the basis for more successful psychosocial functioning in later years and conceptions of self as lovable and others as trustworthy, whereas an insecure attachment affords a much weaker psychosocial beginning and different forms of self and other understanding. In these ways, concepts from object relations theory significantly inform attachment theorists' views of the sequelae of early secure or insecure attachments.

Taken together, Bowlby's theoretical insight was to wed contemporary thinking in developmental psychology with evolutionary biology to provide fresh explanations for important psychoanalytic insights concerning the importance of the mother–infant relationship. Moreover, by bridging formulations in object relations theory, attachment theory also offers valuable perspectives into clinical problems and issues of lifelong adaptation. By and large, Bowlby's formulations have served the field well for more than three decades; however, recent advances in three areas add fresh insights and theoretical challenges.

First, in evolutionary biology, current thinking emphasizes that organisms are equipped with a variety of adaptive behavioral patterns employed contingently based on ecologic demands and other life circumstances ( [Chisholm, 1996](#); [Simpson, 1999](#)). Thus contrary to the view that evolutionary processes have equipped infants with a single adaptive attachment pattern (i.e., a secure attachment) that is based on a species-typical style of sensitive parental care, different patterns of infant attachment behavior can be considered adaptive in different caregiving contexts and in relation to different styles of parental care. This has important implications for cultural studies of attachment, and the interpretation of “insecure” attachment patterns in cultural contexts very different from the United States middle class.

Second, in cognitive developmental psychology, research scientists have moved beyond Piaget's theory to newer formulations that offer a far richer portrayal of the mental life of young children. Thus, the development of early “working models” of self, others, and relationships from attachment theory can be informed by recent studies in the growth of event representation, autobiographical memory, theory of mind, and other cognitive processes that develop significantly during the preschool years ( [Thompson, 1998, 2000](#)). One implication of this research literature is that the representations that guide enduring understandings of self and others probably emerge in early childhood, not infancy, and are influenced by parent–child discourse and other relational influences ( [Thompson, 2000](#)). This broadens understanding of how parental behavior influences attachment security and its sequelae in early childhood.

Finally, research on the ecology of early care reveals that significant changes have occurred in the contexts of early childhood development during the past three decades, and raise new questions about the diversity of attachment relationships, construction of internal working models, and continuity and change in attachment security. Young children now become attached to many caregivers in the family, child care setting, and elsewhere, and it is yet unclear how these relationships make independent or overlapping contributions to the internal representations that constitute working models of self and others ( [Berlin and Cassidy, 1999](#); [Howes, 1999](#)). Furthermore, young children now more often experience changes in family circumstances, including residential relocation, changes in care arrangements, and marital separation and divorce, that can challenge the stability of parent–child relationships and alter attachment security and the working models with which it is associated ( [Thompson, 2000](#)). The implications of these facets of the ecology of early care constitute one of the more important research topics for attachment theorists.

## RESEARCH METHODS

The value of these theoretical formulations would have remained limited, however, without the emergence of empirical tools for assessing individual differences in the security of attachment. There currently exist well-validated measures of attachment security in infancy and early childhood, newer (but less well evaluated) measures of attachment in older children and adolescents, and exciting advances in assessing adult “states of mind” concerning attachment ( [Crowell et al., 1999](#); [Solomon and George, 1999](#)).

### The Strange Situation

Along with her contributions to the conceptualization of these differences, Ainsworth's major contribution to attachment research was the creation of the Strange Situation procedure ( [Ainsworth et al., 1978](#)), a 21-minute laboratory assessment that has become the predominant procedure for assessing the security of attachment in infancy. It is difficult to overemphasize the contribution of this assessment procedure to attachment research. Because it provided developmentalists with a semistandardized, easy to use, and readily scorable means of studying a phenomenon that was long assumed to be fundamentally important to early sociopersonality development, the availability of the Strange Situation (together with Bowlby's provocative theorizing) virtually unleashed an unprecedented amount of research on attachment. This reliance on a single methodology also permits the comparability of diverse studies on attachment using different samples observed in the Strange Situation; this is a benefit rarely enjoyed by students of early social development.

The Strange Situation is designed to create a condition in which critical features of an infant's expectations for the caregiver's helpfulness and accessibility will be revealed behaviorally. Because attachment behavior is instigated when babies are distressed or alarmed, the Strange Situation creates gradually escalating stress for the baby to heighten the child's need for the parent's assistance over the course of seven 3-minute laboratory episodes. After a brief introduction to the setting followed by an initial episode in which the infant plays with toys in the mother's presence (episode 2), a stranger enters the room and plays with the baby (episode 3), after which the mother leaves the baby in the company of the stranger (episode 4). Mother and child are reunited (and the stranger departs) in episode 5, but stress is further incremented by a second separation period with the baby alone (episode 6), and the stranger's subsequent return to the room while mother remains absent (episode 7). Mother and infant are reunited a second time in episode 8, at which time the stranger again departs. Thus, by altering the social setting of the laboratory playroom, the Strange Situation heightens the child's need for the parent's support and assistance, and variations in the security of the infant's attachment to the parent are thought to be revealed most clearly. (See [Ainsworth et al., 1978](#), for further details.)

Attachment researchers focus particular attention on the two reunions (episodes 5 and 8) during which these variations are most apparent. Infants who are deemed securely attached (group B) greet the parent's return with relatively unequivocal pleasure, conveyed either through proximity and contact-seeking efforts or distal interactive behavior (e.g., smiling, vocalizing, and so on). These behavioral reactions are thought to reflect underlying confidence that the parent will be accessible and helpfully responsive to their needs for comfort or assistance. Alternatively, infants may be deemed insecurely attached and assigned instead to one of three other groups. Insecure-avoidant (group A) infants either conspicuously avoid the parent during reunions or, more commonly, mingle avoiding or ignoring the parent with more positive reunion greetings (e.g., a markedly delayed look and proffer of toy). Insecure-resistant (group C) babies combine proximity- and contact-seeking activities with angry, rejecting reunion behavior, or alternatively show extreme passivity during reunions. Finally, insecure-disorganized/disoriented (group D) infants are characterized during reunions not by any distinct behavioral style but by incoherent, confused, or inconsistent behavioral patterns (e.g., approaching parent with head averted) ( [Main and Solomon, 1990](#)). In each case, the behavioral reactions indexing insecure attachment are thought to be reflections of uncertainty or ambivalence concerning the parent's helpfulness following stressful separations, or an expectation that the parent will be unhelpful during reunion.

In most middle-class samples, the large majority (approximately 65%) of infants are deemed securely attached; this proportion tends to be lower in lower-income samples and is markedly depressed in many clinical samples. This is true whether infant–mother or infant–father attachments are studied or, for that matter, attachment relationships with any regular caregiver in the baby's life. As attachment theory predicts, infants develop emotionally meaningful attachments to each of the variety of adults who assume a regular caregiving role, including mothers, fathers, and regular baby sitters and day care workers ( [Howes, 1999](#)). Although these attachments usually vary independently in their security (e.g., an infant may be secure with mother and insecure with father, or the reverse), there is sometimes convergence between these different attachment relationships that may reflect the influence of temperament or other influences ( [Fox et al., 1991](#)).

### Attachment Q-Sort

Research using the Strange Situation accounts for most of the literature concerning the security of attachment in infancy, but this procedure is limited to samples of infants between 11 and 24 months of age. After 2 years, brief separations from the mother do not have the same impact on the child's attachment behavior because

separations are usually much less stressful. As a consequence, attachment researchers have explored several alternative methodologies that are appropriate for older children or can be used with a broader range of ages. Because they assess attachment security differently, these alternative measures capture somewhat different features of secure or insecure attachments than are revealed in the Strange Situation ( [Thompson, 1998](#)).

One alternative is a parent- or observer-report instrument called the Attachment Q-sort, in which individuals who are familiar with the child can systematically describe the child's attachment-related characteristics ( [Waters and Deane, 1985](#)). The Attachment Q-sort consists of 90 brief behavioral descriptors written on cards ("easily comforted by adult") that are sorted by the rater into one of nine piles, depending on how accurately they describe the child. Thus, cards sorted into pile 1 are "very much unlike the child," whereas those put into pile 9 are "very much like the child," with gradations between these anchors. After the sorting is completed, cards are scored (i.e., cards in pile 9 are each assigned a score of 9, cards in pile 8 receive scores of 8, etc.), and the entire card set can then be correlated with a criterion Q-sort that describes the characteristics of a securely attached child. The higher the correlation, presumably, the more securely attached a child is. Although the Q-sort approach is necessarily susceptible to the biasing influences of any observer-report procedure—that is, it indexes an observer's perceptions of the child's behavior, not necessarily the behavior itself—it benefits from the observer's detailed and long-term knowledge of the child and provides the most versatile means of indexing attachment security in children of various ages. Indeed, the Q-sort developed by [Waters and Deane \(1985\)](#) is suitable for children from infancy through early childhood and can be used in longitudinal as well as cross-sectional studies. In infancy, Q-sort scores often concord well with Strange Situation classifications ( [Vaughn and Waters, 1990](#)). However, defining a suitable threshold correlation with the criterion Q-sort for a securely attached child can be challenging, because the Q-sort yields a continuous score. Some researchers use an empirical threshold from previous attachment research (e.g., children with the highest 65% of the correlations in the sample are regarded as securely attached), whereas others establish an a priori threshold (e.g., a correlation of 0.36 or larger), whereas still others take advantage of analytical benefits of the continuous security score and do not try to categorize children at all.

### Other Approaches for Older Children and Adults

Other researchers have sought to develop direct behavioral measures of attachment suitable for older children ( [Greenberg et al., 1990](#)). Among the more notable efforts is a procedure for 6 year olds devised by Main, Cassidy, and their colleagues ( [Cassidy, 1988](#); [Main and Cassidy, 1988](#)). The procedure begins with the family together watching a short film of a child during a 10-day separation from his parents and is followed by an hour-long separation of parents and child during which the child plays with a female stranger and responds to a "separation anxiety interview." Observations of the subsequent parent-child reunion provide the primary basis for classifying 6 year olds' attachment security, borrowing the strategy of the Strange Situation. Attachment classifications for 6 year olds include a secure category as well as insecure-avoidant and insecure-ambivalent (or resistant) classifications. New for this age are additional classifications for insecure-controlling and insecure-unclassified attachments ( [Main and Cassidy, 1988](#)). Other researchers use a conventional, or modified, Strange Situation procedure with altered rating conventions for evaluating the attachment security of older children observed in this procedure.

Other researchers rely on self-report instruments with older children. Examples of these include the Security Scale, by which grade-school children report on the extent to which they perceive a parent as responsive, open to communication, and a reliable source of help in times of distress ( [Kerns et al., 1996](#)), and the Inventory of Parent and Peer Attachment, a measure for adolescents to describe the extent of their trust, communication with, and alienation from parents and close peers ( [Armsden and Greenberg, 1987](#)).

Finally, attachment theorists with a special interest in adolescents' and adults' representations of attachment processes have developed an interview procedure called the Adult Attachment Interview that systematically assesses adults' "states of mind" concerning attachment. These include recollections of the earlier parent-child relationship they experienced, including memories of security and comfort, acceptance by their own parents, feelings of rejection, fears of abandonment, and similar phenomena, and reflections on how these earlier experiences affect present caregiving and attachment relationships ( [Hesse, 1999](#); [Kobak et al., 1993](#); [Main, 1991](#)). Based on the content, emotional tone, and discourse quality of their responses to interview questions, adults are classified as either "autonomous," "dismissing of attachment," "preoccupied with attachment," or "unresolved" to characterize the adult's representations of relationships with each parent.

Research using the Adult Attachment Interview has yielded provocative findings indicating that differences in adults' representations of attachment are associated with variations in parental sensitivity and the security of attachment in offspring. Adults with autonomous (i.e., secure) representations tend to be more sensitive and to have infants with more secure attachments, compared with adults with dismissing, preoccupied, or unresolved classifications ( [van IJzendoorn, 1995](#)). It is yet unclear whether this arises because early patterns of care as a child have long-term effects on parenting capacity—consistent with current interest in the intergenerational transmission of parenting ( [van IJzendoorn, 1992](#))—or whether an adult's attachment representations are composed of the mature self-referential beliefs and attitudes that are shaped throughout life and guide parenting in complex ways ( [Baldwin, 1992](#); [Fox, 1995](#)). Both processes are likely involved and, it is hoped, will be elucidated in future research employing the Adult Attachment Interview and other measures of parenting beliefs ( [Thompson, 1998](#)).

These exciting methodologic advances attest to the fact that attachment researchers have moved beyond their initial concern with infancy to consider attachment processes throughout the life span. Moreover, studies using the Adult Attachment Interview and the Attachment Q-set indicate that these measures have promising validity and reliability and suggest important conceptual and developmental links to processes of attachment in infancy, although attachment security remains a developmentally dynamic process. This methodologic literature is promising, but the focus of the research review that follows is with the more substantive literature on attachment in infancy and early childhood, appraised primarily in the Strange Situation procedure. However, this research raises significant issues about attachment processes that have lifelong importance.

## SECURITY OF ATTACHMENT: ANTECEDENTS, STABILITY, AND CONSEQUENCES

Consistent with traditional formulations of child-parent attachment and the theoretical model developed by Bowlby and his followers, most of the research on the security of attachment has focused on several basic questions. (For comprehensive reviews of this research, see [Belsky and Cassidy, 1994](#); [Cassidy and Shaver, 1999](#); [Colin, 1996](#); [Lamb et al., 1985](#); [Thompson, 1998](#).) First, what are the antecedents of individual differences in attachment security, and in particular, are they associated with variations in the caregiver's sensitivity, helpfulness, and accessibility, as predicted by attachment theory? Second, once consolidated, how stable are differences in the security of attachment over time? In other words, does attachment security or insecurity become an enduring feature of child-parent relationships, or does it change and, if so, under what circumstances? Third, what are the predictable sequelae of a secure or insecure attachment in infancy or early childhood? Equally important, by what processes do these consequences occur? The reader will recognize that although these issues are central to the formulations of attachment theory, they also encompass longstanding theoretical questions concerning developmental continuity and the importance of early experiences ( [Thompson and Lamb, 1986](#)). This helps to account for the widespread interest of developmental scholars in attachment research.

### Antecedents

Consistent with theoretical expectations, attachment researchers have found that infants who become securely attached have experienced more optimal maternal care during the first year than do those who become insecurely attached. In general, the mothers of securely attached infants tend to act more positively, harmoniously, responsively, and sensitively toward their babies compared with the mothers of insecurely attached infants ( [Belsky, 1999](#); [De Wolff and van IJzendoorn, 1997](#); [Isabella, 1995](#)). Using more extreme comparison groups, a number of researchers have found that the large majority of infants experiencing parental maltreatment are insecurely attached, when compared with matched nonmaltreated control groups. Moreover, experimental intervention studies designed to improve the sensitivity of maternal care often succeed in doing so, and this can result in an increase in the attachment security of offspring ( [van den Boom, 1994](#); [van IJzendoorn et al., 1995](#)). These findings substantiate the validity of the Strange Situation as an index of infant-mother attachment as well as confirming several important predictions of attachment theory concerning the association between maternal sensitivity and infant security. Finally, as noted earlier, there is also evidence that the parents of securely and insecurely attached infants themselves differ in their security and in their recollections and representations of the care they received as children, which may contribute to the sensitivity of their care of their own offspring ( [van IJzendoorn, 1995](#)).

Although the quality of early care is an important influence on the security of attachment, it is obviously not the only important influence. Others include the caregiving involvement of the father and the extent of parental satisfaction with the marital relationship, the impact of socioeconomic stress on the family, social support to the mother, and the infant's own temperamental characteristics ( [Belsky, 1999](#); [Thompson, 1998](#); [Vaughn et al., 1992](#)). These findings indicate that the security of attachment is shaped not only by the quality of maternal care, but also by the reciprocal influences of each parent, the baby, the family network, and the broader ecological circumstances in which they live. The importance of adopting a broad, rather than narrow, view of the antecedents of attachment security is underscored by a metaanalysis of attachment research by [Goldsmith and Alansky \(1987\)](#), who found that maternal caregiving quality and infant temperament alone each accounted for a meaningful but small proportion of the variance in the security of attachment ( [De Wolff and van IJzendoorn, 1997](#)). Although the emotional climate of maternal care is important, that climate is influenced by many other aspects of the child's life circumstances ( [Thompson, 1997](#)).

This view is affirmed by cross-cultural studies of attachment, which have found considerable variation between cultures and subcultural groups in the relative proportions of secure and insecure attachments ([Thompson, 1998](#); [van IJzendoorn and Kroonenberg, 1988](#); [van IJzendoorn and Sagi, 1999](#)). For example, insecure-avoidant attachments are uncommon but insecure-resistant attachments occur more frequently than in the United States among samples of infants raised in Japan and on traditional Israeli kibbutzim. By contrast, avoidant attachments are more common among West German infants than US infants. However, there is also considerable variation within, as well as between, these cultural groups. Why do these differences exist? Most researchers believe that cultural differences in the normative conditions of early infant care (e.g., frequency of contact with strangers, regularity of separations from mother) and/or in child-rearing prescriptions (e.g., parental independence-training of young offspring) may help account for these differences. Because the Strange Situation, which was originally designed for middle-class infants in the United States, includes experiences with strangers and separations, it may provide an unusually stressful experience for some infants from other cultures, such as Japanese infants who have had little prior experience with maternal separations. As a consequence, the Strange Situation may not appropriately or validly assess the security of attachment for infants from these settings. Some babies may act insecurely when they are overwhelmingly distressed, for example, but the infant–parent relationship may nevertheless be secure. These studies not only suggest, therefore, that cultural and subcultural child-rearing norms may foster meaningful variations in normative patterns of attachment, but also that an infant's experiential background must be considered very carefully in evaluating the validity of the Strange Situation as an assessment of the security of attachment.

### Stability Over Time

Despite theoretical expectations that early attachments, once consolidated, should remain relatively stable over time because they take shape during a period of heightened sensitivity to early caregiving influences, the empirical evidence is actually quite mixed. Although some studies show that infants or young children retain the same quality of attachment over many years, others indicate that attachment security can change over a period of a few months. In studies of infants from lower-income as well as middle-class homes, for example, the proportion of infants with stable attachments over as little as a 6- to 8-month period in the second year ranges from 48% to 96% in test-retest assessments ([Thompson, 1998](#)). It appears that the security of attachment can, and does, change normatively in early childhood.

Equally important, however, is additional research evidence suggesting that changes in attachment are theoretically predictable: They are linked to circumstances that might precipitate changes in the infant–mother relationship. In a study of low-income families ([Vaughn et al., 1979](#)), for example, attachment security changed in response to financial, legal, and social stresses on the family; in a study of middle-class families ([Thompson et al., 1982](#)), changes occurred in response to significant transitions in caregiving arrangements for the baby; in a third study ([Teti et al., 1996](#)), changes occurred when a younger sibling was born. More broadly, there is considerable research evidence that parental behavior toward offspring changes considerably throughout childhood owing to the maturing capabilities of children, and changes in the life circumstances of parents, that may significantly alter parental sensitivity and parent–child relationships ([Holden and Miller, 1999](#)). In short, changes in the security of attachment are normative and are linked to many kinds of family events that might create a renegotiation of familiar patterns of mother–infant interaction. This is, in fact, exactly what we would expect to find if the Strange Situation sensitively appraises normative fluctuations in attachment relationships in infancy, although considerably more research is necessary to specify the conditions underlying change, and continuity, in the security of attachment.

Such a conclusion is unsurprising, given the variety of antecedent influences shaping the security of attachment outlined earlier. Because infants are embedded in a complex social ecology, changes in that ecology are likely to influence their attachment relationships. These findings indicate that the security of attachment reflects the current—but not necessarily enduring—status of the infant–parent relationship, and efforts to predict whether the current status of this relationship will endure or change must take into account the consistency of the conditions of care experienced by the child. As a general rule, therefore, flexibility rather than resiliency of early attachments seems to be true, and although this view is contrary to some theoretical expectations, it is optimistic with respect to the possibility of intervening into dysfunctional infant–parent dyads by changing familiar patterns of interaction or the broader ecological conditions in which they live ([Lieberman et al., 1991](#)).

### Attachment and Later Development

What difference does a secure or insecure attachment have for later development? Do secure children grow up to become more sociable, well-adjusted children compared to those who were insecurely attached as infants? The association between attachment security in early childhood and later psychosocial functioning is among the most important topics of attachment research because of theoretical views that a secure mother–infant bond establishes a foundation for subsequent psychosocial growth, and that the initial attachment relationship shapes representational working models of self, others, and relationships that color later social interactions. On the other hand, development is complex, and because of the multifaceted, cumulative dynamics of psychosocial growth, few early sociopersonality measures have been found that predict long-term developmental outcomes. This might also be true for the security of attachment.

There is now evidence, however, that a secure attachment in early childhood has predictable outcomes ([Belsky and Cassidy, 1994](#); [Thompson, 1998, 1999](#)). The most important is that it foreshadows a more cooperative, harmonious parent–child relationship in the years that follow. This is important, because parent–child comity makes the child more responsive to the parent's socialization efforts and more likely to adopt the parent's viewpoints, values, and goals ([Waters et al., 1991](#)). There is also evidence that securely attached young children socialize more competently and are more popular with well-acquainted peers during the preschool years, and establish warmer relationships with teachers, camp counselors, and others whom they know well in the years to come ([Sroufe et al., 1993](#); [Thompson, 1999](#)). Securely attached children may also respond more positively to unfamiliar people (e.g., new classmates, a substitute teacher), but the positive or negative expectations for close relationships inspired by a secure or insecure attachment are most apparent in children's encounters with familiar partners. There are also recent findings suggesting that security of attachment is associated with different kinds of self-concept, emotional understanding, friendship conceptions, conscience and moral understanding, memory processes, and other representational processes in children, especially when they are assessed contemporaneously with attachment security. The emerging conclusion that securely attached young children see themselves and others more constructively, and have more sophisticated emotional and moral understanding, is consistent with the notion that attachment is associated with unique working models of self and others ([Thompson, 1999](#)). The research evidence is very weak, however, concerning whether attachment security is associated with features of personality organization or development ([Thompson, 1998, 1999](#)). Perhaps this is because personality is a complex phenomenon that is affected by many factors besides attachment security.

These interesting findings are qualified in several ways. First, the developmental influence of attachment security in early childhood wanes over time: Its effect is most apparent during the preschool years, but its influence becomes less evident with increasing age ([Sroufe et al., 1990](#); [Thompson, 1999](#)). This can occur because of subsequent developmental experiences, or because of changes in family circumstances that alter the sensitivity of parental care (such as marital discord between parents) ([Cummings and Davies, 1994](#)). In these circumstances, the effects of an initially secure attachment on subsequent development are diminished when parents become markedly insensitive and no longer support relational trust or, conversely, when an increase in sensitivity inspires positive developmental outcomes in offspring who were initially insecure ([Erickson et al., 1985](#)). Although some studies reveal a lingering influence of early security of attachment many years later, most suggest that the developmental consequences of early security or insecurity depend on consistency and change in the continuing quality of parent–child relationships. The strongest associations between attachment security and other sociopersonality variables are apparent when both are assessed at the same time, although their causal association is more difficult to discern in these circumstances.

Second, many other influences besides a secure or insecure attachment affect developing sociability, self-concept, relationship representations, and personality organization. Bowlby himself recognized that attachment is only one of several dimensions of the parent–child relationship and, indeed, at the same time that attachment is developing, young children are also learning the skills of cooperation, compliance, and conflict resolution with parents ([Thompson, 1999](#)). This means that even when attachment security is developmentally influential, its impact is in the context of multidetermined developmental processes in which other factors also make significant contributions ([Sroufe et al., 1999](#)). Moreover, with increasing age, new developmental experiences subsume the influences of earlier experiences, like a secure attachment, and may alter their influence on sociopersonality development. Third, and finally, there are some suggestions in the research that the influence of attachment security may also be mediated by a child's temperament, such that children with particular temperamental profiles are differentially susceptible to the effects of a secure or insecure attachment ([Belsky, 1997](#); [Kochanska and Thompson, 1997](#)).

The research on attachment and later development thus indicates that a secure or insecure attachment has diverse but contingent consequences for young children. On one hand, there is increasing evidence that attachment is associated with the growth of sociopersonality characteristics and understanding that are consistent with the view that attachment shapes social behavior and emerging working models of self, others, and relationships. These outcomes are especially apparent early in life. On the other hand, the effects of early attachment security are not necessarily enduring, tend to diminish over time, and emerge in concert with many other developmental influences. It thus appears that early in life—before representational capacities have become sophisticated and well consolidated—young children rely on the continuing harmony of their relationships with parents to develop and maintain positive working models of self and relationships. The security of attachment in infancy is a marker of the quality of parent–child interaction that must be maintained early in life to support positive developmental outcomes. At later ages, as representational capacities become more enduring and self-maintaining, these working models then become incorporated into the network of self-referential beliefs that older children and adolescents begin to construct from a variety of developmental experiences, and become more independent of the current quality of

parent–child interaction. These constitute the basis for the “states of mind” concerning attachment that are assessed by the Adult Attachment Interview and related measures.

## ATTACHMENT AND CLINICAL INTERVENTION

Given the amount of interest they have generated among developmental scholars, it is perhaps unsurprising that formulations of attachment theory have found important applications in a variety of human services fields, including clinical psychology and psychiatry, social work, preventive mental health services, and even family law. This is because attachment theory and research help to articulate the relational needs of young children, adolescents, and adults and describe how early relational experience can have broader consequences for development and personality functioning.

One of the most important applications of attachment theory is to the understanding and treatment of child clinical disorders. This is especially so because the field of early mental health is still in its infancy, and the growth of research on attachment relationships has coincided with the emergence of theoretical and clinical models of psychological disorders in infancy and early childhood. Because attachment researchers are concerned with the formative effects of early patterns of infant–parent interaction, the emergence of early representations of self and others, and the prediction of later behavioral problems from early social relationships, there is a natural affinity with the etiologic, diagnostic, and therapeutic concerns of child clinicians.

There are important conceptual contributions of attachment theory to an understanding of early problems of developmental psychopathology ( [Belsky and Nezworski, 1988](#); [Greenberg, 1999](#); [Rutter, 1995](#); [Sroufe et al., 1999](#)). These include insights into young children's relational needs, such as the importance of the caregiver's warmth and sensitivity, the developmental significance of a young child's trust in the caregiver's helpfulness and accessibility (especially under stress), the ways that relational experience “goes underground” to provide a foundation for representational systems of self-awareness and social understanding, the impact that early relational experience can have on subsequent relationships by shaping a young child's expectations for people and responses to them, and the ways that early relationships can be affected by broader features of the child and family social ecology. Other conceptual contributions of attachment research to child clinical work include an understanding of the nature of development, especially the realization that developmental history interacts with (and can be transformed by) subsequent experience in shaping a child's current functioning, and the importance of risk and protective factors provided by close relationships to the development of mental health. Attachment theory also teaches that early experiences rarely lead directly to later psychopathology, but instead inaugurate developmental processes that may be maintained (or altered) by subsequent experiences ( [Sroufe et al., 1999](#)). Each of these formulations, arising from attachment theory and research, can provide a valuable perspective for thinking about young children's clinical disorders and how best to provide treatment. These ideas are also consistent with the valuable insights offered by the field of developmental psychopathology ( [Cicchetti and Cohen, 1995](#)).

Attachment theory and research is also relevant to understanding specific clinical disorders, because of the importance of relational influences to their origins, maintenance, and remediation. Attachment theory has been applied to understanding conduct disorders, social withdrawal and inhibition, anxiety disorders, childhood depression, and other early clinical problems ( [Greenberg, 1999](#); [Zeanah, 2000](#)). In each case, disturbed caregiving relationships are often one of the significant etiologic features that, in concert with other risk factors (such as temperamental vulnerability) contribute to the onset and maintenance of psychopathology. There is also emerging understanding of the varieties of “disorders of attachment” that arise most significantly in conditions of aberrant care, such as parental maltreatment, institutional rearing, or marked neglect. Disorders of attachment can be manifested in behaviors such as fearfulness and hypervigilance, indiscriminate sociability, aggressive or controlling behavior, blunted emotional responsiveness, or markedly ambivalent or contradictory social behavior ( [Lieberman and Zeanah, 1995](#); [Lyons-Ruth and Jacobvitz, 1999](#); [Zeanah et al., 1994](#)). Although these dysfunctional behavioral patterns are clearly related to more than just disturbed attachment relationships, attachment theory and research offers valuable insights into their etiology and treatment.

Attachment research also has important implications for the treatment of these developmental disorders of early childhood, including underscoring the importance of a family systems perspective, attention to the representational facets of early psychological problems, and understanding the impact of early relational experience on subsequent relationships ( [Crittenden, 1992](#); [Erickson et al., 1992](#); [Fraiberg, 1980](#); [Lieberman and Zeanah, 1999](#); [Marvin, 1992](#); [Zeanah, 2000](#)). More speculatively, attachment theorists have also extended their clinical implications to therapeutic practice with adults, drawing on Bowlby's original formulations concerning the lifelong importance of relational security, the reestablishment of secure working models in the context of a therapeutic relationship, and the association between insecure attachment and defensive styles ( [Slade, 1999](#)).

These clinical applications of attachment theory and research contribute to fulfilling Bowlby's original vision of creating a developmental theory of early relationships that would update and extend the psychoanalytic model and its therapeutic implications. But this is still a young field of inquiry and considerable conceptual and empirical work remains to understand fully how attachment concepts are relevant to problems of developmental psychopathology. Although insecure attachment is probabilistically related to less optimal developmental outcomes than is secure attachment, for example, it is not clear that attachment insecurity places a baby “at risk” for later problems or warrants special intervention ( [Nezworski et al., 1988](#); [Peterson, 1987](#)). Although the Strange Situation has proven to be a valuable research tool in studies of early attachment, clinicians should be cautious in making individualized assessments of infant security or parenting sensitivity based on the Strange Situation alone because of the many factors that can influence any particular assessment in this procedure ( [Rutter, 1995](#)). These are two examples of the problems commonly encountered in translating exciting research findings into individualized assessment and therapeutic implications.

More broadly, there are at least two other issues from the attachment literature requiring greater reflection as this research informs clinical practice. First, the results of research with nonclinical samples, reviewed in the preceding, indicate that there is considerable flexibility, rather than resiliency, to attachment system functioning in the early years of life. Rather than foreshadowing inevitable subsequent difficulties, an insecure attachment is related only conditionally and provisionally to later psychosocial problems ( [Bates and Bayles, 1988](#); [Erickson et al., 1985](#); [Fagot and Kavanagh, 1990](#); [Lewis et al., 1984](#)). Moreover, early attachment foreshadows later developmental outcomes primarily when there is consistency in caregiving influences over time that help to maintain and support early characteristics in offspring. Thus, there is considerable value to considering the extent to which attachment security reflects a characteristic of the child, or of the parent–child relationship, how this changes developmentally, and its implications for treatment of early clinical problems. There is also value in reconsidering the confidence with which clinicians can estimate future developmental outcomes for individual children based on early attachment security or insecurity.

Second, although the concept of “working models” of self, others, and relationships derived from attachment theory is heuristically powerful, very little is known about the developmental origins of individual differences in these representations in children and adults, or how they can best be assessed ( [Thompson, 1998, 2000](#)). When a young child responds to a semiprojective story or provides an account of family experience, for example, it typically reflects many things, of which enduring understandings of self and others is only one contribution. The need for further research on the development and assessment of early attachment-related representations is underscored by the importance of careful, cautious thinking concerning their lifelong significance. Even though there are influential theoretical models positing that adult representations of attachment are directly linked to early experiences of care—and help to account for interest in the “intergenerational transmission” of attachment security—these theoretical models have not yet been adequately tested. This warrants caution in making assumptions about the bases of these attachment representations, which are likely to be quite complex, or about their long-term developmental significance.

There are clearly many valuable applications of attachment theory and research to the concerns of child clinicians, and these applications are already apparent in the design of early interventions and growing understanding of problems of early mental health. Although the formulations of attachment theory are of considerable heuristic value, however, substantially more research (with clinical as well as nonclinical samples) is required to specify more clearly the meaning of security or insecurity of early attachment and its contemporary and subsequent significance.

## CONCLUSIONS

One clear conclusion from the attachment research is that support for relational trust is essential not just in infancy, but throughout the life course as young children, older children, adolescents, and adults are continuously seeing secure relationships and reworking their working models of attachment. As a consequence, developmental researchers, clinicians, and other practitioners have a considerable research agenda for building on the provocative findings of studies reviewed in this chapter. Given the continuing contributions of Bowlby's insightful theory, there is good reason for optimism concerning the future contributions of attachment theory and research.

## Part 1: Developmental Theories

### COGNITIVE DEVELOPMENT AND THE CHILD PSYCHIATRIST

In his essay, "The Basic Functions of a Child Psychiatrist in Any Setting," J. Cotter [Hirschberg \(1966\)](#) proposed

the child psychiatrist brings to any setting his [her] awareness of the child's age in relation to the child's thinking, feeling, and behaving. . . . [and] . . . his [her] awareness of . . . the characteristics of the child's thinking at various stages of growth ( [Hirschberg, 1966](#), pp. 360, 363).

He was alluding to the fact that children organize their experiences of events and of themselves as agents in different ways at different phases of their life. Normative life events (separation from caregivers, birth of a sibling); disruptive ones (abuse, death of a parent); and ongoing conditions (deafness, attentional disturbances) impact differently on the developing child as infant, toddler, preschooler, school-age child, and adolescent. Recurring or significant experiences become structured knowledge about the world and what can be expected from it. Knowledge structures that help the child anticipate, and thereby manage, common events become self-reinforcing and enduring. Cognitive developmental theories help child psychiatrists understand how children organize experiences, good and bad, to create a coherent sense of themselves in their world, be it functional or problematic.

### TERMS: COGNITION, DEVELOPMENT, AND COGNITIVE DEVELOPMENT

#### Cognition

Put simply, *cognition* is the faculty of knowing—the making and using of knowledge. It includes the faculties of attentiveness, information processing, intuition, memory, skill, and many others. *Cognitive psychology* explores how knowledge is deployed both to adapt to circumstances and alter them. *Cognitive developmental psychology* examines how the mind organizes experience into structured knowledge and how knowledge structures, in turn, organize and reorganize the mind from infancy through adulthood. This chapter outlines the principal theories of cognitive development and demonstrates their relevance to the development of the whole person and the puzzling clinical problem of autism.

Examined more closely, cognition is such a protean idea in psychology that it has been hard to comprehensively define it; indeed, [Flavell \(1993\)](#) contends that *all* psychological activity may be cognitive in some sense. Nevertheless, the outlines of cognition as distinct from other faculties of the mind can be drawn from comparing metaphors used to describe it ([Lakoff and Johnson, 1980](#)). For example, [Gregory \(1987, p. 149\)](#) sees cognition as "the use and handling of knowledge." In Gregory's metaphor knowledge resembles a *substance* and cognition its application. Other writers ( [Flavell et al., 1993](#); [Vygotsky, 1934/1986](#)) consider cognition to be "higher mental processes." Here the focus is on mental processes (thinking) rather than mental content (knowledge). In counterpoint to Flavell's assertion, Sandler avers "there is no such thing as a purely cognitive or intellectual process" ( [Sandler, 1987](#), p. 247). For example, [Bruner \(1990\)](#) sees cognition as "meaning-making" that has affective, social, and subjective connotations. Similarly, Piagetians propose that "in order to know objects the subject must act upon them" ( [Boden, 1994](#), p. 8). Clearly, learning depends on the input and feedback generated by actual encounters with the world; however, by what mechanisms do emotions and actions contribute to the origins of thinking? If Sandler is right, can "thinking" be reliably distinguished from "doing" and "feeling"?

Well, perhaps. Philosophers and cognitive scientists define cognition to be "any instance of a mental operation that displays *intentionality*" ([Dunlop and Fetzer, 1993](#), p. 24). Intentionality is "a property [of] any mental state that is representative, or ('about' something—whether or not that something actually exists. . . . Intentionality is uniquely characteristic of minds. . . . Beliefs, memories, goals, desires, expectations, etc. all display intentionality" ( [Dunlop and Fetzer, 1993](#), pp. 67–68). In the language of cognitive science, "Insofar as the information contained in and processed by an information-processing system is *about* anything—that is, insofar as it functions representationally—the states and processes of that system are intentional" (italics added) ( [Stillings et al., 1987](#), p. 317). By contrast, neither feelings nor actions are necessarily intentional.

Coming at affect and cognition another way, Piaget proposed that cognition organizes and channels the psychological energy generated by affect as a car engine

organizes and directs the energy provided by burning gasoline (Cowan, 1981). Piaget's distinction is a qualitative one; cognition is structure, and affect is energy. Yet again, those who view cognition as the processing of information, distinguish it from sensation and perception quantitatively, by the time it takes to process a stimulus from input to output. The more time taken, the more complex the presumed mediating events, the more cognitive the process. Cognition can be distinguished from perception by its processing time and from affect and sensation by its intentionality. In summary, cognition entails *content* and *process, structure, and complexity*: That is, knowledge (content) and thinking (process) are both structured and complex.

## Development

The term *development* denotes a sequential increase in the structural and/or functional complexity of a system. *Structures* are inferred organizational properties that underlie any given behavior. These organizational properties are assumed to change systematically with age. Development of structure means that a system becomes organized in a more complex way, whereas development of function implies that it can coordinate and integrate more complex arrays of information: A change in functional or *processing* complexity entails an increase in structural complexity and vice versa.

Heinz Werner (1948) proposed development to be an alternation of *differentiation* and *integration* (or *coordination*). For example, in biology, unspecialized precursor cells differentiate during development into several types of specialized offspring. These integrate their specialized functions to form organs that, at a higher level, organize themselves into organ systems and, in turn, into organisms. In mental terms, perceptions and symbols are *internalized*—reconfigured internally as *mental representational structures*. *Representations* are “the internalized schemas or frames of reference which the child uses in his interaction with the external world” (Deregowski, 1977, p. 219). They may be in the forms of logic, rules, concepts, images, analogies, and neural connections (Thagard, 1996). Simple representations combine to form complex arrangements that, in turn, differentiate and recombine into ever more integrated and complex structures that then influence the selection and handling of further input.

## Cognitive Development

As there are differences about what cognition is, so there are differences as to how it develops. Some see cognitive development as the increasing speed and sophistication of mental activity, independent of knowledge (Sternberg, 1984); others believe that the contents of knowledge determine cognitive development (Chi, 1988). Some include affect to explain cognitive development (Case, 1985), others do not (Anderson, 1983). Some (Piaget) emphasize the development of the internal, formal, self-constructed qualities of thought; others (Vygotsky) highlight the developmental role of external, social–interactional exchanges. Some see cognition as *domain-specific*. For example, Howard Gardner (1985, 1999) proposed several distinct domains of cognition (“intelligences”) musical, logical, verbal, spatial, kinesthetic, intrapersonal, interpersonal, and others, all quite independent of each other. Those who see cognition as domain-specific often take a *nativist* position; cognitive capacities are innate and development is the biologically preordained coming online, with age, of specialized processing units (modules) minimally influenced by experience or each other. By contrast, both Piaget and Vygotsky see cognition as *domain-general*; that is, as a property of the whole mind. In this *constructivist* (or *constructionist*) view, development takes place as the child internally reconstructs her or his lived experience. Development in one domain informs development in others.

### COGNITIVE DOMAINS: SPECIFICITY VERSUS GENERALITY OF DEVELOPMENT

In cognition, a *domain* is “the set of representations sustaining a specific area of knowledge (language, number, . . . and so forth). . . . A *module* is an information processing unit that encapsulates that knowledge and the computations on it” (italics added) (Karmiloff-Smith, 1992). Information processing follows the general model of a computer based on a *central processing unit* (CPU) that can be deployed to perform computations for a great variety of purposes. The same CPU can run a graphics program, a word-processing program, or a spreadsheet according to the software installed. If we call each application a domain of knowledge, the computer's operating system is domain-general, whereas each software application is domain-specific. Each software application can be seen as a module dedicated to organizing and assimilating informational input into its domain's representational structure as image, text, chart, or whatever. In human cognition, modules are “subsets of our neural networks . . . genetically prestructured for processing different kinds of input information: for example language . . . or mathematical information” (Lee and Das Gupta, 1995, p. 20). In the strong version of this view, modules are “inborn, automatic, . . . unconscious and embodied in dedicated neural mechanisms” (Boden, 1994). They are “cognitively impenetrable”; that is, “other parts of the mind can neither influence nor have access to the internal workings of a module, only to its outputs. . . . Input systems [modules] are inflexible and unintelligent . . . but they are just what a young organism needs to get initial cognition off the ground speedily and efficiently” (Karmiloff-Smith, 1992, pp. 2–3). The whole configuration of operating system plus software makes up the computer analog of a person's *cognitive architecture*.

### DEVELOPMENT AND STAGES

Often a developmental theory is presented as a series of *stages*. Stage theories imply discontinuous development: Periods of stability and consolidation alternate with periods of instability and transition. They also imply qualitative changes in cognition from stage to stage. The notion of stages is controversial; some believe stages reflect a natural rhythm in the developing organism while others see them as artifacts of the method or bias of the investigator. Theories based on a biological metaphor (e.g., Piaget's), tend to be set in stages, whereas nonstage theories usually have a social-learning pedigree.

Each stage organizes all cognition in a characteristic way at any point in the life span in a Piagetian-type stage theory. Each stage entails the hierarchic integration and transformation of the preceding ones; each earlier one becomes a subset of the next later one. Stages succeed one another in an invariant sequence of transformations; a step cannot be skipped nor does the culture change the sequence. Stages are universal; the culture may vary the content but not the structure. Finally, each stage achieves its full range only on completion; most activities in a stage are incomplete and contribute to the final version. The theories of Piaget, the neo-Piagetians (Case), and some Piaget-based social-cognitive (Selman) and moral (Kohlberg) theories are stage theories.

Nonstage theories are represented in this chapter by information-processing (Anderson, 1983) and learning-based theories (Carey, 1990; Ceci, 1996; Chi et al., 1988). In these, development is continuous; they do not distinguish points of qualitative change in cognition nor alternating periods of relative stability and instability. They explain the apparently discontinuous changes of cognitive development as ever-increasing processing efficiency. They do not require invariant sequencing or central processing structures that organize disparate domains of knowledge according to a single blueprint.

### The Six Theories

Sternberg and Berg (1992) identify six distinguishable theories of cognitive development—Piagetian, contextualist, or sociocultural (Vygotsky), information-processing (IP), neo-Piagetian, knowledge-based, and psychometric. The first four are detailed under their own headings in this chapter, whereas knowledge-based frameworks are mentioned more briefly. The reader is referred to Sternberg and Berg for discussion of psychometric theory. In cognitive development, what is innate, constructed, domain-specific, and systemwide, weave in and out through all theories and are not considered separately. The reader is referred to Sternberg (1999) for a current, exhaustive review of the controversies in the field.

## JEAN PIAGET: THE GENEVA SCHOOL

### Piaget's Goals and Methods

Piaget was the first to systematically study the “qualitative development of intellectual structures” (Flavell, 1963, p. 15). As a child, he had been a somewhat solitary prodigy with an interest in natural history; he published his first article, on a species of sparrow, at age 10. He discovered philosophy and psychology in adolescence and, after graduating in biology, worked with Simon in Paris, France, doing standardized intelligence tests on children. He became interested in the reasoning children of different ages used to explain their answers, both correct and incorrect, and proposed a connection between the development of logical thinking in children and the philosophical problem of knowledge—epistemology. He proposed that logic was the basis of all cognitive structures; he called this approach *genetic epistemology*.

Curious about the evolution of the adult capacity for logical thinking, he interviewed children of different ages about their ways of knowing, applying techniques from psychoanalysis and clinical psychology. This *clinical method* allowed more flexible interaction than did formal laboratory procedures. Piaget augmented his early experimental work by systematically observing his own children in their home and posing naturalistic tasks at intervals throughout their childhood. On the basis of these observations, and other, more formal ones, he made inferences about the development of children's capacity to think in terms of formal logic.

## Heredity and the Functional Invariants

Piaget believed psychological organization is the end toward which biological development is directed ( [Langer, 1969](#)). The notions of specific and general heredity were the biological bases of the theory. *Specific heredity* allotted to each member of a species a common physical apparatus that would function in a consistent, species-specific manner in an adequate environment ( [Ginsberg, 1985](#)). *General heredity* ensured what Piaget called the *functional invariants: organization and adaptation*.

### ORGANIZATION: SCHEMES AND STRUCTURES

Piaget proposed that humans are innately predisposed to organize whatever is taken in by the nervous system. In doing so the individual constructs *schemes* that are “the internal representation . . . of some generalized class of situations, enabling the organism to act in a coordinated fashion over a whole range of analogous situations” ( [Gregory, 1987](#), p. 696). Schemes combine to form ever more comprehensive mental structures organized in a stage-specific logical form. For Piaget a structure is [first] a:

unified *whole* whose parts can be identified only in relation to each other and their place in the overall structure. . . . [second] structural alterations are . . . orderly *transformations*. . . . Finally, structures are *self-regulating* . . . in that the nature of the whole is conserved by adaptive compensatory transformations among the parts ( [Boden, 1994](#), pp. 8–9).

### ADAPTATION: ASSIMILATION, ACCOMMODATION, AND EQUILIBRATION

Adaptation is subdivided into the complementary processes of *assimilation* and *accommodation*, by means of which the organism both creates and adapts to new knowledge. During assimilation, the organism adapts by organizing novel stimuli according to schemes already in its repertoire. Accommodation occurs when the cognitive apprehension of a novel stimulus causes the scheme to expand or alter its organizational structure. An infant with a scheme for grasping will attempt to grasp everything in sight, that is, to assimilate newly encountered objects as “things-to-be-grasped.” At the same time, different shapes and sizes of objects oblige the grasping scheme to enlarge and diversify so as to accommodate the variety of things-to-be-grasped. These processes work together with each new encounter until the novelty, which has temporarily unbalanced the cognitive organization, has been adapted to, a new equilibrium is established, and new knowledge has been created. The rebalancing tendency is *equilibration*, which is the fundamental developmental transition process within stages. Each new equilibrium structure is challenged and unbalanced by the next inassimilable novelty. Structure and novelty contend until a new equilibrium is achieved and the process reiterates. It is this *dialectical* process by which the child constructs and reconstructs her knowledge.

### Piaget's Stage Sequence of Development

Piaget proposed that cognitive development is a progression of structural changes. The child continuously adapts to and organizes events by assimilating and accommodating. Schemes are constructed, enlarged, combined, and coordinated to form ever more comprehensive and complex structures. These structures ultimately form a *structure-of-the-whole* that, in each stage, organizes experience across all domains of knowledge. The process is repeated in four stages as the old structure is folded into the newly forming one. Stage transitions—qualitative changes of cognitive structure—involve what Piaget called *reflective abstraction*.

By [which] process the subject extracts certain characteristics of [established cognitive] activities and uses them for new goals . . . in the sense of a . . . reconstruction and reorganization on the higher plane of what is transferred from the lower plane ( [Sinclair, 1992](#), pp. 224–225).

### THE SENSORIMOTOR STAGE (BIRTH THROUGH 18 TO 24 MONTHS)

The infant's first strategies for organizing her or his experience are such innate reflexes as grasping and rooting. During this stage, the infant transforms her or his reflexes into self-generated schemes of action. However, sensorimotor cognition is still nonrepresentational; it can only operate on an environment that is immediately apprehended by the senses and the motor system. By the end of this stage, the development of mental representations permits the transition from a physical to a psychological basis for thought.

The transformation of reflex to scheme begins as the neonate, enacting its reflexive organization, interacts with the environment. As something touches its palm, it grasps; as something touches its lips, it sucks, and so on. The more experience the child has of grasping, the stronger the grasping tendency. The stronger this tendency is, the more things the child will grasp and the greater the variety of things assimilated as “graspable.” The child accommodates by using different grasps for different things. As the grasping begins to differentiate, a scheme of grasping is constructed. Early in the second month, elementary schemes emerge as the infant experiences feedback from its own body. For example, although thumb-sucking behavior was innate, it is now repeated in an intentional way. Piaget called these first schemes *primary circular reactions*—“primary” because they involve the infant's own body, circular because an action–reaction loop is set up. During the middle third of the first year, the infant begins to interact with the external world in the same way, constructing *secondary circular reactions*. For example, coordination of two schemes, such as gazing and reaching, begins to occur. A random arm movement causes a mobile over the crib to move, creating an interesting visual effect. Soon the movements become less random. The infant's arm causes the mobile to move, and the pleasure generated causes the infant to do it again, establishing circularity. Toward the close of the first year, the infant begins exploring, rather than merely responding. In one celebrated sequence, Piaget interposed his hand between that of his infant son, Laurent, and a matchbox that fascinated him. At 7½ months, after earlier unsuccessful trials, Laurent actively attempted to push aside the obstructing hand to reach for the matchbox ( [Piaget, 1952](#)). Using the “means” of removing the obstacle, the hand, to attain an “end,” the matchbox, marks the beginning of complex intentional behavior and an appreciation of causality. During the first half of the second year, infants become more intentional in their explorations. Instead of seeking to reproduce exactly the previous effect, they deliberately vary the procedure so as to cause slight differences each time. Laurent, dropping different objects, varied the position of his arm on release each time. He would repeat the procedure exactly for a few trials, as if to confirm an observation, and then resume his variations. “This interest in novelty for its own sake is called a *tertiary circular reaction*” (emphasis added) ( [Ginsburg and Opper, 1969](#), p. 58).

Children begin to use things to represent other things in the last half of the second year, giving rise to pretend play and more sophisticated language use. Piaget called this new capacity the *symbolic (or semiotic) function*. The transition to symbolic mental representation begins with symbolic physical representation. Piaget's daughter Lucienne, at the age of 16 months, was presented with a matchbox containing a watch chain. She had learned from previous experience either to reach in and remove it or invert the box to make it fall out. This time Piaget narrowed the opening, so that she could not reach in, nor would it fall out. Lucienne stared at the narrow opening and opened her mouth wider and wider. Piaget saw this as a sensorimotor representation of her awareness of the opening and the space beneath it. “Soon after this phase of plastic reflection, Lucienne pulls so as to enlarge the opening. She succeeds and grasps the chain” ( [Piaget, 1952](#), pp. 337–338). Piaget posited that Lucienne's imitative mouth-opening was an analog of the box opening, and by *interiorization*, such sensorimotor analogs become thought as the child's interaction with caregivers provides symbols—words—to represent and express this knowledge; however, toddlers first assimilate language into their own schemas before using it in a conventional way. Piaget wrote of T. at nearly 18 months, “No more” meant going away, then throwing something on the ground and was then used of something that was overturned (without disappearing). He, thus, said ‘no more’ to his blocks” ( [Piaget, 1951](#), p. 218).

### Critique of Piaget's Sensorimotor Stage

Much work has been done on infant cognition over the past 20-odd years using techniques unavailable to Piaget. One is a type of habituation paradigm that electronically monitors eye gaze. The hypothesis is that an infant loses interest in, and stops looking at (habituates to) a stimulus if it has already formed a representation of it. For example, 7-month-old children who had been shown sequentially an array of different stuffed animals more quickly habituated to a novel one compared to other infants who had been exposed to the same toy or none at all. On this basis, the authors argue that very young infants have the cognitive capacity to form the category of “stuffed animals,” irrespective of particulars ( [Cohen and Caputo, 1978](#)). Because infants by 6 months are capable of thought, as memory, reasoning, and problem-solving, sensorimotor thought appears not to be the necessary developmental precursor of representational (symbolic) thought and “[Piaget's] idea that the capacity for symbolic mental representation only emerges. . . at 18 months appears to be wrong” ( [Goswami, 1998](#)).

### THE PREOPERATIONAL STAGE (2 THROUGH 5 TO 7 YEARS)

Achievement of the symbolic function ushers in the preoperational period that is representational but not yet logical. Piaget seemed to dwell more on children's cognitive limitations during this period than on their accomplishments because he was particularly interested in the development of logical thought.

## Object Permanence and Centration

At 10 months Jacqueline could retrieve a toy Piaget had twice put under a cover as she watched. However, if he subsequently put it under an adjacent cover, also as she watched, she looked under the first cover the moment the toy disappeared from view. At 18 months, playing the same game with a coin, Jacqueline watched as her father concealed the coin in his hand, moved his hand from A to B to C, and showed it to her, empty. She pushed aside his hand and searched sequentially in A, B, and, triumphantly, C. For her, the object now has permanence beyond sensorimotor apprehension.

In Piaget's theory, the achievement of *object permanence* is a Copernican event for the toddler in that he or she can now manipulate images and words internally; however, the relationship of one representation to another is not yet fixed, and magical thinking is the norm. "This kind of reasoning proceeds from particular to particular. *Centering* [which follows] on one salient element of an event, the child proceeds irreversibly to draw as conclusion from it some other, perceptually compelling happening" (emphasis added) (Flavell, 1963, p. 160). The child's understanding of things, once subject to its sensations and motor activity, is now dominated by its perceptions. Piaget argued that children tend to center their thinking on one dimension of a problem and have difficulty systematically coordinating it with another; in other words, they process only one dimension of a multidimensional stimulus. At 2 years, 7½ months, Jacqueline saw her younger sister in a bathing suit and cap and asked, "(What's the baby's name?)" Her mother explained that it was a bathing costume, but J. pointed to L. herself and repeated the question several times. But as soon as L. had her dress on again, J. exclaimed very seriously, "(It's Lucienne again,)" as if Lucienne had become a different person on changing her clothes (Piaget, 1951). Jacqueline had centered on the novel clothing and could not "decenter" so as to recognize her sister.

## Egocentrism

An important extension of centration is the controversial notion of *egocentrism*, the apparent inability to see things, at first perceptually and later cognitively, from another's point of view. In a famous experiment, Piaget stood children on the opposite side of a tabletop model of three quite different mountains. He asked each child to indicate how the child thought he, the experimenter, saw the mountains in relation to one another. Young preoperational children maintained that the experimenter saw the model as they did in spite of their 180-degree difference in perspective. It seemed as if the child believed her own point of view to be the only possible one.

Some have extrapolated perceptual egocentrism into the social-cognitive arena and suggested a concomitant conceptual and affective egocentrism that limits the preschool child's capacity for cognitive empathy—understanding another's psychological point of view. This skill is known as *social perspective taking* (Selman, 1980). Elkind (1970, 1978, 1985) proposed that interpersonal egocentrism accounted for limits in social cognition at different stages of development. He saw egocentrism as a way of measuring how a child is moving toward adult thinking along three parameters—distinguishing transient from permanent phenomena, objective from subjective phenomena, and universal from particular phenomena.

## Critique of Egocentrism

Donaldson (1978) challenged Piaget's assertions about early egocentrism because she believed the tasks posed were too abstract and unfamiliar. She cited a study in which preschool children were given a modified version of Piaget's "mountains" task without changing its logical structure. The task was presented in the form of a story/game of hiding a boy doll from policemen dolls standing at various vantage points. Under these conditions, decentration is found in children as young as 2 years pointing, among other things, to the power of a familiar framework such as a game or story as an aid to reasoning. Other studies show the capacity for both perceptual and conceptual perspective taking at 3 years (Borke, 1975; Zahn-Waxler et al., 1977).

The degree of egocentrism attributed to a preschooler thus depends on how the task is presented. If small variations in experimental procedure yield larger variations in the age at which a task is mastered, a Piagetian age-specific logical structure is harder to defend. By contrast, information processing methodology determines how many discrete operational steps are needed to solve a problem. Looked at this way, many logically similar tasks have very different cognitive demands. Sociocultural theorists would interpret the discrepancy between the "mountains" task and the "boy-hiding-from-policeman" version as supporting their developmental premise that children learn by having their problem-solving efforts "scaffolded" by helpful adults, often as narrative.

## THE CONCRETE OPERATIONAL STAGE: 6 TO 11 YEARS

What are the "operations" to which toddlers are "pre" and that for schoolchildren are "concrete"? A preoperational child, shown a collection of colored wooden blocks and asked if there are more wooden blocks than red ones, may reply that there are more red ones. A concrete operational child who can classify understands that "red blocks" is a subclass of "wooden blocks" and is not fooled. A preoperational child, told that Billy is taller than David and that Susan is taller than Billy, may not be sure that Susan is taller than David. A concrete operational child can arrange a series of things according to any one of their several properties, or, in Piaget's terms, can *seriate*. He can form one series of Susan, David, and Billy according to height and a different one according to weight, given the information. A preoperational child who sees a liquid being poured from a short, broad container into a tall, slender one is liable to center on the dimension of height and proclaim the latter to contain more liquid, even though he can see that the same amount of liquid went into both containers. A concrete operational child can mentally reverse the act of pouring and understands that the volume was conserved. For Piaget, a *mental operation* is "any representational act which is part of an organized network of related acts" (Flavell, 1963, p. 166). The three discussed in the preceding—*classification*, *seriation*, and *conservation*—are among the most important mental operations. With classification, recursive relations can be constructed, and concepts can be nested vertically in a branching hierarchy. Seriation permits things to be ordered horizontally in lists and rows according to their properties. Conservation stabilizes transformations because the child can "reverse the film" and mentally restore the transformed situation to its original form, conserving continuity. Once stability of operations has been achieved, the child's representations are connected systematically and logically rather than in the inconstant, intuitive way of the preschooler. As concepts begin to override percepts, the world ceases to be magical and takes on order and predictability. The limit of concrete operations is that children can only operate on things that are present or experienced.

## Critique of Preoperational and Concrete Operational Stages

Piaget's second and third stages have encountered less experimental disconfirmation than the first stage; however, many so-called concrete operational tasks can be performed at ages earlier than Piaget believed. For example, infants of 3 months demonstrate object permanence (Baillargeon and DeVos, 1991). Yet, to be fair, Piaget himself did not insist that his stages were tied tightly to particular ages. So too, in spite of his brief in favor of domain-general cognitive structures, he allowed that similar processes might come on line at different times in different cognitive domains or even within the same one (Chapman, 1988).

## THE FORMAL OPERATIONAL STAGE (11 YEARS TO ADULTHOOD)

An observer may ask a young subject to indicate whether what she (the observer) says about a solid-colored poker chip she holds is true, false, or uncertain. She may say, "Either the chip in my hand is green, or it is not green," or, "The chip in my hand is green, and it is not green." During some trials the chip is concealed, and during others it is not. School-age children tend to depend on the physical, visible evidence of the actual chip to judge the truth of the statements—the "greenness" standard. Adolescents can focus on the formal propositional nature of the statements themselves and recognize that the first statement is true, and the second false, irrespective of the color of the chip (Osherson and Markman, 1975).

This experiment captures an essential difference between the thought processes of a concrete operational school-age child and a formal operational adolescent. The adolescent's thought is not necessarily structured by the percept or the concept of the actual object in question. Where the younger child can form hypotheses about *what is* (*empirico-deductive* reasoning), the older can hypothesize about *what could be* (*hypothetico-deductive* reasoning). Formal operations are the culmination of cognitive development for Piaget because they form the backbone of logical, and, hence, scientific, thought; however, others believe that cognitive development extends beyond formal operations (see Summary).

## Summary of the Piagetian System

Piagetian theory is domain-general and constructivist; it draws attention to the commonalities of cognition across domains at a given age and the child as active constructor of her or his own experience. Piagetian theory also explains why children can solve some logical problems spontaneously at a certain age but not earlier, even with instruction. It does not explain discrepancies in performance on logically similar tasks in different domains nor does it account for improvements, with instruction, in performance on tasks that were theoretically beyond the logical competence of the child.

Piaget's work evokes a metaphor of the child as scientist, exploring her environment and constructing representations, based on logical principles, which organize her

experience. Representations are tested by their ability to assimilate novel experiences. If they cannot, accommodation helps form more adequate ones and cognitive equilibrium is restored. More complex representations and combinations of representations extend her range of interactions and increase encounters with novelty, and so on. Interestingly, this image of a somewhat solitary investigator with the world for a laboratory resembles Piaget himself as a child.

## General Critique

Is Piaget's theory still relevant? David Cohen believes "it is time psychologists ceased being so obsessed with him. It is not that he should be burned but that he should be buried" (Cohen, 1983, p. 152). By contrast, Mike Anderson (1992) contends, "as yet, nothing has replaced Piagetian theory as a general theory of cognitive development." In Margaret Boden's view, "Piaget was often wrong [and] often importantly right" (Boden, 1994). So, then, where was he wrong and where right?

Piaget's position that "knowledge is . . . actively constructed by a dialectical process of assimilation and accommodation" is widely accepted (Boden, 1994, p. xi). However, his bias toward *output systems*, that is, the child's actions on the environment, contrasts with current infant research on innate, domain-specific input systems (modules) by way of which an infant is biased toward processing some aspects of the environment while ignoring others. Such inborn cognitive constraints direct attention to the most developmentally vital qualities of the environment such as human faces and speech. Piaget did not dwell on the infant's predisposition for the uniquely human environment but built his edifice on logico-mathematical structures. "Of all the constructs in Piaget's theory, none has been subjected to more persistent criticism than the notion of a general logico-mathematical structure . . . acquired by an autoregulative process in which children reflect on the adequacy of their existing logical structures and assemble new ones by differentiating and reorganizing their elements. . . . As new data were collected it became apparent that children's intellectual processes were far more content, context and culture specific than he had suggested" (Case and Okamoto, 1996, p. 189). Simply because children's thinking could be parsed in terms of logical structures does not necessarily mean that is how children represent things to themselves. Arguably, "Piaget's theory was better equipped for representing the structure in the mind of logicians than the structure in the minds of young children" (Case, 1992a, p. 6). Finally, Nelson faults him for attending hardly at all to the vital role played by language in cognitive development (Nelson, 1996, p. 3).

## VYGOTSKY: THE CONTEXTUALIST APPROACH

### Vygotsky's Premises

The Russian psychologist Lev Vygotsky was born the same year as Piaget but died much earlier at 38. He was broadly educated in literature and philosophy and a committed Marxist. He worked during the early years of Soviet communism when the relationship between the transformation of the individual and that of the social order was a central philosophical and political issue. Where Piaget saw young scientists exploring the world of things, Vygotsky saw children immersed in an intricate sociocultural system based on a shared set of symbols for organizing and interpreting experience. In his view, the child developed by imitating and internalizing culturally based forms of cognitive mediation—words, for example—used by others in interaction with him. Therefore, "higher" cognitive processes appear first on the social-cultural (*interpsychological*) level and only then on the individual (*intrapyschological*) level. In other words, whereas "Piaget believed that intelligence matured from the inside and directed itself outward. . . . Vygotsky. . . believed that intelligence begins in the social environment and directs itself inward" (Sternberg, 1990, p. 242).

### The Genetic Method

The foundation of Vygotsky's thought is his *genetic method*. As in Piaget's genetic epistemology, the term "genetic" means to understand a phenomenon in terms of how it developed. For Vygotsky, therefore, before one can understand individual development, one must appreciate both the evolutionary origins of human biological organization and the historical origins of one's culture. On this basis, Vygotsky rooted cognitive development in three *genetic domains*—phylogenesis (evolution), cultural history, and ontogenesis (individual development)—each with its own line of development. Developmental change in each line is owing to the emergence of new forms of *mediation*; that is, *tools* and *signs*. For example, the emergence of tool use in primates marked a phylogenetic discontinuity where, from that point on, anthropology explained human development better than biology.

### Internalization, Semiotic Mediation, and Decontextualization

In Vygotsky's terms, both culture and cognition are *semiotically mediated*; that is, expressed through and shaped by, signs and symbols. Tools (implements) are used in the physical world to shape materials, and by analogy, psychological tools (signs) are used internally and shape the form of thought. Cognitive development takes place when the culture's psychological tools, mainly language, are shared with, and *internalized* by the child. Vygotsky examined the representational systems . . . needed to participate in . . . [social] processes—hence, his emphasis on the internalization of speech. In contrast, Piaget's focus on the young child's interaction with physical reality led him to examine the representational systems required to manipulate objects (Wertsch, 1989). For Vygotsky, internalization is "the process of gaining [internal] control over external sign forms" (Wertsch, 1989) or, less technically, "the ingrowing of lived experience into personal meaning" (Frawley, 1997). Developmental transitions occur with a change in the form of semiotic mediation. "Internalisation changes the complexity of what is done. . . . Culturally provided skills are generally more sophisticated than the skills which they replace" (Meadows, 1993, p. 241).

Vygotsky noted that each person is born with a set of biologically given *elementary* mental processes (memory, attention, and so on) analogous to the same capacities in other species. Cognitive development is the super session, in each domain, of elementary mental processes by *higher*, culturally based ones. "The purpose of higher thought is the control of thinking and action, and internalization and mediation are means to achieve this goal" (Frawley, 1997, p. 97). *Elementary attention*, for example, is stimulus-bound and reacts automatically to signals from the environment. The higher level, *voluntary attention* is semiotically mediated—regulated by *inner speech*—selective and self-activated. In the same way, elementary, holistic, *integral perception* becomes the higher, sequential, *analytic perception*. Similarly, *early memory* becomes *logical memory* with "the internalization of a language with which to represent logical problems" (Case, 1985, p. 72).

Higher mental functions are subdivided into *rudimentary* and *advanced* ones according to their degree of "*decontextualization* of mediational means" (emphasis added) (Wertsch, 1989, pp. 56–57). Decontextualization simply means the capacity to use cultural signs independent of any particular referent or setting. For example, when a child first learns to count, she can do so only with particular things; numbers (the "mediational means") cannot be manipulated without a concrete referent. This is a rudimentary higher process. Numbers must be decontextualized before she can understand  $2 + 2 = 4$ , irrespective of what is counted. Decontextualization allows the individual to attain *advanced* forms of higher mental functioning that, in the history of populations, provides the possibility of sociocultural change.

### Higher Thought: Social Speech, Inner Speech, and Metacognition

Prior to their coming together in cognition, Vygotsky believed thought and speech had independent origins. In the first two years of life, children use vocal activity for social contact and emotional expression, so-called "preintellectual speech." Nevertheless, during this period, they can problem-solve and act in goal directed ways unmediated by language—"preverbal thought." However, the child's language soon begins to include "syntactic and logical forms that have parallels in the child's problem-solving activity but are not linked to them in any systematic or useful way" (Meadows, 1993, p. 245). This *egocentric speech* (speech not directed at another) "is found in the transition from [social] to inner speech" (Wertsch and Tulviste, 1996, p. 57). It develops as children start to use language to help with problem solving and to:

talk themselves through problems or . . . count by using their fingers as aids. Finally such aids are internalized and problem-solving thought uses internal dialogue, while language can be used more to reflect on and develop thought than as a prop to support problem-solving (Meadows, 1993, p. 245).

In other words, the internalization of language gives rise to *metacognition*—thinking about thinking. Such higher thought allows one to reflect on how to use one's problem-solving capacities in a particular context, to frame a situation to oneself and to deploy one's cognition appropriately.

Vygotsky believed inner speech to be essential for higher thought. For example, when a child assembling a puzzle asks himself, "Now where does that piece go?" he is orienting his thought toward the next necessary step of the task, no doubt having internalized similar comments made to him as social speech by a helpful adult. Young children "must essentially talk to themselves using their speech to guide thought and behavior. With development, the self-regulatory function of language changes so that children can direct their behavior using inner speech" (Bjorklund, 1989, p. 141). It is important to emphasize that, by internalization, the child has appropriated social speech in the service of her or his own cognitive agenda every bit as much as her or his thinking has been assimilated into the cultural norms. Inner speech—in the sense of metacognitive self-talk—is the means of problem-solving central to cognitive behavior modification (Meichenbaum, 1977).

Social speech has an earlier, *indicative* and a later, *symbolic* function. Indicative speech is highly contextualized; adult, child, and object must all be physically present, as when an adult uses words to draw the child's attention to a particular object in their shared environment. By contrast, symbolic speech abstracts (decontextualizes) properties of an object so that it may be categorized with others of its kind. Further abstraction allows connections among categories and so on. To understand how this faculty develops, Vygotsky posed a block-sorting task to children of different ages. On the bottoms of a particular category in an assortment of blocks of different colors, shapes, and sizes, he wrote a nonsense word. He upturned one and asked children to sort those that they believed would have the same word on the bottom. When each child was done, he showed her the bottom of an unselected piece; either with the same word on it but differing in some way or one that seemed to resemble those selected but had a different word on it, and asked her to try again. He determined that young children tend to sort into idiosyncratic, unorganized heaps, older ones into complexes where there is an obvious relation among the blocks but not a "logical" one and finally, in the oldest, sufficient capacity for generalization and decontextualization allows sorting on the basis of true concepts. "Higher, uniquely human forms of psychological social interactions are possible only because thinking reflects reality in a generalized way" ( [Vygotsky, 1934/1986](#), pp. 11–12). "The stages in the development of *generalization* are directly linked to stages in the development of social interaction" ( [Wertsch, 1989](#), p. 96).

The internalization of speech and its decontextualization forms and transforms cognition. As the child internalizes, decontextualizes, and generalizes she gains control over her cognition. She becomes more aware that he is thinking and problem solving and others are too (see Theory of Mind). This awareness increases cognitive control, efficiency, and effectiveness. She can interact with the culture in ever more sophisticated ways as a storehouse for vast amounts of symbolically mediated knowledge. In doing so, she is not only acquiring knowledge but also developing cognitively.

### The Zone of Proximal Development

Vygotsky's model of development highlights the connection between knower and learner that begins when a child encounters a problem that he or she cannot solve. The adult has to set up an interpsychological space such that the child can, with help, learn to solve the problem. Internalization allows the child to solve the same problem the next time aided only by inner speech. Generalization allows him or her to approach other, similar, problems. Early on, the intersubjective space through which learning passes is context-bound and informal; later, with a shared set of linguistic meanings established, learning can be more formal and decontextualized, as in school; however, it may be structured,

the distance between the actual developmental level as determined by independent problem-solving and the level of potential development as determined through problem-solving under adult guidance or in collaboration with more capable peers is termed the *zone of proximal development* ( [Vygotsky, 1978](#), p. 86).

In order to understand the role of verbal mediation in . . . intrapsychological functioning, [Vygotsky] argued that one must examine speech on the interpsychological plane. In particular . . . the use of directives or commands by adults to regulate children ( [Wertsch, 1989](#), p. 92).

Experimenters who looked at the techniques of effective mother–child instructional interaction noted that the most successful mothers titrated their level of involvement to the child's apparent need. When the child began to fail, a little more instruction was added; as the child succeeded the parent stood back. "One sets the game, provides a *scaffolding* to assure that the child's ineptitudes can be rescued by appropriate intervention, and then removes the scaffold part by part as the reciprocal structure can stand on its own" ( [Bruner, 1983](#), p. 60). Scaffolding is useful for instruction and also provides a narrative structure so that, in a clinical setting, a child can be helped to become aware of what she knows but could not say. Inner speech is a form of self-scaffolding. For example, suppose a 6-year-old girl tells her father that she has misplaced her boots. Although he does not know where they are, he can help her to reconstruct her activities throughout the day until the moment when she remembers where she left them ( [Wertsch, 1988](#)). Even without the necessary information, the father had a systematic strategy for accessing it. The child had the information but, as yet, no strategy. Next time she misplaces something, she may say to herself, "Now, let's see, where did I have it last?"

Because an adult and a child operating in the zone of proximal development often bring divergent situation definitions to a task setting, they may be confronted with severe problems of establishing and maintaining *intersubjectivity*. The challenge to the adult is to find a way to communicate with the child such that the latter can participate . . . in interpsychological functioning and can eventually come to define the task setting in a new, culturally appropriate way ( [Wertsch, 1989](#), p. 161).

Creating an intersubjective field with a child also happens to be one of [Hirschberg's \(1966\)](#) "necessary functions" of the child psychiatrist.

### CRITIQUE OF VYGOTSKY

[Ceci \(1996\)](#) faults contextualist theories in general because they inadequately account for individual intellectual differences. Nevertheless, although some disagree with Vygotsky as to whether internal structure is the product of social interaction or precedes it, few have dismissed the role of adult–child interaction in cognitive development. Vygotsky's developmental transition mechanisms entail co-construction between adult and child and internalization by the child: Cognitive structures do not have to originate primarily by self-organization. In this way, Vygotsky and other contextualists explain, quite economically, how children in any given culture come to similar cognitive stances at approximately the same age. *Individualist* versions of cognitive development invoke biologically based invariant structures (Piaget) or innate modular structures (Fodor) to account for such convergences.

### Thought as Narrative

Jerome [Bruner \(1990\)](#), for decades the major American exponent of the sociocultural position, views the child as a natural maker of meaning and, thus, an apprentice storyteller. He was dismayed that the "cognitive revolution" had reduced cognition to computation and that the computer metaphor had centered development on the private "processing of information" rather than the public and interactional "construction of meaning." He proposed a "cultural psychology" to be "organized around those meaning-making and meaning-using processes that connect [humankind] to culture. . . by virtue of participation in culture, meaning is rendered *public and shared*" ( [Bruner, 1990](#), pp. 12–13). In Bruner's view, the computational model left no room for intentionality without which the individual cannot experience herself as an agent and without a sense of *agency* she or he will not have a sense of personal meaning. Bruner concerned himself not with objectified *behavior* but intentional *action*, specifically, with "action situated in a cultural setting, and in the mutually interacting intentional states of the participants" ( [Bruner, 1990](#), p. 19). These interacting intentional states form the culture and provide an interpretive system for the making of meaning. The form of this interpretive system is *narrative*.

Narrative implies a sequence of happenings, told from someone's point of view, that explains events in terms of the intentional states of the actors. It is a culture's way of interpreting events, including *noncanonical*—extraordinary—events: It is both everyday conversation and the nightly news. Narrative "mediates between the canonical [expected] world of culture and the more idiosyncratic world of [one's] beliefs desires and hopes" ( [Bruner, 1990](#), p. 52). People make meaning as narrative both by innate predisposition and cultural facilitation. There are "certain classes of meaning to which humans beings are innately tuned and for which they actively search" ( [Bruner, 1990](#)). "Social understanding, however abstract it may become, always begins as praxis [enacted experience] in particular contexts . . . the child learns to play a part in everyday (family drama) *before* there is any telling or justifying or excusing required" ( [Bruner, 1990](#), p. 85; [Dunn, 1988](#)). Margaret [Donaldson \(1978\)](#) and others showed how logically competent very young children can be when propositions are embedded in a story with familiar elements. Similarly, some have proposed that children younger than 4 years do not have a "theory of mind"—a representation of what another person may be thinking—because they do not seem to understand deception in stories told them by an experimenter ( [Leslie, 1987](#); [Perner, 1991](#)). However, Chandler found that, if children were participants in the deception, they showed an awareness of others' false-beliefs between 2 and 3 years ( [Chandler et al., 1989](#)). Others dispute this ( [Perner, 1991](#), p. 311).

As the infant interacts with its caregivers, Daniel [Stern \(1995\)](#) suggested that she or he constructs a network of representational formats that he calls *schemas-of-being-with* [another person]. These schemas are in the form of perceptions, concepts, sensorimotor events, event sequences, and affects (as *temporal feeling shapes*, representations of instances of rising/falling affective experiences). Initially they do not form a whole but

from the interplay, coordination, and integration of these lower-level processes, a more global mental event emerges: an emergent property of the mind, which has coherence and sense in the context in which it emerges ( [Stern, 1995](#), p. 89).

Stern calls this the *pronarrative envelope*:

a narrative-like mode of thought that concerns motivated, goal-oriented behavior. . . . When the [infant's] motive or desire is enacted in an interpersonal situation, it creates, subjectively, a narrative-like structure. As the motivated event moves in time toward its goal, it generates a dramatic line of tension,

which is an essential temporal feature of the narrative-like structure . . . as well as a narrative-like mode of perception ( [Stern, 1995](#), p. 89).

Stern's elegant model, of which this is the merest sketch, shows how self representations emerge from interpersonal interaction, are organized in narrative form, and provide the foundation of each individual life narrative.

So then, both the culture as a whole and children as individuals organize experience as narrative and the two levels of meaning-making interact recursively. The culture teaches a child to tell a good story as part of growing up. Most responses to questions in the to-and-fro of the family are, and are expected to be, in the form of a story, often to justify one's actions or displace blame onto the nearest sibling. Katherine Nelson described young Emily's evolving narrative competence between 18 months and 3 years of age ([Nelson, 1989](#)). Time and again, her evolving speech seemed "impelled by a need to get things organized in an appropriate serial order, to get them marked for their specialness to take some sort of stance on them" ([Bruner, 1990](#), p. 89). "In time she imports another genre into her narratives—problem-solving" ([Bruner, 1990](#), p. 94). This last is a direct challenge to the Piagetians and information processing theorists for whom problem solving is the foundation of cognitive development.

## Language and Cognitive Development

Katherine [Nelson \(1996\)](#) contends that virtually all theories of cognitive development underemphasize the vital role of language:

In each [theory] the independence of cognition from language has been maintained. There seems to be an implicit assumption that language is [only] a communicative tool . . . [it] is assumed to exist as a separable system either . . . internally as a mental organ, or . . . externally as a means of expression and reception of language-neutral "information." . . . the increasing acceptance of the modularity of mind has the effect of shunting language off into its own impenetrable module ([Nelson, 1996](#), p. 4).

Nelson proposes that any firm distinction between communication and representation is misleading. Beyond the most basic formats, representation is in the form of language: One does not have a "higher-level" representation and then reconfigure it as language, language is a necessary component for *any* reflective cognition.

In her *experiential view*, she proposes that infants prioritize the organization of what is presented predictably and/or intensively in their human environment. Nelson calls these early organizational structures *situational models*, which are "generalizations of pattern and reorganizations of experience" ([Nelson, 1996](#), p. 6). These models provide a context for action in classes of situations, informed by an appraisal of the "fit" between the model and specifics of the situation at hand. As specific situational models accumulate, the child begins to construct a *world model* that ever more comprehensively guides his actions across situations. Nelson calls these generalized models *mental event representations* (MERs) that are "individual constructions of social situations." Individual constructions, however, are not enough. "The basic mammalian individual representation system . . . [is] . . . solipsistic and egocentric" so, absent social influence on developing MERs through interactions in language, they will remain unaligned with those of others and ineffective as guides to action in a human environment.

Although Nelson draws much from Vygotsky, she does not agree that the mind is originally a social construction. Rather, it begins as an individual mind as the child constructs his or her world from direct experience but becomes ever more socialized and acculturated with development. The young child enters the social-cognitive world by *participatory interaction* with other children and adults, "taking part in activities without a full understanding of what the activity was about or how it was structured" ([Nelson, 1996](#), p. 19). As the child grows, his individual mind becomes ever more consonant with those of others as he compares and aligns his constructions with them and forms his representations as language. Nelson calls this process *collaborative constructionism*, distinct from both the individual constructionism of Piaget and the social constructionism of Vygotsky.

## THE INFORMATION-PROCESSING APPROACH

### The Child's Mind as a Computational Device

The third contemporary explanation of cognitive development is that of information-processing (IP) theory. Information-processing psychology is a part of the larger field of *cognitive science*, a new discipline based on computer modeling and comprising artificial intelligence (AI), psychology, linguistics, neuroscience, philosophy, and anthropology. The central hypothesis of cognitive science is that, "thinking can best be understood in terms of representational structures in the mind and computational procedures that operate on those structures" ([Thagard, 1996](#), p. 10).

Information-processing theory has only recently offered explanations of children's thinking and therefore is a newcomer to the family of developmental theories. Information-processing theory is not tied to the work of a single pioneer investigator, so it is not as unitary as Piaget's or Vygotsky's. Information-processing theories of development, "focus on the information that children represent, the processes that they use to transform the information, and the memory limits that constrain the amount of information they can represent and process" ([Siegler, 1991](#)). The goal is to construct a comprehensive model of the mind—a cognitive architecture—that accounts for the "sort of general information-processing capacities a mind must have in order to do the many things it does" ([Stillings et al., 1987](#), p. 17). The mind is seen to be, essentially, a problem-solving device, and cognitive scientists have constructed computer-based cognitive architectures to model human thought ([McClelland et al., 1986](#); [Newell, 1990](#)). Among many other intriguing innovations are IP models of Freud's Oedipus complex ([Fischer and Watson, 1981](#)) and Piaget's object permanence ([Franklin, 1995](#)). The developmental task of IP theory is to account for the enormous increase, from birth to maturity, in the complexity of a person's knowledge organization and processing capacity.

### Computational Transformation: Data, Information, and Knowledge

In the world of artificial intelligence, *data* are simply "facts without context in a form . . . that can be entered into a computer" ([Thro, 1991](#), p. 76). Once entered, "Human organization and interpretation give data context and meaning, producing *information*" ([Thro, 1991](#), p. 76). If information may be distinguished from data by meaning, knowledge may be distinguished from information by longevity and purpose: *Knowledge* is the "representation of facts (including generalizations) and concepts organized for future use, including problem-solving" ([Gregory, 1987](#), p. 410). In summary, the transition from data to knowledge involves increasing contextualization and more sophisticated rules of application.

A data-processing system—in our terms, a cognitive architecture—must be able to transform input into an internal representation it can operate on; that is, to *encode*. It must be able to hold new information "on screen" for appraisal and transform it into knowledge by connecting it with prior knowledge, in addition to the storage capacity to keep the new knowledge for future use. By analogy, in order to learn, children must first be able to transform data into information by encoding them as mental representations. Children then must hold the representation in active memory while retrieving relevant knowledge from their accumulated store. The new information is brought together with existing knowledge, and if it is deemed important to the ongoing life of the child, the information will be stored with related knowledge for future use. The input system is then freed up to take in new data.

Information-processing theorists and Piagetians agree that children actively modify their own cognition, but disagree as to how. The former analyzed standard Piagetian tasks, for example, the balance-beam task, in terms of the problem-solving steps required instead of analyzing their logical form as Piaget did. In this task children of different ages are asked to predict which side of a balance beam will go down as weights and their distances from the fulcrum on each side are varied. The child's performance is measured in terms of processing capacity relative to *processing demands*—the number of discrete cognitive operations—of the task. The older the child the better is the ability to predict correctly as variations of weights and distance become more complex. These age differences suggest that many tasks that shared a similar logical form imposed quantitatively different processing demands. Many cognitive architectures have been constructed to explain how children go about solving such problems; a sample is presented in the following.

### THE CLASSICAL PROCESSING MODEL

In 1956 [George Miller](#) wrote the landmark paper, "The Magical Number Seven Plus or Minus Two: Some Limits on Our Capacity to Process Information." He argued that

humans are limited to remembering approximately seven items—plus or minus two—in their immediate memory. However, by *chunking* items into composite units, a large amount of information could be contained in seven units (italics added) ([Miller, 1989](#), p. 276).

For example, it would be too difficult for most people to repeat back the 13 digit series 7472462121945 without a strategy. However, if one associated 747 with the aircraft, 246 with the first three even numbers, 212 as the boiling point of water in 8°F, and 1945 as the end of World War II, the original 13 units become 4 and the task is manageable. Chunking is a

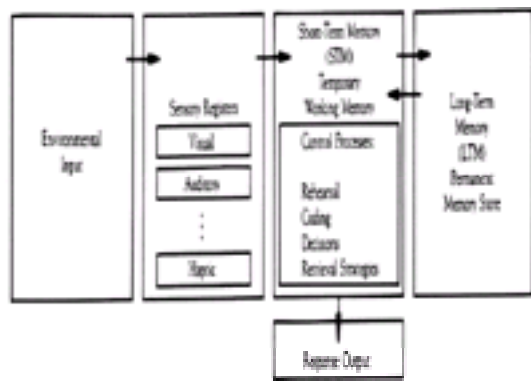

continuous, automatic, experience-based learning mechanism . . . that operates when impasses are resolved . . . [and] . . . converts goal-based problem-solving into long-term memory. . . . Chunking does not just reproduce past problem-solving; it transfers to other analogous situations . . . [it] . . . applies to all impasses (Newell, 1992, p. 430).

Miller's paper gave the newborn movement a name and delineated its central metaphor-processing capacity. He identified "immediate memory" as the locus of information processing and proposed chunking to be the principal strategy for increasing available processing space. Chunks are aggregates of related facts, concepts, or percepts. Chunks become larger and more complex with experience and are often hierarchically integrated, one inside another, like Russian dolls, so as to take up less processing space. Development may be seen as the increasing capacity of "immediate" or *short-term memory*—now refined and expanded as *working memory*. If so, is this owing to biological maturation or increasingly effective and sophisticated strategies to chunk information? Clearly, one's general knowledge base and specific knowledge of memory strategies influence this capacity (Chi et al., 1988).

#### THE DEVELOPMENT OF PROCESSING CAPACITY

Development in IP models is toward faster processing and greater organizational complexity of cognitive architecture. A cognitively mature person can manage more information per unit of time and deal better with complex and ambiguous information than an immature one. Infants cannot handle complex information as well as older children because they would have to "attend to and interrelate more pieces of information than their working memory capacities can handle" (Flavell et al., 1993, p. 85). With experience, elements of a task are chunked into aggregates and processes automatized, which allows more attention for conscious, reflective thinking and problem solving.

Let us follow an item of information through the system according to a version of this classic model (Atkinson and Shiffrin, 1968). The stimulus, for example an auditory or visual sensation, passes first into a modality-specific *sensory register*—"echoic store" for sound, "iconic store" for sight—where, in milliseconds, it is scanned for pattern recognition, tagged as relevant, and transferred into *short-term memory*. In an adult, it may stay there up to 15 to 30 seconds in the form of five to nine (seven plus or minus two) units. (It may stay longer if some deliberate strategy—a *control process*—is used to keep it active. One such process is "rehearsal," wherein a person might repeat the new information to herself or himself until it is either used or retained.) This new information may: (a) be interpreted as insignificant and forgotten, (b) cause a behavioral response, (c) be stored in *long-term memory*, or (d) remain in short-term memory and undergo further processing. These possibilities may be represented as a flow diagram (Fig. 12.1).

**Figure 12.1.** Flow of information through the memory system. (From: Atkinson RC, Shiffrin RM: *The Control of Short Term Memory*. Scientific American, Inc., 1971. All rights reserved.)

In the classic model, the place where new information is held, awaiting further processing, is simply short-term memory. This concept has recently become the more comprehensive *working memory* (Baddely, 1986). Briefly, it consists of an attention-like, central executive in the dorsolateral prefrontal cortex that manages both an articulatory loop system associated with the reception of phonological information and the production of speech, and a visual-spatial scratch pad for encoding images (Eysenck, 1990). Working memory is the principal arena of cognition and its processing capacity determines the sophistication of problem solving. Changes in this capacity account for much development in many IP theories (Case, 1985).

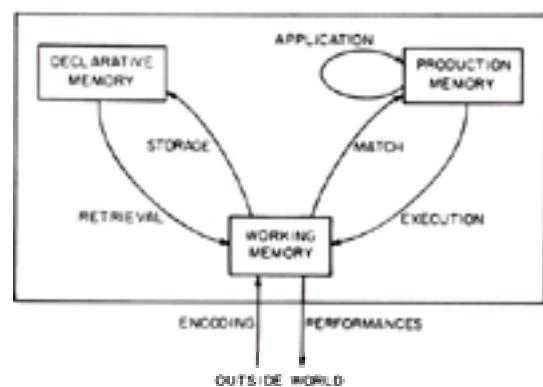

#### SEMANTIC ORGANIZATION: NETWORKS AND PRODUCTION SYSTEMS

Information processing also may be rendered as a series of *production systems*, as in a computer program (Anderson, 1983; Newell, 1990). Production systems are rule-based mental representations in the form of condition-action ("if . . . then") statements stored in long-term memory. If condition A is held in working memory and matches a rule for action in long-term memory, then the unit acts to produce an output that in turn may trigger another production system, and so on. For example, a student reading a text may bring into operation the production system "If the sentence is important, then underline it." This may be followed by a superordinate rule such as, "If the book isn't yours, don't mark it up." There can be a great many of these nested within one another to make up a "program" of great recursive complexity. A more current version of the flow-diagram representation described in the preceding is a network type of architecture also based on production systems. One such is the propositional network of Newell and Simon (1972) called SOAR (Franklin, 1995; Newell, 1990); another was developed by Anderson (1983), which he called adaptive control of thought (ACT).

Anderson proposed an architecture based on two fundamental types of knowledge—*declarative knowledge* and *procedural knowledge*. Declarative knowledge is *knowing that*; it is knowledge of facts and concepts, such as the date and significance of an historical event. It may be stored as language-like representations—propositions—or perception-like representations—images (Stillings et al., 1987, p. 18). Procedural knowledge is *knowing how* to do things, such as read a book or ride a bicycle. It contains elements of declarative knowledge that have been *proceduralized*. That is, copies of elements of declarative knowledge have been integrated into production systems so that one can access this information from production memory automatically and instantaneously rather than consciously searching declarative memory each time the information is needed. Once proceduralized, however, retrieval of these declarative elements requires conscious, focused attention; that is, *controlled* processes. Procedural knowledge operates by *automatic* processes that are unconscious and make no demands on working memory (Schneider and Schiffrin, 1977). Developmentally, the more we proceduralize our knowledge, the more we can do simultaneously and the more complex the tasks we can manage.

As in the preceding, let us follow an item of information through this system. To begin with, an external stimulus or an internal computation is encoded in working memory, which, in ACT, is not separate but designates the currently active part of declarative memory. Information may enter declarative memory as a proposition, image, or representation of a sequence of events. The declarative system is made up of propositions ("I need to study tonight to pass tomorrow's exam") and production systems form the procedural component ("if invited out tonight, then decline").

For a production to apply, the clauses specified in its condition must be matched against the information active in working memory. This information is part of the system's *declarative* component . . . [and] must be retrieved from long-term memory (Anderson, 1983, pp. 10–11) (Fig. 12.2).

**Figure 12.2.** A general framework for the adaptive control of thought production system. (From: Anderson JR. *The Architecture of Cognition*. Cambridge, MA, Harvard University Press, 1983, p. 19.)

If more than one rule may apply, as in the preceding with the “underlining” dilemma, preference may be given to the one that most closely matches the goals currently in working memory (therefore, underline), or because whenever a rule is applied successfully it is strengthened and more likely to be called up again, the prohibition against defacing library books might override the immediate goal (therefore, do not).

Knowledge is represented in declarative memory as a network of *nodes*, and relations among them, or *links*. In Anderson’s scheme, “The nodes of the propositional network stand for ideas, and the linkages among the nodes represent associations among those ideas” (Best, 1989, p. 249). Retrieval of ideas or images from long-term memory involves *spreading activation* (Collins and Loftus, 1975; Quillian, 1968).

Activation controls the rate of information processing . . . Activation spreads through the declarative network along paths from original sources to associated concepts. A piece of information will become active to the degree that it is related to current sources of activation (Anderson, 1983, p. 86).

The “firing” (or not) of a node influences the ongoing direction of the activation. Particular nodes may be more or less easily involved in this chain reaction, depending on the relevance of their content to the current situation and the closeness of their association to already activated nodes.

### NEURAL NETWORKS AND CONNECTIONISM

Anderson’s production system model has been criticized as too “computerized” and remote from the way people actually think (Gardner, 1985). In ACT, as in the classical model, “sets of symbols are moved about from one memory store to another, and are processed by explicit rules applied in sequence” (Eysenck, 1990, p. 66). This “top down” view has been called *representationalism*, and it is contrasted with *connectionism*, which is “bottom-up” (Frawley, 1997, pp. 68–86). Initially, it seemed promising to build a model of cognition based on rules and symbols. However, when programmers first tried to set up software to do things that brains seemed to do easily, they discovered that the simpler the task for a human the harder it seemed for a computer. A program for college-level calculus was easier to write than for grade-school math and it was even more difficult to write one to manipulate an infant’s blocks. So too, when programmers tried to write rule-based programs based on human experts’ experience-derived knowledge in their field, they found that the experts could not articulate their rules to solve any but the simplest problems; they seemed to operate more by a combination of intuition, prototypes, and rules with multiple exceptions than formal logic. These setbacks moved some cognitive scientists to look to the structure of the brain to inform the design of their cognitive architectural software. These revolutionary cognitive architectures are called *neural networks* (Fig. 12.3).

**Figure 12.3.** A whimsical depiction of the layers of a neural network. (From: Kosslyn SM, Koenig O: *Wet Mind: The New Cognitive Neuroscience*. New York, The Free Press, an imprint of Simon and Schuster, 1992. Reprinted with permission.)

The basic design of a neural network is quite simple; a layer of input processing units, or neurons, a layer of connecting neurons and a layer of output neurons (Fig. 12.3). Data are taken in and passed to the connecting layer that has a myriad of interconnections among its elements.

Each neuron takes in signals from other neuronlike components, adds them up, and decides on the basis of the answer whether to send out a signal of its own. In a way the neural units . . . are analogous to people in a jury talking amongst themselves, trying to influence each other to decide one way or another. . . . (Allman, 1989, p. 12)

At some point, output ensues. The relative success or failure of the output in solving the problem at hand constitutes new input and particular connecting pathways are strengthened (*weighted*) or weakened as a consequence (connectionism). In terms of Hebb’s Law, “neurons that fire together, wire together” (Hebb, 1949). Like humans, the system learns from examples, by trial and error; however, it seems likely that infants come into the world with many preweighted structures.

Knowledge is represented as the sum of all these connections at any given moment. It is therefore *distributed*, that is, spread throughout the network; there is no central processor nor distinct memory bank. Unlike a modular system whose components are cognitively impenetrable, all components of such an *interactionist* system are mutually accessible. So too, most or all elements of the system are necessarily active at the same moment as activation spreads among millions of neurons simultaneously, that is, the system works in parallel rather than in sequence. Given these characteristics one of the most developed connectionist architectures is called *parallel distributed processing* (PDP) (McClelland and Rumelhart, 1986). By entering lists of verbs and their past tenses, Rumelhart and McClelland (1986) “taught” a neural network system to change the present-tense form of a verb to its past-tense form and found that, “though it wasn’t designed to do so, this neural network made the same kinds of mistakes that children make when they are learning verbs” (Allman, 1989, pp. 36–37). In other words, “connectionism says that the nature of the brain really matters” (Lakoff, 1995, p. 123).

Neural networks explain better than conventional, rule-based architectures how we make inductive inferences and generalize. As the number of input neurons is virtually limitless all sorts of subtle contextual variations can be encoded so as to enormously increase the capacity to adapt to shifting circumstances and act on incomplete information. Connections resemble rules in that antecedent circumstances influence subsequent ones but the influence is virtually indeterminate because one can never be sure, from instance to instance, how all the inputs will add up. Connections are probabilistic rather than deterministic; rules impose hard constraints, connections soft ones. Parenthetically, neural networks also undergird applications of “fuzzy logic,” a new form of artificial intelligence that allows nonhuman systems essentially to program themselves, taking as input partial truths and incomplete information the processing of which has hitherto been the unique property of the human mind (Kosko, 1993; McNeil and Freiberger, 1993).

Connectionist models may explain more precisely Piaget's concepts of assimilation and accommodation.

Assimilation can be interpreted in terms of the tendency of an interactive network to settle into the most appropriate of its stable ( *attractor*) states . . . when input is presented to it; in Piaget's language this is the schema to which the experience has been assimilated. Accommodation can be interpreted as the changes in activations as well as weights that occur in order to assimilate the experience . . . these processes can actually be designed into networks and observed under a variety of scenarios ( [Bechtel and Abrahamsen, 1991](#), p. 271).

For a detailed and current overview of neural networks and cognitive neurodevelopment, the reader is referred to [Green and associates \(1996\)](#), [Johnson \(1997\)](#), or [Spitzer \(1999\)](#).

#### MIKE ANDERSON'S MINIMAL COGNITIVE ARCHITECTURE

Australian Mike [Anderson \(1992\)](#) has proposed a "minimal cognitive architecture" that accounts both for individual differences in intelligence and cognitive development on the basis of an interaction of generality and modularity in mental functioning. We encounter a similar synthesis in the neo-Piagetian model of Robbie Case.

He begins by noting that individuals differ in data processing speed, measured neurophysiologically as inspection time (IT), reaction time (RT), and average evoked potential (AEP). Average evoked potential is derived mathematically from electroencephalogram (EEG) tracings, whereas IT and RT are measures of how much time it takes subjects to make choices on the basis of rapidly presented sensory stimuli. These measures may represent a sort of general neuronal efficiency and all correlate well with IQ and other measures of cognitive ability. A person's relative performance on cognitive tests remains more or less constant throughout life so that differences in processing speed are likely biologically based. Anderson postulates a wired-in *basic processing mechanism* (BPM) that carries out general computation and varies in speed from person to person. This would account for some individual differences in intelligence ( [Fig. 12.4](#)).

**Figure 12.4.** A diagram of Mike Anderson's minimal cognitive architecture. SP, specific processor. (From: Anderson JR: *The Architecture of Cognition*. Cambridge, MA, Harvard University Press, [1983](#), p. 107.)

On the other hand, there are some things that everyone can do about the same, irrespective of IQ, and that computers find very difficult. For example, virtually from birth, all can extract the features of three-dimensional space, encode phonologic information and organize our own and others' utterances as language. These abilities do not correlate with processing speed, and Anderson suggests these are, like the BPM, part of our genetic inheritance; however, unlike the BPM, they do not vary in efficiency but operate in a modular, all-or-none fashion. They come on line at different points with age.

People differ in their talents and, often, a particular talent is associated with others: Some people are better at art, others at math, and if they are good at math, they are likely to be musical. Indeed, during World War II, musicians were put to work as cryptographers simply because they were handy but they turned out to have unusual gifts for unraveling codes. Standard IQ tests recognize such differences by sorting cognitive abilities into two piles—verbal and performance. Correspondingly, Anderson proposes two *specific processors*, which are "function-specific knowledge-acquisition mechanisms" ([Anderson, 1992](#), p. 118). One such generates problem-solving algorithms for verbal/propositional input (SP1) and the other for visuospatial input (SP2). Specific processors are *experience-dependent* in that they need experience to develop as processing mechanisms. They must "borrow" from the general computational capacity of the BPM to process information so their development is also dependent on the BPM's processing speed. By contrast, modules are *experience expectant*; that is, they need only exposure to an experience, perhaps during a sensitive period, to unfold. Knowledge is acquired either by thought-mediated learning (Route 1, [Fig. 12.4](#)) or by the age-related activation of phylogenetically given modules (Route 2, [Fig. 12.4](#)).

Finally, there are things that some cannot do irrespective of intelligence. For example, dyslexics, even those with a high IQ, cannot decode certain types of language-based information. In some cases, there may be a fault in SP1, in others a defect in the module for phonologic encoding. These possibilities are not mutually exclusive as there are types of dyslexia that are better explained as processing problems and others better explained as pure or modular defects.

For Mike Anderson, "the maturation of modules is the primary cause of cognitive development" ([Anderson, 1992](#), p. 207). In his scheme, development happens either by: (a) the acquisition of new competencies, or (b) the elaboration of knowledge ([Fig. 12.4](#)). For example, the maturation of language-related modules brings a new set of processing competencies to all.

Suddenly having access to linguistic representations will result in a discontinuity of development that is unrelated to individual differences in intelligence. However, elaborating one's knowledge of the world by using this new competence—for example, by building vocabularies—will be constrained by the basic processing mechanism and the specific processors. Thus individual differences in intelligence will have an effect on the elaboration of knowledge but not on the acquisition of new competencies ([Anderson, 1992](#), p. 121).

#### Modules and Learning: Representational Redescription

Annette Karmiloff-Smith posed the following question to herself: Does human cognitive change affect all domains of knowledge simultaneously or does development occur in a domain-specific fashion? ([Karmiloff-Smith, 1992](#), p. 1). In brief, her answer is "both"; however, rather than hardwired, prespecified modules, she posits "a process of *modularization*. . . [whereby] . . . the mind becomes modularized as *development proceeds*" ([Karmiloff-Smith, 1992](#), p. 4). She acknowledges innate cognitive predispositions to preferentially attend to certain classes of stimuli; however, "this endowment interacts richly with, and is in return affected by, the environmental input" ([Karmiloff-Smith, 1992](#), p. 5).

When the innate predisposition is specified in detail, it is likely that the environment acts simply as a trigger for the organism to select one parameter or circuit over others [assimilation?]. . . . By contrast, when the innate predisposition is specified merely as a bias or skeletal outline, then it is likely that . . . [the environment] actually influences the subsequent structure of the brain [accommodation?] ([Karmiloff-Smith, 1992](#), p. 15).

*Representational redescription* (RR) is Karmiloff-Smith's hypothetical mechanism that accounts for the output of modules being used by more general processes to create representations accessible to other parts of the cognitive system [both within and beyond domains] by making implicit representations explicit. "A specifically human way to gain knowledge is for the mind to exploit internally the information that it has already stored (both innate and acquired), by redescribing its representations" ([Karmiloff-Smith, 1992](#), p. 15).

Representational redescription begins with *implicit* (proceduralized) knowledge. A child learning the piano begins by keying each individual note from the sheet music. With practice she learns whole phrases and strings them together until she can play the piece pretty much automatically. Karmiloff-Smith calls this *behavioral mastery*, represented as a connectionist network. Such basic networks are still quite rigid; the pianist cannot yet start anywhere in the piece nor perform variations on a theme. Only representational flexibility and control will permit these latter two skills to develop. In Karmiloff-Smith's terms, representational redescription has to take

place; that is, representations coded in a specified way have to be translated into a common language so that other cognitive components can “understand” them.

In this model, development takes place in three recurrent phases. In phase 1, learning is data driven—the child learns which note on the music sheet corresponds to which key on the keyboard. Phase 1 culminates in behavioral mastery as in the preceding. In phase 2, “internal representations become the focus of change” (Karmiloff-Smith, 1992, p. 19). The child begins to experiment with the music, which introduces new errors and inflexibility. Finally, in phase 3, external data and internal representation are back in synchrony and a new level of mastery is achieved that allows for creativity and thematic variation. The formats that undergird these observable phases are characterized as levels I(implicit), E(xplicit)1, E2, and E3. “These [formats] do not constitute age-related stages of developmental change. Rather they are parts of a reiterative cycle that occurs again and again within different microdomains and throughout the developmental span” ( Karmiloff-Smith, 1992, p. 20).

Information at level I is “not available to other operators in the cognitive system” ( Karmiloff-Smith, 1992, p. 20). Soon, the internal dynamics of the cognitive system, operating unconsciously, begin to generate level E1 representations, a “new compressed format of the procedurally encoded representations at level 1” (Karmiloff-Smith, 1992, p. 21) that have lost some specificity of detail. A zebra could now be more abstractly represented by a child as alternating black and white stripes allowing a perceptual/conceptual link to a (European) sign for a crosswalk depicting the same motif. A child without E1 representation would not understand why such a crosswalk is nicknamed a “zebra crossing.” However, at level 1, the child still does not have conscious access to the representation and cannot speak of it. (It should be noted that as one level emerges out of the preceding one, the original remains; the child can still recognize a zebra: Phenomena are represented at multiple levels simultaneously.) Representations at level E2 are in a similar code to those at E1, but the child is conscious of them. For example, spatially encoded E2 representations still cannot be verbalized but could perhaps be drawn or diagrammed. Finally, at level E3,

knowledge is recorded into a cross-system code . . . close enough to natural language for easy translation into storable, communicable form. . . some knowledge learned directly in linguistic form [may be] immediately stored at level E3 ( Karmiloff-Smith, 1992, p. 23).

Where there was a dichotomy between procedural and declarative knowledge Karmiloff-Smith has created a continuum.

This movement from implicit information embedded in an efficient problem-solving procedure, to rendering the knowledge progressively more explicit . . . is what I think development is about (Karmiloff-Smith, 1992, p. 17).

In RR,

cognitive change involves movement from the procedural to the computationally accessible (where procedures may be recombined or broken apart) and then to the consciously accessible (where the knower can consciously reflect on and manipulate procedures) . . . it is not the operations of the cognitive system that change, but the kinds of representation that are available to the system. In this view, cognition is a self-organizing system that is success-driven rather than failure-driven, as in Piaget's theory ( Nelson, 1996, p. 14).

### Information-Processing and Piagetian Models Compared

Cognition entails mental representation in both Piagetian and IP models, but representations are organized differently in each. Piaget attempted to explain achievements across cognitive domains by way of age-specific logical structures. However, Piagetians have been obliged to recognize that the theory did not account well for uneven performance across tasks with the same apparent logical structure—the phenomenon of *horizontal décalage*. For example, a child may be able to pass a conservation of number problem at age 5 but not pass a conservation of volume task until age 9 or 10. Information-processing theorists (and knowledge-based theorists) emphasize task and domain specificity; that is, the encoding of the task as of one type or another draws together and organizes knowledge to solve it. Cognitive representations have their origins and applications in particular domains. For example, the capacity to perform certain mental operations in the domain of mathematics does not mean that the child can transfer this capacity to the spatial domain: Décalages are discrepancies in domain-specific knowledge that may also reveal discrepant processing demands, concealed by apparent similarities in logical structure.

### Information-Processing and Sociocultural Models Compared

William Frawley (1997) charges that IP theory privileges explanations of cognition as private, internal computations and gives little account of how the computational mind is influenced by its real-life interpersonal situation. However, before anyone performs computations to solve a problem, he has to decide what the problem means in his situation and from what position, if at all, he will respond. This is called *orienting* to the problem and differs from *representing* to oneself the elements of the problem. Orientation is a context-dependent form of metacognition. That is, any instance of computation requires an appreciation of what is the most relevant computation in the moment: The determination of relevance is very hard for autistic children, as we shall see.

### Critique of Information-Processing as a Developmental Theory

The IP approach has been described as:

more a methodology (derived from task analysis) than a theory. . . . There is no agreed-upon nexus between the information-processing parameters and their biological substrate nor is there a description of the contextual mechanisms by which these parameters are initially shaped and later elicited ( Ceci, 1996, p. 197).

Patricia Miller (1989) noted that, although changes in processing capacity have been clearly described in adults as they go from novice to expert, development from child to adult might not proceed in the same way. Siegler does not see this to be a problem. Investigators, he believes, “can better understand the development of children's thinking when [they] know where that thinking is headed” (Siegler, 1986, p. 63). Miller also felt that there has been relatively little application of IP theory to the understanding of emotions, motivation, and social development. Recently, however, IP theory has been brought to bear on explaining autism and Case's neo-Piagetian theory, which has IP components, has been applied to social and emotional development ( Case, 1988).

## NEO-PIAGETIAN THEORY

### The Response to Piaget and Responses to the Response

Case (1992a) summarized the recent history of, and intellectual influences on, the most current theories of cognitive development. First, in reaction to the inadequacies of Piaget's “monolithic, universal and endogenous” system ( Case, 1992b, p. 10), other investigators—*empiricists*—began to study task-specific learning and avoided hypothesizing about how the development of different competencies might resemble one another. As one would expect, these projects explained some of what the Piagetian enterprise could not, but did not account for the similarities among children of divergent cultures and common, age-specific constraints on learning. This impasse prompted three, quite different, responses.

Nativists proposed that cognitive development was based on the maturing of neurologically based modules that biased children's attention to certain types of stimuli (Herschfeld and Gelman, 1994). In the strong version of nativism (Fodor, 1983), there is little development per se, simply the coming on line of more advanced modules. In the weaker version, modules change and develop under the influence of external data and internal differentiation and coordination of elements (Karmiloff-Smith, 1992).

*Knowledge-based* theory put forth a model of development similar to the novice-to-expert transition in adult learning. Development is learning-based, domain-specific, and cumulative. As children acquire more experience in a domain:

they begin to form new connections (whether conceptual, procedural or purely associationistic) among the basic elements of which the domain is comprised. These . . . lead to the integration of knowledge structures that were previously discrete. Once integrated, new knowledge structures or networks lead to new [problem-solving] strategies . . . and to new memorial capacities ( Case, 1992a, p. 14).

These knowledge structures are domain-specific conceptual networks that become ever more integrated until adult-level cognition is achieved ( Case and Okamoto,

1996). The distinguishing feature of knowledge-based cognitive developmental theory is that content influences process; the more one knows in a given domain the better one can think about it (Carey, 1990). Micheline Chi, a pioneer in this approach, did a fascinating study on a 5-year-old dinosaur expert demonstrating reciprocity between knowledge structures and learning strategies (Chi and Koeske, 1983). Similarly, it was supposed that an adult-like understanding of the inevitability, universality, and finality of death was achieved no earlier than 9 years of age in a sequence of age-linked stages (Nagy, 1948); however, Bluebond-Langner (1977) showed that leukemic children, who discovered with each clinic visit that fewer of their fellow-patients remained, acquired a full adult understanding much earlier.

Finally, *neo-Piagetian* groups proposed that there are domain-specific cognitive structures that develop more or less independently. Like task-specific structures, they are dependent on the context of learning and the child's previous experience. Like Piagetians, their application is broad within their domain, and they have common organizational features across domains. They are not based on logical operations (*syntactic* content) as are Piaget's, but on information (*semantic* content). Their pattern of development is hierarchical and recursive, and they are constrained, at any given age, by maturational limitations on the size of working memory and/or the speed of processing.

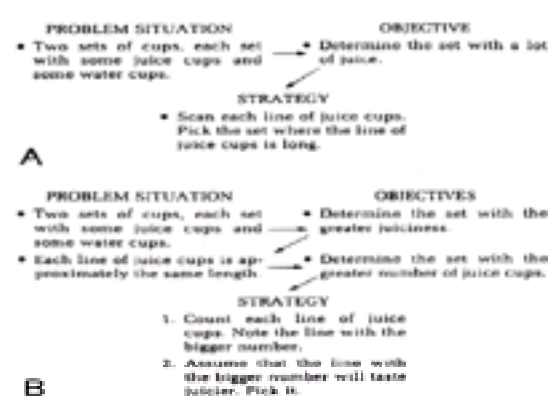

### Robbie Case

A well-regarded example of the neo-Piagetian synthesis is the work of Robbie Case (1985, 1992a, Case and Okamoto, 1996). Originally, Case supported the Piagetian notion of age-related, general cognitive structures evolving in an invariant sequence but also believed that problem-solving strategies, and working memory limitations had to be taken into account. Significantly, he incorporated affect as an important element in his approach. More recently (Case, 1992a, Case and Okamoto, 1996), his work has addressed the question of domain specificity and modularity. That is, is the mind best understood as a general IP device that stretches across domains to approach problems with the same tools or is it a system of phylogenetically shaped modules whose components are each dedicated to processing only particular kinds of input? Or is it both?

### EXECUTIVE CONTROL STRUCTURES

Case (1985) proposed that a child's cognitions are composed of schemes representing "recurrent patterns of stimulation" called *state representations*, and schemes representing mechanisms of transforming these states, called *operations*. The activation of a scheme is attended by a positive, negative, or neutral affect. From the second month of life, children have some control over and attempt to optimize their affective experience. They do this by organizing schemes to represent: (a) a particular, recurrent state (the *problem representation*), (b) an anticipated state of greater pleasure (the *objective*), and (c) the operation that will produce this transition (the *strategy*). These three elements are combined to form *executive control structures*, which are basic problem-solving structures analogous to production systems.

Case applied the concept of executive control structures to the well-known "juice problem" (Noelting, 1975). In this problem, children are asked to compare two lines of small cups, each line containing some cups filled with juice and others filled with water. One line has a large number of juice cups and a few water cups. The other has a small number of juice cups and the same number of water cups as the first, so that it is shorter in length than the other line. The children are asked which line, when mixed together, will taste "juicier." Four-year-old children guess (correctly) the first, because "there's a lot there." This is the earliest that children can solve this problem. At 6, children can go one better. In this situation, the lines of cups are made of equal length, and the same question is posed. By counting juice cups on each side, the children confidently pick the side with the greater number. The executive control structures assembled for the juice problem, for each age group, appear in Fig. 12.5.

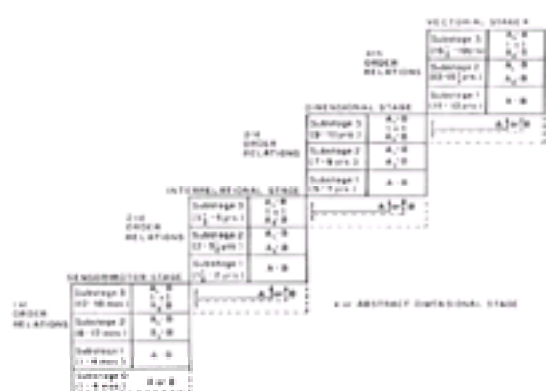

**Figure 12.5.** The executive control structure for solving the juice problem. **A:** Four-year-old control structure. **B:** Six-year-old control structure. (From: Sternberg S (ed): *Mechanisms of Cognitive Development*. San Francisco, WH Freeman and Company, 1984. Reprinted with permission.)

The 6-year-old child's structure is actually two hierarchically integrated structures. It is more quantitatively fine-tuned than the earlier one, more "dimensional." Case (1984) used this analysis to contrast the cognitive organization of 4-year-old children with that of 6-year-old children. For Case, the "4 to 6" transition is a stage transition, one of three linking his four stages. At 6, two different, earlier executive control structures have been coordinated and hierarchically integrated. As a result, a qualitative differentiation occurs wherein a new way of thinking emerges—a *quantitative dimension* of thought. This capacity to dimensionalize, as it were, applies not only to the task at hand; once this dimensional structure is established, the child applies it to a wide variety of tasks. Case calls this higher-level knowledge organization a *central conceptual structure*. It is central in that it can be applied to a broad range of tasks, analogous to, although perhaps less comprehensive than, Piaget's structures-of-the-whole.

### CENTRAL CONCEPTUAL STRUCTURES

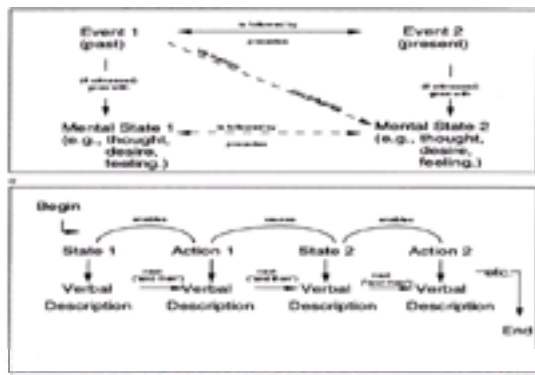

Executive control structures are task and culture specific as in the IP and sociocultural models, respectively. As in the Piagetian model, Case's are transformed according to a "general and universal" sequence of stages throughout development. This takes place stepwise in four age-specific stages (*sensorimotor*, *relational*, *dimensional*, and *vectorial*), as depicted in Fig. 12.6. Case's sensorimotor stage, like Piaget's, describes a physical, sensory representational system. The relational stage is characterized by a global, nonquantified worldview of "up-down," "big-little," "high-low," and the like. It is "either-or," "pass-fail." The dimensional stage is full of measurement and shadings of "this much" more or "that much" taller. The vectorial stage allows the representation of real or hypothetical quantity, which has, as it were, both magnitude and direction. It permits the representation of a multiplicative relationship between two forces.

**Figure 12.6.** The neo-Piagetian system of Robbie Case. (From: Case R: The whole child: Toward an integrated view of young children's cognitive, social, and emotional development. In: Pellegrini AD (ed): *Psychological Bases for Early Childhood Education*. New York: John Wiley and Sons, 1988, p. 159.)

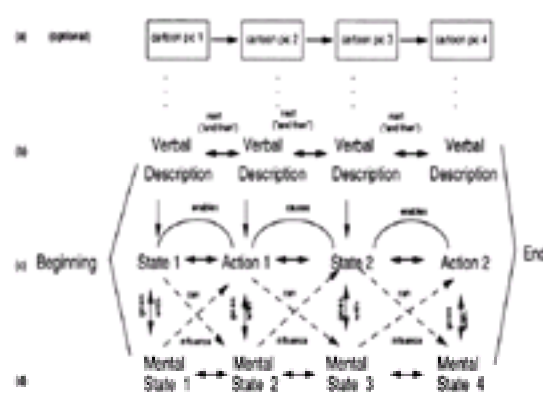

Case's most recent work further explicates central conceptual structures and details the mounting experimental evidence in support of the notion in three domains—mathematical, spatial, and social (Case and Okamoto, 1996). The last is presented in some detail because it is the most germane to child psychiatry. The research stimuli are narratives in four-panel cartoon format depicting event sequences and characters' reactions. Four-year-old children understand how mental states can be modified by external events (Fig. 12.7a). They also understand familiar event structures (scripts) (Schank and Abelson, 1977) and the normal sequence of their unfolding (Fig. 12.7b). However, they cannot yet bring the two "files" together and infer how the mental state of the actor in the script might influence the next event in it.

**Figure 12.7.** Central narrative structures at about 4 years of age. (predimensional/interrelational stage). A: The inner state schema that allows children to infer the thoughts and feelings of others. B: The event sequence schema that permits children to verbalize familiar social scripts. (From: Case R, Okamoto Y: The role of central conceptual structures in the development of children's thought. *Monogr Soc Res Child Dev* 61:10, 1996.)

Between the ages of 5 and 6 years, children become capable of answering such questions in an "intentional" fashion. . . . They have merged the two original files and have formed a superordinate structure (Fig. 12.8). . . . Children can now think of any familiar human activity as a coordinated sequence of events involving two components: a "landscape of action," which is the behavioral component of an event sequence, and a "landscape of consciousness," which is the internal or "intentional" component (Case and Okamoto, 1996).

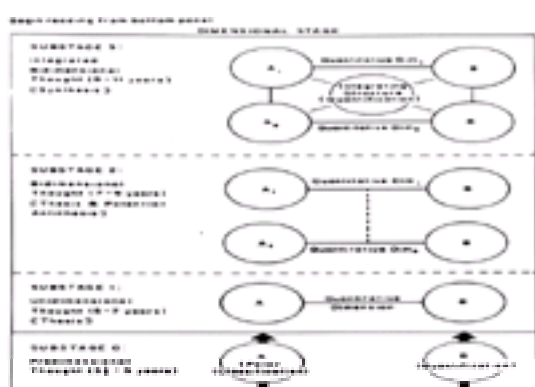

**Figure 12.8.** Central narrative structures at about 6 years of age (unidimensional stage) shows a merging of the two schemes in Figure 12.7. (From: Case R, Okamoto Y: The role of central conceptual structures in the development of children's thought. *Monogr Soc Res Child Dev* 61:11, 1996.)

Further changes take place between 6 and 10 allowing yet more coordination and integration of multiple and conflicting characters, mental states, and story lines. The central conceptual structures for mathematical or spatial cognition in 6-year-old children have the same general layout as the one for social cognition. This resemblance makes Case's point that, in spite of the domain specificity of each, there are common structural elements that gesture toward a domain-general process.

### The Mechanism of Development: Stage and Substage Transition

Stage transition occurs as executive control structures assembled during the previous stage, different in form and function, are hierarchically integrated. Stages are distinguished from one another by the kind of elements of which the executive control structures are made up. For example, when the counting element is integrated with the relative amount element, a whole new type of element—a dimensional one—has been constructed. This is the difference between a 4-year-old and 6-year-old child's approach to the juice problem.

Substage transition also occurs by integration of executive structures, but the integration need not be hierarchical, nor need the elements be different. Within each stage, there is a universal, age-specific sequence of three substages (*unifocal*, *bifocal*, and *elaborated coordination*) differentiated by the number of bits of information they represent, and how these bits are organized. Within the dimensional stage, substages unfold, coordinating two, then three, then four elements. This allows more complex dimensionality in that different sets of counting and relative amount units can be coordinated but does not produce a qualitative transformation as at the stage shift from relational to dimensional thought (Fig. 12.9). Stage transition (Fig. 12.6) is the natural outcome of substage transition (Fig. 12.9). Substage transition is the natural outcome of a growth in the capacity of working memory. Working memory is made up of space for executing cognitive operations and space for short-term storage and retrieval of relevant, but temporarily inactive, elements of the problem.

**Figure 12.9.** Substages within Case's dimensional stage. (From: Case R: The whole child: Toward an integrated view of young children's cognitive, social, and emotional development. In: Pellegrini AD (ed): *Psychological Bases for Early Childhood Education*. New York: John Wiley and Sons, 1988, p. 157.)

Logically, working memory can grow by either some sort of maturational increase in short-term storage space or becoming able to process more efficiently, so that less space is taken up by executing cognitive operations. Although practice does increase precision of representation and operational efficiency, it cannot entirely account for the process of development. Physical maturation, perhaps in the form of increasing myelination, may be ultimately rate limiting. Case (1992b) describes some promising correlations between his developmental timetable and frontal lobe EEG changes. The processes that move development along and their

synchronization may account for cognitive similarities between ages 4 and 10. First, “the tracts connecting the two hemispheres become increasingly myelinated . . . and the activity in the two hemispheres becomes better differentiated and integrated” ( [Case and Okamoto, 1996](#), p. 16). So too, the fibers connecting the frontal and posterior lobes show a strong pattern of dendritic growth between 4 and 10 and the two parts become more synchronous in activity. Second, schooling ensures that children in most cultures are taught mathematics and reading for about the same time each day; therefore, it is no surprise that reasoning about calculation and narrative keep pace.

[Case \(1992\)](#) stays true to his neo-Piagetian roots but incorporates elements from neo-nativism theory (modules), neo-associationist theory (domain-specific learning), and contextual theory (sociocultural influence on cognitive structures). He begins with the premise that children's cognition is innately modular and domain-specific including social, verbal, numerical, and spatial domains, at least. At the heart of children's conceptual systems is the central conceptual structure, which undergoes qualitative shifts at certain ages throughout development. Central conceptual structures are semantic networks that need domain-specific experience to develop both the nodes and links between them. Culturally specific experience, especially academic learning, becomes more important in filling these structures as the child becomes more cognitively advanced. Although there is no intrinsic limit to the growth of these structures in adulthood, there are maturational constraints on the rate of development of children's central conceptual structures. These constraints limit the capacity of executive structures and/or working memory. Finally, consonant with classical Piagetian theory, these structures are actively constructed by the child; grow by differentiation and coordination (integration) of existing structures; undergo qualitative changes by structural reworking; and become more powerful, abstract, and complex with development.

Case proposes a multilevel cognitive system, with levels ranging from the very general to the specific. . . . An increase in capacity ( *general* system-wide change), along with . . . particular experiences . . . leads to a change in the central conceptual structures. These . . . are at an *intermediate* level of generality; each is a representational system of a domain of knowledge such as number or space. These structures interpret specific tasks and affect the problem-solving procedures for these tasks ( *specific*-level change). By including systems that vary in generality, Case accounts for both the evenness and unevenness of cognitive development ( [Flavell et al., 1993](#), p. 14).

## Part 2: Applications of Cognitive-Developmental Theory to Affective Development and Clinical Practice

### A NEO-PIAGETIAN VIEW OF SOCIALEMOTIONAL DEVELOPMENT

#### Cognitive Dimensions of Early Affective Relationships

A neo-Piagetian viewpoint has been brought to bear on early object relationships and “the vital issues that must be negotiated at different stages of development, if these early relationships are to form a basis of healthy functioning in later life” ( [Case, 1988](#), p. 155). Two of the most important questions on which the thinking of psychodynamic psychiatrists and cognitive developmentalists is converging are: (a) How do children represent the affectively powerful transactions that take place with their earliest caretakers? and (b) How do these representations evolve in the course of children's development? For a start, it is assumed that the cognitive construction of both the social and inanimate world is subject to constraints based on the child's general level of cognitive development.

In particular, it is assumed the *level of relationship* children can encode, and the *complexity of event* they can understand which entails such a relationship, increases with age at approximately the same rate, and according to the same epigenetic schedule ( [Case, 1988](#), p. 162).

#### A Social-Cognitive View of Empathy Development

Parental empathy is absolutely necessary for the social, personal, and moral development of the child ( [Feshbach, 1987](#); [Fonagy et al., 1999](#)). [Hobson \(1993\)](#) cites an innate incapacity for affect perception and responsivity as the fundamental reason why autistic children cannot fathom the minds of others (see the following). Gender differences in the development of empathy ( [Hoffman, 1977](#)) are also fundamental to women-centered developmental theories in general ( [Jordan et al., 1991](#)) and moral ones in particular ( [Gilligan, 1982](#)). Empathy has both an affective and cognitive component: It is both a “vicarious affective response to another person” and “the cognitive awareness of another person's internal states” ( [Hoffman, 1984](#), p. 103). The cognitive aspect of empathy is somewhat like social perspective-taking, so that “empathy development must correspond at least partly to the development of a cognitive sense of others” ( [Hoffman, 1984](#), p. 108).

#### A NEO-PIAGETIAN STUDY OF EMPATHY

[Bruchkowsky \(1989\)](#) offers a developmental analysis of empathy based on Case's theory. In her study, children of 4, 6, and 10 years were presented with videotapes of peers enacting emotionally distressing situations. One situation depicted a little girl, Mary, and her dog playing together; shortly afterward, the dog was killed off screen by a car. The subjects were asked, “How do you feel?” “How do you think Mary is feeling?” and “Why is she feeling that way?” Analysis of facial expression during the showing was performed to cross-validate the verbal responses.

Bruchkowsky found no significant age differences in the accuracy of emotional attributions: The children did not differ in terms of what they appeared to feel, what they said they felt, and what they said the other felt. As predicted, 4-year-old and 6-year-old children could attribute only one affect, whereas 10-year-old children could attribute two or more. Bruchkowsky found a “stable developmental progression” in children's reports of why Mary felt as she did, that is, their *empathic cognitions*. Some 4-year-old children could not construct any explanation for their affective labeling of the other's reaction. They would say things like, “Mary was sad because it was raining.” These children were considered “pre-empathic.” Most 4-year-old children, however, were able to offer an explanation for Mary's feelings. They focused on external and salient features of the situation: “Mary was sad because her dog died.” These children could coordinate: (a) Mary's perceived affective reaction with “sad” and (b) “sad” with “her dog died.”

Most 6-year-old children referred to an internal dimension of the other's affective experience in addition to the external event: “Mary was sad because her dog died, and she will miss it.” Ten-year-old children focused on and coordinated two intrinsic dimensions of the other's affective experience: “Mary was sad because her dog died and she loved him and she will miss him.” Some offered as well a coordination of two opposing affects over time: “Mary was sad because at first she was playing with her dog and she was happy, then her dog was run over by a car and she was sad.” In summary, only external cues elicited a response at first, then one internal state was inferred, then two were inferred and coordinated in an elaborated manner. Age differences in children's empathic cognitions depended on a progressive increase in the capacity to coordinate from one to two to four elements. Case's theory, as an example of a cognitive developmental theory designed on the basis of problem solving with physical tasks, also can provide an account for the development of social relationships as well as their maldevelopment ( [McKeough et al., 1994](#)).

### THE DEVELOPMENT OF SOCIAL COGNITION

#### Social versus Nonsocial Cognition

Social cognition is distinguished from nonsocial cognition by the inherent intentionality of humans; people—including oneself—think, feel, and cause things to happen. Both oneself and others may conceal intentions and harbor ambivalences. Thoughts about others are virtually always informed by affects, the social context of interactions, and the need to separate one's own thoughts from those of others. This similarity between the knower and the known poses new cognitive challenges. Working out issues of cause and effect where one's way of thinking influences the way one's object of thought thinks and behaves is quite different from sorting out causality with crib mobile or hidden coins. Other human beings can establish “mutually intentional relations” with the child ( [Stern, 1985](#), p. 124ff).

It is this mutuality of conduct and communication that distinguishes social from merely physical events and that engenders (and requires) a special sort of understanding. The developmental study of social cognition is, in part, a study of this understanding as it grows and changes in the child ( [Damon, 1981](#), p. 159).

There is reciprocity between social and cognitive development: Cognitive skills mediate social interaction, which, in turn, provides the context for further cognitive development.

On the other hand, social cognition holds to many of the same developmental sequences as nonsocial cognition. For example, it proceeds from centration on particular external, perceptually salient events and objects of thought to decentration and the capacity to comprehend multiple interacting factors and internal, conceptual events. The child becomes able to conserve the identities of things and people—the self no less than others—over time and through transformations. Abstract and hypothetical thinking about self and others allows inferences about present relationships and internal activities, as well as hypotheses about future states

of the self, those of others, and relationships.

### The Structure of Social Perspective Taking

One form of social cognition is *social perspective taking*, which entails the capacity to conceptualize: (a) self and other and (b) the relationship between them. [Selman's \(1980\)](#) Piagetian model depicts a stage-developmental sequence of *concepts of persons* (e.g., undifferentiated) and *concepts of relationships* (e.g., egocentric). The capacity for social perspective taking has implications for the development of all social relationships, particularly empathic understanding and moral reasoning.

#### LEVEL 0: UNDIFFERENTIATED AND EGOCENTRIC PERSPECTIVES (3 TO 6 YEARS)

A preschool child's concept of persons does not differentiate objective-physical from subjective-psychological states of self and other. There is confusion between acts and feelings and intended and unintended behavior. Concepts of relations are egocentric in that the preschooler attributes his or her own perspective to the other person. The other is distinguished from oneself, but no commonality is established.

#### LEVEL 1: DIFFERENTIATED AND SUBJECTIVE PERSPECTIVES (5 TO 9 YEARS)

The child's concept of persons now differentiates the physical from the psychological. The other is seen as having a "unique, subjective, covert psychological life" ([Selman, 1980](#), p. 38), although it is seen as unitary, in that multiple feelings and internal conflicts cannot be recognized. The child's concepts of relations are one-way rather than mutual. It is the physical entity of a gift that makes someone happy, not the thought behind it; the intentionality of giving is not yet appreciated. Subjective attributions are made about another if the other is in a situation familiar to the child, by the reasoning "same situation equals same viewpoint."

#### LEVEL 2: SELF-REFLECTIVE/SECOND-PERSON AND RECIPROCAL PERSPECTIVES (6 TO 12 YEARS)

The later school-age child can see his or her own thoughts, feelings, and actions from another's perspective. This second-person perspective allows for reciprocity. However, although each can see self and other, he or she cannot yet see the relationship system between self as an entity distinguishable from the individuals who constitute it. Actions can be seen as different from intentions, and feelings can be seen as multiple and contradictory. Concepts of relations are reciprocal in that the child can differentiate self from other at a psychological level and not merely at the level of overt behavior. Attributions are made with uncertainty because the other is now seen as having an inner life distinct from one's own, and may dissemble.

#### LEVEL 3: THIRD-PERSON AND MUTUAL PERSPECTIVES (10 TO 15 YEARS)

Adolescence awakens the possibility of taking an observer position to the two-party reciprocity of the previous stage. This third-party perspective allows a clearer vision of the mutuality of individual perspectives. Adolescents "see themselves as both actors and objects, simultaneously acting and reflecting on the effects of action on themselves, reflecting upon the self in interaction with the self" ([Selman, 1980](#), p. 39). Thus, the observing ego is born. The concept of relations is a third-person or "generalized other" perspective from which one can coordinate, simultaneously, the perspectives of all parties in interaction, including the self and the social system in which all are embedded.

#### LEVEL 4: IN-DEPTH AND SOCIETAL-SYMBOLIC PERSPECTIVES (12 YEARS TO ADULTHOOD)

One gradually learns that the observing ego cannot always comprehend the complexity of internal relations, that something is always hidden. At this stage the idea of a personal unconscious emerges. When younger, a child may have been able to understand that someone may do something he does not want to; now the child can see that the other may not understand why. Relations are understood to go beyond the third-party stance of the previous stage and can be seen as systems of perspectives in relation to one another. This allows for a *generalized other* perspective of the interplay of multiple social forces and of the participation of self and other in the formation of this "generalized other" point of view. Coming full circle from infancy, one can recognize the possibility of an inner, unspoken mutuality among people.

[Selman and Schultz \(1990\)](#) applied the stages of social perspective taking to observations of children forming peer relationships and negotiating (or not) conflicts that arise in working together. If one child has something the other wants, the child at level 0 will act impulsively and, for example, try to take it away. At level 1, a child will likely try to influence the other, perhaps by a demand, to get what he wants. The effect of the loss on the other is not a consideration. At level 2, the child is aware he will have to influence the other's mental state and attempt to persuade or bargain. At level 3, the child can reflect on both their mental states and suggest compromises that may satisfy both. This work provides a useful guide to social-skills training and education.

### The Development of Emotional Understanding

[Nannis \(1988\)](#) has analyzed the sequential development of the ways that children reason about their feelings. For very young children, feelings are seen as inherent in the situation eliciting them. Getting a gift creates happiness in itself; the inner response of the child is not invoked as an explanation. The control of the feeling is equally external; it is the gift that causes a smile in the recipient rather than her sense of pleasure. Next, feelings are seen as internal, although located somewhat concretely within the child, almost like a body organ. The child experiences little control because the body is represented as a receptacle into which feelings are put. At the next point in development, feelings are understood as being diffuse within the person rather than concrete things in a concrete body. Feelings are now experienced as being influenced by the self; they have become conceptualized. Finally, the most complex conception of affects moves the self to center stage. "Feelings involve the regulation and integration of internal processes and external events. Feelings are part of a system with universal laws or principles. The self has gone from receptacle, to regulator, to mediator" ([Nannis, 1988](#), pp. 102–103). There are close parallels between this sequence and that of Selman's stages of social perspective taking.

The development of emotional understanding parallels the cognitive capacities of the child in other domains. Beyond that, the subject of emotional development is beyond the scope of this chapter. The reader is referred to [Saarni and Harris \(1989\)](#) or [Sroufe \(1995\)](#) for an overview.

### The Development of Moral Reasoning

In general terms, moral development involves increasing the complexity of one's perspective taking, sense of intentionality, and capacity for coordinating complex and often contradictory arrangements of factors. It also entails a diminishing of one's egocentrism, and a better capacity to interiorize one's own and others' motives. Piaget applied his ideas on the development of logical thought to the evolving capacity of the child to make moral judgments. He proposed stages of moral reasoning to parallel his stages of cognitive development. These were elaborated extensively by [Kohlberg \(1969\)](#) and critiqued trenchantly from a feminist point of view by Carol Gilligan. Moral development is discussed elsewhere in this volume (see [Chapter 19](#)).

### Cognitive Developmental Explanations of Autism

Ever since [Kanner \(1943\)](#) described autism, as a "primary disturbance of affective contact," the nature of the developmental deviation has been an enduring clinical puzzle; although autism has a genetic-neurological basis, the question remains by which psychological pathways it is expressed. There is much to support Kanner's intuition of a primary disturbance of affective development ([Hobson, 1989, 1993](#)); however, recent work makes an equally strong case for a primary disturbance of cognitive development ([Baron-Cohen, 1995](#); [Baron-Cohen et al., 1985, 2000](#); [Bruner and Feldman, 1993](#); [Frith, 1989, 1991](#); [Happé, 1991](#); [Perner, 1991](#); [Sternberg, 1987](#)).

#### THE NATURE OF SOCIAL RELATEDNESS IN AUTISM

Autism entails characteristic impairments in the capacity for social relations. Interpersonal communication, if present, is repetitive and self-absorbed or instrumental and literal, without regard for social context; that is, the *pragmatics* of communication are impaired. Pragmatics include tailoring one's speech to a particular listener, turn-taking in conversation, recognizing what is appropriate to say in a given context, staying on topic, and cueing the listener to changes in topic ([Baron-Cohen et al., 2000](#), p. 13). An example of impaired pragmatics is [Langdell's \(1980\)](#) finding that autistic children unable to modify their account of an event even when they knew

their listener had witnessed it. Particular autistic children may learn to communicate with others, but “an inability to participate in two-way reciprocal social interaction persists throughout the lives of autistic people” ( [Baron-Cohen, 1988](#), p. 384).

#### A PRIMARY DISTURBANCE OF THEORY OF MIND

[Baron-Cohen \(1988, 1989\)](#) believes that a disturbance of affective development is not the primary psychological mechanism in autism. Autistic children have emotional responsivity and they do not completely avoid eye contact or physical closeness with others; they simply do not seek it out as normal children do ( [Hermelin and O'Connor, 1970](#)). Autistic children can also show preferential attachment ( [Sigman et al., 1986](#)). Rather, [Baron-Cohen and colleagues \(1985\)](#) argue that, in autism, an innately impaired capacity to develop a *theory of mind* (ToM) is the primary deficit. A child who has a ToM understands that “people have minds and mental states, and that mental states relate to behaviour” ( [Baron-Cohen, 1993](#), p. 59). Without a ToM, children cannot represent to themselves the mental states—the acts of representing—of others and use that to predict their behavior: They cannot *metarepresent* and, as we shall see, cannot therefore have a ToM.

One of the precursors of ToM is *shared attention* manifested by *protodeclarative pointing*. The infant, knowing from early on how to track the mother's gaze, coordinates this with pointing toward something he wishes to draw to the attention of his mother—“Look at that!” The infant's aim appears to be to influence the mother's attention so that the two can share their interest in the same object. Shared attention implies that the infant realizes that his mother has a mental state that he wishes to align with his own. Shared attention is conspicuously absent in populations of 18-month-old children who have are likely to be later diagnosed with autism ( [Baron-Cohen et al., 1996](#)). Autistic infants, however, may display *protoimperative pointing*—“Get it for me!”—intended to influence the mother's behavior rather than her mental state ( [Baron-Cohen, 1995](#)). [Baron-Cohen and associates \(1992\)](#) used the CHAT—the CHecklist for Autism in Toddlers—to pick up deficits in shared attention, protodeclarative pointing, social interest, and pretend play in 18-month-old children at high genetic risk for autism. None of the controls failed on more than one of the key items, whereas four of the 41 high-risk children did. At 30 months these four were found to be autistic.

Children soon come to understand that they share with others the capacity for intentionality, the mind's inherent tendency to form mental representations. The shared attention of mother and child as they point together is based on their mutual representation of each other's intentions. Insofar as children can imagine what another thinks and apply this knowledge socially, they can be said to have a theory of mind. Mike [Anderson \(1992\)](#), Alan Leslie, and others have suggested that there may be a “theory of mind module” that is dysfunctional or absent in autistic people. Simon [Baron-Cohen \(1995\)](#) has proposed a stepwise developmental schedule of such a module (see the following).

Baron-Cohen and others devised an ingenious experiment to look at children's theory of mind ( [Baron-Cohen et al., 1985](#)). Normal children and children with Down's syndrome and autism, matched for mental age (MA), watched a scenario in which two dolls, Sally (beside a basket holding a marble) and Anne (beside a box) are depicted together. Sally puts the marble in her basket and leaves the scene. While Sally is “off stage,” Anne removes the marble from Sally's basket and puts it in her box. Sally returns, and the child is asked, “Where will Sally look for her marble?” Most of the nonautistic children answered correctly, “in the basket.” By contrast, 80% of the autistic children indicated the box (as would children under 4 years). The authors believed the results demonstrated that autistic children have a specific problem inferring the mental states of others, irrespective of their intellectual capacities.

What of the 20% of autistic children who passed the Sally-Anne ToM experiment? [Baron-Cohen \(1989\)](#) called the capacity to attribute belief to another “first-order belief attribution” and recognized that some older autistic children could do this. He devised a more complex study to explore “second-order belief attribution”; that is, the ability to represent to oneself what a second person believes a third person believes. The scenario was a toy village with a park, two houses, a church, and four people. John and Mary are in the park when the ice cream man comes along in his van. John wants an ice cream but has no money and has to go home to fetch some. The ice cream man assures John that he will still be at the park when John returns: Mary stays in the park. As soon as John leaves, however, the ice cream man decides to drive to the church to try and sell ice cream there. On the way, he passes John and tells him where he is going. Mary, who sees nothing of this, goes later to John's house, and his mother tells her that he has gone to buy ice cream. The question is then posed to the child, “Where does Mary think John has gone to buy ice cream?” To answer correctly, the child has to understand what Mary believes about where John believes the ice cream man is. None of the autistic children (mean age 15 years, mean nonverbal MA 10.7 years) answered correctly, whereas 90% of normal (age 7) and 60% of children with Down's syndrome (age 14, MA 6.8 years) got it. Because Baron-Cohen controlled for memory capacity, intellectual ability, and motivational factors, he postulated a specific delay in the development of a second-order theory of mind in autism.

To investigate the specificity of this cognitive limitation, [Baron-Cohen and colleagues \(1986\)](#) showed three disassembled four-panel comic strips to the same three groups of children. The children were told to make a story by sequencing the panels. Properly ordered, each strip demonstrated a specific kind of causal reasoning. The first (a “mechanical” story) depicted a balloon carried away from someone's hand, landing in a tree and bursting when punctured by a sharp branch. The second (a “behavioristic” story) involved a child going into a candy store, buying candy, and leaving. The third (a “mentalist” story) showed a child putting a piece of candy in a box then going out to play. Unseen by him, his mother removes the candy and eats it. The child returns, opens the box, and looks surprised ( [Fig. 12.10](#)). Despite a lower mental age, children with Down's syndrome could sequence the mentalistic story better than children with autism. The two groups performed the same on the behavioral one, and the Down's group worst on the mechanical one. Frith concluded that *mentalizing* is a different sort of reasoning from causal or behavioral reasoning. Mentalizing includes both the ability and the drive to “predict relationships between external states of affairs and internal states of mind,” not unlike intentional reasoning ( [Frith, 1989](#), pp. 156–157). The ability to mentalize implies a theory of mind.

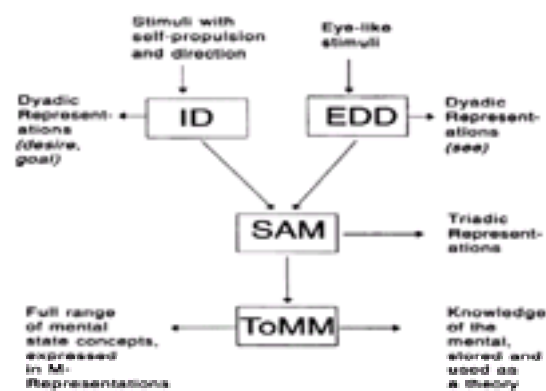

**Figure 12.10.** Cartoon strips illustrating the three types of causal reasoning. (From: Frith U: *Autism: Explaining the Enigma*. Oxford, UK, Blackwell Scientific, [1989](#), p. 164.)

#### DOMAIN SPECIFICITY: A THEORY OF MIND MODULE?

[Baron-Cohen \(1995\)](#) argued for a sequence of development that might give rise to a theory of mind module (ToMM). The centerpiece is the idea that the capacity for shared attention depends on a specific mechanism that he calls a SAM, a *shared attention mechanism*. The SAM has been assembled from two more basic, earlier mechanisms, an *intentionality detector* (ID) and an *eye direction detector* (EDD). The ID appears in infancy: It is a module that “will interpret almost anything with self-propelled motion or anything that makes nonrandom sound, as a query agent with goals and desires” ( [Baron-Cohen, 1995](#), p. 32). The EDD:

detects the presence of eyes or eye-like stimuli, it computes whether [another's] eyes are directed toward it or toward something else, and it infers from its own case that if another's eyes are directed at something then that organism sees that thing. ID interprets stimuli in terms of the volitional states of desire and goal. EDD interprets stimuli in terms of what an agent sees ( [Baron-Cohen, 1995](#), pp. 38–39) ( [Fig. 12.11](#)).

**Figure 12.11.** The mind reading system. (From: Baron-Cohen S: *Mindblindness: An Essay on Autism and Theory of Mind*. Cambridge, MA, MIT Press, 1995, p. 32.)

There is much evidence that infants of 6 months show an active preference for eye-gaze directed toward them. So too, children of 3 can easily figure out what another agent can and cannot see depending on that person's location vis-à-vis some target object; however, the infant can construct only dyadic representations using these two detectors. That is, they can only specify the relations between two entities—agent-self or agent-object. The SAM can specify relations among three things—agent, self, and object: a triadic representation. This permits protodeclarative pointing; the infant is now aware that she or he and mother are both looking at the same thing. Baron-Cohen argues that the ID, EDD, and SAM combine to form the ToMM that generates a theory of mind. In autism, this module does not come on line at the expected age because the failure to develop a SAM precludes the formation of a ToMM. (Note that there is a progression of complexity of representation from two uncoordinated skills, ID and EDD, to the triadic SAM. Case's view of cognitive development as an increasing capacity for coordination and integration nicely explains such a progression.)

Even this most refined theoretical version of ToM, elegant as it is, cannot be taken as proven. In its original form, ToM could not explain how symptoms of disturbed social cognition in autism were detected before age 4 when, presumably, the ToMM was well established. Baron-Cohen's explanation is that ToMM has precursors going back to shared attention seen between 9 and 14 months and that these have failed to progress to SAM much less to ToMM. Bailey and colleagues point out that:

it has not yet been possible to demonstrate a causal relationship between a candidate precursor and later ToM skills. The fact that children with autism show deficits both in precursor behaviours (for example, joint attention or imitation) and in ToM ability does not demonstrate a causal link (Bailey et al., 1996).

#### CRITIQUE OF THEORY OF MIND AS AN EXPLANATION FOR AUTISM

Since the first report of ToM failure in Baron-Cohen, Leslie and Frith's sample of autistic youngsters there have been several attempts to replicate their findings: Some did and some did not. Dahlgren and Trillingsgaard (1996) pointed out that, in earlier studies, between 38% and 60% of autistic children passed first-order false-belief tasks. Leslie and Frith (1988) discovered that success among autistic subjects at false-belief tasks correlated with verbal MA and chronologic age. There have been several other studies that report some autistic subjects as able to pass second-order false-belief tasks (Bowler, 1992; Ozonoff et al., 1991a). Ozonoff and colleagues (1991b) found that Asperger's syndrome (AS) children were better at false-belief tasks than high-functioning autism (HFA) children; another study found no difference.

The success of some autistic-spectrum children on standard ToM tasks has brought into question the specificity of ToM impairment as an explanation for the social cognitive deficits in autism. Nevertheless, impaired ToM remains a robust finding in autism but "is not universal since a small proportion of able children and older people with autism pass the tests" (Bailey et al., 1996). That said,

it is still an open question whether "theory of mind passers," who have IQs within the normal range, have developed theory of mind competence or whether they make use of some alternative strategy to solve the experimental tasks. The latter seems likely, since most of these individuals still seem to suffer profound social impairment in everyday life . . . among "passers" there is a small subset who may have genuine mentalizing abilities, and a larger subgroup for whom a [non-mentalizing] strategy seems a better explanation for task success (Bailey et al., 1996, p. 102).

However, explaining away what appears to be mentalizing in HFA or AS people on the basis of a putative "alternative strategy" risks the charge of circular reasoning.

Baron-Cohen and associates (1997) argued that standard ToM tasks were not subtle enough to capture their mentalizing deficits. Happé (1994) and Baron-Cohen's group (1997) report on two more advanced ToM tasks showing that HFA/AS adults show significant impairment in mentalizing. In Happé's task subjects read a short story about a prisoner of war being interrogated about the location of his army's tanks. The interrogators assume the prisoner will lie. In an effort to save his comrades the prisoner tells the truth. Subjects were asked where the enemy will look for the tanks and why. Happé believes this task requires a "third-order" ToM. Not surprisingly, HFA/AS subjects did worse than controls. In Baron-Cohen and associates' new ToM test, normal IQ HFA/AS adults were matched with patients with Tourette's syndrome and normals. The task was to identify, from a photograph of the eye area alone, complex emotions such as concern versus unconcern, serious versus playful, and so on. Baron-Cohen and colleagues have repeatedly demonstrated the unique significance of the eyes in mind reading by infants, toddlers, and preschoolers (Baron-Cohen, 1995). The HFA/AS subjects did significantly worse than either control group; these latter two did not differ. Nevertheless, Baron-Cohen still feels it would be easier to pass this test than to function in society where the cues are rapidly shifting. For example, all his HFA/AS subjects told him that going to movies was pointless because they cannot adequately keep track of characters' motives. Bailey and coworkers (1996) agree with Baron-Cohen that the ultimate test of one's social cognition is in everyday social interchange and even ToM task passers remain decidedly odd in ordinary settings.

Another complication in fathoming HFA/AS passers relates to the methodology of ToM studies. Charman and Campbell (1997) observe great variation among normal children in ToM tasks and "small changes to the wording or conduct of the task has . . . significantly affected performance." A recent test-retest study had shown only poor-to-moderate reliability within the same group of children given three versions of standard false-belief tasks over a 3-week span (Mayes et al., 1996). Children with general cognitive delays may also fail mentalizing (ToM) tasks (Yirmiya et al., 1998). However, Baron-Cohen argues that

people with autistic-spectrum conditions appear to have mentalizing difficulties for different reasons from . . . people with mental retardation or those who are blind or deaf, since a deficit can be revealed even with the highest-functioning individuals with an autistic-spectrum condition, in whom general comprehension problems can be ruled out (Baron-Cohen et al., 2000, p. 15).

He cited the case of an eminent mathematician with Asperger's disorder who failed a ToM task that normal children easily pass.

#### LANGUAGE AND THE NORMAL DEVELOPMENT OF THEORY OF MIND

Katherine Nelson (1996) points out that false-belief tasks rely on the child's understanding and use of mental-state words. Such understanding and use cannot be assessed without reference to the way in which these words are learned and deployed. Children of 2 and 3 years old can operate in a social domain with empathy and consideration of others before they can use mentalizing verbs with precision. Because they hear others use them, such young children can use "think" and "know" in speech but cannot explain the difference between them: The child may have the *language* of mental states before she has the *concept*. Two- and 3-year-old children are much more sophisticated in understanding the feelings and thoughts of others within their family relationships where it is familiar and their personal interests are at stake (Dunn, 1988).

Children of parents who use mental state words and concepts in conversation with them pass false-belief tasks earlier and have more advanced perspective-taking skills than those whose parents do not (Dunn et al., 1991). For example, deaf children of hearing (but not of deaf) parents have difficulties in understanding and signing mental-state words such as "feeling," "wanting," and so on (Peterson and Siegal, 1995). Deaf parents are skilled enough with signing that they spontaneously use mental state expressions in their communications; hearing parents who are less skilled in signing do not. These findings would support a knowledge-based explanation of, at least, some theory of mind attainments. Recently, Peter Fonagy proposed that mothers of infants who had a well developed *reflective function* (mentalizing capacity) as measured by the Adult Attachment Interview, were more likely to foster secure attachment in their infants. He further suggested that

development of a more mature reflective function is a central goal of psychotherapy ( [Fonagy et al., 1999](#)).

#### AUTISM AS A FAILURE OF NARRATIVITY

Jerome [Bruner and Carol Feldman \(1993\)](#) allow that there is a failure in the autistic child's theory of mind, but they propose a more fundamental deficit. They point to evidence that the autistic child

is incapable of (or highly resistant to) organizing interpersonal encounters into a canonical form that captures . . . regularities in the way in which people's intentional states are situated in typical situations, are expressed in typical action sequences, and require reciprocal response from those who are interacting with them ([Bruner and Feldman, 1993](#), p. 286).

If so, autistic children cannot create, with others, zones of proximal development and are deprived of the interpersonal scaffolding that promotes the development of internalized cognitive structures: In this case, the structures that enable one to construct a coherent self-narrative.

Structures of canonical sequences, or *formats*, depend on the capacity to consistently represent the other's mental state. Bruner and Feldman do not believe, however, that the innate capacity to intuit another's mental state, which they believe to be impaired in autism, entails a theory of mind. They suggest that a theory of mind might follow from the application of the child's innate predisposition to interact and develop representations of cultural formats. "Some autistic children could follow narrative sequences, even those involving intentional states, when such narratives were well scaffolded by pictures and stories told by others" ( [Bruner and Feldman, 1993](#), p. 287). They propose that intelligent children and adults reason their way through interpersonal situations as others would reason through a math problem; they "convert the personal world of intention-regulated social experience into an impersonal world of causally-driven events" ( [Bruner and Feldman, 1993](#), p. 288). In other words, going back to the reasoning task using comic strips (see the preceding), these people could often successfully apply mechanical or behavioral thinking to an intentional situation and so obscure the fact that they were not truly thinking in an intentional way. These children always seem "out of sync" in social exchanges because it takes more time to reason through interpersonal situations than to intuit a response.

#### SUMMARY: CHILDHOOD'S END

As a child develops cognitively, she or he can move beyond the observed to the inferred, beyond percept to concept, beyond concrete to abstract, and beyond intuitive knowing to conscious reflection. She or he becomes aware that events can have internal and symbolic meaning beyond their external and literal significance. As she or he invests events with meaning, the child can go beyond content to appreciate formal similarities, patterns, and processes. As the child reflects on patterns and processes, she or he can reflect on systems, including social systems. Older children can reflect on their own patterns and processes and how they relate to those of others and the larger social world.

As a child becomes aware of himself or herself as part of a larger world—call it decentration, disembedding, or social perspective taking—the universal enters the personal: The "I" becomes at once smaller and larger. With differentiation, the subjective "I" encompasses less of an ever more complex array of possibilities; yet, as a child internalizes personal experience, the sense of self grows in ways hitherto unimaginable. However, in each moment of transition, he or she may become aware that, in order to gain a new sense of self, an old one, usually quite comfortable, must be given up. This may be frightening; the more so because the child does not know why he or she feels anxious and caregivers often are equally puzzled. Yet the adults that form the child's "holding environment" must be intuitively if not consciously aware of these developmental anxieties and support the child in his or her journey from the global undifferentiated "I" of infancy to the smaller but more integrated "I" of true adulthood.

Development also entails an ever-increasing capacity to draw distinctions. Drawing distinctions sets up tensions that, when resolved, are replaced by new distinctions and tensions. Integrating the new into the familiar and transforming the familiar into the new, creating more complex familiarities, is the task of a lifetime. The dialectics of development—differentiation and integration, assimilation, and accommodation, being "a part of" or "apart from"—operate throughout the life cycle.

Later adulthood often brings awareness that life is more process than achievement. For this awareness to happen, Michael [Basseches \(1984\)](#) believes that formal operations, Piaget's last word, must be superseded by "dialectical" thinking. Formal thinking ultimately requires static entities and fixed relationships: It is designed to avoid contradiction. Dialectical thinking does not push for closure; it needs contradiction and creates a lifelong interplay of contrasting ideas ( [Carse, 1986](#)). By old age, the self may become less dependent on externals and integrity comes to rest in a sense that one's life is "the accidental coincidence of but one life cycle with but one segment of history; and that for [one] all human integrity stands and falls with the one style of integrity of which [one] partakes" ( [Erikson, 1959](#), p. 98).

**Acknowledgments.** As always, I am deeply indebted to Professor Anne McKeough of the Department of Educational Psychology, University of Calgary, for her invaluable contribution to my cognitive development.

### [Psychoanalytic Theory: Domain, Concepts, and Theoretical Intentions](#)

#### [Chapter References](#)

The central concern of the theory of child psychoanalysis is the understanding of emotional life—the experiences of love, hate, pain, pleasure, longing, guilt, and concern—and their representation in the child's mind. Psychoanalytic investigation focuses on how children develop into individuals with their own minds, feelings, and desires and how they become engaged with their parents and others who become important to them. The emphases of child analysis are the internal and private experiences of children, from the first months of life through adolescence; the ways in which bodily and environmental processes influence inner life and the child's perceptions of the outer world; the ways in which children represent their experiences and selves; and the mutual interactions between reality and fantasy, inner and outer, adaptation to the shared world of reality and appreciation of personal desires and needs. The theory of child analysis involves cultural and personal history—familial and social influences that have their origin before the birth of the child and that are conveyed to the child through the particular social expectations and caregiving of parents and society, as well as the enduring effects of experience and the continuities and discontinuities in the child's outer and inner life.

Psychoanalytic theories of development begin with the infant's somatic experiences and processes, bodily sensations, and ability to attend to and regulate the impact of internal and external stimulation. With maturation, these inherent functions become elaborated into increasingly sophisticated forms of organization of the child's perceptions of himself or herself and others. The physical requirements of the young infant and the parents' emotional investment in the infant's well being are paradigmatic for the unfolding relationships that serve as the context in which neurologically based systems unfold. At each phase of development, maturing biological demands and capacities assume meaning and find expression in the constructs, including the conscious and unconscious fantasies, that the child develops to make sense of himself or herself and the greater world. The child's functioning at any one point reflects the mutual interactions among many forces; in turn, the child's history and current functioning set the stage for the emergence of capacities and vulnerabilities in subsequent phases of personal development ( [Erikson, 1959](#); [Freud, 1966](#); [Klein, 1958](#)).

Throughout childhood, the processes of maturation and development reflect the interaction between biology and endowment—genetically transmitted characteristics, constitution, and the programming for physical change—as well as experience (in the family and broader social world) and the workings of the child's mental apparatus, as such. The charting of the mutual influences between psyche and soma and their representation in mental life provides a framework for understanding both normal development and illness ( [Freud, 1965](#)).

## DATA OF CHILD PSYCHOANALYTIC THEORY

Child psychoanalytic theories of development have grown out of clinical experiences and research with children in varied settings, including: (a) the home, well-baby clinics, school, and group living arrangements ( [Bowly, 1969, 1973](#); [Freud and Burlingham, 1973](#); [Hellman, 1962, 1983](#); [Mahler et al., 1975](#); [Stern, 1985](#)); (b) institutional settings ( [Provence and Lipton, 1962](#); [Robertson and Robertson, 1958, 1971](#); [Spitz, 1945](#)); (c) medical or rehabilitative settings ( [Burlingham, 1961, 1979](#); [Earle, 1979](#); [Fraiberg, 1968](#); [Freud, 1952](#); [Furman et al., 1968](#); [Moran, 1984](#); [Schowalter and Lord, 1972](#)); (d) the course of determining custody and placement disposition ( [Goldstein et al., 1996](#); [Solnit et al., 1992](#); [Wallerstein, 1996](#)); and (e) child psychoanalytic treatment ( [Anthony, 1980](#); [Bornstein, 1953](#); [Freud, 1945](#); [Frijling-Schreuder, 1969](#); [Marans, 1993b](#); [Meers, 1970](#); [Neubauer, 1987](#); [Sandler et al., 1975](#); [Target and Fonagy, 1994](#)).

Similar to Freud's earliest work, child psychoanalytic theories of development have evolved primarily out of a clinical perspective on infants and children with difficulties. Within the context of clinical care, psychoanalytic observations of children focus on the interplay of features of emotional presentation, cognition, modes of communication, physical activity; themes of play; and discussion and patterns of interaction. However, whether in the "unstructured" hours of ongoing psychotherapy or in observations of children in other settings, child psychoanalytic investigators generally proceed by careful observation of the ways in which the child's interests, concerns, and patterns of functioning unfold. They integrate the data with information from caregivers about current and past life experiences. The data are used to develop multiple hypotheses regarding: (a) implications of the child's biological "equipment" and its impairment on the tasks of development, (b) areas of strength and preferred modalities for adaptation, (c) specific developmental tasks and various ways in which they are negotiated, (d) areas of vulnerability in the path of development, (e) implications of various life events on the course of development, (f) the nature of unconscious conflict, and (g) defense activity and conflict resolution.

Psychoanalytic theories of development have evolved over the past decades in response to new observations and concepts. Using available observational and historical information, the psychoanalyst attempts to reconstruct a narrative history of the child's life—a portrait of the child's inner experiences, relationships, and modes of representing himself or herself and others. There is no one uniform, systematized theory in which all major concepts are formally defined; rather, child psychoanalysis as theory consists of a range of related theoretical perspectives. Although these share an orientation on inner emotional experience and developments, they differ in particular conceptual emphases to a greater or lesser degree. Relating these perspectives to a specific child or phenomenon may highlight theoretical divergences or may provide a sense of the complexity of development and emotional life.

## CATEGORIES OF EXPERIENCE

Psychoanalytic concepts of early development have long been organized according to a hierarchy of dominant body zones. The delineation of oral, anal, phallic, narcissistic, and oedipal phases was meant to map out processes of development from the infant's earliest dependence on the mother to the adult's relative independence and autonomy. The goal of these theoretical constructs was to provide a framework for organizing observations. However, the broadening scope of observations of the development of relationships, concepts about the self, cognition, and the like, highlighted a tension within the theory between the notion of continuity and discontinuity of experience. Although there are nodal points that mark out different experiences in different periods of life—reflecting a degree of discontinuity—the concept of "stage" as defined by body zones is limited when we observe the overlapping of psychological experiences from one period of life to another, or, rather, the underlying continuities. The goal of contemporary "phase theory" is to explicate major modes of psychological organization and changes from one epoch to another. In addition, the theory tries to describe and understand the personal and shared meanings of experiences and tasks that are salient in a given period of life, as well as those that continue to exert influences from earlier periods.

### 0 to 18 Months ("Oral" Phase)

Contemporary psychoanalytic theories focus on the ways in which biological processes in this earliest period of development come to have psychological meaning in the infant's rudimentary sense of the self as distinct from others. That is, how do the infant's bodily sensations contribute to the emergence of an internal,

psychological “self” that experiences the body and increasingly guides its actions?

During the first months of life, the mouth plays a central role in shaping the infant's earliest images of himself or herself in the context of the world. In addition to its role in eating and sustaining life, the baby uses his or her mouth—in the activities of sucking, licking, and biting—as a central organ of perceiving, regulating, and altering sensations. In the absence of hunger, the infant mouths fingers, toes, toys, pacifiers, and mother's breast to self-soothe, at once experiencing the various physical properties and decreasing his or her distress. Similarly, his or her crying when uncomfortable or making high-pitched squeals to attract mother's attention leads him or her to represent the communicative power of the mouth.

The experiences associated with orality—pleasure in the satisfaction of urges and discomfort when satisfaction is not immediately available—continue to be central to psychoanalytic conceptualizations about early development. In addition, the contributions of early infant research ( [Emde, 1982](#); [Klaus and Kennel, 1976](#); [Spitz, 1965](#); [Stern, 1985](#)) have focused on a broader range of inborn processes and their influence on the infant's earliest experience of the body and emergence of a “self.” The study of variations in the sensorimotor system (sight, audition, reflexes, muscle tone) and state regulation (sleep/wake cycles, quiet/alert periods, withdrawal, gaze, responsivity to comforting) have emphasized the contribution of these “nonoral” intrinsic factors to early patterns of mediating endogenous/instinctual or external/environmental stimulation ( [Mayes and Cohen, 1994](#)).

From the beginning of life, the infant's relationship with his or her caregivers organizes the ways in which bodily requirements, inborn processes, and constitutional and instinctual urges find expression. The mother's investment in the infant's bodily needs sensitizes her to the ways she can help diminish the potential for discomfort. Maternal involvement and intimate contact with the infant's body—feeding, cleaning, holding, cooing, and so forth—reflect the mother's earliest attachment ( [Bowlby, 1969](#); [Freud, 1974a](#); [Greenacre, 1957](#); [Klein, 1958](#); [Mahler et al., 1975](#); [Osofsky, 1995](#)); she “reads” the infant's cues according to the recognition of specific sources of pleasure and discomfort. In addition, the mother attributes emotional meaning to gross and subtle changes in the infant's presentation. This guides her response and progressively conveys to the child a sense of meaningfulness of her actions and affection. Inborn hypersensitivities to various stimuli—touch, sound, gastrointestinal, and the like—complicate the mother's task of learning how to understand and establish reliable means of responding to her infant's needs. The infant's neurologic maturation—for example, decreasing the prominence of colic or ease of startling and becoming distressed by noise—and the parent's increased experience often offset difficulties in the early parent–child relationship. It is important to note that the tremendous variation of inborn characteristics in state regulation may play as crucial a role in the infant's early adaptation as the contributions of possible conflicts the mother or father may have about various aspects of parenthood ( [Furman, 1992](#); [Kestenberg, 1956, 1980](#); [Winnicott, 1962](#)).

The parent's efforts to maximize the infant's comfort and to relieve his or her distress take over when the infant is not yet able to soothe himself or herself. By ensuring that the baby is not overwhelmed by discomfort, the parent contributes to the child's experience of effectance; *his* or *her* activities can make things happen that alter the child's own bodily sensations. Repetition of patterns of parental care, in turn, influences and reinforces those behaviors of the infant that promote pleasure and satisfaction of needs. Although diminishing physical tension (between need and gratification) and maximizing pleasure appear to be essential tasks during this period of development, experiences of frustration and discomfort are equally significant in the baby's maturation and development. In fact, the sequence of discomfort followed by relief is mediated, in part, by the absence and appearance of the caregiver and contributes to the infant's growing capacity to more clearly delineate between “me/not me.” The discrepancy between the experience of need and satisfaction may include nuances of interaction—failure to elicit a smile, a cuddle, soothing or playful tone of voice, or physical proximity, as well as hunger or physical discomfort from a soiled diaper. Beginning with the buccal mucosa as a junction between inner and outer, sensations associated with repeated sequences of coordinated activity—sucking, biting, licking, swallowing, looking, listening, touching—foster the infant's capacity to locate and identify the origins of percepts and contribute to the delineation of body boundaries. Although the infant's recognition of the mother's face, for example, is observable from the earliest weeks of life ( [Greenspan, 1989](#); [Mayes, 1989](#)), by the middle of the first year his or her response to her is no longer dominated by the satisfaction of bodily needs. With the appreciation of physical separateness, the infant links the pleasure associated with her ministrations to the person of the mother in her own right. Her presence itself is a source of pleasure and satisfaction: her absence is a source of anxiety. He or she will look at mother to see if a situation is safe or dangerous, and by this process of social *referencing* of the meaning of situations, the baby will be socialized into the family. He or she will learn about the parents' specific ways of responding (muting or exaggerated, calm or fearful), including how they deal with closeness and separation. The child's protests at being handled by others, his or her distress on seeing people other than mother (stranger anxiety), and his or her upset on separations from her stem from the infant's feeling that “not here” is “gone forever.” With the delineation of boundaries, the infant views mother as a bridge between himself or herself and the world. In her absence, he or she may appear panic stricken and “disoriented,” as if he or she had lost the connection with his or her newfound world and with emerging feelings of “self” ( [Fraiberg, 1959](#)). From within the dyadic relationship, how the mother acts on leaving and how she feels on return exacerbate or diminish the child's worries.

Games of peek-a-boo, experimenting with hiding and finding objects, and repeated experiences of parents coming and going help the infant on his or her way to establishing object permanence ( [Beebe and Lachmann, 1998](#); [Piaget, 1952, 1954](#); [Zelnick and Buchholz, 1990](#)), the ability to conceive that things continue to exist even when hidden, that “not here” is “maybe there.” The ability to mentally “hold on to,” or internally represent images of the parents in their absence contribute to the infant's exploration of the world beyond the lap as the child begins to stand, cruise, and then take his or her first steps. The toddler's ability to move away from the parents under his or her own steam provides a vivid experience of physical separateness from them well beyond the earlier activities of averting gaze or arching away from mother's body when held. Although needing periodically to check back with the parents or “refuel” ( [Mahler et al., 1975](#)), the toddling infant's explorations contribute to his or her inner definition of “self;” that is, what the toddler can do in relation to his or her body and the central figures in his or her life ( [Freud, 1965](#)). Increased dexterity, language acquisition, and rudimentary cause and effect thinking provide the tools for this research. Optimally, the young child's investment in these burgeoning capacities leads to the child's “love affair with the world” ( [Greenacre, 1957](#)), in which the pleasure of mastery facilitates the elaboration of these capacities. Alternatively, gross disruptions in the dyadic relationship—including prolonged separations between mother and child, mother's emotional unavailability because of severe depression, or physical abuse—may lead to the earliest expressions of psychopathology, such as failure to thrive, anaclitic depression, hypersensitivity to stimulation, and extreme wariness in interactions with others.

The child's psychological differentiation and separation from the parents is accompanied by tension, sadness, and anxiety as well; he or she may sometimes find “walking away,” or being walked away from, a painful experience. The young child often turns to a specific soft blanket or cuddly toy, specially invested with attributes of the mother, to hold and fondle in her absence. Unlike the real mother of separation, these transitional objects ( [Winnicott, 1953, 1965, 1971](#)) can be controlled and literally held on to by the toddler when the mother is too far away. The capacity to evoke mental images of the self and parents and memories of satisfaction of needs and possible sequences of events are crucial achievements in this phase and have broad implications for the young child's capacity to remember and anticipate interactions with the world. From suckling at the breast to first steps and from random smiling and cooing to words and conversation, the infant's developing organization of “self” as distinct from the body is matched by an accompanying elaboration of mental schemes—conscious and unconscious fantasies—of his or her relationship to the central figures in his or her life. The increased specificity of feelings, both pleasurable and frustrating, associated with the parents during infancy form a foundation on which internal mental structures and attachments to others gain complexity in subsequent phases of development.

### 18 to 36 Months (“Anal” Phase)

This phase of development obviously owes its designation to the role of elimination and toilet training in early childhood. The capacity to control defecation and urination and the demands of the parents to do so have been seen as paradigmatic for a range of tasks and struggles the child encounters with regard to his or her body, relationships, impulses, and fantasies.

In addition to the toddler's continued exploration of the world around him or her, heightened anal sensations in the period of development also promote the toddler's appreciation for the separateness between himself or herself and caregivers. Central nervous system maturation underlies the increased awareness of rectal pressure and anal sensitivity; psychologically, the child's attention becomes focused on yet another area of the body where there is an interface between inner and outer. In defecation and urination, the child experiences a complex process involving bodily feelings, self-control, action, and perception. He or she feels and sees how what is originally inside can become outside, along with a sense of what was previously hidden being public and shared. Defecating and urinating are no longer simple processes that occur in response to physical pressure; they assume meaning as sources of pleasure that the toddler can control.

The ability to label and identify parts of the body is concurrent with the ability to regulate pleasurable sensations through holding and releasing feces and urine; these capacities permit the elaboration of an internal set of representations of the self. A distance is established between the body and the self that experiences the body. As the child represents himself or herself as an object that can be perceived, the child naturally begins to compare his or her body with that of others. This capacity to compare leads to the child's appreciation of anatomic differences between the sexes and child and adult.

Recognition of separateness and specific differences in the body and abilities between the child and adult caregivers (and other children) is crucial in the child's development of “reality testing” and sense of self. In addition, this recognition is also a source of considerable conflict and anxiety. Under the sway of powerful sexual and aggressive desires, the toddler seeks immediate satisfaction of urges that his or her developing capabilities alone cannot always deliver. In addition to the

motivation provided by need satisfaction—seen throughout development—the child now experiences the satisfaction of his or her needs as related to his or her own degree of control and effectiveness. The child's awareness that he or she does not share the powers of the parents increases the intensity of the wish for effectiveness; awareness of dependency is often at odds with the wish for autonomy and omnipotent control. Parents are then frequently confronted with a toddler who is inconsolable about his or her inability to accomplish a given task or satisfy a need. The child may loudly protest what he or she can not accomplish alone and angrily refuse all parental attempts of assistance. The young child crumpling to the floor in tears is a poignant illustration of the struggle between the competing aims of independence and dependence. In this phase, anxiety experienced on occasions of separation from parents is an additional marker of the child's comparison of his or her competence with the parents' and his or her continued need to rely on them for care, safety, and affection. In earlier separations the infant was frightened and disoriented because of an inability to conceptualize the existence of the mother or father in their absence. In this later period of development, however, the child may believe that by his or her voracious demands, anger, frustration, and moves toward independent power the child has become the agent of his or her destruction. Until reunited with mother, the child imagines that she has gone away forever and feels completely alone, bereft, and guilty.

In this period, words can now substitute for actions; remembering simple sequences of events can help the child anticipate the immediate future, and increased coordination can broaden the range of pleasurable physical activities. These capacities promote the young child's sense of effectiveness and offer potential diversion from the intensity of needs and impulses that were previously satisfied only by the parents' immediate response. The child can now tell the mother that he or she is hungry instead of simply crying. And when told by the mother to "wait for a few minutes," the child may be able to mobilize defenses against feeling hurt and sustain the wait by rolling cars on the floor, knowing that "a few minutes" means not too long. Alternatively, the child may again use language to implore mother to hurry or crash the cars or other toys as a way of displacing or deflecting the anger felt toward her for not responding to his or her needs quickly enough.

Although the child is able to tolerate greater amounts of frustration, relative to earlier phases, parental demands to do more or wait just a bit longer introduce conflicts that further the cause of mediating between impulses and action. The child's fear of losing the parent as the result of destructive urges and the wish to please the parent and receive praise are powerful contingencies that often fly in the face of aims of immediate gratification and absolute autonomy. The toddler's alternation between compliance with and obstinate defiance of parental rules, and the attendant tantrums, expresses struggles between passivity and activity, love and hate. As parents expect more from a child in the areas of toileting, self-feeding habits, waiting for help, and attention, for example, they are setting goals for the child to reach. When they are achieved, the child is proud of himself or herself and enjoys the admiration of the parents; when the demands are too difficult, the child may feel frustrated, humiliated, or in danger of losing the parents' love.

Development in language and symbolization, object permanence, and cause and effect thinking sets the stage for the child to elaborate the "representational world" (Fonagy, 1997; Fraiberg, 1969; Sandler and Joffe, 1962; Slade, 1999; Stern, 1988). Within psychoanalytic theory, "self" and "object" representations refer to the organization of the variety of composite images of himself or herself and others that the child has internally constructed on the basis of experiences, urges, and feelings. These concepts are never articulated in consciousness as a sum total but, rather, are expressed as parts in the child's ever-changing fantasies, attitudes, and behavior. At times, the child may comply with the parents' requests in response to his or her inner view of them as wonderful and all-giving. Alternatively, the child's tirades against them may reflect a feeling that they are frustrating figures who are set on depriving him or her of pleasure. They may be seen as sources of safety and comfort or as obstacles in the path toward independence. Simultaneously, the child has rapid shifts in feelings about himself or herself—at one moment victorious and able, at another moment frightened and helpless. Moreover, the child may oscillate between views of himself or herself and parents as all good or all bad, determined by experiences of the child's own and by his parents' loving and destructively hostile urges.

Although the child struggles—internally and externally—with these varying attitudes, the flexibility of the representational world produces greater self-reliance. Now the child's ability to recall loving images of the parents in their absence allows for longer periods of independent activity, sustained by the confident expectation that needs ultimately will be satisfied (Mahler et al., 1975). Second, internalized standards, both prohibitive and encouraging, serve as referents in determining consequences of action (i.e., trial action in thought). Finally, in the absence of real gratification of wishes, impulses and feelings can find expression and discharge in the manipulation of self-object interactions in fantasy. Here, *conscious fantasizing* involves daydreams in which real experiences can be altered or replaced entirely by more gratifying, wish-fulfilling imaginative scenarios. These mental operations involved in fantasizing support the child's capacity to tolerate increasing frustration, whether from his or her own limitations or those imposed by the environment. The young child can now "hold on to" a variety of representations and "play" with them, or pretend. He or she can use imagination for escaping from unbearable disappointment in reality, altering current feeling states, and planning courses of future action. In a broader context, *unconscious fantasies* and their conscious derivatives give expression to the child's deeply felt longings, conflicts aroused by forbidden urges, attempts at resolving conflicts, and preparation for or postponement of action. As such, fantasies may be a source of pleasure and anxiety. When unconscious fantasies give form to unacceptable impulses and wishes, defensive operations are employed to disguise them before they find expression in conscious thought.

In this phase, fantasies and activities that serve to diminish anxiety expand and become more identifiable to the observer when they are at odds with reality or internalized standards. The child's growing disaffection with messiness and disorder, for example, is a signal accomplishment in the anal phase and reflects an active repudiation of pleasurable activities that are in opposition to parental attitudes (reaction formation). By complying with these external demands, the child avoids disapproval and reaps the satisfaction of adult approval. Initially having to yield control of his or her body to the expectations of others, the child's growing identification with parental demands and responses make them his or her own. Although vulnerable to reexternalization, the conflict between competing aims is now internal, belonging to the child alone. Anxiety associated with the dangers of aggressivity and from the conflict between loving and hating may be dealt with via various imaginative mental processes for mobilizing fantasies, which counteract other more frightening fantasies or modulate anxieties in other ways. These "defensive processes" or *mechanisms of defense* (Cramer, 1991; Freud, 1965; Kernberg, 1994) include the child's disavowal of a particular feeling or aspect of reality (denial), a sense that the feeling belongs to someone else (projection), or shifting the target of feelings from parents to himself or herself, others, or a toy (displacement). Hostile impulses that run counter to the love the child feels toward parents, for example, are disowned. Being fearful of others' hatred or frightened of monsters and noises in the night is a preferable alternative to the imagined destruction of loved figures on whom the child depends. These mental activities allow the child to express competing feelings of love and hate without needing to relegate them to completely separate images of himself or herself or the parent (Blum, 1997; Furst, 1998; Marans et al., 1993c; Mayes and Cohen, 1993; Parens, 1979). Real competence in communicating and acting on needs independently and the continued experience of the parent's availability promote a psychological "rapprochement" (Mahler et al., 1975). The child can begin to tolerate an ambivalent attitude toward himself or herself and the parents, between love and hatred, and between total dependence and self-reliance. In this phase, the child's recognition of others as separate entities and ability to appreciate the specificity of his or her own feelings toward them extends to a capacity to empathize with their feelings as well. These achievements are seen in expressed concern for and questions about parental moods and in the designation of feelings to figures used in play.

In the first year of life, physical objects were mouthed and handled as the infant explored their properties as well as the bodily sensations aroused in the process. These activities, as described earlier, aided the infant's delineation of body boundaries (Hoffer, 1949). In the latter part of the second and in the third year, the child uses toys and other play items for the extensive representation and elaboration of daily experiences and fantasies, as well as engaging the caregivers in pleasurable interaction. Moving cars across the floor, carrying and feeding baby dolls, manipulating puppets, and imitating parental activities constitute rehearsals, reworking of experiences, and trying on of new roles. They also are precursors to the development of imaginative and pretend play in which the child will employ complex narrative structures or story lines to elaborate these roles and fantasy scenarios. At age 3, there is a gradual move in the child's view of other children as playthings or things that get in the way of personal pursuits. Increasingly, children not only play side by side but turn to one another as companions and partners in shared activities that are more fun because they are social. Here, the capacity to generalize symbolic representation and empathize with the feelings of others serves as a common basis on which the fantasy configurations of each partner can be mutually enriched and enacted in play.

The achievements in this phase of development expand the young child's range of possible pleasures and the complexity of conflicts. Increased capacity for independent functioning is a source of pride in mastery, whereas the appreciation of separateness and reality highlights limitations and the vulnerability of being little and dependent. Ownership of the body and insistence of bodily urges (drive pressures) air in conflict with the child's sense of the contingent nature of the relationship with his or her parents. That is, *the push* to give expression to his or her own will is at odds with the desire to please the objects of his or her love by submitting to their requirements. As external controls and rewards become internalized, so too do the capacities to retain and elaborate various representations of self and significant others. Whether serving configurations of fantasy or memories of reality, the capacity for representation offers the young child an inner frame of reference that can be a resource for increased frustration tolerance, substitute forms of gratification, trial action in thought, self-esteem, and the companionship of important people regardless of their presence or absence. As the central tasks of the anal phase of development merge into those of subsequent stages, the groundwork is laid for further elaboration of relationships and capacities both within and without the context of the child's family.

### 36 to 48 Months ("Genital-Narcissistic" Phase)

A transitional phase of development has been posited between the anal and oedipal periods. This phase is characterized by an increasing crystallization of gender and concurrent preoccupation with appearance, anatomic differences, and sensations arising from the phallus and testicles in boys, and the vagina and clitoris in girls.

The child's assumption of a specific gender identity—the core sense of being a boy or a girl—obviously has its roots in the first year or two of life. Early gender identification during infancy is the result of multiple, interacting forces, including differential treatment of girls and boys by parents and others; the anatomically distinctive sensations arising from the genitals in the course of parental handling, elimination, and self-stimulation (including penile erection, clitoral stimulation, and the sensations accompanying defecation and urination); and other biological factors, including genetic and endocrine influences on brain and behavior. By age 3, children generally are quite clear that they are either a girl or boy and are aware of the types of play activities, dress, and the like expected of children of their sex. Attempts to alter assigned sexuality after this time, for example, for children with anomalous genitalia, usually are not successful. As a psychologically organizing internal construct, however, gender may not be sharply dichotomous, for either boy or girl, during the first years of life or even much later. Indeed, psychoanalysts have long appreciated that there is a spectrum of gender-related experiences throughout the course of development that may be considered normative bisexuality—the desire for some of the attributes and opportunities of the opposite sex.

Consistent with the psychoanalytic theory of psychosexual stages as developed in relation to the oral and anal phases, “phallic narcissism” ( [Burgner and Edgcombe, 1975](#)) has been used to designate the central zone of sexual sensations during this phase of development. However, the emphasis on the phallus does not recognize the girl's proud and pleasurable experiences of her genitals or the anatomic distinctions that are felt by both girls and boys. A more suitable designation for this psychosexual phase, which arises around age 3, might thus be “gender identification, genital narcissism,” a period in which children become progressively more aware of the pleasurable sensations in their genitals as well as tensions arising from the genital zone, take pleasure in displaying and being appreciated for their genitality, and experience themselves as having a core gender identity, that is, when all goes well, consistent with their anatomic identity. During this phase, both boys and girls may show off their genitals (enjoying how far they can urinate or lifting their skirts) and engage in more focused and sometimes more persistent masturbation (occasionally leading to genital irritation and a cycle of concern by both parents and child). Although the genitals may be a leading edge of narcissistic investment, during this phase, children feel a generalized pride in their bodies and what they can do in rough and tumble play, learning new skills on the jungle gym, displaying their fine and gross motor skills and coordination, and gaining parental attention through exhibitionism (such as dressing up in mother's clothes, clowning, or performing new feats of skill).

As with each phase, there are dilemmas faced by children during this period that are directly related to the developmental achievements. A child whose self-esteem is closely related to the beauty, power, and pleasures of the body may feel hurt, rejected, and enraged by not being noticed or mirrored by his or her parents or from failure in learning or performing some tasks for which the child may still be too immature or small. Although the anal phase was characterized by struggles concerning control, the phase of genital (bodily) narcissism may be burdened by struggles with siblings with whom the child may feel rivalry and with parents concerning issues of competence. The child may be unmindful of or angered by the recognition of his or her personal limitations. The parents' imposition of rules or even their offers of help may be felt by a child as demeaning, and sensitive parents may try to disguise their assistance or attribute the achievements to the child to foster the narcissistic delight in mastery.

There is a gradual transition rather than a sharp boundary between the psychological issues of gender identified, genital narcissism—proud exhibitionism, delight, pleasure, and sense of achievement as a girl or boy—and the issues of the oedipal phase. In some ways, this boundary is crossed as boys become more worried about the loss of their prized genitalia and girls express more concern about the adequacy of theirs, along with a range of increasingly complex feelings about the roles of the male and female parents.

#### 4 to 6 Years (“Oedipal” Phase)

Within contemporary psychoanalytic theory, *oedipal phase* refers to a range of concerns about loving, sexual/rivalry, and aggressive attitudes toward the same/opposite sex parent, which are correlated intrapsychically to the consolidation of mental structures. The achievements of this phase are a consequence of the advance of multiple forces—cognitive, affective, social, bodily—and provide a template for perceptions about the self and intimate relations with others for future development. If the child was an “explorer” in earlier periods of development, the oedipal child is best described as a “scientist,” curious, developing hypotheses, and experimenting in thought and play about: (a) his or her relations with parents, (b) their relationship with each other, and (c) how his or her mind works.

#### PRECONDITIONS

During the first years of life, the child moves through several phases of development, which have been characterized in relation to the “leading” bodily zone (oral, anal, and genital). Within psychoanalytic theory of development, the various tasks, concerns, and processes of these phases lead to a phase of mental integration involving economic factors (biologically driven urges), the direction of love and hate, and the relationship between unconscious and conscious thoughts and feelings in the context of the realities of daily life. The preconditions for the child's successful move into the oedipal phase and its optimal negotiation include overlapping, mutually influencing “preoedipal” achievements in areas such as the following:

1. Social: Good primary attachments to parents, representations of mother and father as separate and good, sense of self as the locus of initiatives that are successful, and capacity for empathizing with the feelings of others.
2. Cognitive: The ability to represent abstractions and call on these in assuming various social roles, taking the perspective of others, tolerating mixed feeling about self and others, appreciating the rights and responsibilities of oneself and others, and sensing that oneself and others can act and feel differently at different times.
3. Moral: A developing sense of right and wrong, good and bad, recognizing the link between actions and their consequences in relation to parents (approval and pleasure versus disapproval and anger) and the self (well-being and pride versus shame and guilt).
4. Physical: The capacity for fine and gross motor coordination for pleasurable and playful activities such as running, jumping, and climbing, as well as self-care (toileting oneself, brushing teeth, hand washing) and imitating adult behavior in play (cooking, driving a car, caring for a baby, building).
5. Emotional: The development of a wide range of feelings (including excitement, happiness, sadness, remorse, fear, disappointment, pride, anger, envy, love, and hate) that can be distinguished, expressed, and communicated to others.
6. Mental: The capacity for remembering personal history, realizing that dreams and imagination come from within oneself, perceiving complex social situations involving causality and time sequences, and developing narrative structures that organize inner and external experiences.
7. Biological: A hypothesized biological state that is analogous to the maturation of psychosexual zones (oral, anal, and genital) and to biological changes seen in puberty, which is now represented primarily in relation to emotions—intensified affective and sexualized longings (love) and raw expression of rivalry and aggression (hate). These are directed to the same/opposite sex parents during the oedipal phase and later are expressed in adolescence toward peers.

When the preconditions are in place, the 4- to 6-year-old child moves naturally into the oedipal phase, as evidenced by new integrations of self and others. During this period, the child recognizes that he or she is the child of his or her parents and that the parents have a relationship to each other that is not solely related to their roles as parents. Appreciating their strong feelings for each other, the child wishes to remain with them as in his or her previous fantasies—the center of their lives. The child knows that this position can be recaptured, if only for a while, through being very good, attractive, and clever or through being very naughty, destructive, and demanding. In addition, the child understands that he or she cannot be the only person for mother or father. Ultimately, the oedipal phase child recognizes the complexity of mother and father as full people. Whereas previously they were seen as either all good or all bad, depending on the child's state of frustration or satisfaction, increasingly, as a result of improved cognitive abilities, he or she feels the need to understand them as autonomous individuals, separate and in relation to himself or herself, to each other, and to others both in and outside of the family.

#### TRIADIC RELATIONS AND THE PRIMAL SCENE

The classical oedipal phase within psychoanalysis in its boldest expression related to one aspect of the Greek myth: the murder of the father by the son and sexual union between son and mother. This mythic beginning for the theory of the oedipal phase had the virtue of drama and suggestiveness but the vice of oversimplifying the phenomenology. The child in the oedipal myth did not know who was being murdered, and the remorse came later. The struggles of the oedipal phase are painful just because of the child's knowledge and continued love for both parents. He or she is confronted with amorous longings and rival wishes *and* the desire to work out possible compromises—how to be powerful and central, feel proud of achievements, and at the same time have the continuing secure presence of both parents ([Marans et al., 1993c](#)).

Crucial to the challenges of this phase is the fact that the girl's wish to exclusively possess her father, and the boy, his mother, cannot and will not find immediate gratification in reality. In order to sustain his or her quest, the oedipal child must be capable of suspending disbelief of denying that he or she is small and cannot enjoy the privileges and pleasures of the grownups ([Freud, 1974a](#)). However, the child is burdened in this quest by anxieties and real deficiencies that must be denied, lessened, or worked through if the child's invincibility is to be maintained ([Peller, 1954](#)). Boys and girls must find ways to explain why they do not win the “exclusive” position in the opposite-sex parent's life in spite of attempts to woo the parent (by impressing the parent with physical and intellectual competence as well

as charm).

Oedipal children are confronted by their exclusion from the parents' special relationship even though each parent may acknowledge how big, strong, attractive, or smart the young suitor might be. A hallmark of this phase is the child's capacity for *triadic relations*: the representation of the parents' relationship with each other and with him or her as *their* child. The child's theories about the parents' relationships with each other in his absence (*primal scene fantasies*) are based on observations of their affective ties as well as on projection of the child's own intense sexual and aggressive urges. Primal scene fantasies are a source of excitement and danger—in the child's view of sexual intercourse as violent—and of narcissistic hurt as well, representing the ultimate adult activity from which the child is excluded. Oedipal children must turn from a passive role in which they might fall prey to dangers and disappointments to an active one in which they can feel as though they are the masters of their own fate ([Freud, 1917](#)). In this task, they increasingly turn to fantasy and its expression in play.

#### REPRESENTATIONS IN PLAY

The child of this age has an increased capacity for reality testing; in addition, he or she continues to have the facility for magical thinking as well as more advanced capacities for guiding integration of competing wishes and aims. His or her ability for daydreaming, fantasy, and pretend play allows greater access to wishes that do not need to be compromised too quickly by reality. The child is thus protected in fantasy from the recognition of ultimate frustration. An increased capacity for symbolic representation opens the door to more elaborate forms of binding anxiety and expressing bodily urges in thought and imaginative activities ([Marans et al., 1993a](#)). Advances in cognitive and motor skills yield functional pleasure, minimize anxieties, and compensate for felt inadequacies in comparison with the adults with whom he or she competes ([Peller, 1954](#)).

Oedipal children can move fluidly through a range of themes determined by the urgency of what is uppermost in their minds, whether exciting, pleasurable, or fearful. The child's push toward mastery combines with curiosity to arrive at solutions in play in which theories may be tested and explored. Do babies come from eating special, magical foods? Do mommy and daddy hurt each other when they are in their bed together without me? ([Cohen et al., 1987](#); [Marans, 1993b](#)).

The oedipal child's play, in particular, reflects a plasticity of representations employed in the service of creating and maintaining the illusion of wish fulfillment and invincible mastery. The guiding motif of the child's creativity is contained in the oedipal wish and in attempts to ward off its attending dangers and disappointing confrontation with reality. The child in this phase of development is able to juggle the inconsistencies he or she perceived both *within* fantasies and *between* fantasies and reality. There is equal flexibility as the constituent themes of the oedipal phase seek expression in fantasy and play. At one moment, aggressive competition with the rival may be uppermost as the child assumes the role of the strongest, most attractive and competent member of the family. The same role may simultaneously give expression to the child's exhibitionistic impulses or wish to protect and care for the object of his or her longings. The play may easily shift from themes of power and strength to scenarios involving the production and feeding of babies. Repeated crashing of toy cars may at one moment express the child's concerns about aggression and bodily intactness. With additional features and elaboration, the same play may articulate the child's fantasies about sexual intercourse. In this latter context, the child's curiosity about the contents arid activities behind closed dollhouse doors or in closets and bedrooms may at once give vent both to sexual excitement and disappointment at being excluded from parental activities. Equally, increased interest in theories regarding the origin of babies, sexually exciting sensations focused on genitals, and anatomic differences and comparisons of physical attributes between sexes and between adult and child versions (same sex) are expressed in the oedipal child's fantasies and imaginative play ([Marans et al., 1993a](#)). Reality events in the child's life—accidents and injuries, as well as surprises and pleasures—are dexterously integrated into fantasies as they stimulate, organize, and accentuate the specific themes with which the child struggles ([Caper, 1996](#); [Cohen et al., 1987](#); [Neubauer, 1987](#); [Solnit, 1987](#)).

#### Infantile Neurosis

The powerful wish to get rid of the same-sex parent and assume his or her role in an exclusive, intimate relationship with the opposite-sex “partner” is also fraught with tension as the child struggles with love and hate felt toward the rival. The experience of hurt, tension, and uncertainty during this phase leads to the achievement of internalized conflict. The child now has the capacity for neurosis, that is, an internal struggle between opposing forces (wishes versus personal values, desires versus parental attitudes and opposing desires). The *infantile neurosis* is theoretically the paradigmatic form for age-appropriate mental disorders engaged by oedipal phase structures. It is expressed by the appearance of regressive behaviors and fears—obsessive-compulsive symptoms, enuresis, encopresis, thumb-sucking, phobias, separation difficulties, nightmares, frequent battling with parents—that are common in this period of development and serve the child's attempts to withdraw from or displace the conflicts aroused by the intensity of his or her oedipal longings. Similarly, in imaginative play, the child will change the narrative script when he or she is unable to maintain an adequate distance from painful reality or anxiety stemming from conflicts. For example, the role of a given protagonist may be elaborated in order to add dimensions that would compensate for the child's intruding sense of vulnerability (e.g., the policeman who is battling robbers is transformed into Superman). Alternatively, the specific role and theme in the play may be abandoned altogether as the child shifts to ones more congenial to the maintenance of pleasure and the prospect of mastery. This shift might be seen in the child's assuming the voice and behavior of a baby, in provocative messing, or in destruction of play materials. However, the child might equally turn to an intensification and insistent involvement in the fantasy, becoming narrower in his or her range of play while trying to overcome anxiety in the repetition of a singular theme.

In these varied ways, the child's internal conflicts and their representation in fantasy, symptoms, and imaginative play constitute the child's research about the self and others. Expanding experience in a broader social context (chiefly through the introduction of nursery and school programs) fosters increased psychological independence. Organized and regular group experiences offer a broader context in which the conflicts and tasks of the oedipal phase of development may be worked through. The capacity and opportunity to engage with peers increases the range of play activities in which fantasies and skills may be “tried on.” Cooperative play (in which role assignment, turn taking, and mutual elaboration of narrative/story line are component parts) often revolves around themes regarding:

1. Exploration of and acquisition of knowledge about physical properties of things and various characteristics of the environment
2. The child's sense of place within the family
3. Size, strength, capacities/competence
4. Theories and feelings about babies and their origins
5. Anatomic differences and attributes of both sexes
6. Curiosity and excitement associated with genital sensations
7. Competition and rivalry
8. Destructive aggression
9. Consequences of wishes and actions

Relationships with children and adults outside of the family capitalize on and promote the youngster's greater frustration tolerance, reliance on increased intellectual and physical capacities, and confidence in the ability to function—with pleasure—in the absence of parents. In addition, the world beyond the family affords the child with a broader range of stimulation and opportunities for using new skills such as reading, writing, and problem solving in the classroom setting.

Although giving rise to considerable anxiety, the oedipal child's experiments in thought and pretend play serve to integrate representations of the self and others. The conflict between loving and hating leads the child to further consolidate and integrate the images of the “good” and “bad” parents into representations of them as whole, autonomous people who have relationships beyond the dyadic parent–child configuration. In muting the intensity of oedipal longings, the child strives to live up to the ideal of being like the rival parent (ego ideal) and to identify with their rules and values (superego). These achievements of internalization allow the child to desist in overt rivalry with the same-sex parent, to feel that he or she has not lost out in the struggles but has in fact taken on the role of the parent internally, and serve as reparative structures for anxiety, frustration, and the hurt narcissism that accompanied the more raw competition. The child's feelings of wounded pride and anxiety serve as “signal affects” and alert the child to how he or she is feeling in response to specific thoughts and actions (in the past, present, and future) and lead to the child's capacity to observe himself or herself and to establish theories of how his or her mind works.

#### THEORIES OF MIND

The “theories” the child develops organize internal experience of affects, bodily urges, memories, parental rules, and praise and personal ideals and provide structure and cohesion for the child's perceptions of self and others. They are tested and elaborated in fantasy, play, and daily life and draw on the many new roles the child assumes in relationship to the parents, as a friend to peers, as a sibling, as a student in the classroom, and the like ([Klin et al., 2000](#); [Marans, 2000](#); [Mayes and Cohen, 1994](#)). The child's theories of how his or her mind works—what makes the child worry, and how does the child enhance good feelings about himself or herself through fantasy, imaginative play, and direct action—lead to decreased egocentricity and increased self-observation ([Marans et al., 1993c](#)). The ability to manipulate ideas and feelings in preparation for action and the capacity to take the perspective of parental representations allow the child to postpone gratification, to balance urges with ideals that are now the child's own. Achievements in delaying immediate satisfaction and identifying the principles of justice/morality are expressed in the

child's social play with companions, where he or she is able to see the world from the view of the other—not grabbing toys, taking turns, playing by implicit rules, developing narratives from shared fantasies—and accepting the fact that he or she is not alone in having important needs. The child's new capacities are also apparent in the child's recognition of the difference between play and work and in his or her sense that industriousness and perseverance brings their own rewards and personal satisfaction. Although parents' approval and praise (and the admiration of other adults and peers) remain important to the oedipal child, the child's ability to refer internal theories about himself or herself—sources of pleasure, memories, ideals, positive and negative consequences of thoughts and actions—allows the child to give up a singular reliance on external sources of reward/response for the regulation of self-esteem ( [Marans, 1993b,1993c](#); [Mayes and Cohen, 1994](#)).

### 7 to 10 Years (“Latency” Phase)

The term latency refers to a decrease in the prominence of preoedipal and oedipal striving in terms of both intensity and direction. Although they do not go completely underground, the degree of preoccupation with sexual impulses and interests that are explicitly connected with the assumption of parental roles is significantly diminished. In fact, it would seem that in the sexual curiosity, excitement, and joking that can be observed among latency-age children, notions about parents as sexual objects/beings must be denied or avoided. Activities and attitudes seen as infantile—dependency on parents, fearfulness, and the like—also need to be avoided at all costs. In the face of conflicts established in the preoedipal and oedipal phases, infantile and incestuous longings are repressed, and a widening array of adaptive defenses, including intellectualization, humor, identification, obsessional interests, and sublimation, are utilized to support the diversion and alteration of the original impulses ( [Becker, 1974](#); [Bornstein, 1951](#); [Etchegoyen, 1993](#); [Freud, 1968](#); [Marans and Dahl, 1998](#); [Sarnoff, 1976](#)).

The continued consolidation of intellectual, sensorimotor, and social skills and opportunities affords the latency child with a variety of pathways for the sublimated expression of urges that dominated earlier phases of development. For example, friendships and group affiliation can serve as an alternative to the exclusive, close tie to the parents while further facilitating the child's exploration of the world outside of the family. The intense interest and curiosity about the origins of babies, the intimate life of parents, and the mysteries of sexual differences can now be employed for and shaped by the challenges of learning that occur in both school and extracurricular activities. Competitive strivings central in the oedipal phase of development can find expression in games and relationships with peers. Exhibitionistic impulses find a broader range of vehicles and audiences in the performance of intellectual tasks and mastery of athletic and creative pursuits. In addition, the demands and rewards associated with a relatively stable conscience (or superego) are increasingly exercised in the latency-age child's interests and activities. Although not without breaches, as seen in cheating and insensitivity to peers and family members, insistence on following the “rules of the game,” empathy with the feelings of others, and a clear sense of right and wrong are hallmarks of the child's establishment in latency. Similarly, descriptively obsessional interests in orderliness, collecting (as in hobbies), and details of functional relationships and properties of physical phenomena serve reaction formations that derive from both benign and prohibitive aims of the superego. These elaborations of defensive and adaptive functions are only possible with and equally reflective of the development of more sophisticated cognitive processes involving the introduction of operational thought.

Optimally, the latency-age child achieves greater autonomy with respect to aspects of daily living such as hygiene, dressing, looking after possessions, and the like. The ability to engage in operational thinking and problem solving, in conjunction with the capacity for increased frustration tolerance, broaden the range of potential achievements and attendant satisfaction. These accomplishments enrich the child's interaction with peers, who are viewed as partners and “best friends” as well as new objects of identification, admiration, and competition.

The central threat to the latency-age child is the reemergence or breakthrough of the original sexual and aggressive fantasies of the oedipal phase, particularly when associated with the impulse to masturbate. Sleeping difficulties; nightmares; worries about burglars, bodily injury, and death; and the ease of regression to earlier modes of relating to parents (struggles over food, self-care, household responsibilities, and the like) may be some of the behavioral phenomena that accompany the child's attempts to defend against and give expression to the residual or persistent intensity of oedipal conflicts in the early period of latency. The elaboration of cognitive capacities, peer group involvement, and academic and extracurricular interests facilitates the late-latency child's sublimation of previous trends in action and fantasy and promotes greater distance from the original objects of oedipal longings. Alternately, these achievements are subject to neurotic interference; school failure is not necessarily an outcome of learning disabilities, and isolation from the peer group is not alone determined by athletic skills, looks, or abundance of toys.

### Adolescence (12 to 20+ Years)

Adolescence is one of the most dramatic phases in the course of development, marked by profound changes in biological, psychological, and social functioning. Preceded by a period between ages 10 to 12 in which there is renewed interest in anatomic differences, sexual curiosity, and masturbation (preadolescence), the transition into *early adolescence* (12 to 14 years) is introduced by the endocrinologic and biological processes of puberty. With much greater intensity, these processes focus the young adolescent's attention on concerns about bodily changes and sexual sensations. The primary and secondary sexual characteristics—growth spurt; voice changes; menarche; nocturnal emissions; breast development; and pubic, axillary, and facial hair—associated with pubertal maturation are often greeted with a mixture of pleasure and trepidation. Preoccupation with comparisons of the rate of changes in others; the intensification of exciting genital sensations and the compelling need for masturbation as a source of relief; and the increased conscious awareness of sexually arousing yet conflictual fantasies, precipitating the urge for and accompanying masturbation, may all arouse a tremendous amount of anxiety for the young adolescent ( [Blos, 1970](#); [Dahl, 1993](#); [Kestenberg, 1980](#); [Laufer, 1989](#)).

Although physical maturation heralds the entry into manhood and womanhood, the changes can be experienced as happening too quickly or not quickly enough. These feelings may be manifested in the exhibitionism, embarrassment, and secretive behaviors seen in the young adolescent's attitudes toward his or her body. In either event, pubescent children may be impressed and made anxious by the lack of control of their own bodies. Menarche and the first nocturnal emission are dramatic, paradigmatic events for the real absence of control that characterizes this phase of development. The young adolescent's relationships with his or her parents may be equally tumultuous as rapid shifts between longings to remain close and dependent and requirements for privacy and strivings for autonomy are experienced. These struggles are often played out around old issues having to do with bodily care and hygiene, cleanliness and orderliness of personal property, insensitivity to the feelings and needs of others, and intense preoccupation with immediate satisfaction of one's own needs ( [Blos, 1962](#); [Eiguer, 1996](#); [Erlich, 1993](#); [Freud, 1958](#); [Hauser and Smith, 1991](#); [Laufer, 1985](#); [Ritvo, 1984](#)).

By *mid-adolescence* (14 to 16 years) maturation levels off; all girls are now in menarche, boys are able to ejaculate, and both have attained secondary sexual characteristics. Physical maturation potentiates the conflictual nature of incestuous fantasies that reemerge during adolescence. Unlike 4- to 6-year-old children, the young person by mid-adolescence is confronted with the reality that he or she now possesses the equipment necessary for carrying out both sexual and aggressive wishes. The adolescent's provocative and battling stance toward the same-sex and both parents reflects renewed oedipal competition and repudiation of both oedipal and preoedipal longings. Disregard for family rules at this point may reflect desperate attempts to achieve emotional distance from parents. However, behaviors that “test limits” are now often implicit invitations for parents to remain involved and take charge; the adolescent's subsequent outrage maintains his or her explicit objection to any parental interference with his or her freedom.

The complexity and difficulties of family relations further stimulate and support the adolescent's activities outside of the home. He or she finds refuge from the claustrophobic pull of family ties in intellectual, athletic, musical, and political interests and potentially in illicit drug use, drinking, and crime as well. Similarly, as the adolescent withdraws from his or her parents, the intensity of the attachment to them is shifted to peer group relations, including same-sex and opposite-sex relationships. Opposite-sex pairing and dating serve as: (a) sexual and emotional experiments in intimacy, (b) a gauge of masculinity and femininity, (c) an opportunity to try on (in reality as opposed to imaginative play) adult relationships, (d) an escape from fantasied or real incestuous and homosexual activity, or (e) a marker of conquest and competence, to be appreciated by an audience of peers. In addition to tighter affiliations with peers, social expectations and the push for mastering anxiety associated with dependency on parents spur the adolescent toward real independent functioning. In this, the adolescent must recognize that the craving for independence implies truly relying on his or her own abilities rather than on parents.

By late adolescence (17 to 20+), involvement in relatively stable peer groups, academic and extracurricular activities and interests, some degree of financial reward for responsibilities associated with jobs, and the like reflect the adolescent's emancipation from the roles and requirements of earlier phases of development. The degree of successful engagement in life beyond the relationship with the parents may be a gauge of the extent to which the adolescent is able to emotionally disengage from and mourn the passing of his or her reliance on these powerful figures.

There is perhaps no more powerful example and test of the adolescent struggle for autonomy from parents—the breaking of preoedipal and oedipal ties—than the fantasied and real search for a new, typically heterosexual partnership. In late adolescence, the young person is very aware of the difference between the love felt toward a new heterosexual partner and the earlier experiences of experimentation. The girl is no longer primarily interested in conquests or simply owning and overpowering the man; the boy is no longer singularly guided by his need to prove his powers of seduction, his masculinity, and his repudiation of homosexual aims. Both are caught up in the desires that had been previously in the domain of oedipal fantasies. Longings for physical intimacy, for exclusive attachment, and to protect and be protected, to admire and be admired, can find full expression in the courtships of adolescence. This new experience of closeness and trust is the essential

climate for surrender to the heterosexual partner in which earlier components of the attachment to parents—dependency, passivity, exclusivity, jealousy, physical intimacy, and so on—may be subsumed. Again, the extent to which these and other longings (such as unresolved childhood wishes to possess the anatomy and prerogatives of the opposite sex) remain predominantly and conflictually tied to their original objects, the parents, determines option for and depth of new heterosexual partnerships.

Although many, and perhaps most, adolescents experience some degree of sexual interest in individuals of the same sex and may engage in some degree of arousing physical contact (such as mutual masturbation or sexual display), their fantasy lives and primary objects of sexual arousal are heterosexual. Typical homosexual experimentation occurs in the context of primarily heterosexual interests. During the usual course of development, heterosexual orientation appears to be based on biological factors that are shaped during gestation and the first months of life and that are reinforced by social experiences in the family and peer group, as well as the developmental sequences of the psychosexual phases. A sizable number of adolescents, however, are primarily involved in thinking about and being aroused by individuals of the same sex; they are not turned on by individuals of the opposite sex. For some, the recognition of the direction of their attraction is clear during the earlier school-age years (latency); for others, the intensity and singularity of homosexual object choices become clear only during early adolescence or somewhat later. There are probably a variety of determinants of homosexual orientation in both males and females; biological factors have been suggested, as well as interactions between constitutional and familial patterns of interaction. There is also a range of variants of homosexuality in adolescence, which for clinical purposes need to be differentiated: Homosexuality may represent a defense against aggression or a negative resolution of oedipal conflicts (i.e., focusing longings for intimacy with the same-sex parent as a way of warding off anxiety associated with incestuous wishes involving the opposite-sex parent), it may be an exaggeration of bisexuality or emerge in specific environmental contexts (e.g., in seminaries or boarding schools), or it may represent the adolescent's immutable and well-integrated sexual orientation, as authentically a part of the adolescent's self as is heterosexuality.

The developmental tasks for homosexual adolescents are complicated by both internal and external factors. The youth's discovery that he or she is excited by and attracted to individuals of the same sex runs counter to what the adolescent may have expected and the experiences of his or her peer group. This feeling of being different compounds the usual feelings of estrangement and secrecy of adolescent sexual development. The homosexual adolescent also usually has no peer with whom to share, in locker room or girl-to-girl intimate chats, the emerging sense of being a sexual person. The homosexual adolescent also lacks socially sanctioned opportunities for sexual experimentation, for finding suitable intimacy, for using the pairing of adolescence to move away from the parental ties. In his or her loneliness, the homosexual adolescent may try to deny sexuality altogether and attempt to be celibate; may attempt to engage heterosexual friends in sexual relations that the other youngster feels initially as experimentation but that for the homosexual takes on more intense, crush-like importance; or may feel the need to engage in brief encounters that may be dangerous psychologically and with the increased risk of human immunodeficiency virus (HIV) infection ( [Downey and Friedman, 1998](#); [Friedman and Downey, 1993](#); [Isay, 1989](#)).

The capacity for more mature, intimate relationships in the latter part of adolescence by no means guarantees their permanence. The task of consolidating the sense of self continues to find expression in shifting interests and ideals; the extent to which they mesh with those of the chosen partner, in part, determine the success or failure of the relationship at any given time. In addition, the amount of emotional energy available for intimate ties with others may fluctuate as the adolescent becomes increasingly involved in making plans for the future. That these may involve the young person's physical departure from home and community often contributes to the end of significant intimate relationships. Even more important is the adolescent's psychological departure from and break with the familiar, as he or she moves further into the realization of independent strivings and autonomous functioning. These are not without considerable practicing, uncertainty, and anxiety, as the adolescent anticipates the breadth or limitations—determined by individual strengths as well as multiple social factors—of opportunities available in the world beyond the family.

Adolescence has long been described as a period of inner turmoil in which the onslaught of biological changes, intensified sexual and aggressive urges, and shifting social relations and responsibilities make the search for a cohesive self a ubiquitous, crisis-laden struggle. Given the reality of the multiple variations in the appearance and behavior of teenagers observed on the streets and in the malls and schools of inner cities, working-class neighborhoods, and upper-middle-class communities, can there be a central theory of adolescent development? Although there are "typical" preschool- and school-age children, what can be said about adolescent development that is true to the tremendous variations seen in this period? The task of a psychoanalytic theory of adolescent development is to delineate those processes that: (a) are generally found in adolescents, regardless of surface differences in behavior, and (b) allow for the broad variations in personal and social situations, explaining why adolescents operate in the context of their families and neighborhoods on the one hand, and in relation to their personal, inner lives on the other. Although there are other approaches to understanding the problems and achievements of this phase of development, the psychoanalytic task is primarily to understand the meaning of the inner experiences of adolescents and their links to behavioral and life choices.

## PSYCHOANALYTIC PHENOMENOLOGY OF ADOLESCENCE

From the psychoanalytic perspective, the phenomenology of adolescence centers around an array of reorganizations of inner life. The primary reorganization concerns the representation of the bodily and sexual experiences: Early in puberty, the child initially feels that these new experiences are external to the self, but when all goes well, he or she gradually integrates the mature sexual body as a source of pride and pleasure. Concurrent with the reorganization of the representation of the body in its mature sexuality and size, there are psychological reorganizations in relation to drives (especially the modulation of aggression and the fusion between aggression and tenderness), values (especially the assumption of personal values that differ from those of parents), concepts of time (especially the adolescent's sense of having a personal history and a future that he or she can more or less envision), and the self and relations to others (especially the possibility for sharing intimate experiences outside the family and the giving and receiving of sexual pleasure). Each of these reorganizations rests on the achievement of various preconditions during earlier phases of development, good enough physical and cognitive functioning, ongoing support from the family and other adults, particularly teachers, and good fortune in finding friends and avoiding irreparable injury.

Although most adolescents do not experience psychiatric disorders ( [King and Apter, 1996](#); [Rutter et al., 1976](#)), this phase represents a period of increased prevalence of a broad range of psychiatric and behavioral disturbances, including affective disorders, anorexia, suicide, and accidents. For children who are vulnerable because of preexisting difficulties, such as chronic medical illness, emotional difficulties, cognitive delays, or the burdens of poorly resolved earlier neurotic conflicts, the entry into adolescence, with the push toward autonomy and new social expectations, may herald major upheavals in previously stable patterns of medical care or parent-child relations.

### The Experience and Representation of the Body

Preoccupation with the body is a prominent characteristic of adolescence. Normal young adolescents devote considerable attention to ensuring its attractiveness to others. Yet the body may also be punished, mutilated, and destroyed by the adolescent who is experiencing turmoil. The balance between the adolescent's love and hatred for his or her body, between self-care and self-destruction, may shift rapidly, repeatedly, and precipitously. The adolescent uses his or her body as the stage for enacting pride or shame, joy or despair, a sense of being beautiful or horrid. The body may be seen as another, to be treated respectfully or thoughtlessly; as a persecutor, to be ignored or attacked; as a lover, to be caressed and narcissistically exhibited.

Psychologically, the adolescent may experience the rapid changes in his or her body in a passive mode that may reverberate with earlier experiences of humiliation or dependence. Here again, the adolescent may feel that he or she is forced to "learn to accept" what is not under his or her control. The adolescent may try to deny what is happening to his or her body and hold on to the interests and social forms of latency. Or he or she may feel comfortable with its increasing potentialities, secure that what nature has in store is consistent with previous good experiences. Or, most commonly, the adolescent may react to the changes in body and drives with a mixture of anxiety and exhilaration, of acceptance of what is in store along with a push toward mastery in which passive is turned into active. In trying to take active control over the passive experiences of puberty, the adolescent may try to improve on nature—to decorate his or her body with hairdos, special clothing, makeup, and tattoos; to improve the appearance of the body's shape by weight lifting, dieting, or gaining weight to increase muscle bulk; or to distort the body's appearance, to make what the child feels is passively weird (in his or her own eyes) into actually weird, through second-hand clothing, wild hair, multiple earrings, long hair, or whatever else the peer group, at a particular moment, has defined as hip, in, or cool. Through such stage design, the adolescent reorganizes his or her representation of the body and the meanings of its various parts in relation to others, including same- and opposite-sex peers and parents. When not carried too far, the experimentation allows the child to take responsibility, to own his or her body in its new form, smells, and modes of arousal.

For the vulnerable adolescent, the manipulation of the body as a thing may become a preoccupation. The adolescent may feel that life is unbearable because her nose is too long, his penis is too small, or she or he is too tall or short. The reorganization of the body representation may also become enmeshed in the reorganization of family relations or other changes in self, leading, along with other determinants, to anorexia, bulimia, self-mutilation, or obesity. When the body becomes the expression of neurotic and intrafamilial conflicts, the reorganization of the self revolves around representations of the body: who owns the body, who is responsible for it, and who enjoys its pleasures and feels its attacks.

## Sexuality: from Autoeroticism to Shared Intimacy

Psychoanalytic theory emphasizes the role of sexuality—of pleasurable experiences through the body—from the first months of life. Autoeroticism and sexuality continue throughout each of the psychosexual phases, with pleasures felt in specific zones (oral, anal, and genital), and in the activity of the body and its musculature as a whole. Puberty heightens the role of sexuality in conscious and unconscious life and focuses sexual feelings on the genitals. As with sexuality in general, psychoanalytic theory recognizes the child's ability to provide himself or herself with sexual pleasures through his or her own activity and fantasy, from the first years of life. With puberty, sexual self-gratification through masturbation and self-regulated fantasy becomes central to the definition of selfhood and the relations between self and others. Adolescent masturbation is an achievement: It includes physical maturation and the capacity for erection/ejaculation or vaginal/clitoral orgasm, the capacity to imagine and sustain fantasies that are pleasurable enough to lead to climax, and the maturity to delay satisfaction, to plan for and carry out masturbatory activities at suitable, private times.

Adolescent masturbation, as a physical act, is accompanied by rich internal processes that have been conceptualized as “masturbatory fantasies.” The adolescent is aware of the conscious story, major themes and images, and cast of characters. Often, these conscious elements are based on current experiences with peers, popular movie star images, and materials such as magazines and the like, as well as on powerful experiences that the adolescent may actually have had earlier (including beatings, active or passive sexual encounters, and primal scene fantasies and observations).

Psychoanalysts such as the [Laufers \(1987\)](#) have postulated that adolescents generally have a fixed and limited number of central masturbatory fantasies—fantasies that are not fully conscious or conscious at all and that underlie the structure or affects of the conscious fantasies. These central masturbatory fantasies may provide a paradigmatic form or emotional tone to the experienced or conscious fantasy—for example, sadomasochistic features, incestuous impulses, teasing, perversity, or passive longings—that may be uncomfortable or the source of anxiety within the conscious masturbatory experience. The central masturbatory fantasies are integrative; they bring current sexual urges together with the child's earlier experiences with being cared for by the mother (tactile, oral, anal), his or her fantasies during the oedipal phase and in relation to primal scene, and the pleasures of gender identification genitality and latency age masturbation and excitements.

When development along the line from autoeroticism to adolescent sexuality has gone well, masturbation provides opportunities for rehearsing sexual behavior, expressing and receiving affection, and trying on the different active and passive roles needed for mutuality in love-making (including how to hold back on orgasm until just the right moment). Probably few adolescents are completely without guilt concerning masturbation; understanding the sources of this guilt reveals the ways in which adolescents may feel that sexuality is the appropriation of parental rights, that their fantasies run counter to their values, especially in relation to aggressively being out of control or oedipally prohibited. Adolescents who are too anxious about sexuality or too frightened by aspects of their masturbatory fantasies may try to abstain completely; other adolescents may compulsively and guiltily engage in masturbation, increasing their guilt and, thus, the tension that leads to masturbation. Through trying to titrate their involvement in masturbation, adolescents reorganize their representations of control over their sexual desires. They learn they can turn on, delay, and discharge their sexual feelings, more or less at will.

## Reorganization of the Self

The “self” has many meanings: It can be understood theoretically as the locus for the integration of intention, abilities, desires, and values; as a mental structure that coordinates the other agencies of the mind; as an internal, conscious and unconscious “representation” of the individual's feelings, ambitions, and goals; or as a component of an individual's experience, quality of experience, and personal identity, which has continuity over time, space, and feeling states. The concept of self has a sense of individuality, distinctiveness, and boundaries—of the separateness of the person from others. Being true to oneself is a value, but self-valuation carried to self-preoccupation is self-absorption and selfishness at the expense of others. On the other hand, giving oneself to others and feeling other's needs as though they were one's own may be enriching of the self as long as one does not lose track of one's own self-interests. The concept of self is recursive, as captured by phenomena such as self-consciousness and self-awareness, as well as by processes such as taking, or not taking, care of oneself.

Adolescents take themselves seriously: They wonder who they really are, how they are different from their parents, how they became who they find themselves to be, what they are becoming. They enjoy losing themselves in crowds and finding themselves in “deep and meaningful” relationships. They search for their true values and refuse to compromise, fearful that any loss of the high ground will lead to the slippery slope of loss of their hard-earned individuality. They become abstractly conceptual, wondering about how their minds work, their values, authenticity, and politics. They may feel that they are obligated and may even have the ability to make a difference, to reduce the suffering or wrongs of the world; or, just the opposite, they may explain to themselves that, “the world being the way it is,” there is nothing they can do but simply get by, get even, go along, drop out, or have a good time. Whatever side of the polarity of involvement in the broader social world that they select, they are likely to think about their choices “philosophically,” in categories of value and history rather than solely or consciously in relation to what their parents believe and they have been taught.

This reorganization of the self involves a heightened cathexis or direction of attention to the internal world (e.g., feeling states and impulses); alternations in the regulation of narcissism; and, concurrently, reevaluation of relationships with friends and partners in intimacy (object relations). These closely intertwined processes are closely associated with sexuality. For example, the adolescent's experience of a crush—of the enchantment of another—at the same time expresses and affects several domains: The adolescent recognizes the power of the other; he or she feels a loss of self-sufficiency and self-control; he or she experiences an enhancement of self through fantasied union with the desired other. Through idealizations and crushes, the adolescent finds ways of dealing with the depressive feelings associated with loss of earlier relations with the parents. When these intertwined processes of reorganization are successful, and the adolescent is fortunate, the adolescent increasingly feels a consolidation of his or her personal identity as a sexual, competent, and reliable individual.

Relations with parents provide a testing ground and launching pad for the reorganization of the adolescent's self. By approaching his or her parents with worries and then striking out at them for intruding or not understanding, the adolescent, who may seem at such times to be paranoid, learns how far he or she has moved toward feeling secure in his or her own abilities to deal with impulses and frustration. Adolescents need to learn how far they can go on their own and also how they can return, when need be, to the security of the preadolescent relations with the father and mother. As they move away and back toward the dependency, adolescents may provoke battles about issues that are of relatively little obvious consequence. In the process of negotiating rules about when to be home at night, whether he or she has carried out the garbage as promised, and the appropriate length of hair or density of makeup, the adolescent boy and girl learn about the modulation of their rage at their parents (in their role as symbols of their own dependency longings) and whether the parents can survive their aggression (in their role as representatives of the adolescent's own abilities to hold together when overwhelmed). When parents break down under the pressure of unremitting aggression, adolescents do not feel victorious. They may feel panicked. And in their distress, they may feel compelled to attack, insisting that the parents be strong, or withdraw in an angry and depressive huff.

Within the family, the adolescent's struggle for self-definition may set off varied reverberations with parents. Parents may feel envious of the youngster's freedom and experimentation, particularly sexual freedoms, or may anxiously overreact to their fantasies of what their child is engaged in. The mother who pounds at the bathroom door when her son stays inside too long knows, and yet does not know, what has happened to her little boy. The sexually mature adolescent daughter may arouse incestuous fantasies in her father, who then, through projection and displacement, engages her defensively in battles about boyfriends and morality. Parents may establish rules that are harshly enforced as externalizations and barriers to the enactment of forbidden (and not fully unconscious) fantasies. Alternatively, parents may vicariously enjoy the exploits of adolescence and too easily relinquish the parental role; they may be too understanding or may implicitly encourage their child's promiscuity, drinking, and fast driving while explicitly condemning him or her for getting into trouble.

## Adolescent Disturbances

The phenomenologic processes of adolescence that move toward consolidation of the self in its many facets also are vulnerable to multiple different types of disorder, from within the adolescent's own bodily changes and mental processes and from the outside world.

There are special burdens to adolescent development that arise from the timing of puberty or its results: precocious puberty, which marks out a child as sexually mature or too tall before he or she is ready, or delayed puberty, which prevents a child from entering fully into the experiences of his or her peers in the discovery of sexuality. There are other burdens that represent the carrying over into adolescence of the sensitivities, conflicts, and poor resolutions of earlier phases: inability to tolerate frustration, predisposition to anxiety, tendency to deal with tension by impulsive activity, and lack of an internal sense of security in relations with parents and within the self. And there are burdens that arise specifically in response to the emergent issues of adolescence: the strength of sexual drives, preoccupation with fantasies, guilt over sexuality and aggression, and troubles coping with the maturing body.

Given the complexity of the developmental tasks involved in reorganization of the self and its representations of the body and others and the modulation of aggression, sexuality, and narcissism, it is no surprise that there is a marked increase in many psychiatric disorders concurrent with puberty. These include affective disorders, particularly depression; personality disorders, which reflect difficulties in self and object representations; disorders of appetite (such as anorexia, and bulimia); and frank schizophrenia. Adolescents also demonstrate breakdowns that elude categorical diagnosis and include dramatic and life-threatening symptoms in various combinations: self-destructiveness, brooding despair, complete social withdrawal, sexual promiscuity and perversity, addictions, immobilizing preoccupations, seeking out and experimenting with danger, and the like. Psychoanalytic investigation of these disorders involves placing the child's inner experiences in the context of his or her personal development and understanding the developmental meaning of the symptoms and activities. Because adolescents are often deeply interested in understanding the lives they are living, they can be engaged, as younger children may not, in reconstructing their histories and reflecting on their experiences; thus, therapeutic work may be in keeping with the developmental tasks faced by all adolescents of finding new representations through reorganization of the self.

Just as adolescence presents difficult tasks of development for each agency of the mind, the achievement of adolescence, as defined by the success of reorganizations, leaves the adolescent with a sense of pride and vigor. Competent, attractive adolescents evoke adult fantasies concerning youth and potentiality, as well as envy and yearning. The image of adolescence in literature—adventurous, seeking, seductive, vulnerable, and emotionally alive and open to new experience—captures the achievements of adolescence and also how the development of adolescents, as the next generation, is intertwined with that of their parents, as reminders of fulfilled longing as well as bearers of hope.

## PSYCHOANALYTIC THEORY: DOMAIN, CONCEPTS, AND THEORETICAL INTENTIONS

The primary domain of psychoanalytic theory is the child's inner world, mental functioning, and internal experiences, as they elaborate over the course of development. First, psychoanalysts are interested in the personal, private, and intimate experiences of life—emotions, feelings, thoughts, wishes, dreamlike states, daydreams, worries, yearnings, pleasures—and how the person becomes aware of these experiences, allows for their unfolding, pushes them outside of consciousness, shares, and hides them. Second, psychoanalysis is interested in behavior—what children do—and the relations between the inner world and action, particularly how the child experiences his or her own action and the actions of others. Psychoanalysis focuses on the child's understanding of his or her own life, of the ways in which the child comes to represent and make sense of his or her inner world and the minds and actions of others. In these ways, psychoanalysis is particularly concerned with highly individualized, detailed, and rich descriptions of mental processes. The major concepts of psychoanalysis are aimed at providing categories and approaches for such descriptions, charting the major domains of experience over the course of development.

Closely related to this descriptive and in many ways historical undertaking, psychoanalytic theory also concerns origins and determinants. The “explanatory” theories of psychoanalysis consist of a range of perspectives, some of which are already outlined by Freud in his classical writings and others that have been described by theorists over the past decades. Freud's primary perspectives were the cathartic (the purging of the mental apparatus of negative experiences by abreaction, closely related to hypnosis and the so-called talking cures), economic (the distribution of psychic forces and the effects of their being pent up or discharged), dynamic (the conflict between wishes and prohibitions and their expression in symptoms), topographic (the distinction between conscious, preconscious, and unconscious mental processes), and structural (the functions of the ego, id, and superego) theories. These theories have been applied and remain useful within child psychoanalysis as well. They have been augmented by perspectives that emphasize development (the emergence of new structures and the changes in each of the classical perspectives over the course of maturation), developmental lines, the organizing role of the self, the importance of social relations (object relations), and the complexities of proverbial experience and mother—child relations.

Alongside the psychological perspectives to explanation or understanding of mental life, psychoanalytic theory has recognized the importance of general theories of psychology ([Fonagy, 1991](#); [Fonagy et al., 1993](#); [Mayes and Cohen, 1994, 1996](#); [Osofsky, 1982](#)), originally conceptualized as autonomous ego functions and adaptation ([Hartmann, 1939](#)), and the role of biological processes—genetic ([Mayes, 1999](#); [Peterson et al., 1995](#)), endocrine ([Moran, 1984](#); [Moran and Fonagy, 1987](#)), and constitutional ([Mayes and Cohen, 1993](#))—and the general health and experiences of illness ([Goldberger, 1995](#); [Lewis, 1994](#); [Moran, 1984](#)) of the individual throughout the course of maturation.

The range of concepts within psychoanalysis is thus enormously broad, encompassing descriptive, historical, and narrative conceptions; multiple perspectives on causation and explanation; and associated conceptions of the roles of learning, adaptation, the environment, and the physical body in mental life. Core psychoanalytic concepts can be illustrated by the central role of conscious and unconscious fantasy as a common pathway for the representation and integration of experiences.

Within child psychoanalysis, conceptual disagreements have revolved around emphasis, timing, and the terminology used to describe normal development and its relationship to clinical phenomena. In this area, the contrasting views of Anna Freud and Melanie Klein and their adherents have been central in the development of child psychoanalytic theory.

With her monograph, *The Ego and Mechanisms of Defense* (1966), Anna Freud (1895 to 1982) became a major contributor to the emerging field of ego psychology and established a new, developmental viewpoint on the broad range of mental functions (intellectualization, sublimation, displacement, reaction formation, identification, turning passive into active, humor, etc.) that individuals can mobilize to reduce anxiety, cope with psychic conflict, or modulate the pain associated with failures in the environment or in one's own achievements. Her work was closely related to the work of Heinz Hartmann, whose *Ego Psychology and the Problem of Adaptation* (1939) was the first systematic exposition of psychoanalytic ego psychology and the concept of the nonconflictual sphere of functioning (memory, reality testing, perception, etc.).

Over the course of decades, Anna Freud articulated a broad, descriptive approach to the charting of the course of children's development and the contributions of biological and experimental determinants. In particular, she emphasized the importance of direct observation and the need to relate theory to observable phenomena; she eschewed speculation about inner life and fantasies that could not be confirmed by the child's own constructions in play or speech. For Anna Freud, conflict among the agencies of mental functioning is not expressed only in symptoms but also in the course of adaptation. She conceptualized the mutually enriching roles of sexual and aggressive instinctual urges in many areas of life; these unfold in relation to the child's parents and the realities of the child's satisfactions and the quality and continuity of responsive caregiving. Anna Freud gave a role to anxiety and tensions as expectable during the course of development, with each developmental phase having modal developmental tasks and specific, normative types of anxiety. She strove to create a developmental point of view, analogous to Sigmund Freud's structural, dynamic, topographic, genetic, and adaptive viewpoints, that recognized that along with maturation there are changes in the functioning of the basic mechanisms of the mind (the functions of the ego, the available mechanisms of defense, the complexity and symbolization of fantasy, the experience of the superego and guilt, etc.). This developmental perspective distinguished disturbances of development (in the emergence of basic capacities for reality testing, memory, social relating, synchronization of functions, unfolding of cognitive abilities, and the physical apparatus) from disturbances that reflected internalized conflict and neurosis.

Psychoanalysts influenced by Klein have felt that Anna Freud was excessively interested in the “surface” markers of children's fantasy life, that she paid too much attention to the influence of the external world of the child, and that she overemphasized the role of adaptation in the course of development. In addition, Kleinian critics feel that Anna Freud undervalued the implications of primitive unconscious fantasies occurring in the first year of life and question the usefulness of her formulation in conducting “deeper” clinical work, particularly with the most severely disturbed patients. Indeed, throughout her career Anna Freud emphasized that the child patient continued to live within the family and that the realities of this life were critical to his or her psychological development, as were the realities of his or her physical and intellectual endowment. As such, the fantasy life of the child was described by Anna Freud as reflecting the mutual influences of factors from these domains and organized according to the unfolding hierarchy of mental functions.

Beginning her work in child analysis at roughly the same time as Anna Freud, Melanie Klein (1882 to 1960) emphasized that instinctual life was shaped from its initiation by the mother—child relationship, not only by the contributions of particular erotogenic zones, and that aggressive as well as sexual forces were operative from within the first months of life. Klein portrayed the inner life of infants as actively organizing their experiences of sexual and aggressive urges in specific and rich fantasies ([Klein, 1984a, 1984b](#)). She described the earliest phase of life in relation to “paranoid” feelings and being persecuted and the next phase centering around the child's “depressive” guilt for aggression directed at the mother ([Klein, 1984b](#)). The working through of this normal depressive phase was, in Klein's theory, an essential step in early development and was a continuing process at various points in life. An important aspect of working through the depressive position was not only acknowledgment of responsibility but also the psychological process of “reparation,” of making amends to the fantasied mother who was the object of the infant's attacks. Unlike for Anna Freud, for Melanie Klein, envy and jealousy as well as the components of the oedipal phase were present during the first year of life. In her broadest metapsychology, Klein adhered to and elaborated Freud's “dual instinct theory” of primary life (eros) and death (thanatos) drives and their instantiation in primitive emotional development, whereas other psychoanalysts have jettisoned Freud's conceptualization of the death instinct.

In large part, controversies stirred by Klein's work related to the precocious timetable she envisioned for the emergence of capacities for fantasy and complex conflict

and her use of pathologic terms to describe normative developmental phenomena. Her ideas, however, provide psychoanalysis with an array of clinically useful constructs concerning fragmentation, splitting, projective identification, and the central role of aggression in fantasy as substrate for experiencing the world and organizing the self. Clinicians working with severely disturbed patients (such as schizophrenics) and in situations where individuals are regressed in their functioning (such as borderline patients in analysis and psychotherapy) have found her ideas especially useful.

At present, there is no fully integrated metapsychology that systematically relates the different levels and approaches to psychoanalytic explanation. Instead, the varying theories and concepts resemble a complex historical geography, rather like an atlas in which topographic, hydrologic, agricultural, military, population, transportation, and other multicolored maps are presented, page after page. There is no single, correct map of the earth; rather, there are different maps for different purposes. Nor is there a unifying geography of the economic, dynamic, topographic, structural, and developmental contours of the mind over the course of individual development. Instead, psychoanalysis provides the explorer with varied sets of signposts and pathways, with assistance in finding one's way into and out of the otherwise overwhelmingly complex and confusing spaces of the child's inner life.

Psychoanalytic theory has perhaps made its major contributions in relation to understanding the difficulties of children suffering from emotional disorders. The validation of psychoanalytic understanding occurs most convincingly in the context of psychoanalytic therapy. In fact, much of psychoanalytic research has involved reporting clinical material from single cases or groups of children with related problems. Critics argue, however, that psychoanalytic propositions employed in treatment have been developed with a lack of scientific rigor ( [Grunbaum, 1984](#); [Kazdin, 1988](#); [Popper, 1963](#)). The broad justification for the use of single case narratives as a database for theory is that they provide a detailed account of the treatment process that is especially suitable for capturing the complexity, variation, and individuality of a particular child's inner life. The single case report generally attempts to highlight and explicate variables that are likely to be seen in other cases. Problems involved in demonstrating the generalizability of findings from single cases include: (a) reliability of the observations, (b) inability to replicate the findings by going back and looking again, and (c) how clinical material should be presented (e.g., verbatim accounts of single hours versus broad descriptive phenomenology versus an emphasis on metapsychological terminology) ( [Marans, 1989](#)). Finding ways of reliably documenting observations for critical study is an important task for psychoanalytic investigators.

For the last several decades, academically oriented child analysts have recognized the limitations of the narrative, single case report and have attempted to develop: (a) schemes for classifying and organizing data, such as the Hampstead index ( [Sandler, 1962](#)) and the Hampstead Diagnostic Profile ( [Freud, 1965](#)), (b) controlled studies of psychoanalytic treatment and outcome ( [Heinicke and Ramsey-Klee, 1986](#); [Moran and Fonagy, 1987](#)), and (c) reliable ratings of children's presentations of clinical and experimental settings using direct observation and recording of children's sessions with analysts ( [Cohen et al., 1987](#); [Marans, 1993b](#)). In a major study of over 700 hundred cases of child psychoanalysis and psychotherapy conducted at the Anna Freud Centre, charts were reviewed and assessed across multiple domains. Examining changes in *Diagnostic and Statistical Manual*, third edition, revised ( *DSM-III-R*) diagnoses and levels of adaptation as measured by the Children's Global Assessment Scale (CGAS), the study identified predictors of improvement and showed that severe or pervasive pathology requires intensive analytic treatment ( [Target, 1998](#); [Target and Fonagy, 1994, 1997](#)). In addition to this retrospective chart review approach, researchers at the Anna Freud Centre have developed a manual of child psychoanalytic treatment and devised a prospective, controlled study that examines both process and outcome in three groups of treatment subjects.

Common to each of these research efforts is the development of measures that are based on operational definitions of theoretical constructs derived from clinical observations. Continued development of strategies that combine the use of narrative process notes, videotaped clinical encounters, manual treatments, and the application of nonanalytic, standardized measures of diagnosis and adaptive functioning (e.g., the Vineland Adaptive Behavior Scales) ( [Sparrow et al., 1984](#)) further psychoanalytic efforts at investigating the developing mind of the child. As psychoanalytic knowledge continues to be enriched by detailed case reports, child psychoanalytic research has developed increasingly sophisticated approaches to systematic research methodology. However, enormous challenges remain as psychoanalytic researchers attempt to retain the breadth and complexity of the psychoanalytic conceptual system while trying to achieve greater clarity and precision in describing the phenomena associated with the inner life of the child as well as the child's experience of the external world.

In addition to its value within the field of psychotherapy, psychoanalytic theory has provided developmental psychology with many major concepts and hypotheses, including the central importance of early mother-child experiences, attachment and separation, the role of anxiety and mechanisms of defense in normal development, and the developmental point of view on emotions and internal representations of the self and others ( [Mayes, 1999](#)). Systematic research outside of the therapeutic situation has supported the heuristic value of many of the concepts of psychoanalytic clinical theory. There is thus a mutual enrichment between the clinical and empathic study of individual children and rigorous research paradigms. In the future, psychoanalytic theory will continue to be elaborated by intensive, well-reported clinical investigation with individual children, as well as by advances within developmental biology, child development, and the neurosciences ( [Fonagy, 1999](#); [Leckman and Mayes, 1998](#); [Solms, 1997](#)).

Similarly, the application of child psychoanalytic principles of development outside of the consulting room continues to lead to the creation of innovative programs and interventions that address a broad range of problems confronting children and their families. The legacy of applied psychoanalysis in the war nurseries operated by Anna Freud and her colleagues during World War II ( [Freud, 1973](#)) is continued in the pioneering work of the School Development Project initiated by James Comer, who has employed psychoanalytic principles of child development in a hugely successful program that engages parents, teachers, and mental health professionals in transforming schools into forums for enhancing self-esteem and family empowerment ( [Comer, 1991](#); [Comer and Haynes, 1990](#)). As a national model for collaboration between mental health and law enforcement professionals, the Child Development-Community Policing Program, trains police officers in psychoanalytic principles of development and human functioning and establishes a 24-hour per day consultation service for children and families exposed to or involved in violence in their homes, schools, and neighborhoods. The program extends the effectiveness of police, as well as juvenile probation officers, child protective service workers and educators in their interactions with children and families while increasing the knowledge of their psychoanalytic colleagues about the psychological phenomena associated with violent trauma and about new ways of delivering psychological services for inner-city children and families ( [Marans and Cohen, 1993](#); [Marans et al., 1998](#)). Similarly, psychoanalytic attention paid to victims of violence and abuse ( [Pynoos, 1988, 1989](#); [Terr, 1991](#); [Twemlow, 1995](#); [Twemlow et al., 1996](#)) and international work with children caught up in the terror of war ( [Apfel and Simon, 1996](#); [Garbarino et al., 1992](#)) have made enormous contributions to our understanding of the developmentally specific and complex phenomena associated with trauma and posttraumatic stress disorder. Where the work of the Robertsons and Edith B. Jackson was responsible for the ways in which we view and deal with the hospitalizations of pediatric patients ( [Robertson and Robertson, 1958](#)), the development of consultation liaison services as part of standard pediatric practice ( [Lewis, 1991, 1994](#)) continues to draw on and develop our understanding of the synergistic relationship between physical and psychological health.

The field of child psychoanalysis encompasses a broad range of clinical inquiry, theoretical conceptualizations, and their applications drawing on detailed observations of the interaction of endowment, maturational and developmental forces, affect regulation, cognitive capacities, and social relationships. Whether the psychoanalyst meets with the child in the consulting room, on pediatric wards, in institutional settings, in custody/placement evaluations, or on the streets of our inner cities, the work is defined by an appreciation of the complex relationship between the inner life of urges, conflicts, defenses, and sense of self that are represented in fantasy, modes of relating, behavior, and adaptive capacities. By attending to the details of the children's experience of themselves and their perspectives of the world and others, psychoanalysts will continue to contribute to our knowledge about the developing mind of the child and enhance the ways in which clinical practice, program development, and social policy optimize children's developmental potential.

[Chapter References](#)

One of the certainties in the study of nature is that the meaning of the first words applied to a phenomenon will change as scientists gather new evidence and, as a consequence, invent new integrative ideas. The sense meaning of temperament, coined over 2,500 years ago, was a set of biologically based features that influenced an individual's acute affects, moods, and behaviors. Hippocrates and Galen would have called these qualities heritable if the concept had existed in ancient Athens and Alexandria. The referential meaning of temperament was limited to a small number of qualities, believed to be universal, for which there was obvious variation among individuals. The set of temperaments proposed first by Hippocrates, and later elaborated by Galen, referred to variation in affect and action profiles that contemporary scholars might call extroversion, frustration tolerance, energy level, and neuroticism. Galen called them sanguine, choleric, phlegmatic, and melancholic. These four temperamental types were created by crossing the natural properties of warm versus cool and dry versus moist, which were presumed to be based on the balance, within each individual, of blood, phlegm, and yellow and black bile. The melancholic was dry and cold because of an excess of black bile; the sanguine individual was hot and moist because of excess blood. Despite the apparent crudity of these ideas, they contain the two current features of the term "temperament"; namely, inherited biologies that influence characteristic moods and behaviors.

Although many American psychologists and psychiatrists minimized the influence of biology on behavior from 1910 to the late 1950s, scholarly return to this topic accelerated following the writings of [Thomas and Chess \(1977\)](#) and remarkable discoveries in the neurosciences. Psychiatrists and psychologists now appreciate that genetic variation can affect the function of many molecules, as well as the structure of microanatomic circuits, which modulate psychological function.

These facts have led to the reasonable suggestion that the term "temperament" refers to the many sources of variation in affect, mood, and action influenced by genetic processes that emerge early in life. The large number of molecules that affect the central nervous system guarantees that there will be a large number of temperaments. Some are obvious, like an active or a fearful child; some are subtle. For example, the concentration of neuropeptide Y in the medulla, which is believed to be heritable, influences cardiovascular function and, therefore, has implications for an individual's feeling tone ( [Stornetta et al., 1999](#)). However, the history and culture of the individual determine the interpretation imposed by someone who is experiencing feedback from the heart.

The context of development always influences the expressed behavioral phenotype. American adolescents who possess a temperament marked by relaxation, low level of arousal, minimal fear to novelty, and high sociability are likely to become leaders and vocational successes if raised in middle-class homes that reward achievement. However, children with the same temperament have a higher probability of becoming delinquents or criminals if raised in broken homes in economically disadvantaged urban ghettos. Two different personality outcomes can emerge from the same initial temperamental bias. All adult personality profiles are combinations of initial temperaments combined with the effects of experience. The only time one might come close to detecting a temperamental bias relatively free, but never completely, of experience is in early infancy before social encounters have had a chance to shape the biological disposition into a personality trait.

There have been two different approaches to the study of temperaments in infants and young children. One group of investigators adopts an empirical strategy unconstrained by strong theoretical biases. A much larger group of scientists, who adopt an a priori style, posits abstract categories based on theoretical assumptions.

[Thomas and Chess \(1977\)](#), for example, define temperament as the style of a person's behavior. [Goldsmith and Campos \(1990\)](#) regard temperament as a set of processes that modulates an emotional profile. [Cloninger \(1987\)](#) believes that the avoidance of danger, seeking of novelty, independence, and social rewards constitute primary temperamental types, although these are usually ascribed to adults. [Buss and Plomin \(1986\)](#) posit emotionality, activity, and sociability as the three major temperaments. However, emotionality in this system refers primarily to anxiety, fear, and depression rather than anger, surprise, shame, disgust, or joy. The sociability factor tends to confound a desire to be with people with the feeling of uncertainty or confidence when with unfamiliar people. The activity factor seems to refer primarily to psychological energy because the answers that best define this construct are: "I am very energetic," "I'm always on the go," and "I like to keep busy all the time."

These types are inferred from factor analyses of questionnaires that ask about qualities that can be described with words from everyday conversations; that do not violate most individuals' ethical sensitivities; and that do not probe deep beliefs, loyalty to relatives, or a preference for hot or cold foods (as Chinese psychologists might do). If Nepalese psychologists constructed personality questionnaires, they would have asked different questions and inferred different temperamental types.

Moreover, a temperamental factor cannot emerge from factor analyses unless there are a large number of questions that reflect the same type. If, for example, there is only one question that measures a significant but rare characteristic and the answer to that question is not correlated with others, it will not emerge as a temperamental factor. A factor analysis of the symptoms of all adult diseases would reveal factors for respiratory problems, cancer, and cardiovascular illness because each has a large number of correlated symptoms. Glaucoma would probably not emerge as a factor because it is less frequent and has a smaller number of symptoms. Although the work of the past 30 years has been useful, new strategies are necessary.

The definition of a personality trait as a stable disposition that is influenced by temperament is unduly permissive and could include unusual musical or athletic ability. Most scientists and clinicians do not regard these talents as having a temperamental contribution because of the implicit consensus that affect states are a salient component of every temperament. Musicians and athletes do not possess a particular set of affective states.

There is also implicit agreement that categories of psychopathology are not the products of temperamental biases, even though they are stable, under genetic control, and can emerge during childhood. For example, Williams' syndrome is not a temperamental category, despite the fact that it is owing to a chromosomal anomaly, because these patients have seriously compromised cognitive abilities. Therefore, the meaning of temperament held by most psychiatrists and psychologists refers to a stable profile of action and mood for which there is variation, a biological foundation, emergence during childhood, and a link to particular affective profiles.

It is likely that future scientists will parse the term "temperament" into different categories depending on the source of the biological variation, whether the varied brain neurochemistries, microcircuitry, or a combination of both. However, those categories remain unknown; hence, this chapter reviews what scientists have learned and accommodates to the concepts and methods characteristic of past research.

### THREE APPROACHES TO THE STUDY OF TEMPERAMENT

## Thomas and Chess

An important reason for the return of interest in temperament after World War II was the influential work of Alexander [Thomas and Stella Chess \(1977\)](#). These psychiatrists conducted lengthy interviews regularly with well-educated parents of young infants and used these data to infer nine temperamental dimensions. The nine dimensions refer to activity level, regularity of bodily functions (especially hunger, sleep, and elimination), initial reaction to unfamiliarity (particularly approach-withdrawal to unfamiliar objects or people), ease with which the infant adapts to new situations, responsiveness to subtle stimulus events, the amount of energy in the infant's behavior, dominant mood (especially whether the child is primarily happy or irritable), distractibility, and attention span-persistence. Reflection on these dimensions, supplemented by factor analytic work, motivated them to infer three more abstract profiles that they regarded as categories. The easy child, the most frequent type and comprising about 40% of their sample, has regular body activity and approaches unfamiliar objects and people with a happy mood. The second category, comprising about 15% of their sample, is slow-to-warm-up to strangers and does not adapt easily to change. The third category, about 10% of their sample, is called difficult. These children show minimum regularity, are frequently irritable, tend to withdraw from unfamiliar events and people, and are poorly adapted. These children were most likely to develop psychiatric symptoms during later childhood and adolescence.

When Thomas and Chess evaluated these subjects during early adulthood, using interviews and questionnaires, they found no relation between the possession of an easy or difficult temperament during the first two years of life and later adult adjustment, although those who had been classified as difficult during the preschool years seemed less able to cope with stress than others. Finally, Chess and Thomas introduced the important concept of goodness of fit, meaning a match between the temperament of the child and the family's notions of the ideal child. They suggested, correctly, that investigators and clinicians must know the match between the family ideal and the child's temperament in order to predict future personality development and the emergence of possible pathology.

## Mary Rothbart

Mary [Rothbart's \(1988, 1989\)](#) bold ideas penetrate contemporary discussions of infant temperament. Rothbart believes that infants vary on two primary temperamental dimensions, which she calls ease of arousal (or reactivity) and self-regulation. The signs of reactivity include both motor behavior and physiologic responses. Self-regulation refers to the processes that modulate (either facilitate or inhibit) reactivity, and they include attention, approach, withdrawal, attack, inhibition, and self-soothing ([Rothbart, 1989](#)).

The notion of ease of arousal is intuitively attractive. Infants differ in their reactivity to stimulation; indeed, even fetal movements are moderately stable over gestational weeks 20 through 35 ([Eaton and Saudino, 1992](#)). Rothbart suggests that the specific origin of the arousing stimulation, whether visual, auditory, or olfactory, is relatively unimportant in classifying an infant as high or low in reactivity. However, this claim is vulnerable to challenge because 4-month-old infants who cry in fear to a recording of an unfamiliar woman's voice without the visual support of a face are different behaviorally in the second and third years from 4-month-old infants who cry to a moving mobile but not the female voice ([Kagan, 1994](#)). [Goldsmith and Campos \(1990\)](#) reported no correlation between the infant's tendency to cry when placed on the visual cliff and to a stranger.

In addition to the importance of the incentive stimulus, the behavioral signs of reactivity are important in judging an infant's ease of arousal. Infants usually vocalize to an auditory stimulus but cry and struggle when their arms are restrained. Thus, one potential problem with the abstract concept "ease of arousal" is that it ignores both the nature of the arousing stimulus and the specific behavior provoked.

The concept of self-regulation also has problems because most infants do something when arousing event occurs; therefore, infants self-regulate to varying degrees. A 1-year-old child who retreats to his parent when a stranger enters the room may be different temperamentally from one who displays a wary face but does not retreat, even though both children are regulating the uncertainty generated by the approach of the stranger. The data suggest that the former child is more fearful in the second year than the latter. Further, it is not clear whether a child who cries to a stranger, compared with one who does not, is less able to regulate fear or is simply more fearful.

Although self-regulation appears to be a useful way to describe the infant, it may be less appropriate for older children because the cause of an emotional reaction in older children is not an external stimulus, but a cognitive interpretation. Most 2-year-old children freeze and stare when an adult dressed as a clown enters a room where they have been playing because the clown is a discrepant event, not because it is an intense stimulus. Further, it is not obvious that the immobility is a self-regulating reaction for the freezing in place may not reduce the child's level of arousal or uncertainty. Indeed, staring at the clown while clutching at the mother's hand might increase the child's level of uncertainty.

The construct of regulation is related to Freud's suggestion that humans seek quiescence and a low level of internal arousal. It is surprising that this idea remains popular, for children prefer to run rather than to sit and to explore rather than to play quietly. Freud made the idea of nervous energy—*vis nervosa*—more attractive to most readers at the turn of the 19th century when he replaced the concept of "depletion of *vis nervosa*," which 19th century physicians believed caused symptoms, with the concept of anxiety.

Because anxiety is obviously unwelcome, any coping response could be called a regulation or defense. This notion, which remains popular among psychiatrists and psychologists, renders the concept of self-regulation appealing.

## Jerome Kagan's Concepts of Inhibited and Uninhibited Children

Avoidance of or approach to novelty and challenge, a concept similar to the Thomas and Chess category of slow-to-warm-up and Bates' idea of adaptability to novelty are two popular temperamental characteristics ascribed to children after the first birthday. The empiric evidence is most extensive for sociability versus shyness with strangers.

Longitudinal data from the Berkeley Guidance Study revealed that boys who were very shy in late childhood, compared with their more sociable peers, married, became parents, and established a career later in adult life. Shy girls failed to develop a career and terminated work once they married or had a child but, unlike the males, married at normative times ([Caspi et al., 1988](#)).

Over 1,000, 3-year-old New Zealand children were rated on a variety of characteristics following a 1-hour interaction in a laboratory. About 15% of the sample was very shy, whereas 30% were sociable. Fifteen years later, at age 18, the subjects filled out a personality questionnaire. The adolescents who had been rated as shy when they were 3 years old described themselves as cautious and likely to avoid dangerous situations ([Caspi and Silva, 1995](#)).

However, it is important to note that a shy posture with children or adults can have different antecedents and, therefore, different meanings. A 4-year-old child in a social setting might play alone because the child: (a) is uncertain in an unfamiliar setting, (b) is concerned over being evaluated by the other children, (c) prefers to play alone, or (d) has experienced traumatic fear-arousing encounters with other children and therefore has a conditioned avoidance to peers. The research of Rubin and his colleagues is exemplary. [Rubin \(1993\)](#) makes a distinction between the child who plays alone and shows signs of anxiety, and an equally solitary child who is actively engaged in activities and does not show signs of anxiety. Both types are stable over time, but the former more often stare at peers and resemble children called behaviorally inhibited ([Coplan et al., 1994](#)).

[Kagan \(1994\)](#) invented the temperamental categories of inhibited and uninhibited to the unfamiliar to capture the differences between these two types of children. The former profile, which emerges in the second year, is characterized by avoidance and suppression of spontaneity to unfamiliar objects, people, and situations. It is important to note that shyness with strangers is only one feature of the category of inhibition. Inhibited children react to many different forms of unfamiliarity with avoidance, distress, or subdued emotion as they pass the first birthday and the developmental stage when discrepancy elicits uncertainty. The contrasting group, called uninhibited, is characterized by approach behavior to the same unfamiliar events. These behaviors are easily quantified, have been observed in animals, emerge early in development, and have implications for later social behavior and therefore adaptation.

## LONGITUDINAL STUDY

A large group of 4-month-old, middle-class, white infants were administered a series of visual, auditory, and olfactory stimuli ([Kagan, 1994](#)). About 20% of the infants showed vigorous motor activity, muscle tension, and frequent crying to the battery of unfamiliar stimuli. It is assumed that these infants, called high reactive, were born with a low threshold of excitability in the amygdala and its projections to the bed nucleus, ventral striatum, hypothalamus, cingulate, central gray, and brain stem.

About 40% of infants display low levels of motor arousal and minimal irritability to the same battery. These infants are called low reactive, and we assume that they were born with a high threshold of excitability in the amygdala and its projections. Of the 450 infants assessed at 4 months old, 250 of these children were evaluated again when they were 14 and 21 months old. The children came to the laboratory and were exposed to a variety of unfamiliar events including social and nonsocial incentives. About one-third of the high reactive infants were extremely fearful or avoidant, whereas only 3% were fearless. By contrast, one-third of the low reactives were fearless in the second year and only 4% showed high levels of fear. Thus, high versus low reactivity in infancy predicts an inhibited versus uninhibited profile in the second year. At 4½ years of age, the high reactives were emotionally subdued; they talked and smiled infrequently compared with the low reactives while they interacted with an unfamiliar woman examiner.

The two groups also differed in their social behavior with two other unfamiliar children of the same sex and age while the trios of children played in a laboratory playroom with all three mothers present. About two-thirds of the children who had been low reactive, but less than 10% of those who had been high reactive, were very sociable with the unfamiliar peers. However, 40% of the high reactives but only 10% of the low reactives were very shy.

These children were seen again when they were 7½ years old. First, questionnaires and telephone interviews with the mothers and teachers of the children were used to determine which children met criteria for anxious symptoms such as fear of harm, dark, animals, separation, and extreme shyness with strangers. Forty-three children who were classified as having anxious symptoms were compared with 107 control children from other temperamental groups who did not meet criteria for either anxiety, conduct disorder, or attention deficit disorder. The children who had been high reactive infants were most likely to have developed anxious symptoms—45% of high reactives, compared with only 15% of low reactives, had such symptoms. The best predictor of the development of anxious symptoms was the 4-month temperamental profile of high reactivity and not level of fearful behavior in the laboratory at 14 and 21 months of age.

Assessment at 13 years of age of another independent cohort of inhibited and uninhibited children, selected originally at 21 or 31 months, revealed that 61% of those who were inhibited in the second year, compared with 27% of those who were classified as uninhibited, were diagnosed as having social anxiety ( [Schwartz et al., 1999](#)). These two groups did not differ in degree of performance anxiety, separation anxiety, or specific phobias, suggesting specificity between possession of an inhibited temperament in early childhood and risk for later social anxiety during adolescence.

However, only 18% of the high reactive infants were consistently inhibited over all of the assessments; that is, they showed a high level of fear at 14 and 21 months, shy behavior with unfamiliar children at 4½ years of age, and anxious symptoms at 7 years. But, not one high reactive infant developed the complementary profile of consistently uninhibited, bold, and fearful behavior from 14 months through 7 years. By contrast, 29% of the low reactive infants were fearless in the second year, extremely sociable at 4½ years, and had no anxious symptoms at 7 years; only one low reactive infant developed a consistently inhibited profile. The infant temperaments of high and low reactivity constrain seriously the likelihood of developing the opposite temperamental profile.

The 23 high reactive infants who developed anxious symptoms were different from the 27 high reactives who did not have such symptoms with respect to facial skeleton, diastolic blood pressure, and magnitude of cooling of the temperature of the fingertips while listening to a series of digits they had to remember. The last two reactions imply a more reactive sympathetic nervous system. The magnitude of asymmetry in the skin temperature of the fingertips of the index fingers of the left and right hands is an index of sympathetic reactivity. A large asymmetry is the result of differential constriction of the arteriovenous anastomoses in the fingertips. The index fingers usually have much larger temperature asymmetries than the other fingers, and the asymmetry typically favors a cooler left hand. The high reactives had larger asymmetries than the low reactives.

The suggestion of greater sympathetic reactivity for high reactives is also supported by the fact that inhibited, compared with uninhibited, 5- and 7-year-old children showed greater pupillary dilation, greater cardiac acceleration, and larger changes in blood pressure to appropriate stressors. Moreover, more high compared with low reactive infants had high fetal heart rates (over 140 bpm) a few weeks before birth and higher 2-week sleeping heart rates while being held erect. Spectral analysis of the infants' sleeping heart rates while erect revealed that high, compared with low, reactive infants had greater power in the low frequency band (between 0.02 and 0.10 Hz). This result, too, suggests greater sympathetic reactivity among high reactives ( [Snidman et al., 1995](#)).

The fact that the spatial skeleton differentiated the anxious from the nonanxious high reactives is in accord with an earlier report revealing that the 14- and 21-month-old infants in this sample who had a narrow facial skeleton were more fearful in the second year than those who had broad faces ( [Arcus and Kagan, 1995](#)). These results imply that the genes that control the growth of the bones of the upper face, which are derivatives of the neural crest and therefore ectodermal in origin, are correlated with the genes that contribute to the development of inhibited behavior.

#### CEREBRAL ASYMMETRY

There is considerable evidence to support the hypothesis that the right frontal area participates more fully in behaviors linked to unpleasant emotional states. Further, visual events symbolic of threat or harm are perceived more accurately, produce larger autonomic reactions, and a larger negative wave at 400 msec in the event-related potential when presented to the left visual field ( [Roschmann and Wittling, 1992](#); [Wittling, 1990](#)). One measure of degree of asymmetry of frontal activation is the difference in degree of desynchronization of alpha frequencies in the electroencephalogram (EEG). Young children who are confronted with a stressful event that increases uncertainty (e.g., maternal absence) show greater activation on the right, compared with the left, frontal area ( [Dawson et al., 1992](#)). In addition, inhibited, compared with uninhibited, children in the third year of life showed greater EEG activation on the right frontal area under resting conditions ( [Davidson, 1994](#)), and high reactive infants who become inhibited at age 2 showed greater activation of the right frontal area at 9 and 24 months ( [Fox et al., 1994](#)).

An unpublished evaluation of our longitudinal sample at 10 years of age corroborates this claim. Asymmetry of alpha power in the EEG during baseline conditions revealed that more high than low reactives had greater activation on the right, compared with the left, frontal area at 10 years of age. Moreover, girls who showed greater activation on the right side were emotionally subdued as they interacted with a female examiner.

The basis for the asymmetry in desynchronization of alpha frequencies is unclear. It could be due either to an asymmetry in projections from limbic or brain stem areas to each of the hemispheres or to inherent differences in intrahemispheric patterns of arousal. In any case, it appears that greater EEG activation on the right compared with the left frontal area is associated with an inhibited style.

#### BRAIN STEM REACTIVITY

An intriguing characteristic of the 10-year-old children who had been high reactive infants involves the brain stem auditory evoked potential (BAER). The Wave 5 component of the BAER is generated by the inferior colliculus to a series of clicks. Activity in the amygdala can influence the excitability of the inferior colliculus and, as a result, produce a Wave 5 magnitude greater than the typical mean of about 0.3 to 0.4 mv. The high reactives, as a group, had a significantly larger Wave 5 component than low reactives ( [Woodward et al., 2000](#)). This result implies greater amygdala activity in the high reactive group.

However, some high reactives who were fearful in the second year and had a large Wave 5 were not exceptionally shy in the laboratory at 10 years of age and told an interviewer that they were neither shy nor anxious. This fact suggests that there can be dissociation between the biological processes that are the presumed foundation of a temperamental category and the contemporary behavioral phenotype.

The possibility of a dissociation between physiology and behavior is illustrated in the data from one high reactive girl who was highly fearful at 14 months, moderately fearful at 21 months, and one of the girls who cried in reflex fear when, during the 21-month assessment, a person dressed as a clown entered the room where she was playing. This 10-year-old girl had the largest frontal asymmetry value, favoring a more active right side, of the entire sample of over 100 children and displayed a Wave 5 value in the 99th percentile. But this girl was relaxed and spontaneous in the laboratory and appeared to the examiner and staff as a mature 10 year old who showed minimal behavioral signs of uncertainty or tension.

Jung acknowledged this distinction between internal biology and external phenotype when he differentiated between *anima* and *persona*. These data remind us that experience can change an early temperamental profile characterized by fear and linked to the excitability of the amygdala to a more normative profile without eliminating completely the excitability of the limbic structures that were the foundation of the infant behavior.

The data from this longitudinal study permit an evaluation of the accuracy of the maternal description of their children's behavior. The mothers of the 10-year-old children were interviewed and, as part of the interview, completed a Q-sort of their child for aspects of inhibited behavior (e.g., becomes quiet in unfamiliar places, is shy with other children and adults, worries about the future), as well as items for uninhibited behavior (e.g., makes friends easily, is easygoing, is a leader with peers, likes to try new things, remains cool under pressure). We compared the contemporary and longitudinal data for the high and low reactives who were described by

their mothers at 10 years of age as equally uninhibited. The children who had been high reactive were more fearful in the second year and, at age 10, had higher resting heart rates and were more subdued with the examiner compared with the low reactives. Thus, the maternal descriptions did not reflect the child's history or behavior in the laboratory.

## HERITABILITY

The profiles of inhibited and uninhibited to the unfamiliar appear to be heritable. Identical twins are more similar in their display of inhibited or uninhibited behavior during childhood than fraternal twins ([Emde et al., 1992](#); [Matheny, 1983, 1990](#)). The heritability of these two temperamental categories at 14 and 21 months, based on direct observations, was between 0.5 and 0.6 ([Saudino and Kagan, 2001](#)). It is relevant that adult social anxiety is three times more frequent in the first-degree relatives of patients with social phobia than in the first-degree relatives of controls.

Although genes make a modest contribution to both infant reactivity and inhibited and uninhibited profiles they also share power with experience. Over one-third of infants who had been high reactive were not exceptionally fearful in the second year and a few were fearless. Observations in the homes of 50 high and 50 low reactive, first-born infants revealed that the mother's behavior with the infant affected the probability that a high reactive infant would become an inhibited toddler. A nurturing parent who consistently protected her high reactive infant from all stressors made it more, rather than less, difficult for that child to control an initial urge to retreat from strangers and unfamiliar events. Equally loving mothers who set firmer limits for their children, by making age-appropriate demands for cleanliness and conformity, helped their high reactive infants overcome their tendency to become inhibited ([Arcus, 1991](#)). Thus, the envelope of the developmental trajectories for these two temperamental groups is not fixed. A child's experiences can mute or enhance an initial temperamental disposition. Infants born with a physiology that biases them to be high reactive at 4 months, but who subsequently experience a supportive environment that helps them overcome fear, need not become timid, shy, inhibited children.

## SOURCES OF EVIDENCE

It is a truism that the meaning of all scientific statements is a function of the sources of evidence. This maxim is also true of the work in temperament. Thomas and Chess recognized that their nine temperamental dimensions and three temperamental categories were a partial function of the nature of their evidence, which consisted primarily of interviews with parents. [Akson and colleagues \(1999\)](#) extracted two types they called temperamental from maternal verbal descriptions of 488 children at both 3½ and 4½ years of age. Application of the statistical technique called configural frequency analysis revealed that about 10% of the sample was low on control of behavior and high on both approach to novelty and irritability—these children could be similar to the Chess and Thomas category of “difficult child.” The second temperamental type, also about 10% of the group, showed the opposite profile of high control combined with low values on approach behavior and irritability—these children seem to be highly socialized and well behaved. Extremely shy compared with sociable children (inhibited or uninhibited children) were not represented in these two categories. This excellent investigation illustrates the earlier statement that all scientific claims depend on the methods used.

The strategy of asking parents to describe their children is reasonable when psychologists are initially probing a complex area. Unfortunately, parent report, whether interviews or questionnaires, is vulnerable to a number of serious biases. The most obvious is the fact that parents typically focus on qualities most relevant to the ease or difficulty of caring for the child, and these qualities may not be components of the most important temperaments.

Verbal reports, whether answers in interviews or check marks on a questionnaire, are characterized by special features that are not characteristic of the natural phenomena that the sentences are supposed to describe. First, human languages are not particularly good at describing internal feeling states. Words such as afraid, happy, and angry fail to provide information on cause, intensity, or duration. The primary function of language is to communicate information about the world, tell others how to perform skilled actions, and communicate rules of conduct. Most words describing behavior imply a static phenomenon and fail to capture the changing, dynamic nature of many events because humans are concerned with whether or not a particular goal was attained, rather than the cascade of events that led to goal attainment; however, rapid change is a primary characteristic of emotional states.

Second, a problem with verbal report is that individuals usually apply, implicitly, the contrast of good versus bad when they categorize people, objects, and events. Therefore, parents impose an evaluative construction on the behavior of their children that represents what they regard as the ideal. Specifically, a parent who values sociability and does not want a timid child is apt to deny shy behavior in his or her child. This evaluative frame influences a person's answers to all questions.

Third, words have quasilogical relations with each other. The relations between words that are antonyms are one example. The term “sweet and sour” are semantic opposites implying that both sensations could not exist simultaneously, even though there are some prepared dishes that provoke both taste sensations. Further, humans are sensitive to the logical consistency of their answers to a series of questions. A mother who reports that her daughter is usually sad will resist acknowledging that the child is occasionally happy and smiling. There is no such demand for consistency in a person's behavior, physiology, or stream of conscious feelings.

Fourth, most English words and sentences refer to discrete categories, and there are few words with blends. For example, there is no word in English that describes the feeling generated when one hopes for good news about a loved one in the hospital but fears the worst.

Fifth, every sentence has an implicit comparison idea. For example, a parent who reads on a questionnaire, “Does your child like to go to parties?” will unconsciously compare that preference with others. If one parent compares going to parties with an activity that the child dislikes, while another parent compares it with one that the child also prefers, the former is more likely to endorse the item than the latter, although both children might enjoy parties to an equivalent degree.

More important, individuals from different social class and ethnic groups do not always extract the same meaning from a word or sentence. For example, mothers who never attended college describe their infants as less adaptive than college educated parents ([Spiker et al., 1992a](#)). Mothers experiencing stress have a lower frustration tolerance and, therefore, are prone to exaggerate their infant's irritability. Depressed mothers with their first child describe their 6-week-old infants as more irritable than experienced mothers or mothers free of depression ([Greene, 1991](#)).

In one study, the parents of 9-months-old infants were asked to rate their infants on fearfulness, smiling, duration of attention, and activity level. Agreement between mothers and fathers was relatively low for these traits. Agreement was especially low for judgments of activity level because the fathers interpreted high activity to reflect a positive emotional mood, whereas the mothers of the same infants interpreted the word as implying a tendency toward anger ([Goldsmith and Campos, 1990](#)).

More seriously, scientists cannot ask parents about qualities that are not observable. There is a small group of children who are minimally irritable, smile frequently, have a low heart rate, minimal muscle tension, and show greater EEG activation in the left, compared with the right, frontal area. A psychologist evaluating the entire corpus of information would be motivated to invent a new temperamental category to reflect this combination of features. Parents do not have access to the biological information and therefore cannot be asked to rate their children on this temperamental type.

Finally, the order in which questions are asked can influence parent's answers. If a parent is asked first about a child's undesirable qualities, the replies given on the rest of the questionnaire will be different from those given if the first questions asked about the child's positive qualities ([Schwarz, 1999](#)).

These problems with questionnaires and interviews imply that those who rely only on questionnaires to study temperament will be forced to restrict their temperamental constructs to a very small number of easily understood ideas, such as level of activity, shyness, or attentiveness, and will fail to detect many significant temperaments. If Thomas and Chess had gathered extensive behavioral observations on their sample, they would have inferred slightly different temperamental categories.

One set of authors summarized the problems associated with asking parents to describe their children. What is clear from the present results is that current methods have limitations that must be recognized in order to forestall both poor decision making with respect to individual children in a clinical setting and misleading interpretations in research studies ([Spiker et al., 1992b](#)). A personal anecdote is relevant. One mother of a child in our longitudinal study who described her child as outgoing and sociable to one of our interviewers wrote a letter to our staff a few days after she had watched her daughter interact with two unfamiliar girls in one of our laboratory playrooms. This was a real eye opener for me. I always thought my child was outgoing and sociable. I now realize that after watching her that she is actually uncomfortable with new people.

This is not the first time self-reports have been criticized. Over 60 years ago, a team of child psychologists noted a poor relation between what actually happened

during the first year of an infant's life and the mother's descriptions of those events when the children were 21 months old ( [Pyles et al., 1935](#); [Yarrow et al., 1970](#)).

If talking to parents about their children's behaviors and moods were such an accurate source of information, the field of personality development would be one of the most advanced domains rather than one in disarray. Our limited progress implies that verbal statements describing the behaviors of others has some, but limited, value because those statements are partly constructions.

History casts aside popular methods in all sciences. Archaeologists now use carbon dating, not informed intuition, to establish the age of a fossil, and evolutionary biologists quantify blood proteins, in addition to anatomy, when they assign an animal to a species. The recognition that questionnaires and interviews, when used alone, are not sufficiently sensitive indexes of all the important temperamental categories should be regarded as progress. Psychologists and psychiatrists hold a deep unquestioned belief in the validity of what people say about themselves or their children. The serious limitations on verbal report should motivate scientists and clinicians to gather behavioral and biological data in addition to self-reports. New temperaments will be discovered when test performances, biological measures, and direct observations of behavior are added to the information that is gained from questionnaires and interviews.

## ARE TEMPERAMENTS CONTINUA OR CATEGORIES?

The decision to regard a temperament as a continuous dimension or a qualitative category is a controversial, but theoretically significant issue. Thomas and Chess regarded the easy, difficult, and slow-to-warm-up children as representing categories. Rothbart regards reactivity and regulations as dimensions. Most psychologists prefer continua to categories for several reasons. First, the use of inferential statistics is the mark of the sophisticated social scientist. Because correlation coefficients and analyses of variance should be computed on continuous variables, investigators find it useful to assume that the entire range of values for a dependent variable is controlled by the same set of causes and is a function of different natural or experimental conditions. Most statistical procedures, such as regression, assume that the forces that produce the distribution of values for a set of variables vary only in magnitude and act similarly on the entire range of scores.

[Meehl \(1995\)](#), who has written persuasively on the utility of considering some profiles as qualitative categories, has described an analytic technique that rests on the assumption that changing magnitudes of association between two indicators of a personality type with respect to a third indicates whether the population consists of two qualitative types or only one type. Application of this analysis to infant behavioral data from our laboratory revealed that some infants are members of a discrete behavioral category and are not on a continuum with other children ( [Woodward et al., 2000](#)). Latent class analysis is another technique that can be used to detect temperamental categories ([Loken, unpublished](#)).

The most important argument for categories over dimension is that nonlinear functions are common in the life sciences. Unique functional relations between variables often emerge at transition points because a small number of subjects with special qualities possess either high or low levels of a variable. These individuals are likely to be members of a category. One example comes from our laboratory. We examined the distribution of average standard scores for heart period and heart period standard deviation for 200, 14-month-old children during an initial sitting baseline. The distribution was divided into quintiles so that a low score represented a very high and stable heart rate (low vagal tone), while a high score represented a low and variable heart rate (high vagal tone). The frequency of smiling to an adult examiner during the subsequent hour of testing was very similar for the children in quintiles 2 through 5, but significantly less frequent for the children in quintile 1 who had the highest and most stable heart rates. Thus, the relation of heart rate to smiling was nonlinear.

## THE MEANING OF AFFECT

Because every temperamental category has an affect state as one of its features, it is important to appreciate that four different phenomena are often awarded the same emotional label. The affect of anxiety provides an illustration, but the following discussion is relevant to all current emotional concepts.

A person's verbal judgment that he is anxious, but given without the presence of any accompanying change in physiology, is one definition of anxiety. It is common for individuals to say that they are anxious over speaking in public, flying, or their health. But if scientists had measured their physiology at the time they made the statement—or even when they are in a situation they said they feared—they would not have detected any particular change in physiology. Let us call this meaning of anxiety “subjective judgment.”

A second meaning is a subjective judgment of being anxious accompanied by a change in physiology, but not the physiology that scientists believe is appropriate. For example, an individual with a viral infection may feel tense and in an attempt to understand the intrusive bodily sensations might decide that she is worried about her job. Let us call this meaning “constructed anxiety.”

The third meaning is the one scientists who work with animals use most often. An event has provoked activity in the limbic structures that are regarded as appropriate indexes of a state of fear, primarily activation of the amygdala and its projections. However, the individual either does not detect the consequences of these physiologic changes or, if detected, awards them another meaning. Let us call this “physiologic anxiety.”

The fourth referent is the one scientists and clinicians would like to believe occurs when the term “anxious” is applied to a person. An event or thought has provoked the physiologic state that is assumed to accompany anxiety and the individual detects and interprets those changes as implying that they are in an anxious state. Let us call this meaning “anxiety.”

Investigators who use questionnaires and interviews rely on the first meaning of subjective judgment; those who work with animals usually adopt the third meaning of physiologic anxiety. There is probably minimal correspondence between these two meanings. That is, the state ascribed to a rat that freezes in a place where it experienced electric shock may not resemble the state of an adult who reports on a questionnaire that he is afraid of spiders.

In addition, we must differentiate between acute emotions provoked by a transient specific event (being pushed while waiting in a line) and chronic moods that are not reactions to a specific external circumstance. Four different emotional constructs are generated by crossing the distinction between detected versus undetected changes in physiology with the distinction between acute emotions and chronic moods. Each of these four phenomena requires a different name. An adult or child temperament usually refers to a chronic mood based on a physiology that is not always detected by the individual.

One reason why there can never be a determinant relation between an underlying biology and a temperamental profile is that historical and cultural contexts influence the interpretation the adolescent or adult imposes on detected changes in physiology. The journals of the writer John [Cheever \(1993\)](#), who died in the second half of this century, and the biography of William James' sister, Alice James ( [Strouse, 1980](#)) who died 100 years before, suggested that both writers inherited a very similar diathesis that favored a melancholic, dysphoric mood; however, Cheever acquired his premises about human nature when Freudian theories were popular. As a result, he assumed that his dour mood was owing to his experiences during childhood, and he used psychotherapy to overcome the conflicts he imagined his family had created.

Alice James believed, with most of her contemporaries, that her dour mood was owing to her inheritance rather than the way she was treated. After trying many forms of somatic therapy, she concluded that because she could not change her genes she wished to die. The historical context of these two creative individuals influenced the interpretation each imposed on their feelings, the coping strategies they selected, and the quality of their emotional lives.

The effect of culture on the interpretation of one's feelings is seen in the comparison of American social phobics, who say why they avoid social situations in order to prevent feeling anxious and embarrassed over being evaluated by others, and Japanese patients, who suffer from what Japanese psychiatrists call “tiajin-kyo-fusho.” The Japanese patients, too, avoid unfamiliar people and social gatherings. However, the Japanese patients explain their behavior by saying that they do not want to cause any psychic disturbance to others. Cultures also influence the content of obsessions. The obsessive thoughts of American patients with obsessive-compulsive disorder usually focus on dirt, contamination, and aggressive and sexual intentions. The most frequent obsessions of patients living in communities in the Middle East involve religious ideas, such as blasphemy, because loyalty to the Islamic faith is a central concern in these regions.

## OTHER TEMPERAMENTS

### Infant Irritability

Variation in infant irritability, which dominates most discussions, is a popular target of study because the referent is obvious, easy to measure, of concern to American

parents, and moderately stable over time.

Differences in the frequency and duration of crying are preserved over the first few months. Irritable newborns smiled and vocalized less often to adults at 4 months than nonirritable newborns ([Birns et al., 1969](#)). Irritable infants, especially those who also show vigorous motor activity to stimuli, often develop a reserved, fearful style in the preschool years.

However, variation in infant crying is not always predictive of later behavior because the bases for the behavior change. A low threshold of responsivity to stimulation causes irritability in the infant. Irritability in a 1-year-old child is influenced in a more important way by reactivity to discrepancy. The major reasons for crying among 3-year-old children include frustrations and parental rewards for crying. Thus, investigators should not be surprised that the predictive correlation between irritability at 1 month and 3 years is low.

### Smiling

Smiling is a less frequent target of study than crying because it is less salient to parents and has no analog in animals. However, variation in this response appears to be heritable ([Freedman and Keller, 1963](#)), stable from 3 months to the end of the first year ([Kagan, 1971](#)), and infants who show greater EEG activation in the left frontal area, compared with the right, are more likely to smile ([Fox et al., 1994](#)).

The tendency to smile to nonsocial stimuli might be a component of temperament. [Kagan \(1994\)](#) observed over 500 4-month-old infants who were exposed to visual, auditory, and olfactory stimuli. Only 10% of this group smiled at least three times during the 45-minute battery. Although three smiles may seem relatively low, that value represented the 90th percentile of the distribution. When these smiling infants were matched on gender and level of motor arousal and irritability with infants who did not smile, the former group had significantly lower sitting diastolic blood pressure when they were 2 years old. This fact suggests that the high smiling infants may also inherit low sympathetic tone in the arterial tree.

### Activity Level

Level of activity, which Thomas and Chess nominated as a temperament, has one meaning when it refers to the vigorous moving of limbs, but a different meaning when children have attained motor coordination after the first birthday. Because the form and vigor of limb activity change a great deal over the first 2 years, it is not surprising that investigators do not find preservation of variation in activity level ([Dunn and Kendrick, 1981](#); [Matheny, 1983](#)). Further, there is no correlation between activity level during the day and level at night ([Korner et al., 1985](#)) and twin studies reveal minimal preservation of activity between 7 months and 3 years ([Saudino and Eaton, 1995](#)). These data imply that a concept of general activity that does not stipulate the age of the child, the context in which activity is being measured, and the time of day may not be useful.

### Attention

The tendency to devote long (or short) bouts of attention to external stimuli might be a temperamental quality. Infants differ in the rapidity of orienting and duration of sustained attention to an object or sound. Neuroscientists posit several attentional networks. One involves the parietal cortex, thalamus, and colliculus, and is modulated by noradrenergic neurons originating in the locus ceruleus that modulate attention to outside events. An anterior attentional network, involving parts of the prefrontal cortex, anterior cingulate, and supplementary motor area, influenced by dopaminergic inputs from the ventral tegmental area and basal ganglia, is more involved in the inhibition of inappropriate responses to a distracting stimulus. A third network mediates maintenance of a vigilant, alert state over a long period of time. The right lateral midfrontal cortex is important for this state and, like the posterior attentional system, is influenced by noradrenergic projections from the locus ceruleus.

Although one study of children from 1 to 3½ years of age revealed stability of variation in attentiveness to varied events ([Ruff et al., 1990](#)), another study, which quantified duration of attention to human faces and forms, revealed no stability from 4 to 27 months and only modest stability from 13 to 27 months ([Kagan, 1971](#)). Because the bases for attentiveness change from prolonged attention to discrepant events during early infancy to the activation of cognitive structures in the second year, investigators should not expect robust preservation of any index of attentiveness from infancy to later childhood.

## PSYCHOPATHOLOGY AND TEMPERAMENT

Temperament makes a contribution to differences among children in their reaction to threatening or stressful events ([Werner, 1993](#)). That is why only a proportion of children develop psychological and/or biological signs of stress to threatening or traumatic events. It is not clear if the temperamental processes that protect against a serious psychological reaction to stress do so by blunting the limbic system's initial reaction to the stressor, shortening the duration of the stressful reaction, or acting directly through inhibitory processes to mute a consciously experienced feeling that is no less intense physiologically than it is in a majority of children.

A child with an inhibited temperament is most vulnerable to the development of social anxiety rather than other types of anxiety disorders. Adults diagnosed with social phobia or avoidant disorder report feeling embarrassed over meeting others they do not know because they fear that strangers will evaluate them as possessing characteristics that deviate from the profile the community regards as desirable. This phenomenology provides a clue to a more fundamental origin of the pathology. All adults know what traits are regarded as desirable by their community and appreciate that strangers and friends evaluate other people with respect to those characteristics. Therefore, we have to explain why a small proportion of the population feel anxious over the fact that others might evaluate them in an undesirable way.

One likely answer is that these patients are experiencing dysphoric body feedback and wish to understand the reason for this feeling. Many are apt to conclude that their behaviors and appearance deviate in an undesirable way from community standards. Social phobia is disproportionately more prevalent among less well-educated women. Hence, it is reasonable to suggest that the women who are vulnerable to dysphoric feelings will conclude that they have fallen short of the society's ideal and, as a result, anticipate embarrassment when they meet strangers who might have a condescending attitude toward them. This description of social phobia implies that a more correct description of the etiology is a vulnerability to dysphoric body tone combined with the belief that one is deviant from the community ideal. An accomplished, attractive individual possessing the same temperament will not feel threatened by meeting strangers and will not become socially phobic.

Most inhibited children will not develop any psychiatric disorder ([Weissman et al., 1999](#)). We estimate that about 15% of children are both high reactive at 4 months and behaviorally inhibited at 2 years. An estimate of the prevalence of an anxiety disorder in older children is about 5%. Thus, about two-thirds of high reactive, inhibited children will not develop a profile serious enough to be characterized by a psychiatrist as an anxiety disorder. Prediction of a shy, restrained introverted personality from early inhibition is the more likely outcome.

Children with parents who have panic disorder are at slightly greater risk than others for becoming inhibited. We gathered behavioral observations on 284 children from 2 to 6 years of age. One group of 129 children had a parent with panic disorder and major depression, 22 children had a parent with panic disorder without comorbid depression, 49 children had parents with major depression but without panic disorder, and 84 control children had parents with neither anxiety nor depressive diagnoses. Behavioral inhibition was most frequent among the children of parents with panic disorder and panic combined with major depression. Approximately 29% of the children of these patients were behaviorally inhibited compared with 12% of controls ([Rosenbaum et al., 2000](#)).

## TEMPERAMENT AND THE MORAL EMOTIONS

Variation in the intensity of the moral emotions of shame and guilt is likely to be influenced by temperamental factors. The experience of these emotions, as an accompaniment to the contemplation or commission of an act that violates personal moral standards, is a continual source of restraint on asocial actions. Even though parental behaviors are important influences on the development of conscience, temperament plays a modulating role. The intensity of the experience of shame and guilt, whose foundations originate in limbic sites and project to the prefrontal cortex, is relevant.

Afferent feedback from the body, which ascends to the medulla and amygdala and arrives at the prefrontal cortex, forms the foundation of a conscious perception of one's internal body tone. Inhibited children, who have a more reactive sympathetic nervous system, might be especially vulnerable to experiencing more salient feedback and therefore more frequent dysphoria. These children are likely to learn, with age, that unfamiliar, asocial, or challenging situations produce an

uncomfortable feeling and, as a result, they will avoid these contexts.

Adolescents will want to understand the reasons for these unexpected feelings of dysphoria. A frequent first guess is that they probably violated one of their ethical standards. The list of moral lapses is so long, few will have trouble finding an ethical flaw to explain the unwelcome feeling and, as a consequence, might become vulnerable to a moment of guilt. The body tone each person lives with is so completely hidden from observers and, at the moment, so far beyond measurement, it does not enter into most theorizing.

[Damasio \(1994\)](#) has described an adult man who lost the ventromedial surface of the prefrontal cortex, which receives information from the amygdala that originates in the heart, gut, and muscles. Without this neuronal surface, individuals cannot experience anticipatory feelings of anxiety. This patient who had been an intelligent and successful adult prior to the surgery began to make impulsive decisions after the surgery despite no change in his measured intelligence.

Low reactive infants, who become uninhibited toddlers, show much less fear to an examiner's criticism compared with those who are high reactive. Further, [Kochanska \(1991, 1993\)](#) has discovered that inhibited children raised by mothers who used reasoning in their socialization developed a relatively strict conscience. Neither the form of maternal socialization nor the child's shyness, considered alone, predicted variation in Kochanska's measure of conscience development.

It is important to appreciate that almost all children are capable of the moral emotions. Although some children inherit a temperament that favors an exaggerated guilt reaction, they need not show pathology in later life. Nor is it likely that most children with a temperament favoring a less intense moral response will become delinquents. Most parents impose appropriate socialization demands on their children. Nonetheless, if the environment is permissive of aggression, stealing, and lying, the child with a temperamental bias for a diluted fear reaction to violations of standards is probably at greater risk for asocial behavior than children with a different temperament growing up in the same circumstances.

A small group of low reactive boys with high vagal tone—about 15% of boys—are a special temperamental group. If these boys grow up in typical American middle-class homes with accepting parents who socialize control of aggression, they become popular and often group leaders; however, the same boys raised by parents who are less consistent in their socialization of aggression are at higher risk for delinquency. Antisocial adolescents who show minimal autonomic reactivity (low heart rate and less frequent skin conductance reactions) are more likely to continue a criminal career than equally asocial youth with normal autonomic tone ([Raine et al., 1990](#)). It is possible that the small group of criminals who commit violent crimes possess a special, but rare temperament. A longitudinal study revealed that violent, young, New Zealand adults were likely to have been rated at ages 3 and 5 as having low control of their behavior (Henry et al., personal communication). However, a minority of impulsive, minimally fearful 5-year-old boys become adolescent delinquents. Their teachers had rated only 28% of high delinquent boys 8 years earlier as asocial ([Tremblay et al., 1994](#)). It is likely that most groups of asocial adolescents contain only a small proportion born with a temperament that placed them at risk for this profile.

## ETHNICITY AND TEMPERAMENT

Differences in temperament among varied ethnic groups remain a delicate issue because of racial and ethnic strife in America and around the world. A team of scientists compared the frequencies of over 100 different alleles for physiologic markers in the world's geographically separate human populations and averaged the differences in frequencies to create an index of genetic distance between pairs of populations ([Cavalli-Sforza et al., 1994](#)). The index of genetic distance was largest when Asians, Africans, and European-Caucasians were compared with each other. But even within European samples, individuals from Scandinavia, England, and Northern Europe were genetically different from those living in Spain, Italy, and the Balkans. The greater the geographic and linguistic distance between any two populations and therefore the greater the reproductive isolation, the greater the genetic distance. It is reasonable to assume that some of the alleles measured in this analysis make a contribution to temperament.

The most consistent set of evidence on early infant temperaments involves comparisons of Asian and white infants. Over 30 years ago, [Freedman and Freedman \(1969\)](#) reported that newborn Asian-American infants, compared with European-Americans, were less labile and more easily consoled. A decade later, [Kagan and associates \(1978\)](#) found that Chinese-American infants living in Boston, Massachusetts, were less active, less vocal, less likely to smile to stimulation, and more inhibited during the first year, compared with European-American infants from the same city. [Kagan and colleagues \(1994\)](#) administered a battery of visual, auditory, and olfactory stimulation to 4-month-old infants living in Boston; Dublin, Ireland; and Beijing, China. The white infants from Dublin and Boston were more easily aroused and distressed than the Chinese infants born in Beijing. It is important that Asian-American adult psychiatric patients require a lower dose of psychotropic drugs than European-American patients ([Lin et al., 1986](#)), implying that Asian populations may be at a lower level of limbic arousal. It is likely that when the genome project is completed, researchers will find that reproductively isolated human populations differ on alleles that contribute to temperament.

## TEMPERAMENT AS CONSTRAINT

Although relations between variables are always contingent, the tightness of any relation varies over a broad range of probabilities, from the near perfect relation between the force with which a stone is thrown and the distance it travels to the far from perfect relation between an infant's Apgar score and grade point average in high school. When the probability of one event following a prior one is high (e.g., about 0.7), it is reasonable to conclude that the prior event influenced the latter one directly. But when the probability is low (perhaps less than 0.4), it is likely that the prior event affected the later one indirectly, only for extreme groups, or in combination with other factors. When this is the case, it is more correct to use the verb "constrain" rather than "determine" to describe the effect of a prior factor on a subsequent one. Only 18% of the children who were high reactive infants became fearful in the second year, very shy at 4½ years, and developed anxious symptoms at 7 years. However, not one high reactive infant developed a complementary profile. Because more than 70% of high reactive infants did not become consistently inhibited and anxious, it is misleading to argue that a high reactive temperament determines a consistently inhibited profile and more accurate to suggest that the high reactive temperament constrains the probability of becoming a consistently uninhibited child. The term "determine" implies a particular developmental course, whereas "constrain" implies a restriction on a particular set of future outcomes. The human genome does not determine any particular psychological outcome. For that reason, we should regard each temperamental bias as imposing a constraint on the probability of developing a particular family of profiles, rather than assume that each temperamental bias determines the development of particular traits.

## EPILOG

Because every individual possesses a unique biology, some might contend that every adult profile contains one or more temperamental contributions. However, it is more profitable in this early stage of understanding to limit the term "temperament" to demonstrated predictive relations between behavioral and physiologic profiles appearing early in life that are preserved, theoretically reasonable, and predictive of a feature in adolescent or adult personality. The adolescent's personality is not a temperament because it is the product of a dozen years of experience.

The evidence implies that high and low reactivity in infancy are probably valid temperamental categories. The data are adequate enough to suggest that irritability, activity, and frequency of smiling and laughter are also temperamental categories. An important task is to find the physiologic foundations of these temperaments.

Finally, although temperamental biases affect the development of psychiatric disorders, each current diagnostic category in *Diagnostic and Statistical Manual*, fourth edition (DSM-IV) is biologically heterogeneous. The assignment of patients to their proper diagnostic group will require the gathering of biological and behavioral data, in addition to the evidence gleaned from psychiatric interviews. Adoption of this strategy by clinicians and investigators will help psychiatry make the progress that the larger community needs and expects.

The modern concept of temperament was introduced by Alexander Thomas and Stella Chess, in the 1950s, motivated to improve our psychiatric diagnostic and treatment skills. The theoretical and clinical relevance of temperament is now accepted in psychiatry, psychology, and pediatrics, as well as education and other child- and adolescent-related fields. In this chapter, we present the history of the New York Longitudinal Study (NYLS); discuss the applications of temperament, theoretical considerations, and controversies; and update recent work.

## BASIC FINDINGS, UNDERLYING CONCEPTS, AND IMPLICATIONS OF TEMPERAMENT

Our interest in the study of temperament arose primarily from our practice in the 1940s and early 1950s. The dominant theoretical formulations attributed exclusive etiologic importance for both healthy and pathologic psychological development to environmental forces. For most the individual differences in behavioral style, evident even in the neonate and young infant; with few exceptions, these were ignored, minimized, or categorized as secondary reactive effects of the caretakers' attitudes and practices.

As clinicians, however, we saw many cases in which this one-sided environmentalist approach could not explain adequately the child's, adolescent's, or adult's personality structure or developmental course. Something was missing. We hypothesized that children took an active as well as reactive role. Development then would reflect the continuous dynamic interaction between the individual and environment at all ages.

These clinical experiences made it imperative to initiate a systematic study of individual behavioral styles. The literature revealed many pertinent reports of specific aspects of behavioral individuality, but none that had attempted a systematic comprehensive study of this phenomenon or provided a methodology adequate for such an endeavor (Thomas et al., 1968). It was clear to us that a prospective longitudinal study was required, from which we could gather data of sufficient scope and pertinence to test our hypothesis; therefore, we launched the NYLS in 1956.

We conceptualized temperament as representing the *how*, or style of behavior, as contrasted to the *why*, or motivations and goals of behavior, and the *what*, or perceptions, abilities, and talents of the individual. Two children may dress themselves or ride a bicycle with the same dexterity and have the same motives for engaging in this behavior. Two adolescents may display similar learning ability and intellectual interests, and their academic roles may coincide. Two adults may show the same reason for devoting themselves to their jobs. These behaviors reflect their motivations and abilities. Yet these two children, adolescents, or adults may differ significantly with regard to the quickness with which they move; the ease with which they approach a new physical environment, social situation, or task; and the effort required by others to distract them when they are absorbed in an activity. These variations reflect differences in their temperament characteristics. Or, in other instances, temperaments may be similar, and abilities or motivations may differ. This analysis of behavior into the *how*, *why*, and *what* also had been suggested by several developmental psychologists, especially Cattell (1950) and Guilford (1959), and a number of important studies of motivations and abilities had been undertaken; however, investigations of the nature and significance of temperament and the relationship of temperament to motivations were still lacking.

### Methodology

Our research into temperament required an anterospective longitudinal study, gathering behavioral data on the same group of children at sequential age periods. Cross-sectional studies cannot trace the developmental course of individual subjects over time. Only a longitudinal study, which follows the developmental course of the same group of subjects over time, can hope to explore individual patterns of change and continuity and their meaning.

A prospective study, in which data are collected at the time or very close to the time of their occurrence, also is essential. Studies have revealed significant distortions in the accuracy of parents' retrospective reports on the early behavioral history of their children, even when development has been normal (Haggard et al., 1963; Robbins, 1963; Wenar, 1963). The problem is the same with adults' recall of their earlier life. Vaillant reports this vividly from his findings of the Harvard Grant Study:

How then may we obtain truth about the adult life cycle? Clearly, it must be studied prospectively. It is all too common for caterpillars to become butterflies and then to maintain that in their youth they had been little butterflies. Maturation makes liars of us all (Vaillant, 1977, p. 197).

### The Parent as a Source of Research Data

In starting the NYLS, we had to determine the nature and source of our raw data. It became evident that the primary child caregivers, usually the parents, were indeed a unique and comprehensive source of information on their infants' behavioral styles. The parents, with their continuous involvement with their infants, could observe and report to us on details of their babies' behavior within all the routines of daily life, the child's sequence of reactions to anything new and different—the first bath, a new food, a stranger, an illness, a move to a new home. An outside observer coming into the home for a few hours could catch only a slice of the overall behavioral repertoire of the child and that slice might not even be typical if some unusual situation and stimulus had just occurred.

To avoid parental bias, our interview protocol focused on detailed, factual, and descriptive items of behavior, especially new events. The description of the child's initial reaction to the new was followed by questions such as, "What did you (the parent) do when the baby responded so-and-so?" "How did the baby respond to what you did?" "What did you do next?" and so on until the whole sequence of the child's reaction to the new and the parent's handling of this reaction had been reported. In this way, we obtained richly detailed data not only on the child's behavior but also on the parents' patterns of childcare. Our initial interview with the parents was scheduled when the child was 2 or 3 months of age.

The sample comprised middle- and upper-middle-class families living in the New York area. A homogeneous sociocultural group minimized the influences that could be introduced by substantial sociocultural variability. Our study protocols did include such phenomena as trauma, unusual events, and idiosyncratic parental attitudes. The use of a relatively homogeneous sample provided a baseline for generalizing the findings to other populations of different economic, cultural, and racial status. We initiated a second longitudinal study of 95 children born in New York of unskilled and semiskilled working-class Puerto Rican families. This group was also followed longitudinally from early infancy through childhood, using the same approach to data collection and analysis as in the NYLS. The reports in the discussion that follows are from our major study, the NYLS.

### Data Collection

Our NYLS sample comprised 129 children from 80 families. There was a retention rate of 97% over this 25- to 30-year period with 129 subjects and their parents. Our semistructured parent interviews were conducted at 3-month intervals during the first 18 months of life, at 6-month intervals until 5 years of age, and yearly until 8 or 9 years of age. The subjects and their parents were interviewed separately in adolescence, and the same procedures were followed in the 18- and 22-year age period. In the follow-ups in the mid- and late twenties and again in the thirties, only the subjects were interviewed. Data were also collected yearly through interviews and observations from nursery school, kindergarten, and first grade. Standard psychometric testing was carried out at ages 3 and 6. A special structured interview to elicit information regarding parental practices and attitudes was held in the child's home with the mother and father, separately but simultaneously when each child was 3 years old.

### THE CLINICAL SAMPLE

A major goal of the NYLS was the determination of the functional significance of temperament for the origins and evolution of behavior disorders. Psychiatric consultation and advice were provided at any point in the child's development.

A full clinical evaluation was offered if the child's undesirable patterns of functioning persisted or became worse. Neurologic or psychological studies were arranged as needed. Teachers were reinterviewed for school problems, and additional observations were done in class. All diagnoses correspond to *Diagnostic and Statistical Manual*, third edition, revised (DSM-III-R). The child's anamnesis was reviewed following the diagnostic evaluation. The formulation of the dynamics of pathogenic child-environment interaction, and the ontogenesis of the behavior problem were derived from a composite of clinical and research information. A decision was made as to direct treatment of the child, parent guidance, or other patterns of therapeutic intervention, and then discussed with the parents. A yearly follow-up was discontinued only if the child showed a sustained recovery.

### Data Analysis

Our data collection was primarily qualitative: parent and teacher interviews, narrative description of the child's behavior at school and during an IQ test, and special interviews with the parents when each child was 3 years old. In other words, our primary data were not obtained through scores or other methods of quantitative ratings. We focused on meaningful subtleties in the developmental course of individual children. It also permitted the raw data to be reexamined.

Herbert Birch then conducted an inductive content analysis of the four parent interview protocols of each of our first 22 NYLS subjects for the first year of life. Blind to our postulated temperament traits, he defined nine categories of temperament, established scoring criteria for each category, and determined a method of rating each item of behavior in each interview. His unique contribution served to transform our narrative data into categories with precise definitions and criteria for the scoring of behavioral items that could then be rated quantitatively for each temperament category.

### TEMPERAMENT CATEGORIES

The nine categories and their definitions are as follows:

1. Activity level: The motor component present in a given child's functioning and the diurnal proportion of active and inactive periods.
2. Rhythmicity (regularity): The predictability and/or unpredictability in time of any function. It can be analyzed in relation to the sleep-wake cycle, hunger, feeding pattern, or elimination schedule.
3. Approach or withdrawal: The nature of the initial response to a new stimulus, be it a new food, toy, or person. Approach responses are positive, whether displayed by mood expression (smiling, verbalizations, and the like) or by motor activity (swallowing a new food, reaching for a new toy, active play, and so on). Withdrawal reactions are negative, whether displayed by mood expression (crying, fussing, grimacing, verbalizations, or the like) or by motor activity (moving away, spitting new food out, pushing new toy away, and so forth).
4. Adaptability: Responses to new or altered situations. One is not concerned with the nature of the initial responses but with the ease with which they are modified.
5. Threshold of responsiveness: The intensity level of stimulation necessary to evoke a discernible response, irrespective of the specific form that the response may take or the sensory modality affected. The behaviors utilized are those concerning reactions to sensory stimuli, environmental objects, and social contacts.
6. Intensity of reaction: The energy level of response, irrespective of its quality or direction.
7. Quality of mood: The amount of pleasant, joyful, and friendly behavior, as contrasted with unpleasant, crying, and unfriendly behavior.
8. Distractibility: The effectiveness of extraneous environmental stimuli in interfering with or altering the direction of the ongoing behavior.
9. Attention span and persistence: These two categories are related. Attention span concerns the length of time a particular activity is pursued by the child. Persistence refers to the continuation of an activity in the face of obstacles.

Qualitative analysis, supplemented by factor analyses, led us to formulate in addition three constellations of temperament made up of various combinations of the individual categories, which appeared to have functional significance. These are:

1. Easy temperament: Typically, this comprises the combination of biological regularity, approach tendencies to the new, quick adaptability to change, and a predominantly positive mood of mild or moderate intensity (approximately 40% of the study population).
2. Difficult temperament: This is the opposite of easy temperament, namely, biological irregularity, withdrawal tendencies to the new, slow adaptability to change, and frequent negative emotional expressions of high intensity (approximately 10% of the study population).
3. Slow-to-warm-up temperament: This category comprises withdrawal tendencies to the new, slow adaptability to change, and frequent negative emotional reactions of low intensity. Such individuals are often labeled "shy" (approximately 15% of the study population).

Temperamentally easy children typically adapt quickly and positively to new situations and demands. The temperamentally difficult child, by contrast, although normal, often finds adaptation to the new distressing and stressful. The slow-to-warm-up child may also present difficulties in management, but her or his negative reactions to new foods, places, or people are expressed mildly, rather than with the violent intensity of the difficult child. Caregivers and teachers can usually tolerate this slow-to-warm-up behavior and give the child time to make a gradual adaptation to the new.

As can be seen from the percentages given in the preceding, not all children fit into these three temperament groups. This results from the varying combinations of temperament traits manifested by individual children. Also, there is a wide range in degree of manifestation among those children who do fit one of these three patterns. Some are extremely easy children in practically all situations; others are relatively easy in some situations but vary in their reactions to others. A few children are extremely difficult with all new situations and demands; others show only some of these characteristics, and only relatively mildly. For some children, it is highly predictable that they will warm up slowly in any new situation; others warm up slowly with certain types of new stimuli or demands but warm up quickly with others.

It should be emphasized that the various temperament categories and constellations all represent variations within normal limits. Any child may be easy, difficult, or slow-to-warm-up temperamentally, have a high or low activity level, be distractible with low persistence or the opposite, or show any other relatively extreme rating score for a specific temperament attribute. Such amodal ratings are not criteria of psychopathology but rather an indication of the wide range of behavioral styles exhibited by normal children, adolescents, or adults.

We have been able to rate our NYLS subjects on the nine categories and three constellations at all age periods in childhood, adolescence, and adult life. As the patterns of behavior become increasingly complex at sequential age periods, the criteria for rating temperament reflect behavioral changes. Thus, behavioral items for scoring temperament in infancy focus on sleep and feeding schedules, the first reactions to the bath, adaptation to new foods and people, loudness and frequency of

crying and laughter, distractibility during feeding, and so on. During the toddler stage, data collection concentrates on peer reactions, play patterns, distractibility, and persistence when playing with a new game or toy. In the older child, the adaptation to school, parties, family, peers, play, and task-oriented activities are of interest. In the adolescent and adult, the identification of temperament is more complex because of the increasing individual variation in activities, such as athletics, hobbies and special interests, social life, school curriculum, and job experiences.

Temperament can be rated in other populations we have studied: children born in New York of unskilled and semiskilled working-class Puerto Rican parents; premature children with birth weights ranging from 1,000 to 1,750 grams; children with mildly retarded intellectual levels; and a large group of handicapped children with congenital rubella.

Having presented convincingly through these studies that temperamental individuality was both a reality and of importance in normal and problem development, pediatricians, nurses, psychologists, psychiatrists, educators, and child care workers evidenced interest in research and practical application. The NYLS method of detailed interviews, although necessary for the initial study, soon proved impractical for large cohorts and clinical situations. Carey and colleagues initiated a series of questionnaires. At this time, questionnaires, covering ages 1 month through 12 years, are available from Sean McDevitt (Behavioral Initiatives, 14634 N. 55 St., Scottsdale, AZ 85254) or Robin Hegvik ([Tempera Metrics, 243 Cohosset Lane, West Chester, PA 19380](#)). Cameron and associates, Rothbart and Bates, and others have developed alternative temperament questionnaires and videotapes.

### The Validity of the Parents' Reports

Controversy exists in the temperament research field as to the accuracy of parents' reports of their child's behavior, whether by interview or questionnaire. Some parents have subjective biases, which may distort their perceptions and reports. On the other hand, the mother and father are in the special position of being familiar with the child's behavior over long periods of time. This special knowledge is shared with teachers and pediatricians, who can compare it with the typical behavior of children under their care. Two independent trained observers, on separate days, observed 18 infants at home for 2 to 3 hours each, and within 2 weeks of a parent interview. These observations were scored for temperament, using the same definitions as for the parent interviews. A significant positive correlation was found between observer and parent reports ([Thomas et al., 1963](#)).

A number of reports from other centers ([Matheny et al., 1995](#); [Rothbart and Bates 1998](#); [Rutter, 1987](#)) have indicated a strong objective component in the mother's report consonant with the findings of an objective observer (Crockenberg and Acredolo, 1983; [Vaughn et al., 1981](#)). In our judgment, the parents' report still represents the best single source of information on the child's temperament, when the data supplied are concrete, descriptive reports of behavior. Studies of specific biological markers for several temperament traits are discussed in the following. Reports from teachers and pediatricians who have experienced repeated contact with children are another valuable source for temperament data. [Weisz and Sigman \(1993\)](#) have observed that "assessing parental reports may be a particularly useful first step because parents have a particularly comprehensive observational base (i.e., more exposure to the child across more settings than, say, teachers or trained observers)." Rothbart and Bates emphasize this issue: "Parents are likely to be in a good position to observe the child's behavior, especially infrequently occurring behavior that is nevertheless critical to defining a particular dimension of temperament" ([Rothbart and Bates, 1998](#)).

### Goodness or Poorness of Fit

Stella Chess did a clinical study for each subject who required evaluation. She added already existing temperament data. We identified expectations and demands on the child. From the evaluations that traced each child's healthy or pathologic psychological development, we formulated our conceptualization of "goodness of fit" or "poorness of fit." We postulated that goodness of fit results when the expectations and demands of the parents or others in the environment are in *consonance* with the child's temperament characteristics and capabilities. With such a goodness of fit, a child's optimal development in a progressive direction was enhanced. Conversely, poorness of fit involved discrepancies and *dissonances* between environmental opportunities and demands and the child's capacities and temperament characteristics. Distorted and maladaptive functioning was potentiated under such circumstances. Goodness or poorness of fit was always determined in terms of values and demands of a given culture or socioeconomic group; it was never an abstraction.

This does not imply advocating eliminating all stress and conflict—quite the contrary. They are inevitable concomitants of the developmental process, in which new expectations and demands for change and progressively higher levels of functioning occur continuously as the child grows older. Demands, stresses, and conflicts, when consonant with the child's developmental potentials and capacities for mastery, have constructive consequences and should not be considered causes of a behavior disorder. The issue involved in disturbed behavioral functioning is rather one of excessive stress resulting in poorness of fit.

Researchers and clinicians in a wealth of illustrations can easily see this concept of a dynamic integration between temperament and environment as conceptualized by goodness or poorness of fit ([Chess and Thomas, 1999](#)); for example, we can spell out the type of fit through the temperament category of motor activity level. The high-activity child whose outlets for exercising muscles are insufficient becomes restless, impulsive, and difficult to manage. Such a child is a nuisance at home, and a disciplinary problem at school if required to sit for long periods of time. All too often, a harassed teacher may criticize the child when this happens, intensifying the disturbance. What emerges is a derogatory self-image. This sequence is an outcome of significant poorness of fit; however, the story is different if thoughtful parents and teachers recognize the child's need for adequate motor activity as legitimate. The parents can seek programs that emphasize active play and not expect the child to sit uninterrupted through a long religious attendance or prolonged automobile ride. The teacher also can give the child class responsibilities with motor activity, such as inventing active errands when noticing that the youngster is particularly restless.

The importance of cultural expectations in the consequences for high-activity level children was dramatized in the contrasting findings in the middle-class NYLS children and the Puerto Rican working-class (PRWC) children living in the congested and underprivileged East Harlem section of New York City. Of the PRWC children with behavior disorders before the age of 9, half had high activity levels. They presented symptoms of excessive and uncontrolled motor activity. By contrast, only one NYLS youngster displayed these symptoms, and this was a brain-damaged child. The PRWC children were more likely to be cooped up at home because of more children and small apartments. Safe playgrounds and recreational resources were meagerly available for these families, and the many household responsibilities did not permit mothers to sit for long periods safeguarding their children's outdoor play. High-activity children were exposed to poorness of fit, excessive stress, and a high risk for behavior disorder development. By contrast, the NYLS families provided their highly active children with ample space and after-school programs. Consequently, clashes with caregivers on this score were few, and a goodness of fit with low risk for pathogenic excessive stress existed.

Any amodal child's temperament trait or constellation, such as the difficult or slow-to-warm-up patterns, may endow daily behavior episodes with much potential for confrontation. Some parents may label the youngster as a psychopathologic or "bad" child. If such a parent or other authority insists that the child conform speedily and fully to the culturally expected norm, excessive stress and a poorness of fit are created. Parents who understand the child's temperament characteristic accept the fact that the behavior is basically normal and healthy. Through patience and the type of helpfulness to the child that conforms both to temperamental necessities and minimum cultural expectations, excessive demands are not imposed, and a goodness of fit results. Goodness or poorness of fit at times can also involve issues other than temperament. Dissonances may emerge from inaccurate parental views of their child's intelligence, talents, motives, and so on.

### Consistency and Change in Temperament Over Time

Our search for categories and ratings of individual differences in temperament initially started with infants and young children. We assumed that specific individual temperament characteristics would remain constant throughout life. The boisterous baby would become the vigorous adult; the shy child would become the quiet grown-up; the youngster who moved toward most new activities would be the "joiner" rather than otherwise in middle childhood, adolescence, and maturity.

As our young children became older, however, we have found that such continuities are not always the case. And, in reflection, how could it be so? All other psychologic phenomena, such as intellectual competence, coping mechanisms, adaptive patterns, and value systems, can and do change over time, as well as other psychological factors, as would be inevitable from our fundamental commitment to an interactionist viewpoint, in which individual behavioral development is conceived as a constantly evolving and changing process of organism-environment interaction over time. Routine functioning may blur a child's earlier characteristic expression of temperament. Infants who showed marked withdrawal from the bath, new foods, and new people may later show positive responses because of repeated exposure and final adaptation. At subsequent age periods, if the youngster experiences few new situations, then his or her withdrawal reactions will not be evident. If child or adolescent is exposed to a number of unfamiliar situations simultaneously, then the withdrawal behavior reactions may be evident again.

When the youngest of the NYLS sample had reached 5 years old, we examined this concept of the consistency of temperament over time ([Chess and Thomas, 1996, 1999](#)). We found significant correlations from one year to another for almost all temperament categories, but the number of significant correlations decreased as the time span increased. Qualitatively we have found both consistency and change in temperament over the years, reflecting changing environment. A recent analysis

compared the temperament ratings of the NYLS sample in early childhood with the ratings of the early adult life follow-up period ( [Thomas and Chess, 1984](#)). The difficult–easy temperament category at age 3 related to early adult life disposition, whereas other temperament categories did not. Some individual subjects suggested significant and sometimes even dramatic consistency in one or another temperament category from early childhood to early adult life ( [Chess and Thomas, 1999](#)).

The subjects of the NYLS had now been followed into their mid- and late thirties. As of January 2000, Lerner had examined data for 20 of the subjects, 10 females and 10 male. Variables examined as factors influencing both change and consistency were: (a) self-awareness, (b) social cognition, (c) motivation, (d) self-esteem, (e) support network, and (f) fortuitous life events. Ages examined were 3 to 3½ years, adolescence, and early adulthood. Ninety-seven percent of the population of the 129 subjects was retained. Trends of data analysis to date show that self-awareness and social cognition increase with age. [Halverson and Deal \(2001\)](#) found stability at the group level but considerable change at the individual level between age 4 and 7.

[Clarke and Clarke \(2000\)](#) summed up their extensive studies and those of other researchers into predictability over time of such characteristics as cognitive development, attachment, and temperament. The data they report reaffirms their earlier thesis that

. . . there is little indication that any one point of development is more critical than another; all are important. And in the ongoing shaping and reshaping of the person's life path, it is to continuing influences that significance must be ascribed (p. 105).

They find continuities only if there are environmental continuities in both cognitive development of retarded children and the influence of early attachment to quality of later relationships.

### Biological Issues in Temperament Research

A number of findings led us to the concept of a biological origin for temperament. Characteristics in temperament are apparent within the first few months of life, become more evident by 1 year, and are dramatic by 2 years. No consistent qualities in parental practices and attitudes have been found to account for this variability in temperament ([Thomas and Chess, 1977](#)). We also compared the temperament scores of our NYLS infants with those in our working-class Puerto Rican families—two groups with marked culturally divergent approaches to child care—and found no dramatic differences in temperament distribution ( [Thomas and Chess, 1977](#)). A literature review by [Korner \(1973\)](#) indicated that parents treat girls dissimilarly from boys even in infancy. Our study and others found only very modest sex differences in temperament scores in boys versus girls, indicating that temperamental individuality in young children is little shaped by any variability in parental attitudes and practices based on gender ([Thomas and Chess, 1984](#)).

These studies challenge the idea that parental attitudes and practices determine infant temperament. Twin studies have demonstrated a genetic factor in shaping individual likeness and unlikeness in temperament, using the classic method whereby the intrapair differences in a group of monozygotic twins, who are 100% genetically similar, are compared with the intrapair differences in a group of same-sex but heterozygotic twins, who are 50% genetically similar on average.

In one study conducted in Bergen, Norway, a sample of 50 same-sex twin pairs was collected at birth ( [Torgersen and Kringlen, 1978](#)). On the basis of blood typing, 34 pairs were identified as monozygotic and 16 as dizygotic. At 2 months of age, there were statistically significant intrapair differences in three temperamental categories, whereas at 9 months, all nine categories showed statistical differences. In all categories, the monozygotic twin pairs were more similar to each other than were the dizygotic twins. The hypothesis was that the residual effects of the birth process had disappeared by 9 months, at which time the definitive expression of temperament was clearer. Buss and Plomin (1975) and [Plomin and associates \(1997\)](#) reported that in a sample of 139 pairs of same-sex twins the intrapair correlations were significantly higher for the monozygotic versus the dizygotic twins for these temperament categories with genetic origin. In addition, a long-term longitudinal study of twins, initiated in 1971 at the University of Louisville, has found that initial analysis, performed at age 12 months, showed monozygotic twins more concordant than dizygotic twins for individual temperaments. This suggested a genetic influence on developmental change itself ( [Wilson and Matheny, 1986](#)).

Other biological nongenetic facts, such as hormonal or other aspects of the prenatal environment or birth process, also may be important. Genetic influence in no way implies fixed predetermination and immutability of temperament. Phenotypic characteristics, as emphasized by modern geneticists, are always the final product of the continuously evolving interaction between genetic and environmental factors ( [Dobzhansky, 1962](#)).

Jerome [Kagan and associates \(1988\)](#) initiated a pioneering study of the relationship of temperament to various physiological and hormonal factors at Harvard University.

### Temperament and Personality

We do not advocate a temperament theory of personality ( [Thomas et al., 1968](#)). Temperament is one of the significant factors in development, but is not identical with personality. In the very young infant, temperament characteristics seem to be the whole personality; over time a host of other factors enter, all of which contribute to personality development. Judd Marmor, a leading student of personality theory, has enumerated 14 types of variables that must be considered. He concludes, “We begin to get a glimpse of how difficult it is to accurately trace the origins of specific personality patterns at all, let alone to try to derive them from just one or two variables” ([Marmor, 1983](#), p. 856).

### Practical Implications

The functional significance of temperament holds the promise for the prevention, management, and treatment of many behavior disorders of children. Parents, mental health professionals, teachers, pediatricians, and nurses can identify and recognize the behavioral individuality of children's temperament characteristics ( [Chess and Thomas, 1999](#)). For the parents, knowledge of the child's temperament may reshape guilt into effective responsibility so that they may strive to reach the optimal parenting style for each pattern of temperament. Clear-cut objective insight into the child's temperament and its implications is now substituted for speculative assumptions of complex psychodynamic mechanisms. Branding a youngster as “sick” or “disobedient” or other negative judgments distort the child's self-image, create inappropriate defenses, and lead toward a self-fulfilling prophecy. If parent or teacher respects the child's behavioral style, he or she can then learn self-confidence and gain mastery of his or her particular behavioral individuality.

The paradigm of goodness or poorness of fit provides a framework for the prevention of treatment of childhood behavior disorders through the valuable tool of parent guidance. The rationale of such a guidance procedure is first to collect the data and analyze the dynamics of goodness or poorness of fit. Specific areas are identified as the centers of unhealthy parent–child interaction, these are described to the parents, and alternative handling is outlined. Half of the parents of behavior problem children in the NYLS were eager and able to carry through the recommended program of behavioral change. Only several discussions were needed for its full implementation. The other parents rejected a temperament interpretation, insisting on a malevolent motivation, and pursued an unchanged approach. In these cases, the child continued to respond to the excessive stress and developed or retained a behavior disorder ( [Chess and Thomas, 1999](#)).

Inevitably, the guidance sessions revealed misconceptions, confusion, defensiveness, anxiety, or guilt in a number of cases. With additional clarifying discussions, parental attitudes and practices that interfered with the child's desirable development were clarified. Some parents responded positively to this new knowledge, but other parental attitudes were so rigidly fixed as to prevent changes in the daily handling of their child. In these cases we recommended direct psychotherapy for the child.

### Longitudinal Studies

There have been several large population prospective longitudinal temperament studies; some are ongoing. Because of their size and prospective nature, they are summarized in the following:

1. Quebec City, Canada. Michel [Maziade and associates \(1990a, 1990b\)](#) explored the clinical relevance of temperament. Their basic population was all the second-grade pupils (97%) in Quebec City with controls. Their 1990 report indicates that children with early extreme temperament in dysfunctional families displayed more clinical disorders at adolescence than the remainder of the 980 adolescents.
2. In the Helsinki Longitudinal Study, Matti Huttunen and colleagues, from the public health centers for the year 1974 to 1975, enrolled 6,401 children born to 6,332 mothers. All social classes were included. Data obtained were: (a) a pregnancy questionnaire at each prenatal visit on somatic and mental health, (b) temperament questionnaires at age 5, (c) an adjustment difficulty scale at age 12, and (d) a teacher behavior rating at age 12. The most recent behavioral data

([Teerikangas et al., 1998](#)), indicated that a fussy and demanding temperament in infancy protected the subjects from developing psychiatric symptoms in adolescence. This correlates with our NYLS experience that difficult children who recovered from early behavior disorder fared well. Roy Martin and colleagues found correlations between nausea during mid- and late pregnancy and temperament in infancy with lowered sensory threshold and heightened activity and emotional intensity. At age 5, the correlation of the pregnancy reports was with low task performance as reported by teachers ([Martin et al., 1999](#)). Martin and associates have also correlated maternal distress during pregnancy and child negative emotionality and behavioral inhibition at age 5. They provide data suggesting a relationship between season of birth (and hence of maternal viral infection during pregnancy) with potentially pathogenic consequences (Martin et al., in press).

3. The Australian Temperament Project promises to be the largest and most unified of multicultural studies on temperament. Initiated in 1983, a cohort of 2,443 infants aged 4 to 8 months was enrolled in the state of Victoria. The main investigators, Oberklaid and colleagues, are based at the Royal Children's Hospital in Melbourne, Australia. The major aims are to: (a) delineate, measure, and determine the stability of temperament; (b) examine the relationship between indices of temperament and concurrent and later behavioral adjustments; (c) examine the significance of social class, ethnicity, and family relationships; (d) examine sex differences in temperament and behavioral adjustment; and (e) identify "at-risk" groups in early childhood to follow through the early school years. The Thomas and Chess conceptualization was the basis of temperament data collection. The authors' (Sanson et al., 1989) summary report found moderate stability of temperament from infancy to preschool, greater stability at both the extreme easy quartile and extreme difficult quartile, indicating that the children with more moderate temperaments may be more influenced by environment. Using the same cohort of 2,443 infants, the authors ([Prior et al., 2000](#)) reported prediction from childhood shyness to adolescent clinical anxiety to be modest for the group. Most of the shy children did not develop anxiety disorders, and most of the adolescents with anxiety disorders had not been especially shy as younger children.
4. An impressive contribution to temperament research and its clinical application has been made by Savita Malhotra, in a series of studies starting with the devising of a culturally appropriate interview guide in Hindi in 1983, and presently ongoing, from the Department of Psychiatry at the Postgraduate Institute of Medical Education and Research (Chandigarh, India). The NYLS interview has been factored and standardized as modified by the Indian colleagues. Although the factors resemble some of those published by Western researchers, such as Bates and Rothbart, their contribution to risk factors is very different. For example, the risk of the constellation of the difficult child is low in the rural culture with a flexible time schedule with few novel situations requiring adaptations. High emotionality (negative mood and high persistence) placed a high risk for psychiatric problems. Temperament relatedness to psychiatric illness such as conduct and conversion disorders, children of mentally ill, and addicted parents were also explored.

### Application of Temperament in Education

[Keogh and colleagues \(1997\)](#) found that children with learning delays and difficult temperament elicited more attention and teacher interactions than those with easy temperament. The difficult children consequently developed better cognitive skills.

[Nelson and coworkers \(1999\)](#), [Rothbart and colleagues \(1998\)](#), [Teqlasi \(1998\)](#), and [Keenan and associates \(1998\)](#) all found correlation between early child temperament and school behavior. Increasing attention is now being given to the inclusion in educators' training of a basic understanding of the development of temperament and individual differences in children's emotional reactivity and attention self-regulation ([Rothbart and Jones, 1998](#)).

### Definitions and Conceptualization of Temperament

The studies of temperament in East European centers have been traditionally shaped by the Pavlovian biological concept of strength versus weakness of the central nervous system ([Strelau, 1983](#)). With his neo-Pavlovian view, [Strelau \(2000\)](#) emphasizes "reactivity as a primary feature of temperament," and the classification of reactivity is based on the concept of individual differences in both degree and intensity (magnitude or amplitude) of expression. Andrzej [Eliasz \(1990\)](#), who is now rector of the Warsaw School of Advanced Social Psychology, and in his "Transactional Model of Temperament" modified Strelau's theory, pointing out that the role of environment in shaping a person's temperamental characteristics is also salient in addition to the genetic roots of temperament. The very important element of his understanding of temperament and its impact on people's functioning is the concept of the goodness of fit. In that way, he bridges the tradition of studies launched by [Thomas and Chess \(1977, 1984\)](#). The outcomes he collected with his associates show that, depending on person-environment fit or misfit: (a) personality mechanisms (resulted mainly from influences of social environment) could be congruent versus incongruent with temperamentally shaped capacities of persons or (b) internal incongruence could lead to disturbances in social interactions and/or health ([Brandstaetter and Eliasz, 2000](#); [Eliasz and Ansletner, 2001](#)).

### Difficult Temperament (the Difficult Child)

We have called attention over the years to the special functional significance of the temperament cluster we have termed "the difficult child," starting with our first detailed report ([Thomas et al., 1968](#)). The constellation of irregularity, withdrawal tendency, predominantly negative mood, slow adaptability, and high intensity appeared in about 10% of the NYLS population, but represented about 24% of the behavior disorders that emerged up to age 9. By age 9, 70% had developed a behavior disorder and 30% had not ([Thomas et al., 1968](#)). This indicated to us that, in middle-class Western society, the temperament features of this group resulted in poor fit in meeting cultural demands for socialization and task mastery at home, in school, and/or with the peer group. We found that the 30% functioning well had been provided with opportunities to adapt at their own slow pace and had not been denigrated for their negative mood expression. With familiarization, negative mood changed to positive acceptance and "zestful" replaced "difficult" and "rotten." They achieved expected social habits, made friends, and demonstrated developmentally appropriate accomplishments.

Several child psychiatrists have questioned the concept of temperament risk factors. They suggested that these factors were in fact a behavior disorder ([Graham and Stevenson, 1987](#)). If correct, this would assume that the child's difficult behavior was primarily responsible for the parents' distressed and often confused behavior. Temperament was assessed by maternal compilation of the Rothbart Infant H Behavioral Questionnaire in a study of 604 3- to 16-month-old infant twins and their parents. Shared environment accounted for cotwin soothability; whereas additional genetic effects accounted for co-twin similarity for distress to limitations to novelty and to the activity level (Goldsmith et al., 1999). John Bates expressed similar doubts regarding difficult temperament ([1998](#)). Plomin suggests that frequent temper tantrums and high activity cause parental concern and sees little value in the difficult child cluster (1997a). In contrast, William Carey, a pediatrician has found important links with colic, night awakening, and other common pediatric complaints. He cautions against labeling a child "difficult" to parents for fear that the pediatrician cause problems that might not otherwise arise, or even create a self-fulfilling prophecy ([Carey, 1998b](#)).

### Attention Deficit Hyperactivity Disorder

Discussing attention deficit hyperactivity disorder is pertinent because there is controversy as to the dividing line between normal high activity level and organically caused hyperactivity. The National Institutes of Health Consensus Development Conference statement on the Diagnosis and Treatment of Attention Deficit Hyperactivity Disorder (ADHD), [2000](#) concludes:

Finally after years of clinical research and experience with ADHD, our knowledge about the cause or causes of ADHD remain speculations. Consequently, we have no strategies for the prevention of ADHD.

Carey, a member of the Conference, has made several specific criticisms over the years.

1. ADHD symptoms and temperament are not clearly distinguishable.
2. There is no clear evidence that ADHD symptoms are related to brain malfunction.
3. There is neglect of the role of the environment as a factor in etiology.
4. The diagnostic questionnaires for ADHD in use are highly subjective and impressionistic.

He concluded: "Is ADHD a valid disorder? What is now most described as ADHD appears often to result from the aversive interactions between biologically intact individuals and their incompatible environments." Carey thinks a recognizable group of approximately 1% to 2% of the child population has pervasive high activity and inattention. Finally, a number of studies have shown that difficult temperament concept is culture-bound as a high- or low-risk factor (deVries, 1984; [Korn and Gannon, 1983](#)).

### Qualitative (Clinical) and Quantitative Analysis

It is of interest that several studies have shown the difficult child factor to have a protective function. Mentally retarded children in special education settings showed a trend toward a lowering of cognitive functioning over time. For difficult children the decline in cognition was less than that of the group as a whole ([Keogh, 1997](#)). In

the Helsinki Longitudinal Study, infants with difficult temperament were protected from having behavior disorders in adolescence ( [Teerikangas, 1998](#)).

## NEW DIRECTION AND OVERVIEW

A number of the controversial issues discussed in the previous section have indicated new directions for temperament work. Beyond these, the expanding temperament literature has raised many new exciting ideas and challenges for current and future theoretical and practical activity. There are discussions in this chapter of stability and change in temperament and some of the steps being taken to explore the facts and their meanings. Such questions and others emphasize the need for greater accuracy and comprehensiveness in the collection of temperament data. A dozen questionnaires that previously described direct observational and laboratory techniques have been elaborated. Parental interviews and interview protocols for adolescents and young adults are available. Clinical observations by child-care professionals are all sources of temperament data. All these methods have received refinement, standardization, and analysis of their reliability and validity. A further important task is the challenge to integrate and combine these separate sources of information, giving full value to the differences in behavior in different situations.

In another study by [Nulman and colleagues \(1997\)](#) there was an examination of the neurodevelopment of children exposed in utero to antidepressant drugs: tricyclic (80 children), fluoxetine (55 children), and 84 children who had been exposed to no teratogenic agents. No significant differences were found in these three groups of children at 16 months and 86 months of the temperamental qualities of mood, arousability, activity level, or distractibility.

### Temperament Research in Nursing

Researches on the application of children's temperaments by nurses have been fruitful. One example is [McClowry \(1998\)](#), from the School of Education at New York University, who is conducting a 5-year clinical trial testing the effectiveness of INSIGHTS, a temperament based intervention. This program is directed at high-risk, minority first- and second-grade children, their parents, and teachers.

A study of Barbara [Medoff-Cooper](#) (personal communication) at the University of Pennsylvania has included 78 premature infants of 1 to 2 months of age. A comparison group is a standardized population of full-term infants of the same postconceptual age. These premature children were significantly more withdrawing, negative in mood, low in persistence, arrhythmical, low in intensity and activity in comparison with the standardized population. The Preventive Ounce ( [Cameron and Rice, 2000](#)) established an Internet program for nurses in collaboration with Nancy Melvin at the Arizona State University College of Nursing. The positive clinical experience at the pediatric units of Kaiser Permanent Temperament Program was the basis for this program. The analysis of the 2,000 pediatric Kaiser patients and controls for prevention of behavior problems and cost effectiveness is now under way. In addition, Cigna, a health maintenance organization, has utilized this temperament program for the past 10 years.

In Vancouver, Canada, [Andersen \(2000\)](#) published a detailed temperament guide for professionals and established a Website in conjunction with McDevitt's Behavioral Initiatives. They distribute the six temperament questionnaires, from infancy through adulthood. In addition Kate Anderson, on the Website (<http://www.b-di.com>) hosts a monthly column discussing temperament issues with "high maintenance" children. Together with Sheeher, they contributed a chapter reviewing existing Parent Training Programs on Temperament-based Intervention in *The Handbook of Parent Training* ([Anderson, 2000](#)).

### Temperament Education

A number of teaching programs involving temperament as an aspect of child development have been ongoing. At the University of San Francisco, Jan Kristal teaches toward a degree as temperament counselor to psychologists, educators, therapists, and child development workers at the University of San Francisco, College of San Marino and Santa Rosa Junior Colleges. As yet there are no formal criteria for training as a temperament counselor. This is now under consideration.

## FINAL OVERVIEW

We present our basic conceptual theme as a final overview: As we have considered the development course of our NYLS subjects, what has come to the fore has been the diversity of interactional processes and personality outcome, so clearly unique as these youngsters matured from infancy to childhood, through adolescence, and into early adult life. The capacity for flexibility, adaptability, and mastery in the face of all kinds of adverse and stressful life experiences has been equally striking. We have also been impressed that our preventative and therapeutic interventions have made differences at all age periods. There is no age at which closure for growth and change occurs.

[Chapter References](#)

To understand the development of attention, perception, and memory is to comprehend the development of the mind. A “consilience” ( [Wilson, 1998](#) ) of perspectives from separate branches of scientific inquiry has fostered a new interest in “mind.” This chapter is based on an interpersonal neurobiology ( [Siegel, 1999](#) ) of mental processes.

The principles of interpersonal neurobiology are as follows:

1. The mind is a process that regulates the flow of energy and information within and between individuals.
2. The mind is at the interface between neurophysiologic process and interpersonal experience.
3. The mind develops as the genetically programmed maturation of the nervous system is shaped by ongoing experience.

The energy consumption of the brain can be assessed via functional brain imaging techniques, whereas the flow of information can be examined via psychometric assessments. However, neurobiological research has tended to focus on the functioning of a single mind, whereas human beings are extremely social. Recent studies indicate that brain is hardwired to place great significance on social experience. For this reason, the second principle of interpersonal neurobiology conceptualizes the mind as being in the context of both brain activity and interpersonal experience.

There has been much debate on the issues of nature versus nurture and genetics versus experience. Recent research clearly demonstrates intricate transactions between genes and experience in the unfolding of brain structure and function. The third basic principle addresses this issue. The genes encode an architectural blueprint about how neurons migrate and how they should grow and prune their synaptic connections. Experience involves neural firing, which directly activates the genetic machinery. Thus, the genes are transcribed and proteins are produced and transported for the creation of new synapses. Debates that pit nature against nurture are simplistic and misleading.

In an interpersonal developmental neurobiology, the flow of energy and information within one brain is conceptualized as being shaped by the interpersonal experiences that occur as life unfolds. Experiences shape and are shaped by the genetically and experientially influenced maturation of the brain. Genes provide the blueprint for how neurons are to grow and connect; physical and interpersonal experiences fine-tune the connections.

## INFORMATION PROCESSING AND NEUROBIOLOGY

The tens of billions of neurons in the human brain are connected via synaptic junctions that average about 10,000 per neuron. In other words, each neuron influences or is directly influenced by about 10,000 other neurons. The on-off firing of the neurons generates a “neural net profile,” the pattern of neural firing at a given moment. It is unknown how neural firing patterns become mental processes. Somehow, neural net profiles yield mental representations experienced as images, sensations, or thoughts ( [Mesulam, 1998](#) ).

The brain region in which the neural net fires determines the modality of mental process (e.g., visual versus auditory). The pattern of firing within the region leads to the particular representation, such as the visual image of a dog or the Eiffel Tower. Thus, neural location (visual processing centers) and neural activation patterns (type of visual image) both contribute to mental processing.

As the infant grows, synapses are created, strengthened, or “pruned” (allowed to die back) in accordance with experience ( [Greenough and Black, 1992](#) ). For this reason, even identical twins do not have identical brains. Experience and chance determine neural firing, which, in turn, activates genes and leads to synaptic growth ( [Kandel, 1998](#) ). A poverty of experiential stimulation can lead to the excessive pruning of synapses or deficiency in the creation of new synaptic connections. Excessive stress can lead to the death of neurons, mediated in part by high levels of circulating cortisol ( [De Bellis et al., 1999a](#) ). Chronic posttraumatic stress disorder is associated with a diminished hippocampal volume ( [Bremner and Narayan, 1998](#) ). Early child abuse is associated with impairment in the growth of the corpus callosum, as well as overall decrease in the size of the brain ( [De Bellis et al., 1999b](#) ).

Memory is related to alterations in the synaptic strength of clusters of neurons. Thus, an individual who has seen a picture of the Eiffel Tower, for example, will be more likely to activate the visual representation of the tower in the future than someone who has never experienced such a stimulus. Memory shapes neuronal connections and is, thus, a fundamental part of brain growth and the development of the human mind.

## THE BASIC PROCESSES OF COGNITION

### Attention

Attention is the mental function that regulates the flow of information. Attention can be conscious or nonconscious. Conscious, focal attention is a linear, content-limited, energy-consuming process. The lateral prefrontal cortex is believed to be a mediator of focal attention or working memory. Working memory is limited by its capacity to focus only on “7 ± 2” items at a time. Nonconscious, nonfocal attention, in contrast, does not involve conscious awareness and is a nonlinear,

low-energy process not limited in capacity. Hearing one's name at a distant location in a loud party while consciously focusing on a close-by conversation is an example of nonfocal awareness.

## Sensation and Perception

Sensation involves the registration of input from the body, brain, or external world. Sensation may have no signal value. Signal value refers to input that has symbolic meaning, encoding information about something other than the thing itself. Feeling abdominal pain is a sensation. Being aware that the stomachache “means” that one is nervous is a perception. We sense the pain but perceive an anxious state of mind. Perceptions transform sensations by utilizing processes that generalize and cluster prior experiences, enabling the filtration of sensory input into perceptual categories. In this way, perceptions are a step removed from the thing itself and a manifestation of top-down processing.

## Representations and Modes of Processing

The mind creates representations of experience in a variety of modalities. One way of dividing representations is to examine sensory, perceptual, and linguistic groupings (Edelman, 1992). Sensation and perception are analogic. Analogic representations are mediated by a mode of cognitive processing that emanates primarily from the right hemisphere of the brain. The right mode of processing is holistic, analogic, and spatiotemporal. Events are represented as experienced, with little evaluation of their “rightness” or “wrongness.” In contrast, linguistic representations are “digital” in that they can be assessed as yes–no or right–wrong. Digital representations are mediated by a mode of processing emanating primarily from the functioning of the left side of the brain (Springer and Deutsch, 1993; Tucker et al., 1995). The left mode of processing is linear, digital, and linguistic. Its logic utilizes syllogistic reasoning in which cause–effect relationships are assessed and information is filtered through a right–wrong process of evaluation.

The asymmetry of subcortical structures in the embryo is the likely origin of the differences in processing between the two hemispheres (Trevarthen, 1996). The specialized function of each side of the brain may enable the mind to carry out functions that would not be possible without anatomic differentiation. Although differentiation between the left and right modes has survival value, integration of these processes may be essential for proper cognitive development. Early in life, the infant has a predominance of right hemisphere activity and development (Chiron et al., 1997). As the child develops, both hemispheres go through spurts of growth (Thatcher, 1997). Furthermore, the fibers that link the functions of each side grow for at least the first two decades of life (Trevarthen, 1990). Conditions such as posttraumatic stress disorder may be associated with impaired hemispheric integration (Siegel, 1999).

## Memory

Memory allows the mind to be influenced by experience. The most fundamental division of memory is between two forms that have been given a variety of names (McClelland, 1998; Siegel, 2001b; Squire, 1992). Early *implicit*, *procedural*, and *nondeclarative* memory are contrasted with later developing *explicit*, *semantic-episodic*, and *declarative* memory. In this chapter, the terms implicit and explicit are used.

Implicit memory operates early in life. It does not require focal attention for encoding, and when recalled, it does not convey the subjective sensation that “I am recalling something.” Implicit memory encompasses emotional, behavioral, perceptual, and possibly, somatic memory. *Mental models* or *schema* are also a part of implicit memory. Mental models enable the mind to abstract generalizations from many experiences, generating a schema for each type of event. *Priming*—the readying of the mind to respond in a certain fashion—is another aspect of implicit memory. Implicit memory does not require the hippocampus for mediation. It is thought to involve neural structures specific to each kind of implicit memory (e.g., the amygdala and orbitofrontal regions are involved in implicit emotional memory).

Explicit memory emerges later than implicit memory, requires focal, conscious attention for encoding, and conveys a sense of “I am recalling something.” Explicit memory has two forms: *semantic* and *episodic*. *Semantic* or *factual memory* is the ability to acquire knowledge, such as the definition of words. It is not associated with a sense of time or self. *Episodic* or *autobiographic memory* involves the sense of time and self as one recalls the events of one's life. The development of the hippocampus is required for the emergence of explicit memory when the child is about 1½ years old. Autobiographic memory also requires the maturation of the orbitofrontal cortex. Autobiographic narratives begin around this time because this region develops after the second birthday.

## Emotion

Emotion has been considered separately from cognition. Modern views of the mind consider this an erroneous division (Damasio, 1998, Damasio, 1999; LeDoux, 1996). Emotion is a mental function that integrates separate processes into a functional whole (Ciompi, 1991). Emotion combines the different elements of cognition into a state of mind that links sensation, perception, attention, memory, reasoning, and self-reflection. Emotion is both regulated and regulatory. Emotional regulation is necessary for self-regulation (Lewis, 1997).

The mind focuses its attention on a salient internal or external event as though to say, “This is important, pay attention!” Next, the event is appraised as either “good” or “bad,” activating the circuits that lead to either approach or withdrawal. These primary emotional processes occur constantly.

As the primary emotional states of the mind continually emerge, particular states may coalesce into a categorical emotion such as sadness, anger, fear, disgust, surprise, joy, or shame. These emotions have been found in all human cultures. They appear to represent the universal ways that the mind and body channel emotional states into visible affects. Mood is the enduring tone of a person's general emotional state.

Emotion encompasses a number of domains (e.g., the subjective, neural, somatic, and interpersonal) that develop during childhood and beyond (Sroufe, 1996). Each of these domains has a fundamental influence on cognition. For example, the regulation of attention is a central part of the primary emotional process. Moods directly influence memory, and perceptual interpretation is intimately shaped by the interpersonal context.

## Metacognition

An important component of mental functioning is the capacity to think about thinking, the mind's creation of mental representations about itself. At first, children learn to understand other people's states of mind. Later, they begin to understand their own minds. Metacognition begins after the third birthday, becoming more and more complex across the life span.

Metacognition encompasses the notion of the appearance–reality distinction: Things are not always as they appear. One aspect of this capacity is that of *representational diversity*: What one person thinks about an event may be different from what others think. *Representational change* refers to the observation that what a person thinks today may be different from what he or she thinks tomorrow (Flavell et al., 1993).

Children learn that emotions influence how people behave. (If a father is in a bad mood, don't ask for candy!) They learn that it is possible to have conflicting emotions about the same person at the same time. The understanding of how one's own memory works is a “metamemory” process that examines the nature of recall.

## Self-Knowledge

As each of these aspects of mental processing develops, it contributes to the child's growing sense of self. Interactions with caregivers have a profound influence on the child's emerging sense of an autobiographic self. Children with emotionally distant or rejecting parents have relatively underdeveloped life stories. The primary caregiver of such a child often has little recall of his or her own early life experiences (Hesse, 1999). Recent brain imaging findings point to the importance of the right hemisphere, prefrontal region, in autobiographic recall (Tulving et al., 1994; Wheeler et al., 1997).

The right hemisphere may be important in mediating a sense of self and a mental model of self with others (Schore, 1996, Schore, 1997). In addition to autobiographic memory, the right hemisphere appears to be predominant in the processing of a number of functions: an integrated representation of the body; the perception and expression of nonverbal signals; the regulation of emotional states; the registration and regulation of the sympathetic and parasympathetic branches of the autonomic nervous system; and the creation of representations of other people's minds (called “theory of mind” or “mindsight”). The right hemisphere dominates growth and activity during the first 3 years of the child's life (Chiron et al., 1997), suggesting that early attachment experiences may rely primarily on the exchange of

right hemisphere representational processes.

These findings suggest that the right mode of processing allows a better access to a patient's sense of self. Right mode communication involves the interchange of nonverbal signals and the attunement to the other person's primary emotional state. Children in particular require more attention to the nonlogical, nonverbal processes of the right hemisphere for communication and understanding.

### Integration and Differentiation

The mind moves toward increasingly complex differentiation of function on the one hand and integration of separate processes into a functional whole on the other (Siegel, 2001a). Chaos theory suggests that development is characterized by the movement of systems (individual, family, community) toward ever more complex functioning (Cicchetti and Rogosch, 1997; Fogel et al., 1997; Globus and Arpaia, 1993; Thelen, 1989). Nonlinear dynamics proposes that complexity is achieved by balancing differentiation and integration. Differentiation is defined as the functional specialization of the components of a system. Integration is the clustering of the differentiated elements of a system into functional wholes (Lewis, 1997).

## THE DEVELOPMENT OF ATTENTION

Clinicians often speak of attention as though it were unitary and distinct. On the contrary, attention is a multidimensional construct composed of such phenomena as strategic scanning, exclusion of irrelevant stimuli, sustained attention, divided attention, inhibition of impulsive action, and selection and monitoring of response. It is not possible to design a test that taps a "pure" attentional faculty. Furthermore, children are unlikely to attend unless they know why they should, they find the task interesting or rewarding, and they are able to distinguish figure from ground and signal from noise.

Under the age of 5 years, the salient features of a novel stimulus capture children's attention; early attention is stimulus bound. Between 5 and 7 years, a shift occurs: Attention comes under the control of inner processes, such as selective search strategies. As children mature, they become more systematic and flexible, and less egocentric. In essence, older children know when and how to attend. Poor learners, on the other hand, spend inadequate time "on task," lack cognitive strategies for analyzing task demands, and mobilize too little effort to succeed (Zelniker and Jeffrey, 1979). The metacognitive processes that facilitate attention overlap those relevant to perception and memory.

Given the frequent reference to defective attention in child and adolescent psychiatry, surprisingly little is known about its normal development. Reaction time, the capacity for vigilance and sustained attention, and the control of impulsive responses, improve up to 12 years. Thereafter, although reaction time stabilizes, accuracy continues to advance as more efficient search strategies are acquired (Salkind and Nelson, 1980). In one of the few studies that have provided age-normalized data, Levy (1979) found that measures of sustained attention, reaction time, and motor inhibition showed strong age and social class effects from 3 to 8 years, and that the three measures improved exponentially between 4 and 6 years of age. Multivariate analysis subsequently isolated a generalized "attention" factor on which reaction time, continuous performance, and motor activity loaded heavily and that was separable from motor inhibition. Subsequently, a study of clinic-referred children demonstrated that the clinical sample performed significantly more poorly than normal children of the same age on measures of attention, motor inhibition, and activity. However, when performance was related to age, the performance curves of the clinic sample paralleled those of the normal children. This study suggests that the diagnosis of attention deficit may be problematic in children younger than 5 years, since normal children show marked variation in activity level, the capacity for sustained attention, and motor inhibition between 4 and 5 years; furthermore, social class has a powerful effect on the capacity for sustained and selective attention in the transitional period between 4 and 6 years of age.

In an extensive review of research into the development of attention, Taylor (1980) concludes that little is known of the development of the capacity for divided attention, other than that it improves with age. It appears that older children are better able to resist distraction by stimuli irrelevant to the task at hand. Younger children find distractions harder to ignore, to the extent that the stimuli are salient, novel, or similar to the stimulus that is relevant to the task.

Barkley (1988) has discussed the importance of motivation in regard to attention. The capacity for sustained, selective attention and reflective, nonimpulsive responding is affected by both maturation and learning. These may be a part of the executive functions that allocate attentional resources. Executive functions regulate the flow of energy and information and direct both focal and nonfocal attentional processing.

Experiential factors may play an important role in disrupting attentional functioning. A child who has neither been expected to concentrate nor rewarded for doing so, is likely to be slow in acquiring the capacity for sustained, reflective attention. Children with disorganized attachment have difficulties with attention, emotional regulation, and social functioning (Carlson, 1998; Lyons-Ruth et al., 1993; Ogawa et al., 1997). This condition is also associated with a propensity to have dissociative symptoms. Disorganized attachment is believed to result from the child's repeated exposure to frightened, frightening, or alarming parental behavior (Main and Hesse, 1990).

If an inattentive child has previously had the benefit of secure attachment and consistent reinforcement and has not been exposed to traumatic events, it is more likely that the origin of the difficulties is in the constitutional neural substrate. Two causative hypotheses have been advanced: (a) the sensory analyzers mediating selective attention might be abnormal or (b) the neural links among memory, punishment, and reinforcement might be defective. (For further discussion of the development of inattention, see Chapter 28.)

Mirsky and associates (1991) propose that attention has the following components: *focus*, *sustain*, and *shift*. Focusing is the selection of target information for enhanced processing. Sustaining refers to the maintenance of focus and alertness over time. Shifting is the changing of focus in a flexible, adaptive manner. The validity of the three components of attention has been supported by multivariate studies of the attention performance scores of both adults and children. Sohlberg and Mateer (1989) hypothesize that attention is a multidimensional cognitive capacity with five levels: focused attention, sustained attention, selective attention, alternating attention, and divided attention. The higher levels of attention require controlled processing, whereas the lower levels are automatic.

## PERCEPTUAL DEVELOPMENT

### Auditory Perception

In the third trimester fetus, external sounds evoke movement, cardiac acceleration, and electrocortical responses (Bench, 1978), while the neonate reacts to loud or sudden sounds with a generalized startle response; however, an infant's intensity threshold is higher than that of an adult, especially for the lower and higher frequencies. Hearing at low and high frequencies continues to improve during the first 20 years of life (Trehub et al., 1989).

The rudiments of hemispheric specialization are apparent soon after birth: Lateral asymmetries in the auditory evoked potential can be produced by speech stimuli (Molfese and Molfese, 1979). The infant is especially receptive to sounds in the human frequency range (Hutt et al., 1968) and sounds with intonational patterns similar to those of speech (Eisenberg, 1979). Condon and Sander (1974) report that infants move in rhythm to the stress patterns of speech. Infants under 6 months of age have been found to discriminate among a number of speech consonants (Eimas, 1975). These important findings suggest that the infant has an inherent tendency to perceive those categorical discriminations that are fundamental to phonological development and that speech processing differs from that for other sounds. By the sixth month, infants can differentiate most of the acoustic contrasts required for phonological development (Lynch et al., 1992).

### Visual Perception

Although the neonate has some visual acuity, adult levels are not attained until 6 months (Lewis et al., 1978). Fantz (1958) was the first to show that neonates see patterns; it has subsequently been established that they tend to fixate on high contrast features within geometric forms (Salapatek, 1975). As the infant develops, increasingly more complex patterns are preferred (De Loache et al., 1978). The infant has begun to recognize the mother's face by 1 month, and moving eyes are of special interest by 2 months (Girton, 1979; Mauer and Salapatek, 1976). In the 2-month-old infant, complex patterns evoke electrocortical responses that may represent a shift from subcortical to cortical processing (Hoffmann, 1978). Field (1979) has shown that infants attempt to modulate the effect of highly arousing stimuli (e.g., animated faces) by averting their eyes. The perception of facial expressions appears to play a central role in the development of affect regulation during the first year of life (Schore, 1994).

As language reflects, adults perceive the continuous spectrum as though it were divided into different colors. Is color categorization an inherent propensity, or is it

molded developmentally by the arbitrary discriminations imposed by such words as “red,” “blue,” and “green?” In short, does the infant perceive categorically? [Bornstein and associates \(1976a\)](#), [Bornstein and associates \(1976b\)](#) found that 4-month-old babies discriminated green from blue but treated a second blue as similar to the first, even though the contrasted green and blue were equidistant in wavelength from the central blue. Like adults, babies tend to perceive the color spectrum in shades of red, yellow, green, and blue ([Bornstein, 1981](#)); however, form and color are not integrated as wholes until 6 months ([Cohen, 1979](#)).

The 3-month-old infant already has the rudiments of shape and size constancy and preferential orientation to the vertical ([Bornstein, 1984](#); [Bower, 1966a](#), [Bower, 1966b](#); [Caron et al., 1978](#); [Hayes and Watson, 1981](#)). Infants of 4 months are sensitive to symmetry ([Bornstein, 1992](#)); however, it is not until the second year of life that babies use landmarks to locate themselves in space, an ability probably facilitated by crawling ([Benson and Uzgiris, 1985](#)). [Coldren and Colombo \(1994\)](#) have found that 9-month-old infants can process compound stimuli in a dimensional manner and that they can solve discrimination-learning problems by the categorical selection and testing of perceptual features.

Visual accommodation, ocular convergence, and motion parallax are used as depth perception cues within the first 6 months. [Field \(1977\)](#) has demonstrated preferential reaching for near objects as early as 3 months. Head retraction to looming objects (which appear to move toward the infant on a collision course) has been noted in early infancy (Ball and Tronick, 1971); however, there has been controversy whether the head movement represents innate fear or interest. According to the index of heart rate change, infants as young as 2 months of age can perceive a visual cliff illusion ([Campos et al., 1970](#); [Gibson and Walk, 1960](#)).

### Taste and Smell

Neonates show their preference for sweetened water by smiling and sucking in longer bursts, with shorter pauses ([Crook, 1978](#); [Lipsitt et al., 1976](#)). Sour or bitter fluids, in contrast, evoke lip pursing or grimacing. Similar responses have been noted in anencephalic infants, suggesting that those responses are of subcortical origin ([Steiner, 1979](#)). Newborns are able to detect strong smells ([Engen and Lipsitt, 1965](#)), discriminate their mother's breast pads (McFarlane, 1975), and grimace at unpleasant odors ([Steiner and Finnegan, 1985](#)). The grimacing response, which is found in anencephalic infants, is probably a subcortical reflex. [Ruff \(1990\)](#) found that mouthing predominated as a perceptual tool during the first 6 months but that fingering displaced it during the second 6 months.

### Cutaneous Sensation

The mouth and genitals of the fetus become sensitive to touch during the first trimester and are followed by the palms, soles, and rest of the body. Thus, before birth, the structural and functional basis of skin sensation has already been established. The motor responses of the neonate to different cutaneous stimuli can be assessed by a number of neurologic tests (e.g., the rooting, sucking, and plantar reflexes). [Emde and colleagues \(1971\)](#) and [Anders and Chalemian \(1974\)](#) noted that neonates fuss and cry during and after circumcision, suggesting that they are capable of experiencing pain.

### Intermodal Perception

[Piaget \(1971\)](#) theorized that the coordination of the senses to form integrated perceptions could be achieved only after multiple parallel sensory experiences. In contrast, [Gibson \(1969\)](#), [Bruner and Koslowski \(1972\)](#), and [Bower \(1977\)](#) have hypothesized that early perception is diffuse and that perceptual specificity evolves from global sensory impressions.

[Mendelson and Haith \(1976\)](#) and [Muir and Field \(1979\)](#) have found that neonates will turn their heads and eyes in search of sustained sounds. [Spelke \(1979a\)](#), [Spelke \(1979b\)](#) has demonstrated that 4-month-old infants prefer to look at films in which sound is synchronized with action (compared with films that are out of synchrony). [Spelke and Owsley \(1979\)](#) have shown that 4-month-olds associate a parental voice with the visual image of that parent. [Meltzoff and Borton \(1979\)](#) have demonstrated mouth–eye crossmodal transfer as early as 1 month, and [Lewkowicz and Turkewitz \(1980\)](#) have found evidence that 3-week-old babies associate loudness and brightness. The global sensation theory appears to have been strongly supported, and there is evidence that premature babies are delayed in the capacity for cross-modal transfer ([Rose et al., 1978](#)).

Neonates can hear, see, smell, taste, and feel. The rudiments of hemispheric lateralization appear quite early, along with a particular sensitivity to speech and to the categorical distinctions associated with human phonologic development. As they grow, infants prefer increasingly complex visual patterns, show a special liking for animated faces, exhibit shape and size constancy, and perceive color categorically. Early sensation appears to be global, but perceptual specificity evolves rapidly during the first year. In brief, nativist theory has been strongly supported by recent research; however, there is clearly an intricate interaction between learning and postnatal neural maturation.

### Perceptual Development and Reading

Of all developmental theorists, [Gibson \(1969\)](#) puts the greatest emphasis on perception. To her, the child is an active perceiver, primed by species-specific genetic evolution to explore the environment and select what is required for adaptation. In contrast to Piaget, who postulates that children construct their own representational worlds, Gibson describes the child as extracting available information from the stimulus field. The information elicited can vary from concrete (e.g., perceiving an object) to abstract (e.g., the apperception of a melodic pattern). Perception grades imperceptibly into conceptualization as the child learns the distinctive features of particular objects (e.g., the mother's face), the common features of similar objects (e.g., the genus of dogs), and the deep structure of stimulus arrays (e.g., the syntax of a sentence). Perceptual processes would not be possible without search strategies, selective attention, and the exclusion of irrelevant input. According to Gibson, perceptual differentiation proceeds in linear fashion, not in stages.

[Gibson and coworkers \(1962\)](#) found that perceptual acuity for letter-like shapes increases from 4 to 8 years of age but that, at all ages, children are able to discriminate, in order of difficulty: (a) figural breaks (C versus O); (b) rotations and reversals (b versus P versus d); and (c) transformations (H versus N). [Bornstein and Stiles-Davis \(1984\)](#) found that, between 4 to 6 years, vertical symmetry begins to assume precedence over horizontal and oblique symmetries, as is the case with adults. Gibson's theory of perceptual development has implications for the acquisition of reading skills. For example, poor readers exhibit the following phenomena:

1. Literal decoding. Poor readers tend to read word for word, without extracting meaning ([Ryan, 1979](#)).
2. Poor comprehension. In that they tend to be oblivious to contradictions or ambiguities in written material, poor readers seem not to monitor what they read for meaning ([Paris and Myers, 1981](#)).
3. Poor strategies for the abstraction of meaning. Poor readers have difficulty abstracting the gist of a story ([Owings et al., 1980](#)). Young children and older poor readers may be unaware of the purpose of reading, and unable to apply such metacognitive strategies as scanning rapidly for meaning, and looking for syntactic and semantic cues. Metacognition transcends concrete perception and are considered further in the development of attention and memory. It has important implications for remedial reading ([Ryan, 1979](#)).

## DEVELOPMENT OF MEMORY

The term “memory” has connotations ranging from the act of recalling a personally experienced event (autobiographic memory) to the automatization of learned behavior (procedural memory) ([Milner, Squire, Kandel, 1998](#)). Memory is inextricably linked to other cognitive processes such as attention, perception, categorization, schematization, consciousness, and metamemory (which assesses the origin and accuracy of memory). The development of memory is not separable from that of cognition in general. Interpersonal experience, as well as neuronal maturation directly influence different forms of memory ([Siegel, 2001b](#)).

### Information Processing

Memory has been studied from the perspective of information processing. In this view, sensory input impacts sensory registers, producing a short-lived sensory memory (<250 msec). At this stage, attentional processes scan information and a small proportion placed in short-term (“working”) memory. Without active processing, short-term memory decays after about 30 seconds. After attention and processing (e.g., by classification or rehearsal), information in short-term memory may be deposited in long-term memory.

Encoding refers to the transfer of information from sensory registers to short-term memory and then to long-term memory. Storage refers to the capacity of the mind to represent information and have it potentially available for later access. Retrieval is the accessing of information from storage. Retrieval processes activate behavior,

emotion, and verbal recounting.

The recounting of autobiographic events often takes the form of a narrative and is related to the capacity to retrieve items from memory, to sequence them in story form, and to communicate them to a listener. Thus, recounting involves both cognition and discourse.

### Early and Late Memory

Cognitive psychologists have described two forms of retrieval: direct and indirect. Direct retrieval includes free recall (at which young children are poor) and recognition (at which they are much better). Indirect retrieval acts on processes and representations that convey a general pattern of action (e.g., long-term memory, sensory imaging) (Siegel, 1995a).

Retrieval can be conceptualized as the reactivation of a neural net configuration similar to that activated at the time of encoding. Memory is reconstructive, not reproductive. Organizing processes such as attention, perception, emotion, and schematization influence encoding, storage, and retrieval. From a developmental viewpoint, the brain's ability to store experience as neural representations with the potential for reactivation depends on the increasing sophistication of encoding, storage, and retrieval. Access to stored representations (i.e., the activation of latent neural net configurations) is dependent on retrieval. Thus, the inability of young children to recall aspects of an experience directly may mean that it was never encoded or that it was encoded and stored but that reactivation is impaired by immature retrieval strategies.

As discussed earlier in this chapter, given the distinction between early, nondeclarative memory and late, declarative memory, one must be clear about what kind of memory is being discussed. Emotional learning and behavioral learning occur early and do not involve an awareness of their origins in the past. Childhood amnesia, for example, refers to an impairment of access to declarative autobiographic memory, whereas nondeclarative (emotional and behavioral) memory may be intact.

Clinicians and researchers have focused on the development of declarative memory; however, early emotional and behavioral learning also influence child development. Attachment theory (Bowlby, 1969; Cassidy and Shaver, 1999; Main, 1995) derives its constructs from the idea that, after repeated patterns of relating, an infant constructs a mental model of attachment. This implicit mental model organizes the infant's behavioral and emotional responses and later influences declarative memory, self-reflection, and autobiographic memory.

Past maltreatment can affect implicit memory and the integration of implicit with explicit processing. The retrieval of early, learned emotional-behavioral responses may be triggered in adulthood by emotional states similar to those that applied in early childhood (Siegel, 2001a). This could explain the transgenerational transfer of child abuse, and the perpetrator's unawareness of its origin. Some of the symptoms of posttraumatic stress disorder (e.g., intrusive memories, avoidance, startle response, traumatic amnesia) could be explained on the basis of a combination of impaired explicit memory with intact implicit memory for traumatic experiences (Siegel, 1995b).

### Domains of Memory Development

#### STRATEGIES

Immature memory strategies limit the young child's ability to encode and store memory and retrieve it in declarative form. As memory strategies develop, the mind becomes better able to encode, store, and retrieve memories. Young children often require help with retrieval cues, whereas older children may be capable of both free recall and effective access to relevant memories.

Encoding and storage strategies are conscious activities that facilitate encoding and storage. They include looking, pointing (to direct attention), naming, and talking about things. Strategies become more complex, flexible, and specific with maturation. Rehearsal strategies help to move items from short-term memory to long-term memory. Organizational strategies, such as clustering, establish associational links that facilitate storage. Elaboration strategies enhance storage by adding meaning to presented items. Finally, the development of efficient strategies to allocate cognitive resources facilitates encoding. The evolution of these complex processes allows the child to search memory more intelligently, efficiently, flexibly, systematically, and exhaustively. As children develop, they tailor the strategy of retrieval to the task at hand.

Research suggests that some memory strategies can be taught; however, all children rely on techniques they have acquired spontaneously in the course of development.

#### KNOWLEDGE

Memory is not as simple as photography. What people already know influences what they learn and remember. Encoding and storage are constructive; retrieval is reconstructive. Memory is organized in part by schemata or concepts that are in flux between organization and reorganization. Neural net representations carry meaning that is fundamental to schematization. Thus, retrieval may involve memory reactivation and cognitive inference, both of which bridge the gaps that block retrieval.

As the child develops, new knowledge schemata and structures shape memory (Johnson-Laird, 1983). The constructive aspect of memory is exemplified by memory for events. General schemata influence event memory. For example, the memory of something occurring at school is influenced by the generic memory of a typical day at school. The predominance of general schemata in early childhood retrieval may be explained by the late maturation of the hippocampus and related brain regions.

*Priming* influences indirect measures of retrieval and involves behavioral learning independent of conscious awareness of prior experience (Schacter and Buckner, 1998). Priming readies the brain to respond in a particular fashion and affects the speed at which a task is learned. The indirect recall characteristic of infancy and early childhood is known as *early memory*, *procedural memory*, *nondeclarative memory*, or *implicit memory*, terms that are used synonymously in this chapter. Implicit memory is multifaceted: It embraces behavioral learning, emotional learning, mental models, and priming.

In contrast, direct recall involves another form of memory, *late memory*, *episodic memory*, *semantic memory*, *declarative memory*, or *explicit memory*. These terms overlap in meaning and refer to a general kind of recall known as "remembering." Remembering involves the recall of facts or concepts (*semantic memory*) or of personally experienced events (*episodic memory*). Semantic and episodic memory are usually explicit or declarative, that is, recountable in words or other symbols. (For further discussion of information processing, see Chapter 12.)

#### The Maturation of Memory

The mature brain contains over 20 billion neurons. At birth, the number is greater. Synaptic connections are created in accordance with both genetic information and experiential stimulation. As discussed earlier, synaptic connections are created, maintained, strengthened, or eliminated (pruned) as a result of the presence or absence of environmental stimulation. Experience induces neurons via gene activation to synthesize proteins that create and modify synapses. The neuronal pruning that occurs during infancy and early childhood is also thought to be both genetically and experientially determined. It is possible that much pruning occurs in adolescence, explaining in part the massive cognitive changes during this period of development.

Neurons interconnect in parallel distributions known as neural networks. Cognitive processes derive from the parallel processing that occurs as a function of the structural and functional properties of these neural nets. As discussed, a mental "representation" is thought to be created from a neural net activation pattern. A "process" can be considered as a neural activity that acts on representations, transforming them, creating new connections, or extracting common features from different representations. The term cognitive "structures" refers to complex functions that have repeated patterns of action, such as focal attention or long-term memory.

Cognition can represent cognition. This process, metacognition, develops during the preschool and elementary school years. One form of metacognition—metamemory—allows the child to understand memory itself. Metamemory conveys knowledge about how memory works as well as how to monitor and regulate it. Metamemory embraces the assessment of the current memory state, the selection of strategies, and the evaluation of progress toward cognitive goals.

An example of metamemory would be the subjective sensation of hunting for a memory and then recalling it.

The capacity to locate the origin of a memory is called source monitoring. One form of source metamemory, reality monitoring, is the process by which the mind determines if a memory is external or imaginary in origin. Reality monitoring becomes more efficient in later childhood ( [Johnson, 1991](#)).

### *Memory Capacity*

If the energy resources allocated to information processing are limited, then the operation of intentional, nonautomatic processes will limit the resources available for other cognitive processes. Thus, in a young child, immature storage and retrieval drains resources from and restricts other memory processes ( [Fivush and Hudson, 1990](#)).

Cognitive development enhances memory capacity by freeing resources for use in other mnemonic activities. For example, as strategies become automatized, storage capacity and retrieval efficiency increase. The automatization of metamemory together with the way that knowledge structures provide scaffolding for storage and retrieval contribute to the uniqueness of each child's memory development. The full development of memory, thus, depends on an interaction among strategies, knowledge, metamemory, and capacity ( [Flavell et al., 1993](#)). The next section illustrates this complex interplay.

### *Development of Autobiographic Memory*

**Memory, Self, and Time.** Autobiographic memory refers to memory of the self at a particular time in the past. Explicit memory, declarative memory, and late memory encompass episodic or autobiographic memory. The retrieval of a particular autobiographic memory conveys a profile of representations of sensations, emotions, facts, and self-in-the-past. In this manner, autobiographic memory can be thought of as an integrative process that involves many layers of mental processing, from mental models of the self to sensory images and cross-time representational processes. These capabilities relate to the concept of "mental time travel" ( [Tulving et al., 1994](#)) in which the mind connects elements of the past and present with imagined aspects of the future.

**Infantile Amnesia.** The maturation of autobiographic memory involves an interaction among language, social interaction, self-concept, and the sense of time. The earliest form of declarative memory is generic event memory. Children construct generalized patterns ("scripts") that represent familiar, oft-repeated events. New experiences are processed in accordance with generic memory. Encoding is biased by expectations based on preexisting structures, whereas accurate retrieval is biased insofar as retrieval scanning is influenced by generic memory. Generic event scripts give rise to preevent and postevent suggestibility ( [Ceci and Bruck, 1993](#)).

The immaturity of autobiographic memory in infancy and early childhood is associated with infantile and childhood amnesia. [Freud \(1963\)](#) proposed that infantile amnesia is owing to an active repression of early experience. The encoding deficit theory ( [Wetzler and Sweeney, 1986](#)) proposes a lack of attention to experiential detail, with impaired encoding and blocked retrieval. A third view ( [Pillemer and White, 1989](#)) hypothesizes a discrepancy between encoding state and retrieval state, in that prelinguistic encoding is incompatible with more mature language-based retrieval. Freud suggested that the repression barrier lifts at 8 years of age. The encoding-deficit and the encoding-retrieval-discrepancy theories propose 5 years of age for the termination of childhood amnesia. [Bauer \(1996\)](#) contends that explicit semantic memory emerges at around 1½ years old and that autobiographic memory may emerge after the second birthday.

As discussed in the following, explicit memory may require the maturation of the hippocampus. The later onset of autobiographic recall may depend on this hippocampal development and the additional maturation of the prefrontal region, especially the orbitofrontal cortex. As these regions mature, the child is able to recall personally experienced events with a sense of self and time. Interestingly, children around 5 years and older may have difficulty explicitly retrieving events that they could recall without difficulty earlier in their lives. This finding has not been explained as yet. Early, implicit memory, which is intact during "childhood amnesia," may influence play therapy and transference within psychotherapy ( [Lewis, 1995](#)).

**Narrative and Autobiographic Memory.** Children begin to tell the story of their experiences during their third year of life. In fact, autobiographic memory is often expressed in story form revealing the finding that autobiographic memory and narrative capacity intertwine. A narrative is a discourse in which the teller takes account of the listener's interests and expectations while recounting a temporal sequence of events, and incorporating the intentions of the characters in the story. One function of the narrative process is the facilitation of personal relationships. Some parents help their children construct narratives; a lack of exposure to coconstruction and memory talk may lead to an impairment of narrative memory. Children classified in infancy as avoidantly attached subsequently tend to exhibit a deficit in autobiographic memory that is correlated with similar deficiencies in their parents ( [Main, 1991](#)). Further research is required to determine whether this correlation is causal in nature.

As language and social competence mature, the child's sense of self and capacity to reflect on self enhance autobiographic memory. Theoretically self-reflection enables the elaboration of memory as "self" experience ( [Wolf, 1990](#)). Both encoding and retrieval may be organized by the self-concept. In other words, self-reflection, social interaction, and language intersect in the facilitation of autobiographic memory ( [Toth et al., 1997](#)). The capacity for sequencing or temporality is also involved. The child's sense of time and order develop throughout the preschool- and early school-age years. As temporality develops, the sense of self-in-time begins to shape autobiographic memory. A sense of personal continuity thus emerges, permitting new experiences to be processed from a temporal perspective.

### *Neurobiology of Attention and Memory*

**Attention.** [Margulies \(1985\)](#) proposes that the hippocampus mediates selective attention. Features or patterns abstracted from sensory data are conveyed to the hippocampus and matched against a cognitive "map" in order to determine whether a particular stimulus is noteworthy. Noteworthiness is determined in accordance with such criteria as novelty, salience, and emotional valence. The threshold and propensity of hippocampal selectivity may be modulated on a phasic basis (by norepinephrine), on a diurnal basis (by serotonin), and on a long-term basis (by corticosteroids). Once a stimulus is selected as noteworthy, efferents flow from the hippocampus to the medial septum (where spatial localization is determined) and the nucleus accumbens (which interrupts thought and allows the integration of the noteworthy stimulus into behavior). The organism, thus, can change the direction of attention toward the new stimulus.

[Hunt and associates \(1987\)](#) and [Zametkin and Rapoport \(1987\)](#) regard the noradrenergic theory of attention deficit disorder as the strongest current contender. According to this theory, attention deficit and hyperactivity are owing to an increase in noradrenergic transmission, possibly emanating from the locus ceruleus. Such an increase could be due to a variety of processes (e.g., heightened postsynaptic receptor sensitivity, or increased presynaptic production or release). It is unclear how the noradrenergic hypothesis of attention deficit fits the hippocampal theory of selective attention; perhaps a tonically high noradrenergic state causes a reduction of the hippocampal threshold to stimuli, leading to increased distractibility.

[Mirsky and colleagues \(1991\)](#) refer their three proposed components of attention—focus, sustain, and shift—to different brain systems. Focusing and execution are related to the superior temporal and inferior parietal cortices and to the corpus striatum. Sustained vigilance is related to the mesopontine reticular formation and to the midline and reticular thalamic nuclei. The capacity to shift from one salient aspect of the environment to another is associated with the prefrontal cortex.

Working memory is mediated by the lateral prefrontal cortex in conjunction with the executive functioning of the anterior cingulate regions. The complex interplay of focal attention, executive function, and encoding is likely to be a central focus of future research on attentional mechanisms. The prefrontal region, especially on the right side, may play an important role in these functions and has been found to be abnormal in numerous imaging studies of children with attentional difficulties ( [Arnsten, 2000](#); [Hendren et al., 2000](#)).

**Memory.** The components of implicit memory function independently of the medial temporal lobe memory system. Implicit memory is thought to be associated with the basal ganglia, amygdala, and possibly, the motor and somatosensory cortices. Recent research suggests that the medial temporal lobe is the key to declarative or explicit memory. Within the medial temporal lobe is the hippocampus, one of the few brain regions that undergo significant postnatal neurogenesis. In humans, hippocampal neurogenesis was believed to occur up to 2 years of age, and synaptogenesis to continue even longer. However, recent research suggests that new neurons continue to grow throughout the life span, especially in the hippocampal region that integrates the processing of disparate areas of the brain ( [Benes, 1998](#)). The relative immaturity of the hippocampus during the first year and a half of life may explain the delayed onset of explicit memory. The later development of the prefrontal regions following the second birthday may explain the onset of explicit autobiographic memory.

The hippocampus is thought to be associated with cognitive "maps" that structure time, space, and sense of self in such a way as to facilitate explicit memory. Autobiographic memory appears to be mediated via the prefrontal regions that draw on representational processes from posterior regions of the brain, especially in

the right hemisphere ([Wheeler et al., 1997](#)).

Clinical disorders caused by lesions to the hippocampus impair declarative memory, whereas implicit memory remains intact ([Squire, 1992](#)). Even in the absence of hippocampal processing, some learning is possible, but it lacks an explicit sense of time, self, or context. Infants exhibit implicit memory postnatally, develop generic event memory, and then, by 2 to 3 years of age, autobiographic memory.

Social interactions that facilitate the sense of self and time may both depend on hippocampal and prefrontal cortical maturation and also stimulate their further development. Individual differences in autobiographic memory capacity may thus reflect the interdependency of social interaction, cognition, and neural substrate ([Siegel, 1999](#)).

Recent research has illuminated a possible cellular substrate of explicit memory. Neurochemical explanations must account for the extraordinary associativity, durability, efficiency, capacity, and rapidity of memory. Some, at least, of those qualities are consistent with long-term potentiation of the hippocampus by brief bursts of high-frequency stimulation. Long-term potentiation is associated with the opening of calcium ion channels by glutamate, an excitatory neurotransmitter. Calcium ions enter the neuron and function as a second messenger system, activating intracellular kinases, proteases, and lipases. The consequent degradation of cytostructural proteins and membrane phospholipids is thought to promote an increase in the number of excitatory receptors, changes in the shape of dendritic spines, and a proliferation of dendritic synapses. These structural and functional alterations would be consistent with long-term potentiation. Furthermore, the coincident activation of multiple sensory synapses on the one association neuron (or set of neurons) could provide a neural basis for crossmodal perception.

It has recently been discovered that the serotonergic stimulation of neurons elevates intracellular levels of cyclic AMP. When a critical level of cyclic AMP is exceeded, the nuclear cyclic response element binding (CREB) gene is activated (by phosphorylation). CREB transcription proteins then activate other genes, which in turn activate memory storage (by an as-yet-unknown mechanism).

## THE DEVELOPMENTAL PSYCHOPATHOLOGY OF ATTENTION, PERCEPTION, AND MEMORY

Although neither attention, nor perception, nor memory is ever exhibited in isolation, in different forms of developmental psychopathology; it is possible to discern defect, hypertrophy, and deviance of each of these functions.

### Disorders of Attention

#### DEFICIENT ATTENTION

Attention deficit is thought to be the cardinal sign of attention deficit disorder, a condition characterized in part by distractibility, difficulty following instructions, difficulty sustaining attention on an imposed task, heedlessness, impulsiveness, and recklessness. [Douglas \(1983\)](#) has described how poor attention and impulsivity can impede the acquisition of concepts, learning strategies, and effectance motivation. However, despite the confidence with which attention deficit disorder is customarily diagnosed, there are many questions concerning the homogeneity and categorical distinctness of this disorder ([Taylor, 1988](#)). As described, since the capacity for sustained and selective attention increases markedly between 48 and 54 months ([Levy, 1979](#)), the diagnosis should be cautiously made in children younger than 4 years of age. It is unclear how inclusive or exclusive the diagnostic criteria for this condition should be; as a result, the estimated prevalence of the condition varies between Europe (where it is relatively low) and North America (where it is much higher). As [Rutter \(1983\)](#) points out, inattention and overactivity are encountered in many situations, from pain, fatigue, illness, and transient emotional upset, to psychopathological conditions such as posttraumatic stress disorder, dissociative disorders, mania, major depression, panic disorder, schizophrenia, intoxication, and confusional states. Furthermore, as previously discussed, attention is not a unitary phenomenon. Not surprisingly, it is unclear whether oppositional defiant disorder, conduct disorder, and attention deficit disorder are distinct, coterminous, or coincidental. [Douglas \(1983\)](#) notes that, although attentional problems are often associated with impulsivity, poor arousal modulation, and an inclination to seek immediate reinforcement, it has not been clearly established that defective attention is the basic dysfunction of attention deficit disorder. An impairment of executive functions that enhance self-regulation might be the central deficit in these conditions. Defective attention has also been found in children at high risk for developing schizophrenia ([Mednick et al., 1978](#)); however, the relationship between this phenomenon and later schizophrenia is unclear. (For further discussion of inattention, see [Chapter 28](#).)

#### HEIGHTENED ATTENTION

Hypervigilance and narrowing of attention occur in situations involving focused fear (e.g., watching a horror movie), night terrors, paranoid conditions (rare in childhood), and in some acute schizophrenic states. Attention fluctuates in delirium and is diminished particularly at night and in situations associated with reduced sensory stimulation. Heightened attention may be associated with perceptual illusions; for example, the anxious or phobic child who mistakes nocturnal rustlings for the approach of an intruder. Cocaine and stimulant abuse are associated with intense, fixed concentration.

### Disorders of Perception

[Ludwig \(1980\)](#) classifies perceptual abnormalities as follows:

1. False perceptions independent of reality
2. False perceptions dependent on reality
3. False perceptions that stem from sensory deficit or dysfunction

#### INDEPENDENT FALSE PERCEPTIONS

Independent false perceptions take the form of hallucinations or pseudohallucinations. A hallucination is a perception that has no basis in objective reality. Hallucinations vary in sensory modality; form (from amorphous to organized); intensity (e.g., loud or soft); clarity (vague or clear); spatial location (internal or external, near or far); and the degree of conviction or urgency they convey.

Epileptic auras and temporal lobe seizures may be associated with poorly formed auditory, olfactory, or visceral hallucinations. Panoramic visions may be described. Delirium is typically associated with poorly formed, unpleasant, visual, auditory, or cutaneous hallucinations. Cerebral space-occupying lesions may be associated with intense, compelling hallucinations, and with bizarre phenomena such as negative hallucinations, autoscopia, the perception of a Doppelgänger, distortions of the body image, depersonalization, and déjà vu experiences. The hallucinations that result from the ingestion of hallucinogens are associated with profound distortions of sensory perception and affective experience and subsequently with traumatic "flashbacks" of intrusive memories of the hallucinatory state.

Schizophrenia is typically associated with unpleasant auditory hallucinations that emerge from amorphous perceptual distortions and take the form of conversations, commands, commentaries on the subject's actions, or echoing of the subject's thoughts. In paranoid states, auditory hallucinations tend to be accusatory, degrading, controlling, or laudatory in nature and consistent with the patient's delusional beliefs.

Disorganized auditory or visual hallucinations are sometimes encountered in mania; whereas in melancholia, depressive hallucinations (relatively rare in adolescence) are consistent with the prevailing delusions of guilt and self-abasement.

[Cantor and associates \(1982\)](#) contend that preschool children can manifest schizophrenia, but this condition is exceptionally rare before 7 years of age and quite uncommon before adolescence. There has been uncertainty whether autistic children are prone to develop hallucinatory psychotic disintegration in late childhood or adolescence ([Petty et al., 1984](#)). The hallucinations in such conditions are said to be relatively unsystematized and perceived as alien, commanding, or threatening in nature.

Pseudohallucinations are experienced in the form of heightened internal thoughts or images. Pseudohallucinations convey less conviction than true hallucinations, and have a content directly related to the individual's psychic predicament. For example, a sexually traumatized adolescent may have recurrent vivid memories ("flashbacks") of being sexually attacked, with accompanying conversations and visual imagery; or a miserable, lonely child may have an image of a deceased relative speaking words of consolation. Pseudohallucinations are common in the overlapping conditions of hysterical psychosis, dissociative disorder, and posttraumatic

stress disorder. Care should be taken to distinguish these common conditions from schizophrenia and temporal lobe epilepsy, with which they are frequently confused. (For further discussion of the development of psychotic thinking, see [Chapter 27](#).)

#### *DEPENDENT FALSE PERCEPTIONS*

An illusion is sensation given a false interpretation, that is, the erroneous perception of a real experience. Auditory and visual illusions are characteristic of intense emotional states (e.g., religious conversion) and physical deprivation (e.g., hunger, thirst, or fatigue). They are also encountered in delirium, intoxication (especially with hallucinogens), epilepsy, hysteria, and acute psychotic conditions. The phenomena of depersonalization, derealization, déjà vu, body image distortion, and alteration of the sense of time are commonly associated with anxiety in adolescence but are also found in intoxication with hallucinogens and in epilepsy, hysteria, dissociative states, and psychosis.

#### *FALSE PERCEPTIONS ASSOCIATED WITH SENSORY DEFICIT OR DEPRIVATION*

Deafness and blindness may be associated with misperception, especially when the individual is delirious, deprived of sensory input, or affected by certain medications (e.g., salicylates).

#### *HEIGHTENED PERCEPTION*

Eidetic imagery has the clarity of real perception and is perceived as though external to the viewer. The propensity to generate accurate, vivid, perceptual memories of events may be a normal variant. It could conceivably interact with stress or metabolic instability to generate visual hallucinations.

#### *PERCEPTUAL IMPAIRMENT*

The association between perceptual impairment and reading retardation has been a topic of investigation and debate for many years. Is dyslexia fundamentally a perceptual disorder? Or is the perceptual immaturity associated with dyslexia secondary to higher-order language dysfunction? Or do children with perceptual disorder represent a subgroup of dyslexics? These issues are discussed in [Chapter 50](#).

### **Disorders of Memory**

Disturbances of memory in children can range from an inhibition of semantic recall and impairment of encoding in the aftermath of head trauma, to a blockage of the retrieval of autobiographic memory in posttraumatic stress disorder. The intricate relationships among attention, perception, schematization, and memory suggest that impairment in a variety of cognitive processes could affect memory. Thus, the clinical assessment of memory in a child requires a broad developmental profile including cognitive development, experiential history, family functioning, and school environment ( [Boyd, 1988](#)).

Memory dysfunction can be present in any of the domains of memory described in the preceding. Thus, clinicians encounter deficits in encoding, short-term memory, access to long-term memory, or retrieval of autobiographic or semantic memory. Cases have been described in which implicit memory is intact but explicit memory impaired. Hippocampal lesions, Korsakoff syndrome, hypnotic amnesia, the aftermath of surgical anesthesia, the side effect of benzodiazepines, and childhood amnesia are associated with this kind of mnemonic disassociation. Memory disturbances can involve a loss of previously attained memory, temporary abnormalities in established functions, or maturational delay. Because memory is embedded in cognition as a whole, specific learning disorder, mental retardation, language disorder, attention deficit disorder, and organic brain disorder are all associated with memory dysfunction.

Depending on the location and extent of brain pathology, neurologic disorders can present with a variety of memory abnormalities. Disorders leading to dementia may produce impairment of the encoding and retrieval of both short-term and long-term memory. Examples of such disorders are infections (e.g., subacute sclerosing panencephalitis, acquired immunodeficiency syndrome [AIDS]), metabolic disorder (e.g., Tay-Sachs disease, Wilson disease), neurocutaneous degenerative disorders (e.g., Sturge-Weber syndrome, neurofibromatosis, tuberous sclerosis), and toxic syndromes (e.g., lead encephalopathy).

Head injury can produce anterograde and retrograde amnesia. Retrograde amnesia is thought to be due to disruption of the cortical consolidation required to establish long-term memory. Seizure disorders can be associated with defects in memory. Generalized seizures impair the retrieval of recently experienced events. Partial complex seizure disorder (temporal lobe epilepsy) causes a disturbance in verbal recall and encoding. Preictal (aura) states are associated with dissociative symptoms (derealization, distortions in the sense of time, perceptual distortion). Ictal and postictal states can impair attention, language processing, and memory retrieval. Other neurologic disorders affecting memory include viral infection (e.g., herpes encephalitis), multiple sclerosis, and brain tumor. The location of the lesion determines the nature of the memory pathology.

Experiential factors affecting memory include attachment disruption and psychological trauma ( [Nelson and Carver, 1998](#)). Culture, family environment, and school all shape memory development. The family's encouragement of intellectual achievement, memory talk, and the shared construction of stories stimulate the domains of memory development: strategies, knowledge, metamemory, and memory capacity.

As described, attachment research suggests that two groups (avoidantly attached children, adults with dismissing states of mind with respect to attachment) exhibit a paucity of autobiographic narrative and diminished access to episodic memory ( [Hesse, 1999](#); [Main, 1991](#)). In the United States, at least 10% of the normal population has impaired autobiographic memory. The factors that mediate this impairment are unclear. It is possible that remote or rejecting parents fail to stimulate their children by telling, sharing, and listening to stories. Another possibility is that the association is genetic.

A failure to tell stories about an overwhelming event may aggravate the effects of psychological trauma. If parent and child cannot talk about the child's frightening experience—for example, if the parent is too misguided, preoccupied, oblivious, or compromised to do so—the child may be at risk of posttraumatic stress disorder. Posttraumatic amnesia is a controversial matter. The mental mechanisms known by clinicians as repression, dissociation, and distortion require empirical validation and clarification. Repression has been ascribed, hypothetically, to the automatization of conscious suppression: Encoding has occurred, but retrieval is blocked ( [Anderson and Green, 2001](#)). Dissociation is akin to the divided attention and altered consciousness observed in hypnotic states ( [Siegel, 1996](#)). The subject's mental state at the time of encoding can influence later accessibility to retrieval. Research using dichotic listening methodology has shown that implicit memory may be intact in the nonattending ear. If a child learns to adapt to trauma by means of autohypnotic division of attention and dissociation, explicit, narrative memory may be impaired whereas implicit memory is intact ( [Siegel, 1995b](#)).

Error and distortion are possible because memory is reconstructive. Both adults and children are subject to preevent biasing and postevent suggestion, for example, by the use of leading questions, persuasion, coercion, or group pressure. After repeated suggestive questioning, some children may begin to construct memories that are consistent but false. This is a serious problem in the investigation of allegations of abuse, particularly with regard to preschool children who have difficulty providing sequential narratives and who often require a certain amount of leading ( [Ceci and Bruck, 1993](#); [Goodman and Bottoms, 1993](#)).

### **CONCLUSION**

Both neurophysiologic processes and interpersonal relationships create the mind. As an individual experiences events, the brain responds by altering the connections among neurons. Thus, genetically encoded information and experience both lead to changes in brain connections. The growth and shaping of neural connections is the physical basis of how the mind remembers and the brain develops.

This interpersonal neurobiology of the developing mind incorporates an interdisciplinary approach to understanding mental processes. Attention, for example, is influenced by the genetically determined unfolding of brain structures that subsume working memory and executive control, as well as experiences that influence the maturation of these regions of the brain. Impairments to attention, perception, and memory may be primarily owing to genetic or experiential variables.

Advances in cognitive neuroscience and developmental psychology can be combined with psycholinguistics, artificial intelligence, anthropology, neurology, psychiatry, and systems theory to create an interdisciplinary view of mental processes. The human mind moves toward ever-increasing levels of complexity. Blockages to this self-organizational process may cause impairments to mental health. The balance of differentiation and integration enables the most complex, and hence, most adaptive states to be achieved. The enhancement of the balance between differentiation and integration may be at the heart of how therapeutic

interventions promote the development of attention, perception, and memory.

[Summary](#)  
[Chapter References](#)

This chapter provides a brief outline of the normal developmental processes involved in the acquisition of communicative skills. We examine the acquisition of these skills within several broad stages, looking first at prelinguistic communication during the first year of life, and then describing the acquisition of basic language skills during the preschool years. More advanced communicative abilities acquired during middle childhood and adolescence are outlined also. In each of these developmental periods, four major components of language are addressed: the processing or comprehension of language, acquisition of speech sounds, expression of words and sentences, and pragmatic or social and contextual aspects of communication.

Readers should be aware that this organizational scheme is not the only way to conceptualize language development. Because there is no consensus on the best model to describe language processing or acquisition, there is no universally accepted categorization method for analyzing the richly integrated system of communication in which we all take part. Bloom and Lahey's (1978) *content/form/use* model (Fig. 17.1) is often used. This divides language into aspects of *semantics* (content) or meaning; *syntax/phonology* (form), the generative rules that govern the formation of words and sentences; and *pragmatics* (use), the way language is used in context to accomplish social communication. This model is useful for understanding normal development, but it does not correspond as closely as the one employed here to the disorders of language learning typically seen in children. *Diagnostic and Statistical Manual, Fourth Edition* (DSM-IV) classifies disorders of language learning along the speech sound/production/comprehension/pragmatics dimensions, and using this categorical scheme will make it easier to discuss these disorders when we look at them in Chapter 49.

**Figure 17.1.** Bloom and Lahey's taxonomy of language. (From Bloom L, Lahey M: *Language Development and Language Disorders*. New York, Wiley, 1978.)

A second caveat readers should bear in mind is that, although the various components of speech and language are described in terms of disparate stages, there is often a good deal of overlap among the stages in reality. These stages of language development are not necessarily discontinuous steps marked by clear transitions or divisions. Nonetheless, it is usually possible to identify which broad stage of development any given child is in, and consequently, these stages represent a useful method of conceptualizing development for discussion.

Finally, readers should be aware that the normal range of language development is relatively wide, particularly during early childhood. The speech and language milestones that are presented here represent the ages during which the various stages of development generally occur. They are, of course, group averages, which to some extent ignore the possibility of specific (normal) individual differences. There are relatively large standard deviations, or normal variation, around these averages, which decrease somewhat with age. For example, the average vocabulary size for an 18-month-old child is 110 words with a standard deviation of 114. At this age, the normal range of variation is over 100% of the mean! By 30 months, though, the standard deviation in vocabulary size declines to 18% of the mean (Stoel-Gammon, 1991). We can see, then, that wide variation in language milestones is very common, especially in the early stages of acquisition. As children grow older, the normal range narrows considerably, which makes the determination of whether a difference represents a disorder much easier in an older child than in a younger one. Generally, the order of acquisition of particular structures, meanings, and uses is similar across children (with some exceptions), although the rate of acquisition can differ. Clinicians should keep in mind that a specific delay in one or several milestones is not necessarily indicative of disordered acquisition unless the delay persists beyond early childhood or that there is a general pattern of such delays across several areas of development.

## PRELINGUISTIC COMMUNICATION

The production of a "first word" is frequently considered by parents as the first step in communicative development; however, infants engage in a great deal of communication long before the first word is heard. From the moment of birth, this communication is an active process between the child and social environment. Far from being a passive recipient of adult speech, even the newborn infant engages in behaviors that rivet the adult's attention and elicit social interaction. Let us look at the areas of communicative development that were outlined in the preceding and examine how infant communication proceeds in each.

### The Infant's Perceptual Equipment for Processing Language

Although, of course, young infants do not understand the literal meaning of language addressed to them, it does appear that newborns begin life with attentional preferences for human, linguistic interaction and with a set of social behaviors that can elicit this stimulation. These abilities appear, because of their emergence so soon after birth, to be innately programmed, and, as such, provide a great deal of economy in the task of mastering language. Certain propensities present from the first days of life include a preference for sounds in the frequency range of the human voice (Hutt et al., 1968) and for speech over other rhythmic or musical sounds (Butterfield and Siperstein, 1974). Newborns look for the source of a voice they hear, register pleasure with facial expression when they identify the source, and remain quiet, inhibiting their movements, until the voice ceases (Owens, 2000). They do not show this kind of recognition when a nonhuman auditory stimulus is heard. Three-day-old infants are able to recognize their own mothers' voices, as opposed to the voices of other women (Hepper et al., 1993), probably as a result of prenatal experience with the mother's voice heard through the amniotic sac (Jusczyk, 1999b). Newborns are also attracted to and prefer to look at faces (Kagan and Lewis, 1965). Parents, conveniently, interpret this preference as a sign of willingness to interact. The newborn appears, then, to be biologically organized to attract

language input and attune to the linguistic environment.

There is evidence that speech perception begins at a very early age and may, in fact, be preprogrammed in human infants (Eimas, 1975). For example, infants only weeks old are able to discriminate among a variety of speech sounds, including /pa/ versus /ba/, /ta/ versus /da/, /ba/ versus /ga/, to name a few (Aslin and Smith, 1988; Eimas et al., 1971; Graham et al., 1983). Even more interesting, infants make these distinctions along the same categorical boundaries as adults do.

The fact that such distinctions can be made as early as 1 month of age could be interpreted to mean that the ability to make them is innate. Alternatively, it could suggest that this perceptual learning happens very quickly. Researchers have attempted to address this question by looking at sound discriminations that infants could not have learned from their environment because they never heard them made. For example, Werker and Tees (1984) found that infants in English-speaking environments were able to distinguish sounds that are not used in English but rather in Hindi. By 1 year of age, though, this ability to discriminate sounds not heard in the native language had all but disappeared. These findings suggest that the infant does have some “built-in” capacity to make discriminations among sounds that are important in speech, but that this ability is modified with experience. Rather than learning to make these distinctions from the language they hear, though, it seems that the infant comes to the task of language with some discriminations “preset.” Depending on what particular distinctions are used by the ambient language, some of these innately programmed distinctions are maintained by the child’s experience, whereas others are extinguished. The acceleration of this process toward the end of the first year might also signal a shift in focus for the language learner from sound discrimination to the mapping of sound to meaning (Werker and Tees, 1999).

Children also acquire a range of differentiated responses to the sounds of language throughout their first year. By 4 months of age, they respond to different tones of voice; by 6 months, they show evidence of selective listening (choosing to respond to some sounds and ignore others). Toward the last half of the first year, babies inhibit their behavior if told “no” in a loud, sharp voice, but they do the same if they hear “yes” spoken in the same tone (Spitz, 1957). Their response at this stage, then, is not to a specific lexical item, but to an emotional tone in the speech.

Young babies also appear to be able to coordinate acoustic information about speech with visual information about oral posture. Kuhl and Meltzoff (1988) showed that the infants looked for a significantly longer time at the picture of the face whose oral gesture corresponded to the vowel the babies were hearing at the time (retracted lips for /i/; open lips for /a/). This surprising finding suggests a very early ability to integrate visual and auditory cues in perceiving speech and would seem to provide children with an excellent foundation for learning the articulatory movements associated with the speech sounds they will eventually learn to produce.

Although children do not understand words per se until near the end of the first year, they appear to begin to develop the bases for the grammatical and semantic categories with which these words will be associated much earlier. Infants are able to use acoustic and phonologic cues to distinguish words based on grammatical class. Shi and colleagues (1999) showed that infants presented with lists of lexical (content) and grammatical (function) words could detect a switch to a word from a different category, although they were not sensitive to changes within the same grammatical category. Colombo and associates (1987) showed babies 6 to 7 months of age slides of various kinds of birds until the children habituated to these stimuli and reduced their visual fixation time. These researchers then showed two new slides simultaneously, one of a parakeet and one of a horse, for example. Babies reliably looked longer at the horse, suggesting that it was more novel to them than the parakeet, which they had also not seen before. Thus, it appears that the children included the parakeet in the category they had formed for the objects viewed previously (i.e., birds). These findings suggest that even at this early age, babies are able to organize their perceptions into conceptual categories that eventually can be mapped onto words.

Infants also appear to have specialized abilities that facilitate the task of segmenting words from the ongoing stream of speech. Saffran and colleagues (1996) showed that by 8 months of age, infants are able to recognize word-like sound units from an ongoing acoustic field, based on expectations they have developed for the likelihood that certain sounds will appear together. Moreover, they accomplish this task, using nonsense syllables presented by examiners, after only 2 minutes of exposure.

Jusczyk and coworkers (1999) also reported that infants at 7 to 10 months of age can use stress patterns in a similar way to recognize word-like elements within an acoustic stream. When presented, for example, with a series of syllables that have a strong-weak syllable pattern (hamster), they show preferences for listening to new combinations that have the same pattern and are more likely to react to strong-weak patterns as if they were words, than to weak-strong patterns (giraffe). As they develop, children acquire increasingly sophisticated means of locating word boundaries in fluent speech. By 11 months of age, children’s sensitivity to word boundaries depends on the multiple sources of information, including the order of sounds in the word, stress pattern in the word, and the way in which individual sounds are pronounced (Jusczyk, 1999a; Myers et al., 1996). This ability to use a variety of acoustic cues to segment words from a speech stream by relying on probabilities of sound structure abstracted from a relatively small amount of listening experience helps to explain how children learn to pick out words from the many sounds they hear in their environments.

Infants also appear to be sensitive to auditory information that is associated with syntactic boundaries. Hirsh-Pasek and associates (1987) showed that babies of this age preferred to look toward a speaker that played sentences containing pauses at clause or phrase boundaries (Cinderella lived in a great big house/ but it was sort of dark/ because she had a mean . . .), as opposed to sentences with pauses in the middle of a clause (Cinderella lived in a great big house but it was/ sort of dark because she had/ a mean . . .). These results suggest that babies as young as 7 months can detect syntactic boundaries, an ability that would greatly economize the amount of information they ultimately need to acquire in order to understand sentences.

Although parents have acted as if they believed their child understood speech almost from the first day of life, true lexical comprehension does not emerge until about 8 months of age. Around the last quarter of the first year, babies begin to respond to certain words that they hear in familiar routines and, for example, will clap hands when mother says, “Let’s play patty-cake.” This early comprehension is contextually bound, however. If the baby is used to playing patty-cake on the changing table but is told to clap hands in the bathtub, she or he will probably not comply.

Chapman (1978) points out that this contextually bound comprehension often leads parents to believe that babies at 8 to 12 months understand much more of language than they actually do. Chapman described a set of strategies for comprehension that are frequently used by infants of this age to comply with parental requests and that give the parent the impression the child is actually understanding language. These are summarized in Table 17.1. For example, babies frequently look at what mother looks at, and this can give the impression that the baby understands what the mother is saying. In fact, though, all the baby has to do is follow the mother’s line of regard.

Age	Comprehension skills	Comprehension strategy
8-12 months	Understands a few single words in routine contexts	Look at object mother looks at Act on object mother looks at Initiate ongoing action
12-18 months	Understands single words outside of routine but still requires some contextual support	Locate object mentioned See evidence of action Do what you usually do
18-24 months	Understands words to identify objects, some two-term comparisons	Act on objects in the way mentioned (pick up object)
24-36 months	Comprehension of three-term sentences, but context or past experience determines meaning; no understanding of word order	Probable location Probable event Apply meaning information

Adapted from Chapman, R. Comprehension strategies in children in: Hooper, J. (Eds.) *Speech and language in children*. Oxford and Chicago: Cambridge University Press, 1978, pp. 103-127.

**Table 17.1. Summary of Comprehension Abilities in Children Younger than 3 Years**

Babies also tend to do something to the objects they notice, and because their repertoire of actions is fairly limited at this stage, parents can, by judiciously choosing their instructions, have a very good chance that the child will comply. For example, a mother might say to the baby, “See the pretty ball!” The baby, following her line of gaze, looks at the ball. The baby is very likely, then, to move toward it. If the mother, at the same time says, “Go get the ball for Mommy,” the baby can appear to comply with the instruction when, in fact, that was what she or he was going to do anyway.

The function of these strategies is to help the baby participate successfully in an interaction. Parents are also trying to get the baby to participate and succeed. They unconsciously behave in such a way as to give the baby ample cues, both linguistic and nonlinguistic, as to their meaning. In this way, parents’ speech to infants can

be viewed as a form of “hyperspeech” that provides contextual support for comprehension on concrete, observable levels ( [Fernald, 2000](#)). When the baby responds appropriately, two things happen. First, babies experience the pleasure of a positive social interaction. Second, they get another example of the way in which language works to encode what they already know about the world. In this way infants move closer to linguistic comprehension.

### Infant Sound Production

Crying is the newborn's principal form of vocal behavior. Beginning in the first month after birth, the infant masters the ability to produce cries that differentiate among affective states. Pain versus hunger cries are differentiated within the first week of life ( [Graham et al., 1983](#)). Other noncry vocalizations also emerge early in life. Contentment vocalizations can be distinguished from distress sounds within the first month ( [Ricks, 1975](#)).

The quality of these infant vocalizations changes drastically throughout the first year of life. [Stark \(1979\)](#) has presented a framework for describing infant vocal behavior ([Table 17.2](#)). According to this framework, the infant from birth to 2 months of age produces primarily reflexive cries and other vegetative sounds. Although the newborn's cries have a profound effect on the adults who hear them, the infant is not using the crying in any intentional way to attract the adult's notice. Rather, the cry is an instinctual response to an internal state such as hunger, cold, or boredom. Vegetative sounds such as burps, coughs, and sneezes are also reflexive, but adults respond to these noises as if they were communicative. This willingness on the part of the adult to attribute intentionality to the infant's early reflexive sound production may be one of the ways in which infants are “taught” to use sound to communicate.

Stage	Age Range	Vocalization Types
I	0-2 months	Reflexive cries and vegetative sounds
II	2-5 months	Cooing and laughing
III	4-8 months	Vocal play and beginning babbling
IV	6-9 months	Reduplicated babbling
V	9-18 months	Jargon babbling

**Table 17.2. A Summary of [Stark's \(1979\)](#) Stages of Infant Vocalization**

As the baby grows, the head and neck anatomy changes, resulting in a greater diversity of sounds that can be produced and a more speech-like resonance associated with vocalization. Between 2 and 5 months of age, babies begin two behaviors that are important for the development of speech and communication. One is the pleasant, somewhat speech-like sound that babies produce primarily in response to social interactions, known as *cooing*, or “comfort” sounds. The name arises from the “oo”-like quality of most of the vowels heard during this type of vocalizing and from the fact that most of the consonants produced sound like /k/ and /g/. Again, the reasons for the “coo” quality of these vocalizations are anatomic. As the baby lies in a prone or semiprone position, gravity operates most strongly on the relatively large posterior portion of the tongue, pulling it back toward the roof of the mouth. This oral posture produces the consonants we recognize as /g/ and /k/, as well as the vowel we recognize as “oo.”

A second new vocal behavior in this stage is the infant's laugh, which emerges around the same time as cooing. Usually accompanied by a social smile, infant laughing is produced in response to an interaction the infant perceives as pleasurable, very often because it is a known routine whose components are predictable. Thus, babies may laugh when mother plays “peek-a-boo” for them or when she assumes a posture as if ready to tickle the baby. Crying becomes less frequent during this period of increasingly diverse and speech-like vocalization.

The next stage of vocal development begins at about 4 months of age and extends to about 8 months. Stark refers to this period as “vocal play.” In this phase the infant begins to pronounce what sound like single syllables with vowel-like and consonant-like components. Although not approximations of words and not meant to convey any referential meaning, these early forms of babbling continue the infant's progress toward increasingly speech-like sounds. The consonants produced tend to be made more toward the front of the mouth than were those used for cooing. The infant's productions at this stage appear to be largely a function of mandibular oscillations, or oral opening-closing alternations, that create a motoric “frame” for speech ( [Davis and MacNeilage, 1995](#); [MacNeilage and Davis, 2000](#)). This notion is supported by co-occurrence patterns between consonants and vowels; for example, there is evidence that labial consonants tend to be accompanied by central vowels in early babbling ( [Davis and MacNeilage, 1995](#); [Vihman, 1992](#)).

Vocal play, unlike cooing, does not appear principally in response to social interactions. Although infants do use vocal play as a means of responding to or initiating contact with adults, babies also engage in vocal play when alone. Vocal play may, then, function as a means for the infant to “practice” the new sound production abilities he or she is acquiring.

[Lenneberg \(1967\)](#) was the first to note that it is during this stage that the deaf baby's babbling begins to differ from that of the normal hearing infant, although prior to the vocal play stage, the babbling of deaf babies resembles that of their normal hearing counterparts. [Stoel-Gammon and Otomo \(1986\)](#) substantiated these observations, showing that hearing-impaired babies at this age level had smaller repertoires of consonants than normal hearing peers and that, in fact, the size of the hearing-impaired babies' inventories decreases between 4 and 18 months, whereas that of the normal hearing babies increases. Thus, the ability to derive auditory feedback from vocal play appears to be important in the development of babbling repertoires and their eventual transition to speech. There is also evidence that vocal learning begins to be shaped in the middle of the first year by imitation of sound patterns in the ambient language. [Kuhl and Meltzoff \(1996\)](#) presented audio and video recordings of three vowel sounds to infants at 12 and 20 weeks and analyzed their vocalizations. Twenty-week-old infants were able to imitate specific vowels with appropriate relative formant frequencies. By 1 year of age, infants' reliance on ambient language models for production becomes evident in spontaneous utterances ( [Kuhl, 2000](#); [Vihman and de Boysson-Bardies, 1994](#)).

[Stark \(1979\)](#) reported that a new form of vocal behavior, which she referred to as “reduplicated babbling,” appears in the second half of the first year of life. This type of vocalization includes consonant-vowel combinations, such as /bababa/ or /nanana/, in which the same syllable is repeated over and over. Consonants most likely to appear include /b/, /p/, /t/, /d/, /m/, /n/, and the glide *y*. Like vocal play, reduplicated babbling often occurs when the baby is alone. [Oller and associates \(1998\)](#) report that this form of vocalization, which they refer to as “canonical babble,” is an important milestone of communication development. Their research suggests that children who do not develop canonical babbling by 10 months of age are at risk for later language disorders.

Toward the end of the first year of life, many babies begin to use “vocalables” or phonetically consistent forms. These are productions that are unique to the child in that they do not closely resemble any adult word, but are used reliably in certain situations. For example, [Carter \(1979\)](#) reported that one child consistently used an /m/ sound along with reaching to indicate that he wanted something. These early consistent forms are sometimes referred to as “protowords.”

### Infant Interaction and Communication

Infants' early vocalizations appear to constitute protoconversations with parents ( [Bateson, 1975](#)). Other early forms of interaction include making eye contact with the parents (around 1 month of age), smiling and laughing in response to speech (at 3 months), and vocalizing in response to sounds (at 4 months). Babies may also begin to imitate some of the parent's intonation patterns ( [Trevarthen, 1979](#)) and by 3 months of age show more vocal responsiveness to their mothers than to other adults. As the baby gains better motor coordination, more formal interactions occur, such as patty-cake or peek-a-boo games, waving bye-bye, or “following” conversations by looking first at one person then another. However, there is evidence that, even during the prelinguistic stages, infants can detect deviant parental interactions and are disturbed by them ( [Cohn and Tronick, 1989](#); [Tronick, 1981](#)). [Tronick \(1981\)](#) found that infants responded to a lack of appropriate maternal reactions by unusual patterns of gaze and finally by self-comforting behaviors.

Babies use gaze extensively to regulate interactions. They look at the parent when they are interested in interacting, and avert their gaze when they become tired or overstimulated ( [Stern, 1977](#)). Likewise, babies are sensitive to changes in parental gaze during interactions. Infants as young as 14 weeks smile significantly more

when an adult's gaze is directed toward them than during periods of averted gaze ( [Hains and Muir, 1996](#)). It seems likely that, from very early on, babies are sensitive to gaze as a signal of initiation and termination of social interaction. Babies can also follow their parents' gaze to attend to an object they look and/or point at, and appear to do so reliably by 1 year of age ( [Corkum and Moore, 1998](#); [Morissette et al., 1995](#)). They also begin to direct the parents' attention by looking at objects themselves. Parents will follow the infant's line of regard and look at what the baby looks at. Frequently, parents will comment on this object of the baby's gaze. These interactions, in which the parent and child share focus on an object, have been called "joint attention routines" ( [Bruner, 1977](#)) and are thought to be very important in laying the foundation for the basic topic-comment structure of language in which one speaker directs the other's attention to a focus of interest, on which the conversation then elaborates.

At about 8 months of age, babies begin to develop the representational and intentional skills that allow them to hold goals in mind long enough to pursue them through action. Cognitive development at this time also supports the ability to understand actions as a means to an end, and babies begin to use communication as a means to the outcomes—in parental attention or the acquisition of objects—that they desire. Such communicative acts usually become manifest at about the same time as other forms of intentional behavior emerge—about 8 to 10 months of age.

Communication at this stage is expressed primarily with gestures, such as holding an object up for the mother to view, or pointing. [Acredolo and Goodwyn \(1988\)](#) reported that the use of idiosyncratic symbolic gestures to communicate is quite common during the last half of the first year of life. They found that some children as young as 11 months of age used relatively stable gestures that resembled manual signs to stand for objects or actions for the purpose of communication. For example, a child might bounce up and down to indicate "rabbit" or press on the eyes to indicate "sun." Often these gestures are accompanied by a look at the parent to see that she is attending.

[Bates \(1976\)](#) categorized these early intentional behaviors into two broad types based on their communicative function: protoimperatives and protodeclaratives. Protoimperative speech acts are those in which the child attempts to get the listener to do something for him or to stop doing something, and would appear to evolve into linguistic imperatives or commands. Protoimperative speech acts include requests for objects, which the child can indicate by pointing or reaching. Requests for actions, which the child can convey by miming some part of a familiar ritual, also fall into this category. For example, the child might climb on the mother's lap and touch his nose to indicate that he wants his mother to play the "body-part-naming game" that is frequently a part of interactive routines at this stage. Protests or rejections also occur, in which the child communicates, by pushing away or turning away, the desire to turn down some object or activity the mother is attempting to offer.

Protodeclarative speech acts direct the mother's attention to an object of the child's interest by pointing to it, holding it up, showing, or giving it. These acts are thought to lay the basis for the later use of referential language. Protodeclarative speech acts are thought to evolve out of the earlier established joint attentional routines that appear to be very important for later language development. Several studies of language-impaired individuals ( [Baron-Cohen et al., 1996](#); [Paul and Shiffer, 1991](#); [Wetherby et al., 1989](#)) suggest that children who have various types of language disorders use protodeclarative speech acts with restricted frequency.

As the babies begin to evidence this intentional communication, parents "up the ante" ( [Bruner, 1978](#)), requiring a more sophisticated form of response in order for it to "count" as the child's contribution. Whereas we saw earlier that mothers accepted any child behavior, such as a burp or a cough, as a communicative response, when true intentionality does develop, the mother requires the child to do something more communicative in order to fulfill a turn. The child is now expected to imitate the mother, produce a conventional gesture, and eventually vocalize. In this way, the baby's communication is "shaped" into language.

## LEARNING THE LANGUAGE BASICS

Children's first words usually appear around the first birthday. From this time, until they reach the end of the preschool period, their communication develops at an enormous rate. Vocabulary grows from two or three words to over 5,000, sentence lengths grow from one word to five or more, and the sophistication of their pragmatic skills often amaze and astound the adults around them. We examine the four areas of language development that were outlined in the preceding, to get a sense of how these changes proceed.

### Understanding Language

Comprehension skills begin with the understanding of single words. Before children say their first word, they typically understand the meanings of several ( [Benedict, 1979](#)). This gap between receptive and expressive vocabulary size continues to exist throughout development. Even adults can often recognize meanings for words that they never use in their own speech. The meanings that children attach to their first words are not identical to the meanings of those words in the adult lexicon. Studies of vocabulary acquisition suggest that children use a "fast mapping" strategy ( [Carey, 1978](#)) to acquire an incomplete notion of the meaning of a word that allows them to use the word and refine its definition through subsequent feedback. This kind of strategy could help to explain the exponential rate at which words are acquired during this second year ( [Kay-Raining Bird and Chapman, 1998](#)). Fast mapping of novel vocabulary appears to be greatly influenced by maternal labeling practices as well as the child's orientation and focus. Mothers tend to combine labeling of novel items with physical designation of the items, a behavior that increases the likelihood that the child will make an accurate connection between label and object ( [Masur, 1997](#)). In the same way, children are more likely to correctly map novel vocabulary when focusing on the referent ( [Dunham et al., 1993](#)). For children who have difficulty following the speaker's locus of attention and associating novel words with the object on which they are focusing, as is often the case in children with autism, attempts to teach novel vocabulary can be less successful ( [Baron-Cohen et al., 1997](#); [Chapman, 2000](#)).

At first, as we saw, comprehension is context-bound, and children understand words only within familiar routines. Comprehension begins to be freed from the context around 18 months of age, when children are first able to respond to words for objects that are not immediately visible. When asked to "go get a diaper," at this stage, for example, they can fetch one from another room.

Certain classes of words tend to be acquired in comprehension during this period. By the age of 15 to 16 months, the child can point to his or her own nose, eyes, mouth, and other body parts on request, and by around 20 months, the child can point to these body parts on a doll or on another person. Names of animals the child has toys to represent or sees in picture books, and names of family members tend also to be acquired in receptive vocabulary at this time. By around 2 years of age, children understand the meanings of several prepositions (e.g., in, on, under) ( [Wiig and Semel, 1980](#)) and action verbs (e.g., run, hit, jump), although comprehension of verbs begins slightly later than the comprehension of nouns.

During the 12- to 24-month period, children's production of sentences is limited to one or two words. Are they able to understand much longer ones? Many parents believe so and often claim that children as young as 12 months "understand everything" said to them. Linguistic comprehension is still quite limited in this period, however ( [Chapman, 1978](#); [Paul, 2000](#)). Children manage to convince adults that they understand more than they do by employing a series of strategies or shortcuts for responding to the language that they hear, as they did at the end of the first year. Strategies in the second year, however, integrate emerging linguistic knowledge with the understanding of contexts and interactions.

[Chapman \(1978\)](#) characterizes the 12- to 18-month-old child's comprehension as demonstrating the use of "lexical guides to context-determined responses." Here, the child pairs his or her newly acquired knowledge of the meaning of single words with knowledge about what usually happens in interactive situations. This integration allows the child to act on objects the mother mentions by name, even if she does not look at them. Knowledge of how objects are conventionally used gives the child access to a "do what you usually do" strategy. This results in the child's using the mentioned object for its intended purpose, without having to understand the full linguistic force of an instruction. Thus, if told to "Brush your hair," the toddler is able to comply without fully understanding the instruction, simply by recognizing the word *brush* and knowing for what brushes are used.

In the latter half of the second year, as the child begins to combine two words in his or her own speech, the ability to understand two-word combinations also emerges, but comprehension is probably limited to not much more than two words per sentence. Understanding two words in a sentence allows the child to respond to apparently complex instructions without having to process their full linguistic form. For example, a child in this stage might successfully comply with the request, "Why don't you go and close that door for me?" not because the child understands the whole question, but because she or he was able to pick out the words *close* and *door* and knows that adults usually ask children to do things ( [Shatz, 1978](#)). There is also evidence that children at this age continue to make use of prosodic information, sentence length cues, and key word position cues in sentence comprehension ( [Shady and Gerken, 1999](#)).

Around the age of 3 years, there is a considerable expansion in the number of vocabulary and linguistic items (e.g., plurals, present verb tense, adjective comparison forms) that are understood. During the period of rapid growth in expressive language abilities, there is a corresponding rapid growth in the ability to understand language. The 3-year-old child understands much of what is said to him or her, but there are still some sentence types that cause problems, and children continue to

use comprehension strategies in responding to these difficult utterances. For example, the probable event strategy is used to respond to sentences that contain prepositions the child does not fully understand. Young 2-year-old children, for example, if asked to put a spoon *under* a cup, would be most likely to put the spoon *in* the cup, because they know that containers like cups are usually used to put things *in*.

By the age of 4 years, the young child has learned many of the basic grammatical rules of the language. But preschool children often have difficulty understanding complex sentences in which the order of mention of clauses does not correspond to the order of events, such as, "Before you brush your teeth, turn off the water." And they have a hard time understanding sentences with conjunctions such as *unless* and *although*, which involve negative hypothetical propositions (Owens, 2000). Preschoolers and young school-aged children also typically misunderstand a few other specific sentence forms that violate the regular rules for sentence interpretation (Chomsky, 1969). Although the preschooler sounds much like an adult speaker in terms of the production of grammatical sentences, it is possible to trigger misinterpretations of sentences with forms that violate the general rules of the language.

## Speech Sound Production

Typically, children pronounce their first understandable word around 12 months; however, the range of 8 to 18 months is considered normal (Morley, 1965). Although children begin using real words around their first birthday, babbling and nonmeaningful sound play continue to coexist with speech for some time. In both speech and babbling, the same sounds tend to be used. Stark (1979) calls the sound play heard during the second year of life "nonreduplicative babbling" or "expressive jargon." This babbling is more varied than the earlier, reduplicated form. It involves new types of consonants, particularly those known as *fricatives*, that involve constriction rather than complete obstruction of the airway. The /s/ sound is one common early fricative. In addition, more than one consonant may appear within an utterance. So instead of /bababa/, a child may produce /pata/. Syllable structures that are produced also become more complex. Reduplicated babbling primarily contains consonant-vowel sequences (/ba/). But jargon babbling may, in addition, contain vowel-consonant-vowel sequences (/aba/), as well as consonant-vowel-consonant productions (/bap/). Still missing from this form of babbling are the liquid sounds (/l,r/), and any combination of consonants, such as the *pi* in *play*. Sounds made in the front of the mouth, such as /b/, /p/, and /m/ are more frequent than those made in the back, such as /k/ or /g/. Jargon babble begins to take on the intonation contours of the ambient language at this time, so that the child's vocalizations sound as if the child is speaking, but the listener is unable to understand the words.

Regardless of the language being acquired, the first words children say are generated from a limited set of consonants that are similar to those used in jargon babble. This phenomenon is referred to as *phonologic selectivity*, or *phonologic bootstrapping* (Chapman, 2000). These include sounds produced toward the front of the mouth (e.g., /b/, /p/, /m/, /n/, /t/, /d/) (Jakobson, 1968). Although there is some individual variation in the precise order of acquisition of speech sounds, the acquisition of speech sounds does follow certain general patterns across all children (Bernthal and Bankson, 1998). The vowel inventory is mastered quickly (by the age of 18 months), whereas acquisition of the full inventory of consonant sounds continues for several more years. The first consonant sounds to be consistently articulated correctly are nasals (/m/, /n/, /ŋ/), stops (/p/, /b/, /t/, /d/, /k/, /g/), and glides (/h/, /w/, /y/). Subsequently, most fricatives (/s/, /ʃ/, /v/, /f/) are articulated correctly. Liquids (/l/, /r/), affricates (/tʃ/, /dʒ/), some fricatives (*th*; voiced [thy] and voiceless [thigh]), and consonant clusters (*bl*, *st*, *tr*, *str*) are among the last types of sounds to be consistently articulated correctly.

The first words children say usually have simple syllable shapes, such as consonant-vowel combinations (CV), or reduplicated syllables (CVCV): "ma," "mama." Between 18 and 24 months of age, however, children's repertoire both of sounds and syllable shapes expands with his or her expanding vocabulary. Stoel-Gammon (1987) found that by 24 months of age normal children produce nine to 10 different sounds and at least a few words with consonant clusters, like the *pi* in *play*. Paul and Jennings (1992) report that by 24 months normal children produce many syllables that contain two different consonants as well as some multisyllabic words. Stoel-Gammon (1987) also showed that 70% of the consonants produced by normal 24-month-old children were correct according to the adult target word.

Although 2-year-old children are accurate in their production of speech sounds most of the time, they do tend to make some characteristic changes in their pronunciation that serve to simplify the task of articulation. They may leave off the last sounds in words (*ca* for *cat*), delete unstressed syllables in long words (*nana* for *banana*), make the sounds in a word more alike (*doddie* for *doggie*), change certain sounds that are hard to pronounce (*wabbi* for *rabbit*; *sair* for *chair*), or leave out one of the consonants in a consonant blend (*pay* for *play*). These types of errors are very typical of children's speech in the 24- to 36-month period (Grunwell, 1982; Shriberg and Kwiatkowski, 1980; Vihman, 1998).

As we have seen, there is considerable individual variation in normal communicative development. Among the individual variations that have been reported with regard to the production of speech sounds are the avoidance of certain sounds or preference for certain sounds (Farwell, 1977; Vihman, 1981), a tendency toward consistency versus inconsistency of pronunciations (Vihman, 1981), reduplicating the first syllable of a word instead of producing a completely different second syllable (Ferguson, 1978; Schwartz et al., 1980), and using particular modifications of specific sound sequences (Ingram, 1974).

Between ages 2 and 4, though, most of these sound changes, both the typical and the idiosyncratic ones, drop out. Figure 17.2 shows the general order in which these errors, often referred to as *phonologic processes*, are resolved. Children older than 4 years who retain use of a significant number of these processes, so that the intelligibility of their speech is affected, would be considered to have an articulation, or phonologic, disorder.

**Figure 17.2.** A sequence of phonologic processes based on Grunwell (1987). *Language Disorders from Infancy through Adolescence: Assessment and Intervention*. St. Louis, Mosby, 2001.

By age 4 the normal child is fully intelligible, producing nearly 100% of speech sounds correctly. If errors remain, they are likely to occur on the last sounds to develop: *l*, *r*, *th*, and possibly *s*, as well as on the production of several consonants that occur together within a word, as in *scrape*. Normal preschoolers also continue to have difficulty with multisyllabic words, such as *spaghetti* or *aluminum*. About 5% of children enter school with phonologic deficits (Shriberg et al., 1997), but most of these involve residual errors on one or two sounds.

During the stage of systematic acquisition of speech sounds, speech dysfluency or stuttering may appear. It appears that approximately 75% to 85% of the young children who stutter during this period of time recover spontaneously within a few months' time (Homzie and Lindsay, 1984; Yairi and Ambrose, 1999). Consequently, intervention is generally not recommended at this age, unless there is evidence of distress, fear of talking, or avoidance of speech.

## Producing Words and Sentences

### EXPRESSIVE VOCABULARY DEVELOPMENT

The first words of children learning to speak any language share some properties in common. They tend to be words for objects and activities with which the child has direct contact. So, *shoe*, which a child can put on and take off by himself or herself, is more likely to be one of the first words than *shirt*. First words also tend to be those used very frequently in social interactive routines, such as *hi* and *bye-bye*. Although most first words are nouns, or names of things, not all are. *More*, *up*, and *no* are frequent entries in lists of early words.

Children, like adults, understand many more words than they say. What determines which of these comprehended words will be produced? One characteristic that

seems to be a factor is the sound structure of the word. Children are more likely to produce words that have at least a beginning sound that is already in their repertoire than they are to produce a word with sounds that are not under their control ( [Leonard et al., 1978](#)). This active process of selection and avoidance of words based on their sound structure is typical of children in this very early stage of language acquisition ( [Bernthal and Bankson, 1998](#); [Ferguson and Farwell, 1975](#)).

Children's use of words during this period also may not always conform to adult usage. Two common types of errors seen are *overextension* and *underextension*. Overextension is using a word to mean more than its true meaning (e.g., using "doggie" to mean "animal"), whereas underextension is using a word to mean only part of its true meaning (e.g., using "car" to mean "a car that is moving"). Overextension errors are most often based on shape (e.g., using "moon" to mean "sliced grapefruit") and taxonomic relatedness (e.g., using "banana" to mean "apple") ( [Gelman et al., 1998](#); [Graham and Poulin-DuBois, 1999](#)). It is important to note, too, that words are overextended in production much more often than in comprehension. [Rescorla \(1976\)](#) reports that children who label both a truck and a plane with the word *car* can very often point to pictures of the correct items when *truck* and *plane* are named for them. [Gelman and colleagues \(1998\)](#) examined overextensions in children of three age groups and found that although children in the two younger age groups (2:0 and 2:6) made overextension errors more frequently on production than comprehension tasks; this effect was not significant in the older group of children (4:5).

During the period of the first 50 words, children's "sentences" consist of one word at a time. These early one-word sentences are sometimes called "holophrases" because they seem to function as sentences and may convey meanings that are more complex than mere labels. For example, a baby saying "Mama" may actually be trying to convey a more complex message, such as "Mama, come here." First sentences tend to express the same protoimperative and protodeclarative intentions as children expressed during their first year with gestures and vocalizations.

Average expressive vocabulary size at 12 months is three words; at 15 months it is ten words ( [Templin, 1957](#)). By 18 months, most children are producing more than 50 words ( [Nelson, 1973](#)), and average number of different words produced is about 100 ( [Fenson et al., 1990](#)). By 20 months, average expressive vocabulary size is about 150 words ( [Dale et al., 1989](#)). The average 24-month-old child says 300 different words ( [Dale, 1991](#)). There is a great deal of individual variation in expressive vocabulary size, but recent studies suggest that children of 24 months of age who produce fewer than 50 words can be considered to be performing below the normal range of expressive language and are at risk for chronic linguistic handicap ( [Paul, 1996](#); [Rescorla, 1989](#)).

The rate of growth of vocabulary during the second year of life is not linear. Typically, there is slow acquisition of the first 50 words, with points at which new acquisition appears to halt for a time. Some words may temporarily drop out of the vocabulary. But about the time, the child acquires the fiftieth word or so, around 18 months, a spurt in vocabulary acquisition is seen, and vocabulary size increases suddenly and sharply ( [Fenson et al., 1994](#); [Hamilton et al., 2000](#)). The failure of a child to undergo this spurt in vocabulary growth during the second year of life may be another warning signal of risk for chronic delay.

Both expressive and receptive vocabulary size continue to grow rapidly during the third year. [Smith \(1926\)](#) estimated expressive vocabulary size at 36 months to be about 900 words, a threefold increase over this size at 24 months. As children increase their vocabulary, they develop mastery over a range of semantic categories. Spatial terms including *in*, *on*, *under*, *beside*, *next to*, *on*, *off*, *out*, and *over* ( [Boehm, 1969](#)) are generally mastered by 3 years of age. *Big* and *little* are the first pair of dimensional adjectives to be acquired, with *long* and *short* following soon after, both generally learned by 3 years. 2-year-old children use color terms occasionally. By 36 months, most typical children name two to three colors correctly. Children also learn to produce and understand question words *what* and *where*, and occasionally use *who* and *how* by age 3 ( [Tyack and Ingram, 1977](#)). Pronouns including *I*, *me*, *my*, *mine*, and *it* are usually used by age 3. *You*, *your*, *she*, *them*, *he*, *yours*, *we*, and *her* are frequently mastered by age 3 as well (Haas and Owens, 1985). The child's ability to use first-, second-, and third-person pronouns correctly appears to be strongly linked to his or her capacity for perspective-taking ( [Loveland, 1984](#); [Ricard et al., 1999](#)).

The average spoken vocabulary size at age 4 is about 1,500 words, and about 2,100 words at age 5 ( [Smith, 1926](#)). Receptive vocabulary size continues to exceed these levels at each age. Children learn to use and understand a great many classes of words during the preschool period. They master the use of most pronouns, with the exception of the reflexives (*himself*, *herself*, *ourselves*, etc.), which are not learned until school age. Kinship terms in addition to *mother* and *father* or their diminutives, which are part of the child's earliest vocabulary, enter the lexicon. Depending on the child's experience, most terms for extended family members are at least partially understood by age 5 ( [Haviland and Clark, 1974](#)), but full comprehension is not achieved until age 10 or so. The preschooler, for example, may know that he has a brother, but may not realize that he is a brother to someone.

Temporal terms enter the vocabulary at this time, with *before*, *after*, *since*, and *until* coming in earliest. These are used first as prepositions ("I'll go *after* school."), and only later as subordinating conjunctions ("I'll go *after* I get home from school.") Question words *why*, *how*, and *when* are used with greater frequency during this period, and questions containing these words are answered correctly more often, although the context of the question has an influence on correct responding ( [James, 1990](#)). Children are more likely to answer most types of wh- questions correctly when they can see the person, object, or event to which the question refers.

Children learn to refine their use of adjectives, adding more precise terms to their vocabulary during the preschool years. Although a 3-year-old child may know only *big* and *little*, by 5 years children generally learn *large/small*, *tall/short*, *long/short*, *high/low*, *thick/thin*, *wide/narrow*, and *deep/shallow* ( [Owens, 2000](#)). The positive member of the pair is usually learned first. *More* and *less* and *same* and *different* are other pairs of dimensional adjectives usually learned during the preschool years. *More* and *less* may be used initially interchangeably. By 5, most children use these terms correctly.

## DEVELOPMENT OF SENTENCES

Another important language milestone appears at about the time the child produces the fiftieth word, usually around 18 months of age. The child begins to combine words into "telegraphic" sentences ( [Brown, 1973](#)). Structurally, these two-word utterances are not random combinations of words, but follow a "minigrammar," with the positions in which certain words may occur being governed by specific rules ( [Bloom et al., 1975](#); [Braine, 1963](#)). Two-word utterances may express a variety of different types of meanings ( [Clark and Clark, 1977](#)), including an agent who performs an action (e.g., "baby cry"), an action that affects an object (e.g., "hit baby"), an entity given a location (e.g., "Daddy home"), or an object or person with a description (e.g., "nice Mommy"). These utterances resemble telegrams in that they include the most important words of the adult sentence, while leaving out the function words and word endings. Consistent production of telegraphic utterances is typically observed in children who have achieved vocabularies of between 100 and 200 words ( [Fenson et al., 1994](#)).

By the end of the second year of life, most children are beginning to produce some three- and four-word sentences. These early longer forms tend to include the most meaningful elements that were left out of the telegraphic sentences. So, although the telegraphic child might say "Daddy ball," to indicate that dad should toss the ball, the slightly older child may say, "Daddy throw ball." Many small function words and word endings are still omitted ( [Owens, 2000](#)).

An enormous amount of growth takes place in the child's production of syntax between 2 and 5 years of age. And, as is true for vocabulary development, the child's acquisition of syntactic skills depends on his or her ability to share attentional focus with those who are providing language models ( [Rollins and Snow, 1998](#)). During this period, children learn to elaborate telegraphic utterances through the use of *grammatical morphemes*, the units of meaning that are expressed as inflections on nouns and verbs, or as functor words such as articles (*a*, *an*, and *the*) or *be* verbs. [Cazden \(1968\)](#) studied the acquisition of 14 of these morphemes that seemed to undergo substantial change in children's usage. Her studies and others that followed found that children learning English acquired the morphemes in a relatively consistent order. Between 2 and 3 years, children were found to learn to produce the *-ing* ending, plural */s/* and possessive (*'s*), and the prepositions *in* and *on* in nearly all the contexts in which they were required by the adult grammar. Children learning other languages, though, do not acquire these morphemes in the same order as do English-speaking children ( [Kvaal et al., 1988](#)). The differences found across languages in the order of acquisition of grammatical morphemes are thought to reflect the fact that some languages have more difficult or complicated ways of expressing the meaning encoded by these morphemes. For example, in English, articles are learned relatively late, but in Spanish, children produce articles as one of their earliest morphemes. The relative ease of acquisition of articles in Spanish is thought to be a result of the fact that English articles are somewhat harder to hear in running conversation, whereas the Spanish forms, *el*, *la*, *los*, *las*, and so on, are more salient acoustically.

Between 3 and 5 years, children learning English acquire mastery of many grammatical morphemes studied by [Cazden \(1968\)](#), including use of *be* verbs, articles, and third-person singular *s* marking on verbs (I run, you run, he run *s*). Children also master the use of past tense markers during this period. Typically, children start out by marking irregularly formed past tense verbs, such as *come/came*, *see/saw*, and *go/went*, correctly, before they begin using the regular past tense marker *-ed*. Between 3 and 5 years, the regular marker is acquired and, when it is, the child very frequently overgeneralizes it, marking incorrectly those irregular forms that were produced right earlier. This overgeneralization of past tense markers results in productions such as, "I falled down and got hurted." This replacement of an early correct form by an error that is the result of a process of overgeneralization is often taken as evidence that the child is actually inducing rules from the input language and not merely memorizing the forms heard because, presumably, adults do not produce these overgeneralized forms. The use of overgeneralized past tense forms may persist to age 5 or 6. Some overgeneralized plural forms (foots, mouses) may also appear during this period. Other grammatical morphemes that are mastered during the preschool period include the comparative (small/small *er*) and superlative (small *est*), as well as the agentive *er* marker, used to denote one who performs an action (teach/teacher) ( [Carrow, 1999](#)). As children gain knowledge about syntactic elements such as morphologic markers, they use this information to "bootstrap"

their way into learning of new forms. For example, children can discern the form class (e.g., noun) of a novel word by analyzing co-occurrence patterns of function words (e.g., articles *a*, *an*) and bound morphemes (e.g., plural *-s*) (Behrend et al., 1995; Chapman, 2000; Naigles and Hoff-Ginsberg, 1995).

A second aspect of syntactic development includes the expansion of the two basic units of simple sentences: the noun phrase (usually the subject or object of a verb) and the verb phrase, or sentence predicate (Miller, 1981). During the telegraphic period, the noun phrase and verb phrase segments of the sentence generally contain only one word. During the third year, the child learns to elaborate these elements by adding additional words to each. Noun phrase elaboration starts with the addition of a single element, usually an article or a modifier. Modifiers frequently used by 2-year-old children include *this*, *that*, *these*, *those*, *a*, *the*, *some*, *a lot*, *more*, *two*, *my*, and *your* (Miller, 1981). A child just beginning noun phrase elaboration, for example, would be likely to say, "My doggy!" but not "My black doggy." By the end of the third year, children are embedding elaborated noun phrases within sentences. When this occurs, the elaboration is most likely to occur on the object noun phrase at the end of the sentence, rather than on the subject at the beginning (Miller, 1981). So the 3-year-old child is apt to say, "Kitty has black spots," but not, "My new kitty has spots."

Verb phrase development begins with the production of single verbs that are unmarked for person, tense, or number. The child may say, "He throw ball" to mean, "Daddy threw the ball to me." *Can* and *will* are the earliest auxiliary verb forms to be used. Forms of the auxiliary verb *be* may also emerge at this time, but will not be used consistently or with correct marking (Miller, 1981). So the child may say, "You am going," or "You going home." Some use of irregular past tense forms (*came*, *saw*, *went*, *felt*) may appear by age 3, although regular past tense forms, which are marked by *-ed*, may continue to be produced without any marker (Tranham and Pedersen, 1976). The child may use both, "I came home," and, "I help Daddy" to refer to events in the past.

Children continue to increase both the elaboration of basic noun and verb phrases, as well as the complexity of sentence types produced during the preschool years. Young 3-year-old children consistently include a subject noun phrase in sentences, no longer omitting it as 2-year-old children do. Noun phrase elaboration becomes richer and more flexible throughout the preschool years by means of the ability to mark either the subject or object noun phrase with a broader range and greater number of modifiers. Toward the end of the preschool period, children begin using clauses rather than single words or phrases to modify nouns. These relative clauses, again, usually are used first to modify nouns in object position ("They're boys *that I know*"). Modification of subject nouns with relative clauses ("The boys *that I know* are big.") is seen in children's speech very infrequently until school age.

Verb phrase elaboration during the preschool period consists of the mastery of the verb inflections for past and third singular marking, as we saw. In addition, new auxiliary verbs are acquired, including *could*, *would*, *should*, *must*, *might*, and *shall* and past tense forms of the verb *to be*, that is, *was* and *were*. Auxiliary verbs *have*, *had*, and *has* are used very infrequently during the preschool period (Miller, 1981). When preschoolers do use auxiliary verbs, they use only one at a time. They rarely produce sentences with multiple auxiliaries, such as, "I *could have* helped you."

A third area in which syntactic development is seen is the production of the various sentence types available in the language. Two major sentence variants have been found to show significant development between ages 2 and 3 years in children acquiring English: negative sentences and questions. Negative intentions appear very early, as we saw; one of the first preverbal intentions children express is the desire to reject, protest, or deny their interlocutor's utterance. As we saw earlier, *no* is one of the first words almost every child says. Children in the telegraphic period can produce some simple sentence variations. Negative sentences, for example, are produced by putting a *no* or *not* at the beginning or end of a two-word phrase (Klima and Bellugi, 1966). Therefore, the child may say, "No Daddy go," meaning, "Don't leave, Daddy," or, "Go bed no," meaning, "I don't want to go to bed."

Between 2 and 3 years of age, the child learns some new negative markers. These include *can't* and *don't*. It is interesting to note that these early negative forms appear before their positive correlates *can* and *do* are used (Brown, 1973). When *can't* and *don't* are added to the repertoire of negative markers, the child also modifies the rule for placing them in sentences. Although negative markers were first placed at the beginning of the sentence, between 2 and 3 years of age, the child begins to move them inside, generally putting them between the noun and the verb. So the 2-year-old may say, "Daddy, no eat my candy" or "I can't find it."

Negative sentences are generally produced correctly by age 3. Forms such as *isn't*, *aren't*, *doesn't*, and *won't* are added to the repertoire. By age 4, children are also using past tense negative markers such as *wasn't*, *wouldn't*, *couldn't*, and *shouldn't*. By 4½, children use indefinite negative markers such as *nobody*, *no one*, *none*, and *nothing* but may err by producing these forms in double negatives ("Nobody didn't come.") (Miller, 1981).

Children also ask questions early in their language development, although these tend to be routines that are limited to a few memorized forms such as, "Whazzat?" and "Where (X) going?" A rising intonation contour is used to express questions that require a yes/no answer ("Have cookie?"), as it sometimes is by adults (Klima and Bellugi, 1966). Between 2 and 3 years, the child moves beyond the first routine questions to produce *what* and *where* questions that are novel, and not the result of a learned formula. They can now, for example, not only ask, "Whazzat?" but also, "What you eating?" Similarly, they can not only ask, "Where daddy going?" but also, "Where my glass of milk?" Still, these questions usually leave out auxiliary and *be* verbs. Yes/no questions continue to be marked only by rising intonation in this period (Klima and Bellugi, 1966).

Auxiliary verbs begin to appear in both the yes/no and *wh-* questions of young 3-year-old children. Yes/no questions are produced with auxiliaries that are appropriately inverted, or placed before the subject, at this time ("We *can* go."/"*Can* we go?"). Rising intonation also remains an option for asking this type of question. Shortly after they begin using and inverting auxiliaries in yes/no questions, children begin to use auxiliaries in *wh-* questions as well. At first, these questions are often produced without inverting the auxiliary (Tyack and Ingram, 1977). Instead of asking, "Why *can't* I have a cookie?" preschoolers may say, "Why I *can't* have a cookie?" They leave the auxiliary between the subject and the verb, as it would be placed in a declarative sentence, rather than moving it before the subject, as the rule for forming questions in English requires. Not all preschoolers make this mistake (Klee, 1985), although it is quite common. By age 5, most children produce all questions and negatives with auxiliary verbs appropriately placed.
