The most severe tic disorder is best known by the eponym, "Gilles de la Tourette's syndrome." Typically, the disorder begins in early childhood with transient bouts of simple motor tics such as eye blinking or head jerks. These tics initially may come and go, but eventually they become persistent and begin to have adverse effects on the child and his or her family. The repertoire of motor tics can be vast, incorporating virtually any voluntary movement by any portion of the body. Although some authors have drawn attention to a "rostral-caudal" progression of motor tics (head, neck, shoulders, arms, torso), this course is not predictable. As the syndrome develops, complex motor tics may appear. Often they have a "camouflaged" appearance (e.g., brushing hair away from the face with an arm) and can only be distinguished as tics by their repetitive character. Rarely, complex motor tics can be self-injurious and further complicate management (e.g., punching one side of the face or biting a wrist). Single tics may occur in isolation, or there may be well-orchestrated combinations of motor tics that involve multiple muscle groups.

On average, phonic tics begin 1 to 2 years after the onset of motor symptoms and are usually simple in character (e.g., throat clearing, grunting, squeaks). More complex vocal symptoms, such as echolalia, palilalia, and coprolalia occur in a minority of cases. Other complex phonic symptoms include dramatic and abrupt changes in rhythm, rate, and volume.

Motor and phonic tics tend to occur in bouts. Their frequency ranges from nonstop bursts that are virtually uncountable to rare events that occur only a few times a week. The timing of tics appears to have a fractal character in which bouts of tics occur in bouts and bouts-of-bouts of tics occur in bouts ( [Peterson and Leckman, 1998](#)). This pattern of self-similarity over differing time scales is characteristic of fractals and suggests that the same multiplicative processes underlying the occurrence of bouts of tics may govern the basic neurobiological systems that generate tics at shorter time intervals (milliseconds), as well as the waxing and waning course over longer time intervals (months).

The forcefulness of motor tics and the volume of phonic tics can also vary tremendously, from behaviors that are not noticeable (a slight shrug or a hushed guttural noise) to strenuous displays (arm thrusts or loud barking) that are frightening and exhausting.

Consistent with available epidemiologic data, tic disorders tend to improve in late adolescence and early adulthood ( [Leckman et al., 1998b](#)). In many instances, the phonic symptoms become increasingly rare or may disappear altogether, and the motor tics may be reduced in number and frequency. Complete remission of both motor and phonic symptoms has also been reported ([Bruun, 1988](#); [Shapiro et al., 1988](#)). In contrast, adulthood is also the period when the most severe and debilitating forms of tic disorder can be seen. In addition to the tic behaviors, associated behavioral and emotional problems frequently complicate Tourette's

syndrome. These difficulties range from impulsive, “disinhibited,” and immature behavior to compulsive touching or sniffing. There is no clear dividing line between these abrupt and disruptive behaviors and complex tics on the one hand and comorbid conditions of ADHD and obsessive-compulsive disorder (OCD) on the other.

Although most children with TS are loving and affectionate, maintaining age-appropriate social skills appears to be a particularly difficult area for many patients with TS ([Bawden et al., 1998](#); [Dykens et al., 1998](#); [Stokes et al., 1991](#)). Whether this is caused by the stigmatizing effects of the tics, the patients' own uneasiness, or some more fundamental difficulty linked to the neurobiology of this disorder is unknown. Coexisting ADHD, if present, can aggravate these difficulties ([Bawden et al., 1998](#); [Dykens et al., 1998](#); [Spencer et al., 1998](#)). Similarly, children with autism and other pervasive developmental disorders are at higher risk for developing TS ([Baron-Cohen et al., 1999](#)).

---

#### CASE ILLUSTRATION

Arthur is an 11-year-old prepubertal boy who was referred for psychiatric evaluation and possible placement in a residential treatment facility. His past psychiatric history included symptoms suggestive of ADHD from an early age and the presence of motor and phonic tics that had increased steadily over the past 2 years. The immediate reason for referral was the emergence of loud coprolalic utterances of “fuc...” that would interrupt class and reverberate through the house. His parents reported that, initially, both his teachers and parents saw his tic symptoms as intentional and deliberate. He was teased by his peers and regularly provoked the anger of his parents. Six months earlier, during the course of an educational evaluation, the school psychologist suggested that a medical consultation was needed because of probable attention deficit disorder and possible TS. Shortly thereafter, a pediatric neurologist saw him, diagnosed TS, and placed him on 2 mg/day of haloperidol. Within a week, the tics had diminished considerably; however, he continued to do poorly in school and began to put on weight. Over the Christmas vacation, the tics again worsened despite increasing the haloperidol to 6 mg/day. On return to school, his tic symptoms were severe, and he was unable to concentrate on his schoolwork. His parents became increasingly alarmed at his dazed appearance and weight gain and abruptly took him off the haloperidol. Initially, he appeared to do better, but within 2 weeks, the situation had completely deteriorated, with a marked exacerbation of his motor and phonic tics. A day before the evaluation, the parents had been told that Arthur could no longer remain in school.

#### Comment

The waxing and waning character of tic symptoms frequently continues despite the use of medications. “Chasing” the symptoms with increases in medication often is not an effective strategy. Reassurance and educational interventions with both the family and school often are sufficient to help a child over a period of tic exacerbation. Exacerbations of tics some weeks after neuroleptic withdrawal are frequently observed and are usually self-limiting over a period of 4 to 8 weeks.

---

## NEUROPSYCHOLOGICAL FINDINGS

Although motor and phonic tics constitute the core elements of the diagnostic criteria for TS, perceptual and cognitive difficulties are also common ([Walkup et al., 1998](#)). Neuropsychological studies of TS have focused on a broad array of functions. The most consistently observed deficits occur on tasks requiring the accurate copy of geometric designs, that is, “visual-motor integration” or “visual-graphic” ability. (See [Schultz et al., 1998](#), for a review.) There was no evidence to suggest that comorbid ADHD or depressive symptomatology could account for the observed group differences. Even after controlling statistically for visual-perceptual skill, intelligence, and fine motor control, children with TS continued to perform somewhat worse than controls on the visual-motor tasks, suggesting that the integration of visual inputs and organized motor output is a specific area of weakness in individuals with TS. However, these findings reflect a mild to moderate deficit with the performance distributions overlapping greatly across TS and control subjects, and with most of the patients performing within the normal range.

## ETIOLOGY AND PATHOGENESIS

### Genetic Factors

Twin and family studies provide evidence that genetic factors are involved in the vertical transmission within families of a vulnerability to TS and related disorders ([Pauls and Leckman, 1986](#)). The concordance rate for TS among monozygotic twin pairs is greater than 50%, whereas the concordance of dizygotic twin pairs approaches 10% ([Hyde et al., 1992](#); [Price et al., 1986](#)). If cotwins with chronic motor tic disorder are included, these concordance figures approach 90% for monozygotic and 30% for dizygotic twin pairs. Differences in the concordance of monozygotic and dizygotic twin pairs indicate that genetic factors play an important role in the etiology of TS and related conditions. These figures also suggest that nongenetic factors are critical in determining the nature and severity of the clinical syndrome.

Other studies indicate that first-degree family members of TS probands are at substantially higher risk for developing TS, chronic motor tic disorder, and OCD than are unrelated individuals ([Pauls et al., 1991](#); [Walkup et al., 1996](#)). For example, in one study ([Pauls et al., 1991](#)), the risk to male first-degree family members approximates 50% (18% TS, 31% chronic motor tics, and 7% OCD), whereas the overall risk to females is less (5% TS, 9% chronic motor tics, and 17% OCD).

The pattern of vertical transmission among family members has led several groups of investigators to test whether or not mathematical models of specific genetic hypotheses could account for these data. The bulk of this work favors models of autosomal-dominant transmission ([Pauls and Leckman, 1986](#)). These studies have also led directly to the identification of large multigenerational families with the disorder, to facilitate genetic linkage studies ([Kurlan et al., 1986](#)). Thus far, traditional linkage studies have not been successful in determining the chromosomal location of the putative TS gene or genes ([Pakstis et al., 1991](#)).

More recently, nonparametric approaches using families in which two or more siblings are affected have been undertaken ([The Tourette Syndrome International Consortium for Genetics, 1999](#)). This sib-pair approach is suited for diseases with a complex mode of inheritance and has been used successfully in studies of other complex disorders, such as diabetes mellitus and essential hypertension. In this study, two areas are suggestive of linkage to TS, one on chromosome 4q and another on chromosome 8p. Currently, this international consortium of researchers is completing high-density maps of these genomic regions in an effort to refine and extend their preliminary results. In addition, a new sample of sibling pairs is being ascertained to determine if these preliminary linkage results can be replicated.

It is also noteworthy that none of the chromosomal regions (e.g., 3 [3p21.3], 8 [8q21.4], 9 [9pter], and 18 [18q22.3]) in which cytogenetic abnormalities have been found to cosegregate with TS showed any convincing evidence for linkage in the sib-pair study; however, it is still possible that rare susceptibility genes may be found in one or more of these regions using molecular cytogenetic techniques.

### Neuroanatomic Substrates

The basal ganglia and related structures in the midbrain and cortex are likely to serve as the neuroanatomic substrates for TS and related disorders ([Leckman et al., 1997](#); [Peterson et al., 1998a, 1998b, 2001](#)). This speculation is based on an emerging appreciation of the functional interrelationships among these structures and their regulation of cognitive and sensorimotor activities, the occurrence of stereotypies, and the formation of habits. Preliminary neuropathological and neuroimaging studies, and a large body of neurochemical and neuropharmacologic data have also directly implicated the basal ganglia and related cortical structures in the pathobiology of TS.

The basal ganglia have long been recognized as providing a critical way station in cortico-striato-thalamo-cortical (CSTC) circuits involved with motor control and sensorimotor integration ([Marsden, 1982](#)). The identification of interrelated circuits that link thalamic sites with areas in the prefrontal and limbic cortex ([Alexander and DeLong, 1985a, 1985b](#)) has intensified speculation concerning the role of these structures in the pathobiology of TS ([Leckman et al., 1991b, 1997](#); [Leckman and Riddle, 2000](#)) and OCD ([Rapoport, 1989](#)).

Animal studies have indicated that the balance of activity of medium spiny neurons located in the striosomes versus the matrix of the striatum may crucially determine an individual's vulnerability to a range of sudden, repetitive tic-like head and paw movements, as well as sniffing ([Canales and Graybiel, 2000](#)). Neurons located in the striosomes receive afferents from prefrontal and limbic regions. Tic-like movements and vocalizations emerge when these striosomal cells are differentially activated.

Habits involve the automatic and coordinated activity of thousands of medium spiny neurons ([Graybiel, 1998](#)). If habits are coordinated ensembles of action, then conceptually tics may be conceptualized as prewired bits of behavior (motor or vocal) that are available to be assembled into habits ([Leckman et al., 2000](#)). Like habits, tic sequences often arise in response to a heightened and selective sensitivity to particular environmental cues from within the body or from the outside world. In the case of TS these perceptual cues include faint premonitory feelings or urges that are relieved with the performance of tics, and a need to perform tics or compulsions until they are felt to be “just right.”

Few neuropathologic studies have been performed. [Balthasar \(1956\)](#) reported hypoplasia of the corpus striatum (caudate and putamen), with a loss of the interneuronal neuropile. These findings, however, were based on a single case and were not consistent with an earlier report that found no distinctive histological pattern ([Dewulf and van Bogaert, 1941](#)). The case reported by Dewulf and van Bogaert was atypical with regard to age of onset (18 years) and the unremitting

progress of this individual's neurologic symptoms. [Laplaine and coworkers \(1981\)](#) described two intriguing case reports of individuals with basal ganglia lesions that were associated with tics, obsessive-compulsive symptoms, and deficits in motivation.

Neuroimaging studies have provided limited support for the involvement of the basal ganglia and related cortical structures in TS ([Braun et al., 1993](#); [Peterson et al., 1993](#); [Singer et al., 1993](#)). More recent large-scale morphometric studies have identified cortical changes that are age- and sex-dependent ([Peterson et al., 2001](#)). Similarly, recent functional magnetic resonance imaging (fMRI) studies present a more complex picture in which altered patterns of activation and/or deactivation in the prefrontal cortex likely influence voluntary tic suppression or active ticking ([Peterson et al., 1998b](#)). If confirmed, these findings are consistent with the view that prefrontal cortex-basal ganglia circuits participate in the shaping of the motor output of the basal ganglia (Leckman and Riddle, in press). A similar picture has emerged in the study of individuals with OCD using functional neuroimaging techniques ([Baxter et al., 1992](#)).

Recent studies using transcranial magnetic stimulation have reported altered patterns of cortical inhibition/excitation in TS patients. Specifically, following focal transcranial magnetic stimulation to the primary motor cortex, [Ziemann and colleagues \(1997\)](#) have documented that the cortical silent period was shortened and the intracortical inhibition reduced in TS patients. This suggests either disinhibited thalamic input or impaired intracortical inhibition directly at the level of the motor cortex.

In summary, converging lines of evidence for pathology in CSTC circuitry in TS comes from a number of preliminary neuroimaging, neuropathologic, and neurophysiologic studies. Thus far, these findings generally suggest subtle developmental differences.

### Neurochemical Systems and Neuropharmacologic Data

The functional status of a number of neurotransmitter and neuromodulator systems has been evaluated in TS. The most compelling evidence has focused attention on nigrostriatal and nigrocortical dopaminergic projections; serotonergic projections from the dorsal raphe to the substantia nigra, globus pallidus, and striatum; and noradrenergic projections from the locus ceruleus ([Leckman et al., 1997](#)).

Based largely on parallels between the tics, vocalizations, and obsessive-compulsive behaviors seen in some patients with encephalitis lethargica, [Devinsky \(1983\)](#) has suggested that TS is the result of altered dopaminergic function in the midbrain. The substantia nigra and the ventral tegmental area (VTA) are adjacent midbrain sites that contain large numbers of dopaminergic neurons. The dopamine cell bodies in the substantia nigra give rise to the ascending nigrostriatal pathway. The dopamine neurons of the VTA send ascending projections to various cortical regions, including the anterior cingulate gyrus and other limbic structures. The dopamine neurons in the substantia nigra and VTA also give rise to descending pathways projecting to the dorsal pontine tegmentum in the region of the noradrenergic locus ceruleus.

Other data implicating central dopaminergic mechanisms include clinical trials in which haloperidol and other neuroleptics that preferentially block dopaminergic D2 receptors have been found to be effective in the partial suppression of tics in a majority of TS patients ([Shapiro and Shapiro, 1988](#)). [Friedhoff \(1986\)](#) has suggested that the relationship between D2 and D1 dopamine systems may be of interest in TS in that a blockade of the D2 receptors by relatively selective agents such as haloperidol and pimozide disinhibits the D1 system.

Tic suppression has also been reported following administration of  $\alpha$ -methyl-para-tyrosine and following trials of tetrabenazine ([Shapiro and Shapiro, 1988](#)). In contrast, Tourette's-like syndromes have appeared following withdrawal of neuroleptics, and tics are often exacerbated following exposure to agents that increase central dopaminergic activity, such as L-Dopa and central nervous system (CNS) stimulants, including cocaine.

These pharmacologic data, taken together with reports of altered baseline and post-probenecid mean cerebrospinal fluid (CSF) levels of homovanillic acid (HVA) (a major metabolite of brain dopamine) in some TS patients compared to available contrast groups ([Butler et al., 1979](#); [Cohen et al., 1978](#); [Singer et al., 1982](#)), have led several groups of investigators to suggest that TS is a disorder in which postsynaptic dopaminergic D2 receptors are hypersensitive. Although preliminary positron emission tomography studies (PET) of brain dopamine receptors do not support the view that there are increased numbers of D2 receptors in all TS patients ([Brooks et al., 1992](#); [Singer et al., 1991](#)), [Wolf and colleagues \(1996\)](#) did find that differences in D2 dopamine receptor binding/affinity in the striatum were correlated with the degree of difference in observed tic severity among monozygotic twins discordant for TS. If confirmed, this finding suggests that certain environmental factors, as yet unknown, may influence tic severity via the density of D2 dopamine receptors.

Preliminary postmortem studies have suggested that there are an increased number of dopamine transporter sites in the basal ganglia of patients with TS ([Singer et al., 1991](#)). This work has been extended to *in vivo* single photon emission computerized tomography (SPECT) studies of dopamine transporter sites ([Malison et al., 1995](#)), which confirm the earlier postmortem data in a small number of subjects. Additional imaging and neuropathological studies are needed to address fully the potential abnormalities of receptor number, affinity, and distribution. If confirmed, the increased number of dopamine transporter sites in the striatum may reflect a dopaminergic hyperinnervation of the striatum in some patients. Given the role of dopaminergic projections in mediating the output of the basal ganglia ([Aosaki et al., 1994](#)) and the importance of the balance of D1 versus D2 dopamine receptor stimulation ([Filion and Tremblay, 1991](#); [Filion et al., 1991](#)), it is possible that the severity of tics may, in part, be mediated either by an increased density of D2 versus D1 receptors and/or by dopaminergic hyperinnervation of the striatum.

In summary, although the evidence that dopaminergic pathways are intimately involved in the pathobiology of TS is compelling, the exact nature of the abnormality remains to be elucidated. Multiple mechanisms may be involved and patients appear to differ with regard to the nature of the dopaminergic alterations observed ([Leckman et al., 1997](#)).

Although serotonergic mechanisms have been repeatedly invoked as potentially playing an important role in the pathophysiology of TS, there is very little hard evidence to support this contention. Serotonergic inputs from the dorsal raphe to both the substantia nigra and striatum have been identified and partially characterized, but there are no direct neuropathologic data implicating them in TS. Medications that act by increasing or decreasing serotonergic activity do not consistently alter tic symptoms. Studies of CSF 5-hydroxyindoleacetic acid (5-HIAA), the principal central metabolite of serotonin, have reported a range of low and normal levels in TS patients compared to contrast groups ([Butler et al., 1979](#); [Cohen et al., 1978](#); [Singer et al., 1982](#)). Despite this lack of evidence, serotonergic hypotheses continue to be attractive. Circumstantial evidence includes their neuroanatomic projections and their likely involvement in the pathophysiology of OCD.

### Stress-Related Neuroendocrine Factors

Tic disorders have long been identified as "stress-sensitive" conditions ([Chappell et al., 1994](#); [Jagger et al., 1982](#); [Shapiro and Shapiro, 1988](#); [Silva et al., 1995](#)). Typically, symptom exacerbations follow in the wake of stressful life events. As noted by Shapiro, these events need not be adverse in character to exacerbate tics ([Shapiro and Shapiro, 1988](#)). Clinical experience suggests that, in some unfortunate instances, a vicious cycle can be initiated in which tic symptoms are misunderstood by the family and teachers, leading to active attempts to suppress the symptoms by punishment and humiliation. These efforts can lead to a further exacerbation of symptoms and a further increase in stress in the child's interpersonal environment. Unchecked, this vicious cycle can lead to the most severe manifestations of TS and dysthymia, as well as maladaptive character traits. Although psychoanalytic and dynamic formulations of TS have been largely discredited ([Mahler and Rangell, 1943](#)), the intimate association of the content and timing of tic behaviors with dynamically important events in the lives of children make it difficult to overlook their contribution to the intramorbidity course of these disorders ([Cohen and Leckman, 1994](#)).

The neurobiologic substrates for these effects may involve the central noradrenergic pathways and their role as a regulator of the hypothalamic-pituitary-adrenal (HPA) axis. For example, a series of adult TS patients were found to have elevated levels of CSF norepinephrine ([Leckman et al., 1995](#)) and high levels of urinary norepinephrine in response to the stress associated with a lumbar puncture ([Chappell et al., 1994b](#)). These elevated levels of CSF norepinephrine may also contribute to the elevations in CSF corticotropin releasing factor and increased plasma levels of adrenocorticotrophic hormone seen in some TS patients ([Chappell et al., 1996](#)).

The neurobiological interface between a heightened stress response and the appearance or exacerbation of tics is not well understood but may relate to the emotionally laden inputs from the amygdala, the orbital frontal cortex, and other limbic structures to the striosomal medium spiny neurons ([Leckman and Riddle, 2000](#)). Activation of these afferents would then lead to a differential activation of these neurons and the emergence of tics (stereotypies).

In addition to the intramorbidity effects of stress and anxiety, which have been well characterized, some authors have suggested that premorbid stress may play an important role as a sensitizing agent in the pathogenesis of TS among vulnerable individuals ([Leckman et al., 1984](#)).

## Perinatal Factors

The search for nongenetic factors that mediate the expression of a genetic vulnerability to TS and related disorders has also focused on the role of adverse perinatal events (Leckman and Peterson, 1993). This interest dates from the report of Pasamanick and Kawi (1956), who found that mothers of children with tics were 1.5 times more likely to have experienced a complication during pregnancy than mothers of children without tics. Other investigators have reported that, among monozygotic twins discordant for TS, the index twin with TS uniformly had a lower birth weight than the unaffected cotwin (Hyde et al., 1992; Leckman et al., 1987). Severe maternal life stress during pregnancy and severe nausea and vomiting during the first trimester also have been implicated as potential risk factors in the development of tic disorders (Leckman et al., 1990). Other studies have reported that low birth weight children with parenchymal lesions involving the basal ganglia are at an increased risk for developing a tic disorder (Whitaker et al., 1997). In addition to disrupting the functional integrity of the cortical-subcortical pathways, some of these factors may have an enduring effect on the status of the developing dopaminergic or noradrenergic pathways (Friedhoff, 1986) or stress responsivity. For example, animal studies have shown that severe maternal stress toward the end of gestation can lead to enduring changes in stress responsivity of the HPA axis in the adult offspring as well as long-lasting changes in the dopamine sensitivity (Henry et al., 1994, 1995)—changes similar to those seen in some TS patients (Chappell et al., 1994b).

## Sex-Specific Neuroendocrine Factors

The increased prevalence of TS and other tic disorders among males may be related to exposure of the developing male CNS to elevated levels of dihydrotestosterone and/or other gender-related factors (Leckman et al., 1993; Peterson et al., 1992). This hypothesis is based on a series of interrelated observations. First, although TS is more prevalent among males, it does not appear to be genetically transmitted as a sex-linked trait (Pauls and Leckman, 1986); therefore, the observed sex differences are unlikely to result from a genetic cause. Second, the onset of tics is typically well before puberty, so that activation of the hypothalamic-pituitary-gonadal axis during puberty is not crucial for the development of tics. Earlier hormonal effects during gestation (Sikich and Todd, 1988) or during adrenarche therefore may be more important (Peterson et al., 1992). Third, high levels of exogenous androgens can induce a marked and persistent tic exacerbation (Leckman and Scahill, 1990). Fourth, some, but not all, Tourette's disorder patients respond to compounds that block androgenic receptors (Peterson et al., 1998b). In summary, there is strong evidence to support a role for sex-specific hormonal factors in the pathogenesis and intramorbidity course of TS; however, the precise mechanisms and timing of these events remain to be elucidated.

## Postinfectious Autoimmune Mechanisms

It is well known that group A hemolytic streptococci (GABHS) can trigger immune-mediated disease in genetically predisposed individuals (Bisno, 1991). Speculation concerning a postinfectious etiology for tic disorder symptoms dates from the late 1800s (Kushner, 1999). Acute rheumatic fever (RF) is a delayed manifestation of GABHS, occurring approximately 3 weeks following an inadequately treated upper respiratory tract infection. Inflammatory lesions involving the joints (polymigratory arthritis), heart (rheumatic carditis), and/or central nervous system (Sydenham's chorea [SC]) characterize rheumatic fever. SC, TS, OCD, and ADHD likely share common anatomic targets—the basal ganglia of the brain and related cortical and thalamic sites (Husby et al., 1976). For example, SC patients often display motor and vocal tics, obsessive-compulsive, and ADHD symptoms (Mercadante et al., 1997; Swedo et al., 1989).

It has been suggested that pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS) represents a distinct clinical entity (Swedo et al., 1998). The most compelling evidence that acute exacerbations of TS and OCD can be triggered by GABHS comes from two independent reports demonstrating that the vast majority of patients with TS or OCD have elevated expression of a stable B-cell marker (Murphy et al., 1997; Swedo et al., 1997). The D8/17 marker identifies close to 100% of RF patients (with or without SC) but is present at low levels of expression in healthy control populations. The identity of the D8/17 epitope is not yet known, but several non-B-cell types can express it (Kemeny et al., 1994). Additional evidence comes from Swedo and colleagues (1998), who reported that in children who met PANDAS criteria, GABHS infection was likely to have preceded neuropsychiatric symptom onset for 44% of the children, whereas pharyngitis (no culture obtained) preceded onset for another 28% of the children. There were 144 episodes of symptom exacerbation among these 50 children. Cognitive deficits, oppositional behaviors, and motor hyperactivity were reported to be “particularly common” in addition to tic and obsessive-compulsive symptoms during periods of exacerbation. Thirty-one percent of these exacerbations were associated with documented GABHS infection, and 42% with symptoms of pharyngitis or upper respiratory infection (no throat culture obtained). These results are intriguing, although preliminary. The magnitude of some of the reported associations may have been biased upward because individuals were selected for having a recent or recurrent history of GABHS infections.

In summary, a substantial body of circumstantial evidence exists that links postinfectious autoimmune phenomena with TS; however, these data are not compelling with regard to specific immunologic mechanisms (Singer et al., 1998), nor do they establish where these immune changes occur in the sequence of causal events. These potentially important findings require replication in independent samples and warrant more intensive investigation.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of simple motor tics includes a variety of hyperkinetic movements: myoclonus, tremors, chorea, athetosis, dystonias, akathic movements, paroxysmal dyskinesias, ballistic movements, and hyperexplexia (Towbin et al., 1998). These movements may be associated with genetic conditions, such as Huntington's chorea or Wilson's disease; structural lesions, as in hemiballismus (associated with lesions to the contralateral subthalamic nucleus); postinfectious autoimmune processes, as in SC (Swedo et al., 1989); idiopathic functional instability of neuronal circuits, as in myoclonic epilepsy; and pharmacologic treatments, such as acute akathisia and dystonias that are associated with the use of neuroleptic agents. Differentiation between these conditions and tic disorders is usually accomplished on clinical grounds and is based on the presentation of the disorder and its natural history. For example, although aspects of tics, such as their abruptness, paroxysmal timing, or suppressible nature, may be similar to symptoms seen in other conditions, it is rare for all of these features to be combined in the absence of a bona fide tic disorder. Occasionally, diagnostic tests are needed to exclude alternative diagnoses.

Complex motor tics can be confused with other complex repetitive behaviors, such as stereotypies or compulsive rituals. Differentiation among these behaviors may be difficult, particularly among retarded individuals with limited verbal skills. In other settings, where these symptoms are closely intertwined, as in individuals with both TS and OCD, efforts to distinguish between complex motor tics and compulsive behaviors may be futile.

Involuntary vocal utterances, in the absence of a tic disorder, are uncommon neurologic signs. Huntington's disease may be associated with sniffing and brief sounds. Involuntary moaning can be heard in Parkinson's disease, particularly as a result of L-Dopa toxicity. Complex phonic tics, characterized by articulate speech, can be distinguished from other conditions, including voluntary coprolalia. Phonic tics can play an important role in differential diagnosis because of their rarity in other syndromes.

Anamnesis, family history, observation, and neurologic examination are usually sufficient to establish the diagnosis of a tic disorder. There are no confirmatory diagnostic tests. Neuroimaging studies, electroencephalogram-based studies, and laboratory tests are usually noncontributory, except in atypical cases.

Inventories such as the Yale Child Study Center Tourette's Syndrome/Obsessive-Compulsive Disorder Specialty Clinic Questionnaires (Appendices I and II, Leckman and Cohen, 1998), completed by the family prior to their initial consultation, can be valuable ancillary tools to gain a long-term perspective of the child's developmental course and the natural history of the tic disorder. In addition, several valid and reliable clinical rating instruments have been developed to inventory and quantify recent tic symptoms, including the Yale Global Tic Severity Scale (Leckman et al., 1989), the Shapiro Tourette Syndrome Severity Scale (Shapiro et al., 1988), and the Hopkins Motor and Vocal Tic Scale (Walkup et al., 1992). Some clinicians also make regular use of standardized videotape protocols to assess current tic severity (Chappell et al., 1994a; Shapiro et al., 1988; Tanner et al., 1982).

## ASSESSMENT

Table 59.2 presents an outline of clinically relevant areas that should be assessed in patients presenting with a tic disorder. Once the diagnosis has been established, care should be taken to focus on the overall course of an individual's development, not simply on his or her symptoms. This may be a particular problem in the case of TS, where the symptoms can be dramatic and the temptation to organize all of an individual's behavioral and emotional difficulties under a single all-encompassing rubric is relatively great.

**Table 59.2. Clinical Evaluation of Tic Disorders and Closely Related Conditions**

The principal goal of an initial assessment is to determine the individual's overall level of adaptive functioning and identify areas of impairment and distress. Close attention to the strengths and weaknesses of the individual and his or her family is crucial. Relevant aspects include the presence of comorbid mental, behavioral, developmental, or physical disorders; family history of psychiatric and/or neurologic disease; relationships with family and peers; school and/or occupational performance; and the history of important life events.

Medication history is important, particularly if the disorder is long-standing or medications have been prescribed for physical disorders. It may be necessary to evaluate the adequacy of prior trials with pharmacologic agents used to treat tic disorders.

## TREATMENT

Tic disorders are frequently chronic, if not lifelong, conditions. Continuity of care is desirable and should be considered before embarking on a course of treatment. Major approaches include education, supportive interventions, and treatment with neuropsychopharmacologic agents. Typically, patients with chronic motor tics alone do not require drug treatment. Psychoanalytically oriented psychotherapy can be a useful adjunct in selected cases to help address the adverse effects of chronic illness on self esteem, social acceptance, coping skills, and character formation. Behavioral and dietary treatments have not yet provided consistent positive effects.

### Educational and Supportive Interventions

Although the efficacy of educational and supportive interventions has not been rigorously assessed, they can have profoundly positive effects by reshaping negative expectations (Cohen et al., 1988). This is particularly true when the family and others have misconstrued the tic behaviors as voluntary and intentionally provocative. Families also find descriptions of the natural history comforting, in that the disorders tend not to be relentlessly progressive and usually improve during adulthood. This information often contradicts the impressions gained from the available lay literature on TS, which typically focuses on the most extreme cases. In addition, the characterization of TS as a neuropsychiatric disorder determined by a neurobiological vulnerability and influenced by psychosocial factors can help families fend off the stigmatizing effects of a purely mental disorder. For children, contact with their teachers can be enormously valuable. By educating the educators, clinicians can make significant progress toward securing for the child a positive and supportive environment in the classroom. Self-help organizations such as the Tourette Syndrome Association can also be of assistance in providing audiovisual aides as well as peer support and counseling.

### Pharmacotherapy of Tics

The decision to begin medication is based on the level of symptoms and the clinical presentation of the individual case. Many cases of TS can be successfully managed without resorting to the use of medication. When patients present with coexisting ADHD, OCD, depression, or bipolar illness, it is often better to treat these "comorbid" conditions first, as successful treatment of these disorders often will diminish tic severity.

A variety of therapeutic agents are now available to treat tics (Chappell et al., 1997; Kurlan 1997; Leckman et al., 2000). Each medication should be selected on the basis of expected efficacy and potential side effects. Dopamine D2 receptor antagonists remain the most predictably effective tic-suppressing agents in the short-term. Documentation of haloperidol's effectiveness in the early 1960s was landmark in the history of TS, as it called into question the prevailing view that tics were psychogenic in nature (Kushner, 1999). The most widely used D2 receptor antagonists are haloperidol, pimozide, fluphenazine, and tiapride (not presently available in the United States). Favorable data from double-blind clinical trials are available for each of these agents (Borison et al., 1982; Eggers et al., 1988; Sallee et al., 1997; Shapiro et al., 1989; Tourette Syndrome Study Group 1999). The US Food and Drug Administration has approved TS as an indication for haloperidol and pimozide use. Long-term with these agents experience has been less favorable, and the "reflexive" use of these agents should be avoided (Kurlan, 1997; Silva et al., 1996). Typically, treatment is initiated with a low dose (0.25 mg of haloperidol or 1 mg of pimozide) given before sleep. Further increments (0.5 mg of haloperidol or 1 mg of pimozide) may be added at seven to 14 day intervals if the tic behaviors remain severe. In most instances, 0.5 to 6.0 mg per day of haloperidol or 1.0 to 10.0 mg per day of pimozide administered over a period of 4 to 8 weeks are sufficient to achieve adequate control of tic symptoms. Common potential side effects include tardive dyskinesia, acute dystonic reactions, sedation, depression, school or social phobias, and weight gain. In many instances by starting at low doses and adjusting the dosage upward slowly clinicians can avoid these side effects. The goal should be to use as little of these medications as possible to render the tics "tolerable." Efforts to stop the tics completely often risk overmedication.

More recently, "atypical" neuroleptics, including risperidone, ziprasidone, and olanzapine have been used to treat tic symptoms. These agents have potent 5-HT<sub>2</sub> blocking effects, as well as more modest blocking effects on dopamine D<sub>2</sub>. Initial favorable double-blind clinical trials have now been reported for both risperidone and ziprasidone, although ziprasidone is not currently available in the United States (Bruggeman et al., 2001; Sallee et al., 2000). Risperidone use often causes weight gain and complaints of sedation. Ziprasidone appears to have a more favorable side effect profile, but more data are needed before a judgment can be made regarding its efficacy and safety.

Clonidine is a potent  $\alpha_2$ -receptor agonist that is thought to reduce central noradrenergic activity. Although initial open studies were favorable, subsequent double-blind clinical trials have had mixed results (Goetz et al., 1987; Leckman et al., 1991a; Tourette's syndrome study groups, 2002). Clinical trials indicate that subjects can expect on average a 25% to 35% reduction in their symptoms over an 8- to 12-week period. Motor tics may show greater improvement than phonic symptoms. The usual starting dose is 0.05 mg given either on awakening or at bedtime, if the individual's sleep-wake cycle is disturbed. Further 0.05 mg increments at 3- to 4-hour intervals are added weekly until a dosage of 5 mg/kg is reached or the total daily dose exceeds 0.25 mg. Although clonidine is clearly less effective than haloperidol and pimozide for immediate tic suppression, it is considerably safer. The principal side effect associated with its use is sedation, which occurs in 10% to 20% of subjects and usually abates with continued use. Other side effects include dry mouth, transient hypotension, and rare episodes of worsening behavior. Clonidine should be tapered and not withdrawn abruptly, to reduce the likelihood of symptom or blood pressure rebound (Leckman et al., 1998b). Initial results from a double-blind clinical trial with the closely related compound, guanfacine, are also promising (Scahill et al., 2001).

Many other medications have been used in the treatment of tics; however, with the exception of flutamide, an androgen receptor antagonist, and pergolide, a dopaminergic agonist, none have been evaluated in double-blind randomized clinical trials (Gilbert et al., 2000; Peterson et al., 1998c). Promising agents include agents that deplete presynaptic dopamine concentrations (tetrabenazine) (Carpenter et al., 1999). Cholinergic agents, including nicotine formulated as a patch and used in combination with a neuroleptic, have also been recommended (Sanberg et al., 1997; Silver et al., 2000). Building on its success in treating dystonia, reports have appeared concerning the benefits of botulinum toxin injections that temporarily weaken muscles associated with severe motor or vocal tics (Jankovic, 1994). Finally, GABAergic agents, particularly clonazepam, have also been widely used.

### Special Populations: PANDAS

Postinfectious autoimmune mechanisms are likely to contribute to the pathogenesis of 10% to 20% of TS cases (Swedo et al., 1998). Preliminary evidence suggests that individuals with abrupt onset and coexisting ADHD and/or OCD may be at greater risk (Peterson et al., 2000). As in SC, the precise mechanisms are in doubt. Clarification of these mechanisms is likely to lead to improved treatment and possibly preventive interventions. Although initial results from immunomodulatory treatments, including plasma exchange, are promising, caution is warranted (Perlmutter et al., 1999). It is also premature to recommend prophylactic antibiotic

treatment ([Garvey et al., 1999](#); [Shulman, 1999](#)).

## FUTURE DIRECTIONS

A deepening appreciation of the clinical phenomenology, recent progress in neuroanatomy, systems neuroscience, functional *in vivo* neuroimaging, and genetics has set the stage for a major advance in our understanding of TS. The evidence supporting a genetic basis for TS is stronger than any common neuropsychiatric disorder other than Huntington's disease. The age of onset, stress sensitivity, and sex distribution are specific clues that TS syndrome. Success will lead to the targeting of specific brain circuits for more intensive study. Diagnostic, prognostic, and treatment advances also can be expected as the neural circuits involved are identified and as techniques are developed to modify their activity ([Vandewalle et al., 1999](#)).

Given this potential, TS can be considered a model disorder to study the dynamic interplay of psychological and neurobiological systems during development. It is likely that the research paradigms utilized in these studies and many of the empirical findings resulting from them will be relevant to other disorders of childhood onset, especially OCD and ADHD, and will enhance our understanding of normal development.

## DEFINITION

The definition of schizophrenic disorders in childhood has been the topic of considerable debate. There is ample evidence from clinical, neuropsychological, brain imaging, and neurobiological studies to suggest that the patterns of abnormality are similar in both childhood and adult schizophrenia ( [Frazier et al., 1997](#); [Jacobsen et al., 1996b](#); [Zahn et al., 1997](#)). However, controversies have surrounded the stringency of diagnostic criteria and assumptions about the nature of the disorder. *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) ([American Psychiatric Association, 1994](#)) criteria for the condition are presented in [Table 60.1](#). In light of the available evidence supporting a fundamental continuity among childhood, adolescent, and adult schizophrenia, the criteria apply to all age groups.

**Table 60.1. DSM-IV Diagnostic Criteria: Schizophrenia**

Relative to the DSM-III-R ([American Psychiatric Association, 1987](#)) criteria for schizophrenia have been simplified and the disorder is defined on the basis of characteristic psychotic symptoms, deficits in adaptive functioning, and duration of at least 6 months. The criteria for the characteristic psychotic symptoms have been streamlined with examples moved out of criteria into text; these characteristic psychotic symptoms include delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms such as flattened affect. As indicated in Criterion B, some consideration of age should be made relative to social and occupational dysfunction. Signs of disturbance must be present for at least 6 months with at least 1 month during which active symptoms are present. The disorder cannot be diagnosed in the presence of schizoaffective or mood disorder with psychotic features, nor can it result from the direct effects of substance abuse or a general medical condition.

Unfortunately, the attempt to produce a more concise and efficient criterion set may complicate the task of diagnosis of childhood schizophrenia; certain symptoms such as disorganized speech and behavior are relatively common in nonpsychotic children, and the lowered threshold for Criterion A may similarly produce overdiagnosis ([Werry, 1996](#)). On the other hand, particularly in adolescents who develop schizophrenia and where there is a history of substance abuse, Criterion E may tend to produce underdiagnosis of the condition. The reworking of the criterion related to comorbid diagnosis of schizophrenia and autism (Criterion F) reflects the finding that there is no more than a chance association of these conditions ( [Volkmar and Cohen, 1991](#)). Given the lack of familiarity of many clinicians with schizophrenia in childhood, the condition may be misdiagnosed in both directions; that is, both false-positive and -negative diagnoses are common ( [McKenna et al., 1994](#)). The DSM-IV text indicates differences in symptomatology in children and addresses some aspects of differential diagnosis relevant to children. Review of both text and criteria is indicated relative to a diagnosis of schizophrenia in children and adolescents. The approach to diagnosis of the disorder in *International Classification of Diseases* (ICD)-10 is roughly similar ( [World Health Organization, 1990](#)), although that definition is even less developmentally oriented than DSM-IV ([Werry, 1996](#)).

Although DSM-IV and its predecessor, DSM-III-R, in some respects represent substantial advances in the classification of schizophrenic disorders, certain problems with respect to diagnosis of the disorder in childhood remain. Problems arise both in applying concepts such as psychosis to children and in the specification of criteria applicable to disordered children.

The concept of psychosis, as applied to children, is problematic in several respects. It is clear from the work of [Piaget \(1954\)](#) and others that children's conceptions of reality change over the course of normal development and that fully adult conceptualizations of reality are achieved only in adolescence. Many children have normatively appropriate beliefs in fantasy figures, which would not of themselves suggest psychosis. Finally, it is important to note that comorbid associations with conditions such as mental retardation or other developmental disorders might pose additional problems in assessing psychotic thinking in children because many of these severe disorders have important deleterious effects on development. Issues of the definition of psychosis or thought disorder become extremely complex in relationship, for example, to children who do not talk and are likely never to do so ( [Caplan, 1994](#)). These observations suggest the importance of incorporating a truly developmental point of view in conceptualizing the nature of psychosis in childhood.

Changes in diagnostic practice and the relative infrequency of the disorder have complicated the development of better definitions of childhood schizophrenia. The relatively few studies evaluating DSM-III criteria ( [American Psychiatric Association, 1980](#)) for schizophrenia in childhood have provided mixed and somewhat conflicting results.

In DSM-III, the term childhood schizophrenia was discarded as a separate diagnostic concept, whereas the validity of infantile autism as a diagnostic concept was recognized; this major change in classification reflected the consensus of most investigators that the term childhood schizophrenia had been used too broadly ( [Rutter, 1972](#)). [Cantor and coworkers \(1982\)](#) noted problems with this approach because several subjects they believed exhibited schizophrenia had evidenced signs of the

disturbance relatively early in life; important developmental correlates of psychotic symptoms were noted. This report suggested that it is more difficult to apply DSM-III criteria for schizophrenia to younger children. In a study comparing schizophrenic and autistic children, [Green and associates \(1984\)](#) suggested that DSM-III criteria for schizophrenia could be meaningfully applied to younger children. In a review of 228 children with childhood “psychosis” using DSM-III criteria, [Volkmar and associates \(1988\)](#) noted difficulties in applying DSM-III criteria for schizophrenia, particularly in relation to documenting a period of deterioration associated with the illness or, in younger children, in relation to the stringency of criteria for hallucinations and delusions. At present, the extent to which adult criteria for schizophrenia can be applied to children remains unclear. Some children clearly do meet such criteria, but the classification of children—particularly younger or developmentally delayed individuals—with schizophrenic-like disorders remains problematic. It is hoped that these issues will be addressed in future editions of DSM.

## HISTORICAL NOTE

There have been marked changes in the way childhood schizophrenia is both conceptualized and diagnosed. These changes reflect both the recognition of similarities to adolescent and adult forms of schizophrenia and the difficulties inherent in simplistic extensions to children of concepts derived largely from work with adults. In the 19th century, considerable interest centered on the role of experience versus endowment; by the mid-19th century, Maudsley proposed an extension of concepts of “insanity” to childhood. By the late 19th century, Kraepelin had proposed the term dementia praecox to describe a severe disorder with an onset in late adolescence or early adulthood and with characteristic features. This concept, now termed schizophrenia, proved particularly influential. [Kraepelin \(1919\)](#) noted that some cases appeared to have an onset in childhood; [De Sanctis \(1906\)](#) proposed the term dementia praecocissima for children who developed the disorder in childhood. Although [Potter \(1933\)](#) attempted to define childhood schizophrenia on the basis of specific features (e.g., loss of interest in the environment, disturbances in thinking or affect, or changes in behavior), the term became synonymous with childhood psychosis despite the fact that the disorder in children appeared less common than in adults and was more difficult to characterize.

It is important to note that disagreements regarding the nature of the adult schizophrenic syndrome resulted in rather different diagnostic approaches to the disorder. Different clinical features, such as a deteriorating course, disturbances in thinking or specific pathognomonic symptoms were variously emphasized ([American Psychiatric Association, 1987](#)). These controversies were also reflected in the apparent relative overdiagnosis of schizophrenia in adults in the United States compared with that in the United Kingdom ([Cooper et al., 1972](#)). Similarly, some investigators' approaches to childhood schizophrenia have been narrower and more conservative ([American Psychiatric Association, 1987](#); [Potter, 1933](#); [Rutter, 1972](#)), whereas others, particularly those of [Bender and associates \(1947\)](#), have argued for a very broad and inclusive definition. Early attempts to propose definitions (e.g., by the British Working Party on Childhood Psychosis) ([Creak, 1963](#)) were overinclusive, and schizophrenia was broadly defined so as to include all “psychotic” children. Although the narrow view currently predominates, it should be noted that this is a relatively recent historical phenomenon and that, for example, until DSM-III ([American Psychiatric Association, 1980](#)), childhood schizophrenia was the only “official” diagnostic term available to describe all psychotic children.

More importantly, the modern controversy over the relationship of childhood psychosis to adult schizophrenia can be traced to [Kanner's \(1943\)](#) description of the syndrome of early infantile autism. Kanner's initial report of autism noted various ways in which his proposed disorder appeared to differ from schizophrenia; at the same time, his use of the term autism suggested some point of phenomenologic similarity. The continuity or discontinuity of autism with schizophrenia became the topic of considerable debate. In retrospect, it appears that a central aspect of this controversy related to an assumption of continuity based on severity; that is, because autism is a severe psychiatric disorder with a very early onset, must it not be the case that it represents the earliest manifestation of a similarly severe psychiatric disorder in adults?

By the 1970s, various lines of evidence began to suggest that infantile autism and childhood schizophrenia differed in important ways. The work of [Kolvin \(1971\)](#) and [Rutter \(1972\)](#) suggested that differentiations could be made within the broad group of “psychotic” children on the basis of various features (e.g., age of onset, clinical characteristics, family history, and evidence of central nervous system [CNS] dysfunction). In particular, it was apparent that almost all cases of childhood psychosis fell into one of two groups on the basis of age at onset of the disorder, and this is true for series of cases collected at different centers in various countries ([Fig. 60.1](#)). The early-onset group exhibited difficulties in the first years of life more consistent with Kanner's description of autism, whereas the late-onset group exhibited the delusions, hallucinations, and clinical features more commonly associated with schizophrenia ([Kolvin, 1971](#)). It was also clear that family members of the late-onset cases were more likely to exhibit histories of schizophrenia. Thus, a major difference between autism and childhood schizophrenia is the early-onset of the former (always by, and usually well before, 36 months) and the comparatively much later onset (usually after 7 years and more commonly after puberty) of the latter. Together these various lines of evidence convinced most investigators that autism and schizophrenia were unrelated; this was reflected in the 1980 edition of DSM ([American Psychiatric Association, 1980](#)). It should be noted that, although most investigators, including the authors of this chapter, have adopted this view, a small number continue to advocate the earlier, broader diagnostic conceptualizations ([Cantor, 1988](#)).

**Figure 60.1.** Reported age of onset of childhood psychosis. (From Volkmar FR, Cohen DJ, Hoshino Y, et al.: Phenomenology and classification of the childhood psychoses. *Psychol Med* 18:191–201, 1988.)

Recently, the distinction between autism and schizophrenia in childhood has been extended to a consideration of the clinical spectrum of these disorders. Specifically, there have been attempts to identify subgroups of children within the broader spectrum who do not meet DSM criteria but who do show some features of the disorders. Rapoport and colleagues have been examining children with treatment refractory childhood-onset schizophrenia as part of a National Institute of Mental Health (NIMH) study since 1990. Of the children and adolescents referred with a diagnosis of childhood-onset schizophrenia, about 20% of the cases screened met DSM-III-R criteria; of those excluded at screening, 30% presented with complex developmental disorders and brief psychotic symptoms ([Jacobsen and Rapoport, 1998](#); [Kumra et al., 1998c](#)). A subgroup of children was proposed, labeled multidimensionally impaired (MDI), that shared the following features: (a) poor ability to distinguish fantasy from reality; (b) nearly daily periods of emotional lability disproportionate to precipitants; (c) impaired interpersonal skills despite desire to initiate social interactions; (d) cognitive deficits, indicated by multiple deficits in information processing; and (e) absence of formal thought disorder. This group was predominantly male, and further characterized by marked comorbid attentional and impulse control difficulties. A similar subgroup within the larger pervasive developmental disorder not otherwise specified (PDD-NOS) category has also been described ([Cohen et al., 1994](#)). Termed multiplex developmental disorder (MDD), this subtype is defined by difficulties in social interaction, deficits in affect regulation, and vulnerability of thought process. The two subtypes reflect the varied emphasis of features closer to childhood schizophrenia or PDD. A further distinction may lie in family history; [Kumra and colleagues \(1998c\)](#) found that family members of children with MDI were affected with schizophrenia spectrum disorders but not autism or mental retardation. More careful research is needed, and it should be noted that none of these terms is as yet broadly accepted, but represents current attempts to understand the broader phenotype of these disorders.

## PREVALENCE AND EPIDEMIOLOGY

Given the marked changes in the diagnostic concept over the past decade, it is not surprising that information on the prevalence and epidemiology of the disorder, as strictly defined, is quite limited. Few studies conducted prior to 1980 are readily interpretable, and major epidemiologic studies have yet to be conducted. Accordingly, information is limited to estimates provided from case series and comparisons of the frequency of schizophrenia in relation to diagnoses of autism. Available research indicates that the disorder is probably less common than autism. For example, in [Kolvin's \(1971\)](#) series of cases, autism was noted to be 1.4 times as common as childhood schizophrenia. Similarly, using DSM-III criteria, a prevalence study in North Dakota of schizophrenia presenting in childhood revealed that the disorder appeared to be far less common than autism ([Burd and Kerbeshian, 1987](#)).

Characteristics of four samples of children with schizophrenia from four studies using rigorous diagnostic criteria are presented in [Table 60.2](#). Reported sex ratios of the disorder have varied across studies. Both a slight male predominance, on the order of 2 males to 1 female ([Kolvin, 1971](#); [Russell et al., 1989](#); [Volkmar et al., 1988](#)), and essentially equal sex ratios ([Eggers, 1978](#); [Jacobsen and Rapoport, 1998](#)) have been reported. It has been found that children with schizophrenia generally function in the low average to average range of intelligence ([Table 60.2](#)). In addition, in contrast to early reports of a high-socioeconomic-class association with autism ([Chapter 46](#)), there is some evidence that suggests that children with schizophrenia may be observed more commonly in both less educated and professionally successful families ([Table 60.2](#)).

	Study			
	Kolvin et al., 1971	Green et al., 1984	Volkmar et al., 1988	Russell et al., 1989
N	33	24	14	35
Male/female	24/9	15/9	10/4	24/11
Sex ratio (M:F)	2.66:1	1.67:1	2.5:1	2.2:1
Mean IQ	85	88 (±16.0)	82 (±12.5)	94 (±10.5)
Social class				
I and II	16%	0	25%	54%
III	37%	17%	33%	23%
IV and V	47%	83%	42%	14%

**Table 60.2. Sample Characteristics: Childhood Schizophrenia**

## CLINICAL DESCRIPTION

### Precursors of Schizophrenia

Various attempts have been made to identify possible childhood precursors of adult schizophrenia; both follow-back and prospective studies have been employed. Follow-back studies of the childhood histories of adult schizophrenic patients have suggested some early patterns of developmental difference from children who did not develop schizophrenia ([Goldstein, 1980](#)). Similarly, prospective studies that follow children presumably at greater risk for developing adult schizophrenia have attempted to identify various factors that may contribute to adult schizophrenia. Follow-up studies of children with psychiatric disorders have not shown a clear-cut pattern among children who go on to develop adult schizophrenia; although some differences are noted, it does not appear that shy, withdrawn children are particularly likely to develop adult schizophrenia. The applicability of both types of studies to childhood schizophrenia is somewhat questionable; the limited available data arise from case series.

### Premorbid Course in Childhood Schizophrenia

The developmental history of children with schizophrenia indicates significant deficits in language and motor functioning, as well as impairments in social functioning ([Alaghband-Rad et al., 1995](#); [Asarnow et al., 1995](#); [Hollis, 1995](#); [Nicolson et al., 2000](#)). In these samples, approximately one-half to three-quarters of the children had motor (e.g., delayed milestones, poor coordination); language (expression and comprehension); and/or social (e.g., social withdrawal, aloofness) disturbances years prior to the onset of psychotic symptoms. [Eggers and colleagues \(2000\)](#) observed that the first prominent signs of dysfunction in premorbid development in their sample seemed to be disturbances in adaptive social behavior and a tendency for withdrawal, suggesting that these be considered vulnerability factors. Attentional issues and hyperactivity also characterize the early history of many of these children ([Alaghband-Rad et al., 1995](#); [Asarnow et al., 1994a](#)). In several cases, a diagnosis of ADD/ADHD preceded the onset and diagnosis of schizophrenia. Depressive symptoms and conduct problems have also been noted ([Asarnow et al., 1994b](#); [Russell, 1994](#); [Russell et al., 1989](#)). A subset of children is reported to display early features common to the PDDs such as echolalia, hand flapping, and/or a pervasive lack of responsiveness ([Alaghband-Rad et al., 1995](#); [Asarnow et al., 1995](#); [Russell, 1994](#)). In addition to being a chronic disorder, childhood-onset schizophrenia is associated with a more severe premorbid course that has implications for school performance. [Alaghband-Rad and colleagues \(1995\)](#) reported that 50% of the children with schizophrenia in their sample had repeated at least one grade before the onset of psychotic symptoms, 65% had been placed in special education classes, and 30% were diagnosed with a specific learning disability. When compared to children with major depression, children with early-onset schizophrenia showed poorer levels of overall premorbid adjustment and greater premorbid impairment with regard to peer relationships, school performance, school adaptation, and interests ([Asarnow et al., 1995](#)). There is also evidence to suggest that the pattern of developmental disturbances varies with age of onset; relative to adolescent/adult onset schizophrenia, impairments of language, but not social or motor functioning, were more common for childhood-onset schizophrenia ([Hollis, 1995](#)). [Alaghband-Rad and colleagues \(1995\)](#) reported sex differences for premorbid developmental history, specifically with regard to motor abnormalities (boys more affected than girls), but [Hollis \(1995\)](#) did not find this.

### Onset of the Disorder

The age at which a diagnosis of childhood schizophrenia is made varies in association with the criteria used to a considerable extent; however, most studies that employ reasonably stringent criteria suggest that the disorder is very rarely observed before age 5. [Russell \(1994\)](#) reported that, in their sample, the mean age of onset of nonpsychotic disturbance was 4.6 years and the mean age of onset of psychotic symptomatology was 6.9 years, with diagnosis of the full disorder at 9.5 years. The onset of disturbance is generally described to follow at least three patterns: (a) acute onset, without apparent premorbid signs of incipient disturbance; (b) insidious onset, with a gradual deterioration in functioning; and (c) insidious onset with an acute exacerbation of disturbance ([Green et al., 1984](#); [Kolvin, 1971](#)). The most common pattern appears to be insidious onset of illness ([Alaghband-Rad et al., 1995](#); [Asarnow et al., 1995](#); [Eggers et al., 2000](#); [Russell, 1994](#)). The course is characterized by early emergence of various developmental, behavioral, and psychiatric problems, followed by gradual onset of psychotic symptoms (about 2 to 3 years later), and then eventual diagnosis of the full clinical syndrome, which tends to be chronic. Some sex differences have been reported. As with adult schizophrenia, males appear to have an onset of their disorder earlier in childhood ([Green et al., 1984](#)). In addition, boys have been reported to be more likely to show early signs of abnormal development and have an insidious onset relative to girls with the disorder ([Alaghband-Rad et al., 1995](#); [Asarnow et al., 1995](#); [Hollis, 1995](#)). Distinctions between “early onset” and “very early onset” in childhood and adolescence have been suggested ([Werry, 1996](#)).

### Thought Disturbance

Available research data on the phenomenology of thought disturbance in childhood schizophrenia are limited. Only a handful of studies have been conducted using reasonably stringent diagnostic criteria. (See [Caplan, 1994](#), for a review.) Additional problems are posed by the lack, at least until recently, of valid and reasonably standardized assessment instruments, as well as by the difficulties inherent in clinical assessment. However, the results of the few available studies are surprisingly similar ([Green et al., 1984](#); [Kolvin, 1971](#); [Russell et al., 1989](#); [Volkmar et al., 1988](#)). [Table 60.3](#) summarizes the results from several series of cases. Auditory hallucinations are consistently the most frequently reported symptoms, usually exhibited by about 80% of cases. Auditory hallucinations may include persecutory or command hallucinations, voices conversing, voices commenting about the child, and the like ([Russell et al., 1989](#)). Visual and somatic hallucinations are reported less frequently. Although delusional beliefs can be difficult to assess, available studies suggest that these are exhibited in at least 50% of cases. Delusional beliefs can involve persecution, somatic concerns, ideas of reference, or grandiose or religious ideas ([Russell et al., 1989](#)). The content of hallucinations and delusions appears to vary with age; younger children typically express less complicated hallucinations or delusional beliefs, and the content of the delusions or hallucinations may center on parents, fantasy figures, and animals ([Arboleda and Holzman, 1985](#); [Russell et al., 1989](#)). The reported presence of formal thought disorder varies considerably from study to study, reflecting the nature of specific definitions used. Magical or illogical thinking, incoherence, and loosening of associations are often observed and distinguish these children from their typically developing peers. However, levels of thought disorder may not differ significantly between children with schizophrenia and children with major depression, suggesting that although frequent, this feature is not specific to childhood-onset schizophrenia ([Tompson et al., 1997](#)). In addition, it is sometimes the case that children, particularly in the early phases of the illness, may not clearly exhibit a degree of thought disturbance sufficient to satisfy strict diagnostic criteria. Furthermore, assessment of thought disturbance can be particularly problematic in younger or developmentally delayed children ([Caplan, 1994](#); [Russell et al., 1989](#); [Volkmar et al., 1988](#)).

Study	Thought Disorder (%)	Delusions (%)	Hallucinations	
			Auditory (%)	Visual (%)
Kolvin et al., 1971	60	58	82	30
Green et al., 1984	100	54	79	45
Volkmann et al., 1988	93	86	79	28
Russell et al., 1989	40	63	80	13

**Table 60.3. Characteristics of Thought Disturbance in Childhood Schizophrenia**

## ETIOLOGY AND PATHOGENESIS

### Neurobiological Mechanisms

Although various lines of evidence suggest the involvement of biological processes in syndrome pathogenesis, no specific biological marker for the disorder has been identified. The work of [Bender \(1947\)](#) suggested that childhood schizophrenia, broadly defined, is commonly associated with signs of neurologic immaturity, such as delays in motor development and neurologic “soft” signs. Similarly, [Cantor \(1988\)](#) proposed that a constellation of hypotonia and hyporeflexia characterizes at least some children with schizophrenia. Studies of electrophysiologic activity have also provided some general, although nonspecific, evidence of CNS dysfunction. Differences have been noted in the electroencephalograms (EEGs) of children with schizophrenia as compared to children with various disorders ([Waldo et al., 1978](#)), and abnormalities in event-related potentials also have been observed ([Strandburg et al., 1984](#)). Autonomic nervous system (ANS) activity and reactivity has been an area of interest in adult onset schizophrenia. In the one study of ANS functioning in childhood schizophrenia, a pattern of abnormality was observed, similar to adult findings ([Zahn et al., 1997](#)). The results were interpreted to suggest an inability to allocate attentional resources so as to distinguish important from less important stimuli. Investigations of neurotransmitter systems have been uncommon and have not produced consistent results ([Werry, 1996](#)); some researchers have suggested a possible role for the cholinergic system in syndrome pathogenesis ([Cantor, 1988](#)). Cerebrospinal fluid monoamine metabolites were studied in relation to treatment response and revealed no significant changes in monoamine ratios and concentration, despite improved clinical symptomatology ([Jacobsen et al., 1997a](#)). Immune processes similarly have not been found to mediate clinical response to antipsychotic medications, but a relative failure of cellular immunity was observed in children with schizophrenia compared to children with ADHD and children with obsessive-compulsive disorder (OCD) ([Mittleman et al., 1997](#)). Three additional areas have been the subject of more focused study and are considered in the following.

### SMOOTH PURSUIT EYE MOVEMENTS

There have been numerous studies of smooth pursuit eye movements in adults with schizophrenia, with consistent findings of abnormalities. This measure is of particular interest because it may represent a physiologic marker sensitive at identifying genetic risk for schizophrenia ([Ross et al., 1999](#)). In studies of childhood-onset schizophrenia, the results have been similar to those of previous studies of adults. Compared to age-matched controls and ADHD children, children with childhood schizophrenia showed significantly greater smooth pursuit impairments, a lower amount of time overall spent engaged in tracking the target, and a higher rate of anticipatory saccades ([Jacobsen et al., 1996b](#)). In a study designed to address markers of genetic risk for childhood schizophrenia, two physiologic markers were examined: Anticipatory saccades during smooth pursuit eye movements and P50 auditory evoked response to repeated stimuli ([Ross et al., 1999](#)). In a previous report, these researchers showed that abnormal inhibitory gating of the P50 auditory evoked response to repeated stimuli is transmitted in families in adult-onset schizophrenia as a single gene trait, with a close link to the  $\alpha 7$  nicotinic receptor gene locus on chromosome 15q14 ([Freedman et al., 1997](#)). The same may be true for anticipatory saccades, although this evidence is preliminary and it is noted that other smooth pursuit eye movement measures have been linked to chromosome 6p ([Olincy et al., 1997](#)). The results of the current study showed P50 ratio abnormalities in all 10 children with schizophrenia in the sample, as well as abnormal and more severe elevations of anticipatory saccades in nine out of 10 of the children ([Ross et al., 1999](#)). For both markers, 15 of the 20 parents examined also showed these abnormalities. Elevated P50 ratios and anticipatory saccades may represent physiologic markers of some part of the genetic risk for childhood-onset schizophrenia. Additionally, there was evidence in this study to suggest that inheritance of these schizophrenia-risk genes from both parents may result in increased genetic risk for childhood-onset schizophrenia.

### BRAIN MORPHOLOGY

Structural differences in the brain have been examined in childhood schizophrenia using magnetic resonance imaging. Current findings represent the systematic investigation of researchers at the NIMH, which have been detailed in a series of reports ([Giedd et al., 1999](#); [Jacobsen et al., 1996a, 1997c,d](#); [Nicolson et al., 2000](#); [Rapoport et al., 1997](#)). It is important to note that these results are preliminary and need to be independently replicated; however, quantitative analysis of the brain has revealed several significant differences in this NIMH sample. Smaller total cerebral volume, increased ventricular volume, and reduced area of the thalamus were obtained in the childhood schizophrenia group compared to healthy controls, which is consistent with findings in adult-onset schizophrenia. Increased size of the corpus callosum and reduced cerebellar volume also were shown ([Jacobsen et al., 1997b,c](#)). Differences in the volume of the prefrontal lobes were not found ([Nicolson et al., 2000](#)), although there is some evidence from functional imaging studies that is suggestive of abnormalities in this region ([Bertolino et al., 1998](#); [Jacobsen et al., 1997e](#)). Lateral temporal lobe structures, particularly the superior temporal gyrus, were significantly enlarged in the group of children with schizophrenia compared to controls. Medial temporal lobe structures also have been examined. The volumes of the amygdala and hippocampus were not significantly different in the two groups, although there were discrepancies in symmetry patterns ([Jacobsen et al., 1996a](#)). Area measurements of the planum temporale also did not reveal significant differences ([Jacobsen et al., 1997d](#)), consistent with a pattern of relative sparing of some temporal lobe structures. Repeat scans have been obtained as part of a prospective longitudinal study ([Jacobsen et al., 1998](#); [Rapoport et al., 1997](#)). The results of these studies revealed a differential decrease in thalamic and temporal lobe structures and a differential increase in ventricular volume. In addition to structural differences, there is evidence to suggest progressive changes in the brain in childhood-onset schizophrenia that are present during adolescence and may taper off in adulthood ([Giedd et al., 1999](#)).

### GENETIC STUDIES

Genetic and family studies provide what is probably the most convincing evidence of some biological basis for the disorder. Rates of schizophrenia and related disorders among the first-degree relatives of children with schizophrenia are substantially elevated in comparison to those observed in the normal population, as is the case in relatives of adult schizophrenic patients ([Kallman and Prugh, 1971](#); [Kolvin, 1971](#); [Nicolson et al., 2000](#)). It is reported that approximately 10% of parents exhibit a schizophrenic disorder ([Kallman and Prugh, 1971](#); [Kolvin, 1971](#)). Genetic risk for childhood schizophrenia has also been associated with physiologic markers of liability observed in unaffected relatives (see the preceding). Additional abnormalities, other than schizophrenia, may represent a risk factor relevant to the early-onset of the disorder. [Alaghband-Rad and colleagues \(1998\)](#) report a preliminary finding of an increased rate of mental retardation in the siblings of children with schizophrenia, which may also be associated with sex chromosome abnormalities. Cytogenetic abnormalities have been examined in children with schizophrenia and also show an increased rate ([Kumra et al., 1998](#); [Nicolson et al., 1999b](#); [Usiskin et al., 1999](#)). In particular, there is support for an association between deletions on chromosome 22q11 (velocardiofacial syndrome) and schizophrenia. In these cases, the loss of gene product balance may represent another factor predisposing the child to greater risk or susceptibility to additional genetic and environmental events. A role for apolipoprotein E alleles, trinucleotide repeats, and human leukocyte antigen also has been examined in childhood-onset schizophrenia, with negative findings to date ([Fernandez et al., 1999](#); [Jacobsen et al., 1998](#); [Sidransky et al., 1998](#)). The nature of the underlying mechanisms that might account for the early onset of schizophrenia in some individuals remains uncertain. General considerations include a higher genetic loading, as well as the complicated interaction of various factors in combination with some genetic predisposition ([Asarnow et al., 1986](#); [Werry, 1996](#)).

### Neuropsychological Function

Neuropsychological studies have revealed deficits in attentional capacities and the processing of information. Current findings chiefly represent the report of a series of investigations conducted by Asarnow and colleagues ([1994a, 1995](#); [Karatekin and Asarnow, 1998a,b](#); [1999](#)). They have found that rote language skills and simple perceptual functions are not impaired in children with schizophrenia, but they do show significantly reduced performance on measures of fine motor speed and tasks that place demands on attention and/or short-term memory. On a measure of conceptual reasoning and capacity to shift set (Wisconsin Card Sorting Test), the group

of children with schizophrenia made more perseverative errors than normal controls. They also showed a tendency to perform more slowly and make more errors on a guided visual search task (Rey's Tangled Lines). [Kumra and colleagues \(2000\)](#) report a similar pattern of neuropsychological deficits in the areas of auditory attention, verbal memory, and mental flexibility. Deficits in some areas of spatial organization also were observed.

More detailed studies of performance on visual search tasks have been conducted, which are thought to tap into the presumed core attentional deficit in schizophrenia. Children with schizophrenia have been shown to perform more poorly on span of apprehension tasks ([Asarnow et al., 1994](#)). Although this finding could reflect delayed initiation of search, it appears to result from the use of a less efficient strategy (e.g., impairment in top-down control) when dealing with more complex information ([Karatekin and Asarnow, 1998b, 1999](#)). A slower reaction time on measures of visual attention and guided search have been interpreted to indicate a failure to adopt and maintain a major "set to respond" ([Zahn et al., 1998](#)). Taken together, the findings are suggestive of inadequate representation of context and use of self-guided hypothesis testing for control of action in children with schizophrenia ([Karatekin and Asarnow, 1999; Zahn et al., 1998](#)).

On measures of intelligence, children with schizophrenia are generally found to perform in the low average range. When groups of children with childhood-onset schizophrenia and high functioning autism were compared, they did not differ in their full-scale intelligence quotient (IQ) score or performance on the perceptual organization and verbal comprehension factors of the WISC-R ([Asarnow et al., 1994](#)). The childhood-onset schizophrenia group did show a significantly lower score on the distractibility factor. There is also a report of significant decline in full-scale IQ score in children with schizophrenia, when measured prior to and following onset of psychosis. This did not represent a deterioration of performance but rather a failure to make age appropriate gains as indicated by a comparison of raw scores on this test ([Bedwell et al., 1999](#)). This pattern of intellectual decline was interpreted as evidence of an ongoing or progressive pathologic process in childhood-onset schizophrenia.

### Psychological Processes

The interpretation of studies of children at high risk for schizophrenia is complicated because the disorder is low in frequency, even among those children presumed to be at greatest risk, and other factors may complicate the interpretation of results. There is no evidence at present to suggest that unusual psychological trauma accounts for the earlier age of onset in this group. In addition, no single personality pattern or pattern of premorbid adjustment appears to uniformly characterize preschizophrenic children. Various studies have reported an increased incidence of signs of neurosensory and neuromotor deficits in children with schizophrenia and those presumably at risk for the disorder ([Bender, 1947; Cantor, 1988; Fish, 1986](#)). Disturbances in attentional capacities have been noted in children with schizophrenia; these problems may precede the emergence of frank psychosis and may account, in part, for observed associations with various learning problems. Compared to autistic children, those with schizophrenia are much less likely to exhibit mental retardation ([Green et al., 1984; Russell et al., 1989; Volkmar et al., 1988](#)); however, problems in the assessment of retarded individuals may make it more difficult to establish the diagnosis with certainty in such cases. In particular, in addition to the presence of hallucinations, thought disorder is a characteristic feature of schizophrenia. Formal thought disorder (e.g., impaired organization and processing of thoughts) and impaired use of cohesion (e.g., ability to communicate their ideas) have been found to measure different aspects of thought disturbance ([Caplan et al., 2000](#)). However, this can sometimes be difficult to assess in young or delayed children. From a developmental perspective, these are areas of functioning that children are normally acquiring; children become more organized in their thinking and communication of ideas over time. In addition, it is reported that some children with schizophrenia have been experiencing psychotic symptoms for years that were not obvious to parents and teachers ([Russell, 1994](#)). Rather, the disorder may present outwardly as a significant behavioral disturbance suggestive of ADHD or conduct disorder. It has been proposed that when psychotic symptoms appear in early development, they may not be readily distinguished from normal experience. Thus, for some children, early in the course of the disorder, their psychotic symptoms may not be experienced as frightening, markedly disorganizing, or ego-dystonic ([Russell, 1994](#)).

### Family and Interpersonal Dynamics

Various studies have examined patterns of family interaction in the families of individuals with schizophrenia. The available research is primarily concerned with adult patients. The few studies available regarding family dynamics in childhood schizophrenia are difficult to interpret because fairly stringent diagnostic criteria were not used and many early reports were really about autism rather than schizophrenia. Available studies have emphasized disturbances in patterns of communication (e.g., in relation to inconsistent communications or communications with unusual patterns of affective expression, such as high levels of expressed emotion). Various unusual personality profiles have been noted in family members ([Kolvin, 1971; Singer and Wynne, 1963](#)), and it clearly is the case that family members are at greater risk for the disorder themselves ([Kolvin, 1971](#)). Unfortunately, most theoretic models have not been empirically tested, and the significance of reports of unusual patterns of familial interaction is unclear. In addition to the obvious possibility that unusual patterns of interaction cause schizophrenia in children, it is also quite possible that these abnormalities are reactions to the child's disorder or, alternatively, that they reflect the same underlying vulnerability exhibited more directly by the affected child. At the present time, the role of family dynamics in syndrome pathogenesis remains to be established.

### Environmental and Social Influences

In addition to genetic factors, a role for environmental events has been considered in the pathogenesis of schizophrenia. Studies of adult schizophrenic individuals suggest that complications in pregnancy, labor, and delivery may be more frequent and related to an earlier age of onset, but this has not been the finding in childhood-onset schizophrenia ([Nicolson et al., 1999a](#)). In addition, there does not appear to be a relationship between age at onset of puberty and onset of psychotic symptoms ([Frazier et al., 1997](#)). There is evidence that stressful life events may play a role in precipitating psychotic episodes in children ([Birley and Brown, 1970](#)). The study of cases in which the onset of the disorder follows a clear environmental precipitant are of some interest because they may clarify how psychological processes interact with biological predispositions for the disorder. Available data suggest that children with schizophrenia are more likely to come from lower socioeconomic status (SES) families. However, it is not clear to what extent SES suggests a role for the environment in pathogenesis, because lower SES also might be the result of parental psychopathology leading to a downward drift in occupational status. It is furthermore noted that, with adults, exposure to certain pharmacologic agents (e.g., stimulants) may produce hallucinations and a schizophrenic-like psychosis.

### ASSESSMENT

To date, no single biological marker for schizophrenia in childhood has been found, although this remains an important goal for future research ([Tsuang et al., 2000](#)). Because overt psychosis can be observed in association with organic mental disorders, it is important to conduct a careful medical history and examination, particularly if there are unusual or atypical features. If history or physical signs suggest substance abuse—particularly of stimulants or phencyclidine—then appropriate toxicological screening should be obtained. Given the infrequency of the condition, a complete neurologic examination including an EEG is indicated. Genetic testing, in some cases, may also be advised given the findings of a higher rate of cytogenetic abnormalities in children with schizophrenia that, notably, had been previously undetected.

Schizophrenic disorders in childhood are not typically associated with mental retardation, although various developmental and learning problems may be associated with the disorder. Psychological testing is helpful both in documenting current levels of intellectual and adaptive functioning and in pointing out areas of specific strength or weakness important for educational programming ([Chapter 43](#)). In addition to information provided by formal intellectual assessment, projective tests should be administered. It has been reported that many children with schizophrenia did not exhibit disorganized thinking at interview ([Russell, 1994](#)). Thus, projective tests may provide important information about the severity of thought disorder and psychotic thinking, supplementing information obtained from other sources. Several assessment instruments have been developed explicitly for the assessment of psychosis or thought disorder in childhood ([Caplan, 1994; Caplan et al., 1989; Puig-Antich and Chambers, 1983](#)). Communication assessments should be obtained, particularly in cases where communication problems are prominent.

### DIFFERENTIAL DIAGNOSIS

The diagnosis of schizophrenia in childhood is probably most readily made in older children and adolescents. For children less than 10 years of age or those with developmental disabilities, difficulties in communication, changes in conceptions of reality, and the nature of symptom expression may complicate the diagnostic picture. The diagnosis should be made only after careful evaluation and after it is clear that the symptoms do not reflect the presence of an organic process (e.g., the effects of substance abuse or seizure disorder). Generally multiple informants must be interviewed to obtain an adequate history, and usually several sessions with the child are required to obtain an adequate mental status examination. The differentiation of schizophrenia from affective disorders can be difficult because mood disturbance can be observed in schizophrenia to some degree. Prominent mood disturbance that is prolonged and not brief relative to the total duration of the apparent schizophrenic illness suggests the need to consider the various affective disorders and schizoaffective disorder in the differential diagnosis ([American Psychiatric Association, 1994](#)). Occasionally, patients with an OCD may exhibit ideas that are difficult to distinguish from delusions, although usually the individual recognizes the irrational nature of such ideas. Hallucinations are occasionally reported as an isolated symptom: A diagnosis of childhood schizophrenia should not be

made in such cases. Sometimes only the subsequent course clarifies the diagnosis. Assessment procedures are summarized in [Table 60.4](#).

---

Historical information
1. Early development and characteristics of development
2. Age and nature of onset
3. Medical and family history
Psychological/communicative examination
1. Assessment of intellectual level (IQ)
2. Assessment of adaptive behavior
3. Projective testing
4. Assessment of communication skills (particularly if communication problems are evident)
Psychiatric examination
1. Evaluate thought disturbance, hallucinations, delusions, etc.
2. Evaluate associated affective problems
3. Note unusual features of course/presentation
Medical evaluation
1. Physical examination for signs of associated medical conditions
2. Evaluate possible substance abuse
3. Neurologic consultation (including EEG)
4. Toxicology screen if indicated

---

**Table 60.4. Evaluation Procedures: Childhood Schizophrenia**

Schizophrenia can be observed in association with various other psychiatric and developmental problems, for example, conduct disorder, learning disabilities, mental retardation, and even autism; comorbid conditions should be noted when present ([Russell et al., 1989](#)). Adherence to a multiaxial approach aids in this process. In individuals with mental retardation, autism, or developmental language disorders, a diagnosis of schizophrenia should be made only if it is clear that the apparent disturbance in thinking does not reflect communication impairments. Although the bulk of available evidence has suggested that childhood schizophrenia and autism are unrelated, a few investigators have speculated on possible continuities between autism and schizophrenia; and DSM-III-R as well as DSM-IV, in contrast to DSM-III, do allow both diagnoses to be made ([American Psychiatric Association, 1987, 1994](#)). The change in DSM-III-R reflects awareness that presumably autism does not protect an individual from also developing schizophrenia; however, individuals with both conditions do not seem to be common ([Volkmar et al., 1988](#)). The diagnosis of PDD-NOS should not be made concurrently with a diagnosis of schizophrenia. Clinicians should be particularly alert to the possibility of a diagnosis of schizophrenia when multiple different diagnoses have been given over time, or concurrently.

## TREATMENT

As with other aspects of the disorder, studies of treatment are few in number and limited in various respects. Apparent variations in the natural history of the disorder ([Eggers, 1978](#)) pose further problems for assessing treatment studies. Practice parameters for assessment and treatment have recently been published ([McClellan and Werry, 1994](#)). To a considerable extent, treatment programs should attempt to address the specific patterns of strength and weakness exhibited by the individual child; treatment modalities also depend on the stage of illness (i.e., the presence of active psychotic symptomatology). Typically, multiple treatment modalities are needed, including medications, educational and family interventions, and supportive psychotherapy. Inpatient treatment may be indicated depending on the clinical situation.

The few available reports suggest that major tranquilizers have a role in treatment and may diminish the positive symptoms of the disorder (e.g., hallucinations and delusions) ([Kydd and Werry, 1982](#)). However, concerns about the possible long-term side effects of these medications suggest the need for informed consent, careful monitoring, and periodic reevaluation ([McClellan and Werry, 1994](#)). In general, no specific major tranquilizer is clearly superior, and the choice of medication should be guided by the particular constellation of problems exhibited. Particularly for children and adolescents whose disturbance does not respond to more usual agents, the "atypical" antipsychotic clozapine may be considered; although considerable interest has centered on this agent in adult "nonresponders," data in children are more limited ([Frazier et al., 1994](#); [Jacobsen et al., 1994](#); [McClellan and Werry, 1994](#)). In the only controlled trial of clozapine in childhood-onset schizophrenia, clozapine was found to be superior to haloperidol for both positive and negative symptoms in children nonresponsive to typical neuroleptics ([Kumra et al., 1996](#)). However, almost half of the patients have had to discontinue use of clozapine because of seizures, hematologic abnormalities, or treatment nonresponse over time. A "second generation" atypical antipsychotic medication, olanzapine, was subsequently studied in an open trial ([Kumra et al., 1998a](#)). The results were suggestive that this medication was effective in decreasing psychosis in at least some of the neuroleptic-nonresponsive children. However, many children in the sample remained poor responders to all forms of treatment. The authors suggest that given the relatively safe side-effect profile of olanzapine and enhanced therapeutic effects for some children in their study, it represents a good "first-line" agent for schizophrenia but not any other disorders in childhood. The agent is new and clinical experience reflecting its use in the pediatric population is limited ([Kumra et al., 1998a](#)). Evidence regarding the use of other classes of medications is even more restricted. Given the potential for stimulant medications to induce a psychotic illness, their use is probably contraindicated.

Examination of withdrawal dyskinesias (WD), tardive dyskinesia (TD), and extrapyramidal (EPS) side effects in children and adolescents who were in the early years of their treatment with neuroleptics showed that almost half presented with WD or TD at some point ([Kumra et al., 1998b](#)). There appeared to be an association between TD/WD and greater premorbid impairment, severity of illness, and duration of neuroleptic exposure. However, the abnormal movements seen in these patients were generally not severe, involved mostly the orofacial region, and improved over time. The incidence of EPS was lower in patients who received clozapine and the long-term use of this medication did not appear to be associated with development of TD. Recommendation was made for using the minimum effective dosage of antipsychotic medication in all cases, attempting to reduce gradually the dose of antipsychotic medication after the patient has been stable for 1 year. In addition, observing children and adolescents with psychotic disorders medication-free was found to be clinically informative as continued neuroleptic treatment was no longer warranted in some cases (e.g., owing to remission or an error in diagnosis) ([Kumra et al., 1998b](#)).

Studies of psychotherapy with this population are difficult to interpret given changes in diagnostic practice. It does appear that supportive psychotherapy may be of benefit to some children ([Cantor and Kestenbaum, 1986](#)). The usefulness of intensive, insight-oriented therapy is much less clear. Family interventions should aim to increase levels of appropriate family involvement and interaction to support the child's development and enhance communication among family members. Behavior modification procedures may be useful in reducing levels of maladaptive behaviors and increasing the availability of the child for educational and other interventions.

Many children with schizophrenia exhibit associated problems in development and learning that must be addressed through the provision of a comprehensive educational program. The disorder can have a deleterious impact on the acquisition of basic developmental and adaptive skills. Special education should be provided to address associated learning and developmental problems. It is important that the treatment program provided be integrated and that all the various professionals involved be aware of the need for close communication and the provision of a consistent program.

## OUTCOME AND FOLLOW-UP DATA

As with other aspects of the disorder, only limited data are available regarding the course and outcome of childhood schizophrenia, if the disorder is strictly defined. [Bennett and Klein \(1966\)](#) reported a follow-up of [Potter's \(1933\)](#) series of rather well-documented cases of children with schizophrenia. In these cases, the outcome of a 30-year follow-up was quite poor; only one case had made a satisfactory readjustment, although the histories of prolonged treatment in institutional settings may have worsened ultimate outcome.

[Eggers \(1978\)](#) conducted a 20-year follow-up of 57 children who exhibited schizophrenia before age 14. Unfortunately, the study is somewhat limited because the accuracy of early diagnosis and clinical information is questionable in these cases. About 20% of cases had apparently experienced complete remission, about 30% had improved, and the remaining 50% had had moderate or poor outcomes. The worst prognostic feature was an early onset (before age 10) in children with premorbid personality difficulties; all such cases had a poor outcome at follow-up. In a more recent report (mean follow-up period 38 years after onset), [Eggers and colleagues \(2000\)](#) also noted that the individuals in their sample showed a change in diagnostic subtype at different points in the total course of their disorder, indicating marked variability in the production of psychotic symptoms in the course of childhood-onset schizophrenia. [Kydd and Werry \(1982\)](#) reported on 15 children originally diagnosed as schizophrenic between 1971 and 1981. At follow-up, all cases were re-diagnosed using DSM-III. Of the 15 cases, 11 appeared unequivocally to exhibit schizophrenia, with the remaining four cases exhibiting a schizophreniform disorder. Earlier onset was associated with poorer prognosis; about half of the more strictly diagnosed schizophrenic cases exhibit chronic difficulties. In a more recent study, [Asarnow and colleagues \(1994b\)](#) found that most children (14/18) continued to meet criteria for schizophrenia 1 year after hospitalization. Of the remaining children, two showed schizoaffective disorder, one was in remission, and another showed no evidence of psychosis (but was diagnosed with conduct disorder, dysthymia, and ADD). At final assessment, between 2 and 7 years after hospitalization, a continued diagnosis of schizophrenia was present for 11 of 18 individuals. Patterns of outcome were also examined and showed substantial

variability when global adjustment was considered. Several of the children (8/18) showed relatively severe impairment throughout the follow-up period, and 10 out of 18 showed more substantial improvement.

As with adults, the use of psychotropic medications appears to be of particular benefit in relation to the “positive” symptoms of the disorder, although the dearth of studies in this area makes this observation only tentative at best. [McKenna and colleagues \(1994\)](#) reviewed 71 cases of children and adolescents referred for evaluation of what was presumed to be schizophrenia; only 19 children appeared to meet stringent criteria for the condition. As with adult schizophrenia, “negative” symptoms in childhood schizophrenia appear to be less responsive to pharmacologic intervention. There is some suggestion that the presence of more affective symptoms or a more schizoaffective clinical picture is associated with a more favorable course ([Eggers, 1989](#)). In general, it would appear that better outcome is related to acute onset, older age at onset, better premorbid adjustment, and well-differentiated symptomatology.

## RESEARCH DIRECTIONS

Research on essentially all aspects of the disorder is critically needed. Given the apparent wealth of information on childhood schizophrenia as broadly defined during the 1950s and 1960s, it is somewhat paradoxical that the available information on this disorder is now clearly less than that regarding autism. The relationship of childhood schizophrenia to adult forms of the illness remains an important topic for research; although essential points of phenomenologic similarity are apparent, the relative infrequency of the condition in childhood, the severity of the disorder and reason for its earlier age of onset, and the apparent relationship of subsequent outcome to early-onset suggest areas of ongoing research as well. The study of childhood schizophrenia would appear to be of considerable interest in the extent to which it may clarify aspects of syndrome etiology and pathogenesis. Studies of clinical populations are generally important for illuminating aspects of the disorder's natural history, neurobiology, treatment, and diagnosis. The applicability of current criteria for schizophrenia to children remains controversial; younger children may not as readily fulfill adult diagnostic criteria for the disorder, when rigidly applied. Misdiagnosis of the condition remains common ([McKenna et al., 1994](#)). The development of more precise and developmentally appropriate diagnostic criteria should facilitate research. Limited efforts to subtype affected individuals have been made ([Cantor, 1988](#)); the reliability and utility of such schemes remain to be established, but clearly, such work is critical ([Tsuang et al., 2000](#)).

Neurobiological studies have been relatively few in number; explication of underlying biological substrates of the disorder remains an extremely important area for future research ([Caplan, 1994](#); [Werry, 1996](#)). It will be important to explore further and determine the genetic basis for childhood schizophrenia and the factors associated with its earlier onset. Carefully designed follow-up studies are also needed to identify those factors most strongly related to ultimate outcome.

---

### CASE ILLUSTRATION

Kristine was the second of two children born to upper-middle-class parents after a term pregnancy complicated by maternal viral illness and a prolonged labor. At birth, she was noted to be in good condition. She was a somewhat fussy baby whose motor and communicative development appeared to proceed appropriately. She appeared to be normally related and enjoyed social interaction with her parents and older sister. She was enrolled in a nursery school program at age 4 and subsequently in regular kindergarten and first grade classes; although she was noted to be somewhat shy, no other concerns were expressed about her cognitive or emotional development. At age 6 years 11 months, she exhibited an episode of acute hallucinations and delusions. This episode had been preceded by a period of several weeks during which she had seemed increasingly withdrawn and was observed talking to herself. The hallucinations were predominantly auditory in nature, but were not well described, and apparently consisted of hearing single words; delusions revolved around fears of being kidnapped. Kristine became markedly anxious and developed complex rituals and compulsive behaviors apparently involving some aspect of her delusional fears. She was hospitalized, but extensive medical investigation failed to reveal a specific medical explanation for her difficulties. A positive family history of schizophrenia in a maternal aunt was noted, and a presumptive diagnosis of schizophrenia was made. Low doses of neuroleptics led to partial remission of the hallucinations and delusions, although she remained quite withdrawn. After her hospitalization, she began twice weekly psychotherapy and was transferred to a private school where she received extensive special education.

She was seen for comprehensive reevaluation at age 10. At that time, psychological testing revealed a full scale IQ in the borderline retarded range with associated deficits in adaptive behavior. Projective testing revealed marked thought problems. Communication assessment revealed significant difficulties in communication, with marked difficulties in social interaction, use of irrelevant language, and neologisms. On psychiatric examination, Kristine was an attractive girl with a generally bland affect. Her initial comment on meeting the examiner was to say, “love you.” Associations were loose, with marked tangential thinking and irrelevant associations. She denied auditory hallucinations but did admit to seeing “monsters” on occasion; a relatively elaborate delusional system was present. Some obsessional thinking was also in evidence, as were a few peculiar mannerisms.

Kristine continued to have marked difficulties in adolescence. Although she received a comprehensive educational intervention program, deficits in academic performance and cognitive skills increased in severity. In late adolescence, the onset of marked behavior problems led to another hospitalization and subsequent placement in a residential institution.

#### Comment

This case illustrates various points at which childhood schizophrenia differs from autism: The onset, in this case, was after some years of apparently normal development, the disorder was characterized by prominent delusions and hallucinations, and there was a family history of schizophrenia. Children with an onset of schizophrenia in childhood have a less favorable prognosis than those with onset in adolescence.

[Chapter References](#)

Child psychiatrists and neurologists can benefit from a shared neuropsychiatric perspective that connotes sufficient familiarity with each other's field so as to enable each to optimally meet their patients' needs and to foster appropriate interdisciplinary communication.

A major requirement for the psychiatrist is to be sensitive and responsive to indications of neurogenic substrates that may underlie what may at first appear to be purely psychopathologic phenomena. The psychiatrist should also be prepared to diagnose and formulate treatment plans for psychiatric complications of primary neurologic disorders. (For information on neuropsychiatric signs, symptoms, and syndromes, see [Chapter 30](#); for information on acquired brain disorders, see [Chapter 33](#).)

This chapter deals with psychiatric aspects of the following representative neurologic disorders: epilepsy, brain tumors, and neurodegenerative and neuromuscular disorders. It is hoped that the perspective developed herein will be of value to the contemporary child and adolescent psychiatrist who, in the face of accumulating clinical and research data, is called on to marshal greater sophistication regarding diagnostic and therapeutic challenges at the neurology–psychiatry interface.

## EPILEPSY

Epilepsy is a condition characterized by sudden, recurrent, and transient disturbances of mental functions or body movements that result from excessive discharging of groups of brain cells ([Smith and Darlington, 1998](#)). As such, epilepsy does not refer to a specific disease but rather to a group of symptoms that have many different causes in different individuals. The underlying causes are static in some individuals and progressive in others. All of the underlying causes of epilepsy have in common the quality of causing cerebral neurons to become excessively excited. The statistically more common causes of this neuronal hyperexcitability generally involve either structural abnormality of the brain or biochemical aberrations of a metabolic, infectious, or other physical etiology. This broad spectrum of etiologies clearly includes both genetically based and acquired varieties of brain pathology, as well as potential combinations of these.

Reviews of the literature on the psychogenic precipitants of epileptic seizures ([Williams and Bergtraum, 2000](#); [Williams et al., 1993](#)) clarify that numerous studies in both experimental animals and patients have substantiated the capacity of emotional stress to precipitate epileptic seizures in neurologically vulnerable individuals. Hence, there is an important role for the psychiatrist not only in helping patients and their families to cope with the troubling psychiatric consequences of epilepsy, but also in potentially intervening in some cases with regard to the stresses that may bring on seizures.

The signs and symptoms of epilepsy are manifold. Among the most common manifestations are episodes of partial or complete loss of consciousness, localized or generalized muscular spasms or jerks, or apparently purposeful behavior performed while awareness is depressed. The multifaceted modes of clinical manifestation of epilepsy and the fact that electroencephalogram (EEG) recordings are not always diagnostic, lead to another major diagnostic and therapeutic challenge at the neuropsychiatric interface: recognizing and treating psychogenic nonepileptic seizures.

### Epidemiology

Estimates based on epidemiologic studies indicate that up to 1% of the population in the United States has epilepsy and that new cases appear at an annual rate of 40 per 100,000 (Hauser et al., 1991). Furthermore, the rate is highest in children younger than 5, with another peak of incidence at the age of puberty. Thus, it is clear that children and adolescents merit special consideration with regard to developmental issues that interact with the psychiatric complications of epilepsy.

There is evidence that socioeconomic factors play an important role in the development of epilepsy. For example, the incidence was found to be higher in black (1.96%) than white (0.95%) children living in New Haven, CT ([Hauser and Hesdorffer, 1990](#)). However, the cause of this difference is uncertain: The relative importance of perinatal factors, trauma, nutrition, other environmental influences, or genetics is unknown.

The relative role of inheritance in epilepsy is controversial. It is often difficult to distinguish social and economic factors from primary genetic predisposition, because poor nutrition and inadequate perinatal care frequently run in families. However, several studies indicate that, in patients with generalized epilepsy, close relatives have a twofold to fourfold increase in incidence of convulsive disorders, strongly suggesting a genetic component of vulnerability.

### Classification of Epileptic Seizures

A revised International Classification of Seizures based on a more contemporary understanding of seizure pathophysiology, which has served to improve professional communication, is summarized as follows ([Alarcon, 1998](#)):

- I. Partial seizures (seizures beginning locally)
  - A. Simple partial seizures (consciousness not impaired)
    1. With motor symptoms
    2. With somatosensory or special sensory symptoms
    3. With autonomic symptoms
    4. Compound forms

- B. Complex partial seizures (with impairment of consciousness; temporal lobe or psychomotor seizures)
  - 1. With impairment of consciousness only
  - 2. With cognitive symptomatology
  - 3. With affective symptomatology
  - 4. With "psychosensory" symptomatology
  - 5. With "psychomotor" symptomatology (automatisms)
  - 6. Compound forms
- C. Partial seizures secondarily generalized
- II. Generalized seizures (bilaterally symmetric and without local onset)
  - A. Absence seizures
  - B. Myoclonic seizures
  - C. Infantile spasms
  - D. Clonic seizures
  - E. Tonic seizures
  - F. Tonic-clonic seizures
  - G. Atonic seizures
  - H. Akinetic seizures
- III. Unilateral seizures
- IV. Unclassified epileptic seizures (because of incomplete data)

Space limitations preclude more detailed consideration of these clinical subtypes here, but it clearly behooves the psychiatrist working with a seizure patient to be cognizant of the specific seizure manifestations, associated clinical and prognostic features, and specific medication requirements as determined by the patient's specific seizure type.

## PSYCHOLOGICAL AND PSYCHIATRIC ASSESSMENT

### Cognitive Functioning

An early review of several studies in this area ([Stores, 1981](#)) indicated that, although many children with epilepsy function normally at school, proportionately more of them have learning problems as compared with nonepileptic children. In the Isle of Wight study, for example, which concentrated on 9- to 11-year-old children, over twice as many of those with epilepsy showed serious specific reading retardation when compared with nonepileptic children.

Developmental considerations are important. [O'Leary and associates \(1981\)](#) administered a neuropsychological test battery to 48 children age 9 to 12 with tonic-clonic seizures. The children with seizures of early onset (before age 5) were significantly impaired, compared to the children with seizures of later onset, on eight of the 14 measures in the battery. The deficits were seen on tasks whose requirements included attention and concentration, memory, complex problem solving, and motor coordination.

Seizure type, duration, and degree of seizure control are also pertinent in the findings of some studies. [Farwell and coworkers \(1985\)](#) did detailed neuropsychological testing of 118 epileptic children, age 6 to 15, and a control group of 100 children without seizures. The Wechsler full-scale IQ of seizure patients was significantly lower than that of control subjects and was related to seizure type. Children with minor motor or atypical absence seizures had the lowest average full-scale IQ. All seizure types, except classic absence alone, were associated with below-control intelligence. Intelligence was also correlated with degree of seizure control. A highly significant inverse correlation between years with seizures and intelligence was found. Finally, children with seizures had been placed in special education or had repeated a grade in school almost twice as frequently as control subjects, and their academic achievement was behind grade placement more often than that in the control group.

[Seidenberg and colleagues \(1986\)](#), who examined the academic achievement scores of 122 children with epilepsy, supported the essential features of the preceding study. As a group, these children were making less progress than expected for their age and IQ level. Academic deficiencies were greatest in arithmetic, followed by spelling, reading comprehension, and word recognition. Here also, clinically relevant variables included age of seizure onset, lifetime total seizure frequency, and presence of multiple seizures.

The study by [Ellenberg and associates \(1986\)](#) is illuminating lest one falls prey to the erroneous assumption that childhood epilepsy necessarily engenders intellectual deterioration. They compared the full-scale IQs at 7 years of age of children who had experienced one or more nonfebrile seizures, with the IQs of their seizure-free siblings who were tested at the same age in a large longitudinal study. Among 98 children with seizures, the mean score on IQ tests at 7 years was not significantly different from the mean score of their siblings. Mental retardation was more common among the children with seizures, but children who had had neurologic abnormalities before the first seizure accounted for the excess of retardation. It seems likely that sampling differences account for the differences in findings between this and previously cited studies, with the study by Ellenberg and associates drawing a larger proportion of "mild" cases (i.e., better controlled) than the previous studies.

More recent studies, utilizing more comprehensive neuropsychological assessments, have substantiated deficits in both verbal and visual attentional skills in children with epilepsy ([Williams et al., 1998](#)). Furthermore, the finding of diffuse cognitive dysfunction across all seven cognitive domains assessed was documented in a sibling-controlled study of epileptic children with complex partial seizures ([Schoenfeld et al., 1999](#)). A large, retrospective study, involving 251 children with epilepsy, pointed to multiple factors impacting on the degree of cognitive impairment, including age of onset and duration of epilepsy, seizure frequency, and number of antiepileptic drugs used ([Bulteau et al., 2000](#)).

Anticonvulsant drugs, especially in combination, have been shown in a variety of studies to interfere in significant ways with cognitive function, including attention, concentration, memory, motor and mental speed, and mental processing ([Reynolds, 1985](#)). These sometimes-subtle effects are easily overlooked but may accrue to the point of substantial impairment, particularly for children in learning situations ([Gerber et al., 2000](#)).

Other studies have shown that most epileptic patients can be controlled on single-drug therapy and that there is often little difference in antiepileptic efficacy between the major antiepileptic drugs within designated seizure categories ([Voorhies, 1988](#)). Consequently, the relative influence of each drug on cognitive function may prove to be a most important factor in the choice of an anticonvulsant drug. In this regard, it should be noted that several studies have shown significant associations between long-term use of phenytoin and phenobarbital and cognitive deterioration in children. By contrast, carbamazepine has been noted in some studies to be less prone to contribute to cognitive impairments in both short- and long-term use in both normal volunteers and seizure patients. This finding needs to be qualified, however. [Forsythe and colleagues \(1991\)](#) found, in a controlled, prospective study of newly diagnosed childhood epilepsy, that carbamazepine in moderate dosage adversely affected memory, but phenytoin and sodium valproate did not; valproate had the fewest side effects.

More recent controlled studies have suggested a more sanguine outlook when anticonvulsants are carefully monitored. [Mandelbaum and Burack \(1997\)](#) did a 12-month prospective follow-up study of 43 children with a variety of seizure types. Analysis of the children's performance after 6 and 12 months of antiepileptic therapy showed no significant deterioration attributable to medication. Other studies of children whose seizures were controlled at therapeutic doses of antiepileptic drugs (AEDs), similarly found no evidence of AED-induced cognitive impairment ([Aldenkamp et al., 1998](#); [Bates et al., 1998](#)). Nevertheless, the clinician must be vigilant in identifying subgroups of children who may be particularly vulnerable to cognitive and/or behavioral side effects of particular AEDs or combinations of AEDs ([Aldenkamp et al., 1998](#); [Bourgeois, 1998](#)). In all likelihood, the greater sophistication in AED serum monitoring, coupled with more sophisticated methodology and study design account for the more favorable outlook of more recent studies ([Cochrane et al., 1998](#); [Espie et al., 1999](#)).

In light of the preceding observations, one should not assume that all cognitive impairment of youngsters with epilepsy is owing to either static cerebral pathology or the side effects of anticonvulsant medication. [Siebelink and coworkers \(1988\)](#) studied 21 children with epilepsy having subclinical epileptiform EEG discharges in the waking state, using telemetered EEG studies during psychological testing. The authors found a total IQ for the children with epilepsy below that of control populations, which was accounted for by that subgroup of children who exhibited discharges during the test; those who did not show discharges at that time were unimpaired. These findings have been replicated and amplified by [Aldenkamp and associates \(1999\)](#), who similarly identified a subgroup of children with epilepsy and learning disabilities who had difficult-to-detect seizures, demonstrating that uncontrolled seizures can impair academic functioning even when the seizures are of short duration and have subtle symptoms. These studies have implications both for the interpretation of neuropsychological test results in children with epilepsy and also

for the drug treatment of those who continue to exhibit subclinical EEG discharges when overt seizures have been controlled.

It can be discerned readily from the preceding that primary attention should be given to periodic formal monitoring of the cognitive functioning of seizure patients, with particular view to picking up signs of progressive cognitive impairment that might otherwise be overlooked. It is certainly within the purview of a psychiatrist treating such a patient to ascertain that such monitoring has occurred and that therapeutic serum anticonvulsant levels have been documented and to discuss the possible need for a change in anticonvulsant regimen when indicated by the patient's level of cognitive functioning with the treating neurologist ( [McConnell and Duncan, 1998](#)).

### **Behavior and Personality**

The literature on personality changes in epilepsy has been prolific, long-standing, and controversial. According to some estimates, for example, 30% to 40% of patients with temporal lobe epilepsy (complex partial seizures) experience persistent psychiatric symptoms that, more frequently than uncontrolled seizures, become the most incapacitating aspect of the illness ( [Tucker and McDavid, 1997](#)). Multiple clinical reports in adult temporal lobe seizure patients have delineated characteristic features, including deepened emotions, changes in sexual function, aggressivity, development of intense religious or philosophic interests, circumstantiality, and interpersonal viscosity.

A study in children with unilateral temporal lobe seizure foci failed to disclose characteristic differences in cognitive or personality features between right and left temporal lobe seizure patients ( [Camfield et al., 1984](#)). Yet, when the two groups of unilateral seizure patients were combined, 10 of 27 patients (five with left focus, five with right focus) were seen to have personality maladjustment on formal assessment. Furthermore, the group as a whole showed significantly lower neuropsychological test functioning than normally adjusted children.

Developmental considerations may help understand the evolution of certain psychopathologic correlates of the seizure state over time. Thus, [Flor-Henry \(1983\)](#) has studied severe psychopathologic syndromes (psychosis) seen in adult seizure patients. He found that schizophreniform psychosis in these patients was related to pathology in the dominant hemisphere, whereas depressive psychosis (and neurosis) was related to pathology of the nondominant hemisphere. In relation to this, [Lindsay and colleagues \(1979\)](#) did a long-term outcome study of 100 children with temporal lobe seizures. Mental deficiency, the hyperkinetic syndrome, and cataclysmic rage outbursts were prominent in childhood. Indeed, only 15 of the 100 probands were wholly free from psychological problems in childhood. Yet follow-up indicated that the occurrence of overt psychiatric disorder in adult life was relatively low: Of those survivors who were not gravely mentally retarded, 70% were regarded as psychiatrically healthy. Overt schizophreniform psychoses developed in 10% of the survivors. Males with continuing epilepsy and left-sided foci were at special risk: 30% of such patients became psychotic. In consonance with the noted findings of Flor-Henry and others, no patient coded as having a right-sided focus in childhood became psychotic by the time of follow-up 13 years later. Lindsay and colleagues emphasize the surprising and hopeful change from the overwhelming presence of psychopathology in the childhood sample to the predominance of relative psychological intactness by adulthood. They note that the majority of their patients received psychiatric intervention in their early years and emphasize the importance of providing such service in the appropriate management of epileptic children.

A study by [Hoare \(1984a\)](#) reflected further indications of the probably primary role of central nervous system (CNS) dysfunction in the psychiatric vulnerabilities of patients with epilepsy. Two groups of epileptic children, one newly diagnosed and one with chronic epilepsy, were contrasted with two comparable groups of diabetic children and with a nonpatient sample in order to evaluate the development of psychiatric disorder. The results confirm previous findings that children with chronic epilepsy are significantly more disturbed than children with chronic physical illness not involving the CNS and children in the general population. Children with newly diagnosed epilepsy were also significantly more disturbed than those with newly diagnosed diabetes and children in the general population. In both groups of epileptic children, those with focal EEG abnormalities and/or complex partial seizures were particularly vulnerable to psychiatric disturbance. The development of inappropriate dependency was also greater in the two epileptic groups of children than the comparison groups ( [Hoare, 1984b](#)).

Similar findings are reported by [Austin and associates \(2000\)](#) in a follow-up study that disclosed that patients with high seizure frequency at baseline and follow-up, particularly girls, developed higher rates of behavior problems than a comparison group of patients with asthma. [Schoenfeld and coworkers \(1999\)](#) reported increased social and school competence problems, particularly of the internalizing type, when comparing pediatric epilepsy patients with complex partial seizures to sibling controls.

An additional finding pointing to the increased risk of psychopathology among children with epilepsy is an epidemiologic study by [Hackett and colleagues \(1998\)](#). Additional specific risks in various comparative studies of epileptic children include hyperactivity, when the epilepsy is associated with severe intellectual disabilities ( [Jones and Cull, 1998](#)), and depression ( [Dunn et al., 1999](#)) in nonselected adolescent epileptic patients, as well as thought disorder and schizophreniform psychosis in pediatric patients with complex partial seizures ( [Caplan et al., 1997, 1998](#)).

In addition to the previously noted capacity of anticonvulsants to engender untoward cognitive side effects, these medications also can cause behavioral and emotional symptoms. The capacity of phenobarbital to generate or exacerbate attention deficit hyperactivity symptoms in children is well documented ( [Voorhies, 1988](#)). Additionally, [Brent and coworkers \(1987\)](#), in a study comparing 15 epileptic children on phenobarbital to 24 treated with carbamazepine, found a much higher prevalence of major depressive disorder in those on phenobarbital (40% versus 4%,  $P > 0.02$ ) and suicidal ideation (47% versus 4%,  $P > 0.005$ ), as determined by semistructured psychiatric interviews. The differential prevalence of depression between medication groups was only noted in those with a family history of a major affective disorder among first-degree relatives.

It should be noted that not all studies of psychopathology among children and adolescents with epilepsy find an increased incidence in these youngsters as compared with control groups ( [Kaminer et al., 1998](#)). Thus, [Kokkonen and associates \(1997\)](#) studied psychosocial outcome of young adults who had epilepsy in childhood. They found that the social handicaps found in some of these patients as young adults was largely associated with the neurologic and cognitive impairments accompanying the epilepsy, rather than the epilepsy itself or associated anticonvulsant medication.

Yet the preponderance of studies suggest that youngsters with epilepsy are at increased risk with regard to the development of psychiatric disturbance. Certainly not every youngster with epilepsy requires psychiatric attention, but a substantial proportion does stand to benefit therefrom. A psychiatrically sophisticated neurologist who routinely follows these youngsters and can make appropriate early referral for psychiatric assessment when needed is probably the best conduit for such intervention. Once this has been done, assessment should follow a standard age-appropriate format for the patient and family, with special focus on those areas of vulnerability noted in the preceding.

### **Psychogenically Precipitated Epileptic Seizures and Psychogenic Nonepileptic Seizures**

Based on the substantial evidence pointing to the enhanced cognitive and emotional vulnerability of youngsters with epilepsy, it is not surprising that one manifestation of this vulnerability would be a worsening of their presenting seizure symptoms under circumstances of emotional stress. It is important, however, for the clinician to be thoughtful and sensitive in exploring this area because of the many complexities that abound in both differential diagnosis and treatment.

[Williams and Bergtraum \(2000\)](#) reviewed several studies pointing to the role of environmental stress and emotional experiences as precipitants of true epileptic seizures. These included reports of the emotional activation of EEG abnormalities in patients with convulsive disorder, particularly those with sensory (simple partial) and complex partial seizures when exposed to stress interviews. Furthermore, the direct emotional activation of seizures has been documented in several animal species when seizure-prone animals were exposed to various forms of environmental stress. In addition, certain stressful cognitive tasks can also generate epileptiform EEG activation, though more commonly in patients with idiopathic generalized epilepsies ( [Matsuoka et al., 2000](#)). These stimulus-induced seizures are designated here as psychogenically precipitated epileptic seizures.

In contrast to the preceding, the term psychogenic nonepileptic seizures has been used to designate seizure-like phenomena of purely psychological origin produced by patients with varying degrees of conscious or unconscious intentionality and for a vast array of psychological reasons. Although reviewed in detail elsewhere ( [Williams, 1997](#)), it is worth noting the general categories of diagnostic classification to be considered in the process of assessment, including somatoform disorders, factitious disorders, and malingering.

Sometimes it may be extremely difficult for the clinician (neurologist, psychiatrist, or other) to be certain about the distinction between epileptic seizures (whether psychogenically precipitated or not) and psychogenic nonepileptic seizures, even after a thorough review of the history, physical examination, and laboratory findings. This is not only because of the protean manifestations of epileptic phenomena but also because many patients frequently possess an artful capacity to mimic epileptic

seizures on a conscious or unconscious basis.

Simultaneous videotape and EEG recording has been a significant aid in the differential diagnosis of epilepsy and pseudoseizures ( [Gates, 1998](#)). The procedure focuses one camera on the patient, who is wired with electrodes connected to an electroencephalograph, while a second camera is focused on the EEG write-out. The picture of the patient and the simultaneous EEG tracing appear on a split-screen video monitor. This combined recording is stored on the videotape for future analysis and interpretation. Studies using this technique have helped clarify that, even patients with clearly documented psychogenic nonepileptic seizures, there may be a coexisting neurogenic seizure disorder in from 15% to 50% of patients.

One limiting factor with the differential diagnostic capacity of video-EEG monitoring, despite its allowing a much longer observational period than a routine EEG, is that the patient may not experience a typical seizure event during the monitoring period. To augment the diagnostic yield of this valuable monitoring technique, a variety of suggestive procedures, including intravenous placebo infusion and hypnosis have been used ( [Walczak et al., 1994](#)). Placebo infusion elicits typical psychogenic events in most patients with psychogenic seizures. However, atypical events or epileptic seizures may occur in a minority of patients. This points to the need for an adequate monitoring period, corroboration with family or other observers that the elicited events are typical, and close collaboration between the neurologist and psychiatrist in conducting a comprehensive evaluation of both these overlapping areas.

Some brief guidelines may be outlined for psychiatric intervention in such situations. First, if the diagnosis is not entirely clear at the time of initial psychiatric consultation, as is most often the case in these circumstances, it is best to approach the patient and family with a candid acknowledgment of this. The role of the psychiatrist is explained as that of exploring the possibility that emotional factors may play a role in symptom formation, as they can with virtually any physical symptom (e.g., headache, peptic ulcer, hypertension, etc.). Second, a traditional psychiatric assessment of the patient and parents, separately and together, is then pursued, with particular focus on possible sources of stress or conflict that might contribute to symptom formation. It is best to conceive and discuss any psychodynamic or other formulation deriving from such an exploration in tentative, hypothetical terms, with due regard to the patient's self-esteem and especially avoiding any confrontational or accusatory stance with the patient or family. Third, if the combined outcome of neurologic and psychiatric assessments points to the probability that emotional factors do contribute to symptom genesis, then a treatment plan tailored to the individual circumstances of the child and family needs to be formulated ([Williams and Bergtraum, 2000](#); [Wyllie et al., 1999](#)).

### **Epilepsy and Aggressive Behavior**

There is controversy in the literature regarding the association between epilepsy on the one hand and aggression and violence on the other ( [Herzberg and Fenwick, 1998](#)). This continues to be so despite accumulating evidence pointing to the clinical validity of subacute postictal aggression ( [Gerard et al., 1998](#)) and to neuroimaging studies pointing to a neuropathologic substrate for the phenomenon ( [Woermann et al., 2000](#)). One well-controlled study of 83 children with epilepsy found an association between the presence of anterior temporal lobe epileptiform spike activity and increased aggression scores on the Achenbach Child Behavior Checklist ([Whitman et al., 1982](#)). The authors note, however, that such biological variables predictive of behavioral disorder accounted for only small amounts of the variance in their comparison of children with temporal lobe and generalized epilepsies. In this regard, they recommend that more consideration be given to delineating the "situation-centered" variables predictive of behavioral disorder in children with epilepsy.

Using a different research strategy, clinical studies of violent incarcerated adolescents by [Lewis and coworkers \(1985\)](#) have suggested that epilepsy, especially psychomotor (complex partial, temporal lobe) epilepsy, is more prevalent in young offenders than the general population. Furthermore, psychomotor epilepsy in this population was particularly associated with violence. The authors review some of the diagnostic difficulties inherent in establishing the diagnosis of psychomotor seizures in an individual where such a clinical diagnosis may interact with the perception of legal responsibility for a violent act. Despite some of the imprecision inherent in diagnosing psychomotor seizures, however, added circumstantial support of the diagnosis was lent by the very frequent history of severe CNS trauma, owing to such factors as perinatal difficulty, CNS infection, head injury, or a history of frank grand mal seizures. Of note also was the frequent association of reports of severe physical abuse in the histories of these youngsters. The latter association in particular certainly addresses the probable role of situational variables in fostering violence in youngsters biologically at risk by virtue of a greater predisposition to impulsivity and aggression. Most important, Lewis emphasizes in this and subsequent reports that a clinician called on to evaluate a violent delinquent may render a valuable service in identifying potentially treatable neuropsychopathology, so appropriate intervention can occur ( [Lewis, 1997](#)).

### **TREATMENT**

In view of the generally acknowledged enhanced psychological vulnerability of epileptic patients, particularly to the effects of anxiety and depression ( [Robertson, 1998](#)), it is clearly advisable to provide appropriate intervention when such symptoms are in evidence. In this regard, the elevated risk of suicide in epileptic patients is noteworthy. Psychiatric interventions with such patients should be geared to the nature of the presenting symptomatology, while taking note of the relevance of the patient's epileptic condition.

An important consideration in treating any child or adolescent with epilepsy and an associated psychiatric problem is the need to take into account family dynamics pertinent to the genesis of the problem, as well as family resources that can be mobilized in the service of effective treatment. This is particularly relevant in light of the frequently encountered problem of heightened dependency needs in such patients, noted in the preceding. Finally, the importance of maintaining open lines of communication between the neurologist and mental health practitioner to ensure appropriate psychobiological treatment integration cannot be overemphasized.

### **PSYCHOTHERAPEUTIC INTERVENTION**

A somewhat unique psychotherapeutic challenge in this population is that of treating psychogenically precipitated epileptic seizures and psychogenic nonepileptic seizures. There are many reports of successful psychotherapeutic or psychobiological treatment interventions for purposes of seizure control ( [Williams and Bergtraum, 2000](#)). It should be emphasized that appropriate differential diagnostic assessment is a prerequisite to appropriate treatment planning in this area. The various treatment approaches utilized may be summarized under the following broad headings: conditioning techniques, psychodynamic approaches, relaxation and hypnosis, and biofeedback. Often several such approaches may be usefully integrated in the service of maximizing therapeutic impact to facilitate symptom relinquishment and foster improved adaptation by the patient.

It should be noted for patients with refractory epileptic seizures, that seizure surgery, with recent improvements in technique and technology, has been offering some very promising results ([Engel, 1996](#)). Thus, [Meyer and colleagues \(1986\)](#) reported that of 50 child and adolescent patients receiving temporal lobectomy for medically refractory seizures, 78% became essentially seizure-free, and 88% benefited significantly from the operation in terms of improved seizure control. The importance of careful and extended presurgical seizure monitoring cannot be overemphasized, however. Our own clinical experience includes a patient who illustrates this point.

---

### **CASE ILLUSTRATION**

R., a 9-year-old girl with an IQ of 117 and a history of gelastic (complex partial) seizures dating from the first year of life, was referred for seizure surgery because of a progressive worsening of her seizures despite numerous anticonvulsant medication trials. Seizure surgery was not performed, despite a diffusely abnormal electroencephalogram (EEG), because a circumscribed seizure focus accessible to surgical removal could not be delineated. While in the hospital, her histrionic and manipulative style was observed, as was the fact that her seizures were more numerous when her parents were present, reaching a peak of more than 300 a day. In light of no further deterioration in her previously abnormal EEG, the consulting psychiatrist postulated a hypothesis of either psychogenically precipitated epileptic seizures or psychogenic nonepileptic seizures, or both, superimposed on a preexisting epileptic seizure substrate. After conferring with the neurologist, an intervention of intensive psychotherapy was initiated, including individual, parental, and family sessions, behavior modification, and hypnosis. Within 2 weeks, seizure frequency had diminished to zero, and R. was discharged from the hospital. She immediately returned to school and continued to be seizure-free as she was followed over 6 months in supportive outpatient psychotherapy. Her anticonvulsant medication was gradually tapered, and she continues seizure-free off all anticonvulsant medication for a 10-year period. In retrospect, the hypothesis of spontaneously remitted epileptic seizures and superimposed psychogenic seizures has been confirmed by the patient's clinical response to treatment. The absence of video-EEG monitoring during this hospitalization made it impossible to define whether psychotherapy had been primarily beneficial in alleviating psychogenically precipitated epileptic seizures, psychogenic nonepileptic seizures, or both.

---

### **Psychopharmacologic Considerations**

The need for the clinician to be aware of potentially cognition-impairing effects of various anticonvulsants, particularly phenytoin and phenobarbital, has been noted. Additionally, the frequently observed capacity of phenobarbital to generate hyperactivity, irritability, and aggressivity in children should be borne in mind ( [McConnell and Duncan, 1998](#)). Consequently, it is clearly important to advocate the lowest reasonable dose of the least toxic anticonvulsant consonant with good seizure control. Carbamazepine, for example, has been reported in a number of studies to manifest mood stabilizing, as well as anticonvulsant properties ( [Evans et al., 1987](#)). However, it has been recognized that negative psychiatric consequences of carbamazepine also may be encountered ( [Pleak et al., 1988](#)); therefore, careful clinical

monitoring is in order.

Another developmentally important consideration in children and adolescents is their different rates of metabolizing anticonvulsants. Children generally require higher milligram per kilogram doses of anticonvulsant than do adults by virtue of their metabolizing the drugs more efficiently. There is a shift toward the adult rate in early adolescence. Consequently, an anticonvulsant dose that yielded therapeutic blood levels in late childhood may be transformed insidiously into a toxic dose in early adolescence if not monitored closely. An associated consideration is the advisability of immediately checking a youngster's serum anticonvulsant level if there is any sudden change in cognitive, emotional, or behavioral functioning, or a worsening of seizure control. Questions of compliance in taking anticonvulsant medication always should be considered ([Shope, 1988](#)).

In many epileptic patients, even when the anticonvulsant regimen is optimized, there may still be indications for the additional use of psychotropic medication for comorbid psychopathology. Benzodiazepines have a valid place in this regard when minor tranquilization is needed. The value of intravenous diazepam or lorazepam in status epilepticus is well known, so there is clearly no danger of its lowering the seizure threshold, but the capacity to enhance sedation by interaction with a coexisting anticonvulsant or to generate behavioral disinhibition should be noted ([Stewart et al., 1990](#)).

Although there is a theoretical basis of concern about stimulants lowering the seizure threshold based on animal studies involving high dosages, clinical experience suggests that methylphenidate and other commonly used stimulants may be a safe and effective treatment for certain children with seizures and concurrent attention deficit disorder, provided that titration is pursued judiciously ([Stimmel and Dopheide, 1996](#)).

Major tranquilizers do have a place in the treatment of interictal psychoses in patients with epilepsy ([McConnell and Duncan, 1998](#)). It should be noted, however, that several neuroleptics, particularly chlorpromazine and clozapine, have a significant capacity to lower the seizure threshold and induce seizures. Of the neuroleptics currently available, molindone, haloperidol, and risperidone appear to be the safest in this regard.

Most tricyclic antidepressants also have the capacity to lower the seizure threshold and induce seizures ([Wroblewski et al., 1990](#)). Although the serotonergic antidepressants as a group have less of a tendency to lower the seizure threshold, several can interact with anticonvulsants; therefore, close monitoring of blood levels of anticonvulsants is warranted. Clinically, one must balance the potential benefits in combating depressive symptoms against the potential impact of possible drug interactions or lowering of the seizure threshold.

There is clinical evidence of the potential benefit of adding propranolol to the medication regimen of epileptic patients with uncontrolled aggressive outbursts that have not been controlled by optimal anticonvulsant medication adjustment ([Connor and Steingard, 1996](#); [Silver et al., 1999](#); [Williams et al., 1982](#)). Although this has not yet been subjected to controlled study, open clinical experience to date suggests that a significant proportion of such patients demonstrate improved behavioral control of aggressive behavior and irritability on propranolol. As long as titration is gradual, with appropriate monitoring of ECG, pulse, and blood pressure and with cognizance of the relevant contraindications to using adrenergic blocking medication, side effects are minimal and well tolerated.

## Prevention

Efforts at prevention of epilepsy are best addressed to the most common and remediable etiologies. These would include improved perinatal care, genetic counseling of individuals with family histories of epilepsy, and early intervention with those infectious, traumatic, or metabolic aberrations known to predispose to epilepsy. Efforts at prevention of the psychiatric complications of epilepsy include judicious use of anticonvulsant medications to minimize adverse side effects, as well as appropriate education of the patient and family to enable early recognition and appropriate early treatment of psychiatric complications should they arise. Finally, educating the public about epilepsy is important to minimize the unwarranted stereotypic stigmatization and discrimination that have long burdened these patients and their families.

## BRAIN TUMORS

The incidence of intracranial tumors in youths below the age of 15 years ranges from two to five in 100,000 per year, which ranks these tumors second only to leukemias as neoplasms in children. Brain tumors make up roughly half of all solid tumors in children. Although supratentorial tumors constitute the majority of brain neoplasms in adults, infratentorial tumors predominate in children. Generally, infratentorial or posterior fossa tumors (i.e., those of the cerebellum and brain stem) are more silent than supratentorial tumors, and psychiatric symptoms such as personality change are less common. Instead, children with brain tumors tend to show more signs and symptoms of increased intracranial pressure, often with insidious onset and without localizing signs ([Herskowitz and Rosman, 1982](#)). The majority of intracranial neoplasms in children are primary tumors of glial origin, whereas metastatic tumors and meningiomas are quite rare. Thus, the location, presenting symptoms, and representation of the various types of brain tumors in youth differ from those of adults.

The etiology of most nonmetastatic intracranial tumors is unknown; therefore, prevention is not possible. Craniopharyngiomas and teratomas are of congenital origin, arising from developmental malformations. Intracranial sarcomas are increased by cranial irradiation. Some tumors are associated with certain systemic conditions (e.g., Wiskott-Aldrich syndrome, renal transplantation, and leukemia) and neurocutaneous syndromes (e.g., ataxia-telangiectasia, neurofibromatosis, and tuberous sclerosis) ([Evans, 1987](#)).

## Clinical Features

The presenting symptomatology of brain tumors is largely dependent on tumor location and rate of growth. Because of the predominance of infratentorial and midline locations, most brain tumors in children tend to lead to obstruction of cerebrospinal fluid circulation (CSF), resulting in increased intracranial pressure. The symptoms and signs of increased intracranial pressure (IICP) are somewhat variable and are presented in [Table 61.1](#). It should be noted that IICP has multiple etiologies (e.g., metabolic encephalopathy, intracranial infection, pseudotumor cerebri, and trauma) and is not pathognomonic for brain tumor. Headache is rarely localizing and is not qualitatively different in these brain tumors from that seen with other conditions. Transient accommodation of the brain and skull to IICP is thought to account for the remitting and exacerbating nature of the headache, which is often worse after periods of recumbency or with straining. Similarly, vomiting is often mild, variable, and intermittent.

1. Headache: Bifrontal or occipital; often mild; worse in the morning, after recumbency, and with coughing or Valsalva; progressively persistent.
2. Vomiting: Often mild, not usually projectile; intermittent; occurs on rising; with or without headache; progressively more frequent.
3. Personality changes: Restlessness and irritability, memory loss, academic impairment; later, lethargy, apathy, depression, somnolence, and altered consciousness.
4. Papilledema (more common in children after suture fusion).
5. Diplopia, strabismus (cranial nerve VI palsy), impaired upward gaze and proptosis ("setting sun"); cranial nerve III palsy.
6. Bulging fontanelle and delayed fontanelle closure (infancy).
7. Widened sutures on x-ray and increased head circumference (3-2 years).
8. Altered vital signs: Increased blood pressure, increased or decreased pulse, decreased and irregular respirations.
9. Diffuse slowing on EEG.
10. Generalized seizures.

**Table 61.1. Signs and Symptoms of Increased Intracranial Pressure in Children, in Approximate Order of Presentation**

Neuropsychiatric symptoms are common but nonspecific (e.g., deterioration in school functioning) ([Kaye and Duffner, 1998](#)). Personality changes can be seen, such as quietness and decreased motoric activity (in an attempt to lessen headache), restlessness and irritability (often owing to headache as well), and diminished levels of consciousness, leading to coma. Presenting symptoms other than those owing to IICP are discussed for each tumor type.

Besides the neurologic and psychiatric history and examination, intracranial tumors are diagnosed by skull radiography and especially by computed tomography (CT) and nuclear magnetic resonance imaging (MRI) of the brain.

Characteristics of various brain tumors are presented in [Table 61.2](#). Classifications of childhood brain tumors are arbitrary and have undergone change in recent

years ([Becker, 1985](#); [Swaiman, 1994](#)). The classifications are still rather controversial, partly because of the unusual patterns of growth seen in these tumors, which are comprised of embryonic or poorly differentiated cells. Further details concerning these tumors are discussed in the following, especially the psychiatric symptomatology and the effect of treatment on neuropsychological functioning.

**Table 61.2. Characteristics of Brain Tumors in Children**

### Infratentorial Tumors

Infratentorial tumors are those of the cerebellum, fourth ventricle, and brain stem. For all of these tumors, IICP is a prominent feature and may be the only cause of symptoms early on. Other presenting symptoms are owing to compression of brain stem structures and include progressive cranial neuropathies, often involving ocular and facial muscles; nystagmus, which is nonlateralizing; spasticity; ataxia; cervical pain; and head tilt.

Astrocytomas and medulloblastomas are the two tumor types of the cerebellum and have approximately equal incidences. Cerebellar astrocytomas (primarily pilocytic) are slow growing and mostly noninvasive. The onset of symptoms is insidious, usually beginning many months prior to diagnosis with mild vomiting and/or headache. Increased intracranial pressure is caused by compression of the fourth ventricle and cerebellar-pontine angle cisterns ([Laurent and Cheek, 1986](#)). Nystagmus, ataxia, unilateral hypotonia, and intention tremor also may be present. The course is usually benign. Treatment consists of resection; CSF shunting, if required; and radiation therapy, depending on malignancy and extent of the resection. Medulloblastoma, in contrast, is rapid growing and highly malignant. This tumor arises from the midline cerebellar vermis and may seed into the fourth ventricle and other structures. The onset of symptoms is acute, with vomiting, headache, and axial ataxia presenting several weeks to 2 months prior to diagnosis. Involvement of the reticular activating system may lead to an altered state of consciousness known as a coma vigil or akinetic mutism. Treatment consists of excision and chemoradiotherapy (owing to universal recurrence and inability to resect the entire tumor). The prognosis is not good; however, the 5-year survival rate has improved to about 50% with aggressive surgery and high-dose irradiation ([Cohen and Duffner, 1994](#)).

Fourth ventricle tumors include ependymomas and choroid plexus papillomas. Ependymomas, which may arise in any ventricle, predominate in the fourth ventricle in children and may lead to early CSF flow obstruction. Increased intracranial pressure is the presenting condition and, when the tumor is infratentorial, may be accompanied by nystagmus, head tilt, and ataxia. Following excision and irradiation, survival rates range from 15% to 100%, depending on the malignancy of the ependymoma and whether seeding has occurred ([Cohen and Duffner, 1994](#)). Choroid plexus papillomas arise primarily in the fourth or lateral ventricles, are highly vascularized, and produce CSF, which results in IICP. Additional symptoms reported in one 12-year-old boy by [Blackman and Wheeler \(1987\)](#) consisted of somatic complaints, separation anxiety, school refusal, fearfulness, and crying episodes for a year. This child also had mild ataxia and impaired coordination since the age of 2 and had a head circumference at the 98th percentile. CT scan made the diagnosis during the second psychiatric hospitalization. Tumor resection resulted in amelioration of the depressive and anxiety symptoms.

Brain stem tumors are primarily gliomas of the pons. Increased intracranial pressure may not be present. Common symptoms are cranial nerve deficits, ataxia, spasticity, and gait disturbance and a classic triad of progressive cranial neuropathies, pyramidal tract signs (hemiparesis), and cerebellar pathway signs (truncal and extremity ataxia and nystagmus) have been described ([Cohen and Duffner, 1994](#)). Although the duration of symptoms is usually brief, one case with a 6-month history of headaches precipitated by postural change has been reported ([Novak and Moshe, 1985](#)). Radiation is the treatment of choice, as surgery does not alter the course. Prognosis is very poor, even with irradiation and chemotherapy.

### Supratentorial Tumors

Supratentorial tumors include cerebral and parasellar or midline neoplasms.

Cerebral hemisphere tumors can be in any lobe, the basal ganglia, and/or the lateral ventricles and can be of various types, such as those listed in [Table 61.2](#). Increased intracranial pressure is not usually found until late in the course, unless the tumor is rapidly growing and malignant (e.g., glioblastomas, in which the duration of symptoms is only about 6 weeks) ([Cohen and Duffner, 1994](#)). With low-grade tumors such as pilocytic and anaplastic astrocytomas, the duration of symptoms is often several years. Personality changes may be some of the earliest manifestations but may be subtle and difficult to ascertain in young children. Hence, these tumors may grow quite large before detection. These personality changes may include intermittent irritability, listlessness, depression, and decrements in school performance, memory, attention, social awareness, and personal hygiene, although these are less well documented in children than adults. In the child with academic or behavioral deterioration, funduscopic examination is important, as it may show papilledema if a brain tumor is the underlying cause ([Herskowitz and Rosman, 1982](#)). Headache is also an early complaint. Aggression is sometimes seen with temporal lobe tumors. Seizures (which can be generalized tonic-clonic, complex partial, and/or focal motor) and focal neurologic deficits such as motoric weakness, hemiparesis, aphasia, alexia, agraphia, and hemianopsia tend to be later signs that result in diagnosis. In most cases of cerebral tumor, total resection is not possible, and excision is often followed by irradiation. Prognosis varies with tumor type: For low-grade astrocytomas, 5-year survival after excision and irradiation is 50% ([Laurent and Cheek, 1986](#)).

Parasellar tumors are those arising in proximity to the sella turcica. Craniopharyngioma is the most common of these, arising from remnants of the pharyngeal duct near the pituitary stalk. This leads to endocrine dysfunction, and infiltration of the hypothalamus leads to hypothalamic dysfunction. Growth retardation and delayed sexual maturation are frequent but are difficult to appraise early on. Obesity, somnolence, visual and olfactory hallucinations, and alterations in body temperature and blood pressure may occur. Later signs may be those of IICP and visual disturbances owing to optic chiasm compression. Treatment is by resection, with irradiation if resection is subtotal. The prognosis is good; however, these patients have both transient and permanent endocrinologic abnormalities requiring treatment. Pituitary adenomas are rare in children and are manifested by growth retardation and visual loss. Optic nerve and chiasm gliomas are not uncommonly associated with neurofibromatosis. Visual defects are the primary presentation. Treatment is irradiation and possible chemotherapy. In infants, optic gliomas are usually aggressive, and the prognosis is poor, whereas in older children the glioma is often benign and self-limited ([Kanamori et al., 1985](#)). A rare case of a disseminated parasellar germinoma involving the basal ganglia in a 13-year-old boy included early psychotic symptoms, with delusions and thought disorder, obsessive-compulsive features, aggression, mood lability, and suicidal ideation ([Mordecai et al., 2000](#)).

Midline tumors are those in the third ventricle, hypothalamus, or thalamus, in addition to the parasellar region. Pinealoma is the only brain tumor in children with a marked sex difference, having a male:female ratio of about 3 to 4:1. Pinealomas may be in the pineal region or in the posterior third ventricle ([Laurent and Cheek, 1986](#)). Symptoms include those of IICP, endocrine disturbance, and visual defects. Diabetes insipidus, growth retardation, delayed puberty, or precocious puberty may be present. Parinaud syndrome (paralysis of upward gaze with bilateral ptosis owing to pressure on the superior colliculi) is characteristic but may also be a sign of IICP ([Cohen and Duffner, 1994](#)). Other nonspecific signs (e.g., ataxia, nuchal rigidity, central deafness, and nystagmus) may be seen. Resection and/or irradiation are the recommended treatments. Colloid cysts of the third ventricle are rare. Movement of the tumor by flexion of the head results in intermittent obstruction of CSF flow, leading to intermittent symptoms of sudden headache, vomiting, and somnolence. Many of these tumors, although occurring in childhood, are not diagnosed until adulthood. Hypothalamic gliomas are rare and cause a characteristic diencephalic syndrome in infants. The infant appears alert and euphoric but becomes markedly emaciated. It is differentiated from failure to thrive by the activated state of the child. Hypothalamic gliomas in later childhood may present with accelerated growth and precocious puberty. Radiation therapy is the only treatment possible. Thalamic tumors are also rare. These often mimic cerebellar tumors but may have more characteristic signs, such as rhythmic alternation of extremities, athetosis, and posturing.

## Psychiatric Sequelae of Brain Tumors and Brain Irradiation

Consideration must not only be given to the presenting neuropsychiatric symptoms of brain tumors but also to those symptoms secondary to the sequelae of the tumor after treatment and the treatment itself. Standard neurologic examinations have little prognostic value for quality of life in children with brain tumors ( [Milstein et al., 1985](#)). Until recently, as survival rates have increased, very few studies had been done to assess functioning after treatment by means other than neurologic examinations. Several studies, using global and specific measurements, have shown many surviving children functioning at near normal and some achieving high levels of education, although substantial proportions of this population, ranging from 40% to 60%, have intellectual and emotional disturbances ( [Bamford et al., 1982](#)). Emotional disorders that have been reported include psychotic symptoms, immaturity, depression, anxiety, and oppositional and antisocial behavior ( [Danoff et al., 1982](#)). Many early investigations that reported functional deterioration did not or were not able to separate important variables, including tumor characteristics, age of the child, and treatment modalities ( [Mulhern and Kun, 1985](#)). Tumor location is often divided grossly into infratentorial or supratentorial locations for these studies. Impairments from infratentorial tumors are variable, with predominant visual-motor problems and about a 30% to 60% incidence of neuropsychiatric deficits, behavior disturbance, and need for special education ( [Mulhern and Kun, 1985](#)). These latter types of impairments are much more common with supratentorial tumors, with about a 50% to 85% incidence ( [Kun et al., 1983](#)). In five children with temporal lobe tumors, [Mulhern and Kun \(1985\)](#) found impulse control problems and special education needs in all, with more severe deficits than in adults with temporal lobe tumors. Further subdivision on the basis of location yields sample sizes too small for generalization.

Age at diagnosis and treatment appears to be positively correlated with better functioning if diffuse CNS damage has occurred, whereas younger children with focal injuries have better recovery than do older children ( [Eisner, 1981](#); [Mulhern and Kun, 1985](#)).

Increased intracranial pressure has been postulated to be responsible for some of the long-term intellectual deficits with brain tumors; however, it does not seem to have a lasting impact after treatment ( [Mulhern and Kun, 1985](#)).

The treatment modalities of cranial irradiation and CNS chemotherapy have been shown to adversely affect intellectual functioning. Children with acute lymphocytic leukemia (ALL) provide a useful comparison group for investigating the effects of CNS irradiation and chemotherapy in children with brain tumors, allowing separation of irradiation and chemotherapy effects from those of the tumor and neurosurgery. Cranial irradiation is a standard treatment for ALL, and many children with ALL develop a postirradiation syndrome within 4 to 8 weeks of treatment (somnolence, anorexia, and lethargy). Longer-term changes consist of cerebral atrophy, distractibility, memory and attention deficits, and declining IQ and achievement test scores, all of which are greater with higher radiation dose and combined irradiation-chemotherapy in the younger child ( [Cohen and Duffner, 1994](#); [Halberg et al., 1992](#); [Mulhern and Kun, 1985](#)). Nonverbal and information-processing skills may show cumulative deterioration ( [Anderson et al., 2000](#)). Even without radiation, CNS chemotherapy causes neurocognitive deficits, especially in academic achievement, that may take 3 to 4 years to appear ( [Brown et al., 2000](#)). Children with brain tumors are thought to be at greater risk for these effects, as radiation dosages for brain tumors are much higher than those for ALL. Indeed, more severe sequelae have been demonstrated, with either pervasive intellectual deterioration or more selective performance and mathematic deficits ( [Duffner et al., 1985](#); [Kun et al., 1983](#)). These effects have become more noticeable and problematic as rates of survival have increased, especially because these adverse consequences are more prone to occur in younger children, tend to worsen over time, and may take 2 to 5 years to be fully noted despite initial improvement in the first 6 months after treatment for older children ( [Duffner et al., 1985](#); [Mulhern and Kun, 1985](#); [Packer et al., 1989](#)). Irradiation also poses the additional adverse effects of long-term growth hormone suppression with resulting decelerated growth, hypothyroidism, hearing deficits, leukoencephalopathy, and oncogenesis (especially of sarcomas) ( [Cohen and Duffner, 1994](#); [Duffner et al., 1985](#)).

The diagnosis of brain tumor in a child is clearly devastating to the family. Often there is little time to optimally adjust to this news before the operation and treatment are begun. With increased survival, the family frequently must cope with a "changed" child, and joy over the child's survival can be challenged and tempered by the sorrow over his or her cognitive, behavioral, and emotional deterioration. This may occur even in the child with an IQ in the normal range ( [Cohen and Duffner, 1994](#)). As with other chronic disease, the parents tend to become unrealistic and overprotective ( [Danoff et al., 1982](#)). They may infantilize their child and avoid discussion of such issues as tumor recurrence and death. Marital and intrafamilial stress is not uncommon. Long-term psychiatric sequelae of brain tumors in childhood include cognitive deficits, school failure, social difficulties, and unemployment and appear more severe with supratentorial tumors and with cranial irradiation ( [Glauser and Packer, 1991](#); [Kaye and Duffner, 1998](#); [Mostos et al., 1991](#)). Educational and psychological services, such as special education, psychotherapy, and national or local brain tumor groups provide much-needed support for the child and family.

## Conclusions

Brain tumors in youth are primarily infratentorial, and initially presenting psychiatric symptoms are not as common or obvious as in adults. When present, these changes are often subtle and include irritability, declining school performance, memory impairment, decreased attention, depression, and changes in sleep (somnolence). Symptoms of IICP are often the primary presentation. Children with academic and behavioral deterioration deserve a neurologic examination, and the index of suspicion for intracranial mass should be high if headache, vomiting, alterations in consciousness, visual disturbances, cerebellar signs, or neurologic deficits are present. With recent increases in survival rates, long-term sequelae of intellectual, emotional, and behavioral deterioration have been noted. In general, these neuropsychiatric deficits are worse for supratentorial tumors, in younger ages at diagnosis and treatment, and after cranial irradiation. IQ, achievement, and memory testing should be done before and after treatment and followed for several years thereafter to assess long-term sequelae of cranial irradiation. Educational and emotional support services for the child and family can have a beneficial impact on adjustment after treatment.

## NEURODEGENERATIVE AND NEUROMUSCULAR DISORDERS

For convenience, this section covers neurodegenerative and neuromuscular disorders together. As with brain tumors, the classification of these disorders is controversial, and neurocutaneous disorders are sometimes considered under nervous system tumors rather than under degenerative diseases ( [Menkes, 1995](#)) ( [Chapter 1](#), [Chapter 6](#), [Chapter 7](#)). [Table 61.3](#) lists major categories of these disorders and selected diseases for each. Only those diseases that have reported psychiatric manifestations are discussed here.

Cerebral vascular

possible autoimmune disorders and/or slow virus infections. Varying degrees of intellectual impairment are present; and spasticity, optic atrophy, ataxia, weakness, and seizures are common. In most cases, treatment is purely symptomatic and supportive.

*Krabbe's disease* (globoid cell leukodystrophy) is a cerebral storage disease resulting in demyelination. It usually begins suddenly at 4 and 6 months of age and rapidly progresses to death, although later onset and slower progression have been observed ( [Menkes, 1995](#)). Restlessness, irritability, stiffness, seizures, and peripheral neuropathy are seen.

*Metachromatic leukodystrophy* (MLD) has different forms with different enzyme defects and different ages of onset, from infancy to adulthood. In the late infant or young child, early hypotonia gives way to spasticity; impairment of speech and intellectual deterioration gradually develop, accompanied by gait disorders, coarse tremor, athetoid movements, decreased deep tendon reflexes, and later, seizures ( [Swaiman, 1994](#)). Death ensues within several months of diagnosis. In the juvenile form of MLD, onset begins between 5 and 7 years with ataxia and movement disorders and progresses slowly to spasticity.

*Multiple sclerosis* (MS) usually begins in the young adult; however, rare cases of MS have occurred in children. Few children have symptoms before 10 years of age; most occur after puberty. As with adults, the course is unpredictable and characterized by waxing and waning symptoms, and the symptoms are similar: Ataxia, weakness, blurred vision, paresthesias, dizziness, headache, mood lability, and incontinence can occur ( [Menkes, 1995](#)). Diagnosis is made retrospectively and is bolstered by CSF abnormalities (especially pleocytosis and elevated g globulins), abnormal evoked potentials, and visualization of demyelinated lesions on CT or MRI. The etiology remains unknown, but MS is thought to be autoimmune in nature, perhaps because of a slow virus infection in early life. We have encountered cyclothymia as the presenting feature of this disorder in a 10-year-old girl who was admitted to our child psychiatry inpatient service with an initial diagnosis of bipolar affective disorder. The patient's complaints of visual disturbances were originally interpreted as probable conversion symptoms until fundoscopic examination yielded evidence of optic neuritis and led to the appropriate underlying neurologic diagnosis.

*Schilder's disease* (diffuse cerebral sclerosis) is an acute and progressive demyelinating disorder similar to MS, with onset often between ages 5 and 12. Intellectual impairment, emotional lability, gait disturbance, and seizures are early manifestations. Late signs include visual complaints, aphasia, deafness, and cranial nerve palsies, followed by death within 1 to 2 years ( [Menkes, 1995](#)).

### System Degenerations

These disorders involve progressive degeneration, primarily of one neurologic system ( [Swaiman, 1994](#)).

#### BASAL GANGLIA

*Parkinson's disease* has a rare juvenile form, with the onset around age 10 to 15 years of resting (pill-rolling) tremor, bradykinesia, rigidity, and intellectual deterioration. Treatment is the same as the adult form, but death usually occurs by the third decade.

*Huntington's disease* can begin as early as age 3, although only 1% to 3% of cases have their onset in childhood ( [Hecht, 1987](#)). The inheritance is autosomal dominant, and the juvenile form is usually inherited from the father. Commonly, the disease presents with dementia, personality change, and seizures between ages 5 and 10, followed by marked rigidity and hypokinesia. Chorea-athetosis may be absent. Death occurs within 3 to 10 years after onset.

*Dystonia musculorum deformans* is a genetic disorder marked by increased muscle tone with gait disturbance and abnormal foot positioning, torticollis, and/or dystonic movements, without intellectual impairment. Onset may occur around age 5. The limbs become distorted but relax during sleep. Fixation and incapacitation may ensue. These cases are not infrequently misdiagnosed as conversion disorder or hysteria, but the reverse can happen as well, with psychogenic dystonia sometimes resulting in inappropriate medical therapy or even surgery (such as insertion of straightening rods or thalamotomy) ( [Fahn and Williams, 1988](#)).

*Wilson's disease* is an inborn error of copper metabolism resulting in degeneration of the basal ganglia and hepatic cirrhosis. Initial presentation is hepatitis and/or dystonia and gait disturbance in mid-childhood ( [Menkes, 1995](#)). Intellectual impairment, affective lability, anxiety, and psychotic symptoms are common, as are tremor, dystonia, dysarthria, ataxia, and choreoathetosis. Oral chelating agents and restriction of dietary copper lead to only partial recovery.

#### CEREBELLAR

*Friedreich's ataxia* presents with gait disturbance, with peak onset between ages 10 and 13. By age 20, most cases are nonambulatory. Dysarthria and hearing loss can occur, but cognitive deficits are unusual. [Hart and coworkers \(1986\)](#) reported on two children with Friedreich's ataxia who had deficits in information-processing speed, sustained attention, and memory, which occurred early in the disease course and progressively worsened.

#### BRAIN STEM AND SPINAL CORD

Degenerations in these structures, such as *Werdnig-Hoffmann disease* and *familial juvenile amyotrophic lateral sclerosis*, have no characteristic psychiatric symptoms.

### Neurocutaneous Diseases

These diseases, sometimes referred to as phakomatoses, involve both skin and nervous system, which have a common embryonic ectodermal origin. The etiologies are of hereditary enzyme and metabolic defects.

*Neurofibromatosis* (von Recklinghausen's disease) is characterized by café au lait spots and numerous Schwann cell tumors along nerves and nerve trunks. Giant neurofibromas may cause overgrowth, of the limbs, trunk, and face ("elephantiasis") ( [Swaiman, 1994](#)). Intracranial tumors are seen, with optic gliomas common in children; and acoustic neuromas, ependymomas, and meningiomas frequent. Mental retardation is often present to varying degrees, visual-spatial integration deficits may be present, and hyperactivity and learning disorders are common ( [Varnhagen et al., 1988](#)). The inheritance is autosomal dominant, but about half of the cases represent new mutations of a gene on chromosome 17 ( [Martin, 1987](#)).

*Tuberous sclerosis* may present with infantile spasms as early as 6 months, hypopigmented nevi (ash-leaf spots), adenoma sebaceum, shagreen patches (large, raised, leathery areas of the skin), subungual fibromas, and retinal tumors. There are cardiac, renal, and pulmonary lesions. Sclerotic nodules that may calcify are found in the brain: These are responsible for developmental delay or arrest, hypersarrhythmia on the EEG, and mixed seizures. Psychiatric symptoms vary: Although some children may have average intelligence, most show significant cognitive impairment, and up to 50% are autistic ( [Harrison et al., 1999](#)). [Hunt and Dennis \(1987\)](#) have shown that normal intelligence is associated with the absence of infantile spasms, whereas the majority of cases with a history of infantile spasms show mental retardation and/or classic symptoms of autism. Aggression, obsessions, hyperactivity, psychotic symptoms, and impaired social behavior and communication are prominent; these behavioral features are often the most pressing concern of the parents. The inheritance of tuberous sclerosis is autosomal dominant with variable penetrance ( [Menkes, 1995](#)).

*Sturge-Weber syndrome* is manifested by a facial port-wine nevus in the distribution of the trigeminal nerve. Intracranial angiomatous malformations may give rise to focal seizures and hemiplegia, beginning by age 1. Symptoms progress relentlessly, with seizures becoming intractable. Most children are mentally retarded, and dementia becomes severe.

*Von Hippel-Lindau disease* occasionally presents in children as ataxia and spasticity, with hemangioblastomas of the cerebellum, kidney, liver, pancreas, and epididymis. Symptoms of posterior fossa tumor occur.

*Ataxia-telangiectasia* is a cerebellar degenerative disorder with characteristic telangiectasias of the conjunctivae and, less commonly, of the ears, face, and chest. These appear around age 4 and are usually preceded by ocular motor apraxia (difficulty breaking visual fixation without turning the head), ataxia, and intention tremor. Later, dysarthria, choreoathetosis, and intellectual deterioration are seen ( [Evans, 1987](#)). Many of these children have immune dysfunction with recurrent infections and a tendency to develop leukemias and lymphomas. Incapacitation occurs in adolescence, and death occurs in the early twenties.

## NEUROMUSCULAR DISORDERS

The predominant feature of neuromuscular disorders is weakness, with a variety of manifestations. The child psychiatrist should be familiar with these disorders, because they may have associated psychopathology or may be misdiagnosed as psychosomatic disorders. Two types of neuromuscular disorders are considered here: polyneuropathies and muscular dystrophies.

### Polyneuropathies

*Guillain-Barré syndrome*, juvenile myasthenia gravis, and most other polyneuropathies do not have characteristic psychiatric symptoms. However, because of their presenting symptoms, they are not uncommonly discounted as being conversion disorders. Guillain-Barré syndrome is a postinfectious inflammatory neuropathy, usually preceded by a viral infection or immunization. Within a few weeks of an upper respiratory or other infection, the child typically begins to complain of paresthesias in the extremities, which can have a glove-and-stocking distribution. Difficulty in walking and ataxia follow, and weakness rapidly ascends from the lower to upper extremities. Maximum deficits occur over several weeks to a month, followed by a plateau phase, then rapid recovery over several months ([Menkes, 1995](#)). Early in the course, the child may be seen as malingering to avoid school or other responsibilities. In many cases, respiratory insufficiency can occur, necessitating ventilatory support. Most patients recover with no sequelae. [Buschbacher \(1995\)](#) reported a documented case of a 15-year-old girl who was diagnosed and treated for Guillain-Barré syndrome and, within a few months, made a full recovery. Subsequently, she had recurrent episodes of a conversion disorder manifesting identical symptoms of her original Guillain-Barré syndrome. Each episode was associated with substantial stress at school or home.

*Juvenile myasthenia gravis* may also be misdiagnosed as psychosomatic. The symptoms are generally the same as in adults and usually occur after the age of 10 years. Ptosis and diplopia are hallmark signs, with waxing and waning fatigue that may be worse at certain times of day ([Menkes, 1995](#)).

### Muscular Dystrophies

The muscular dystrophies are inherited diseases characterized by progressive, symmetrical muscle weakness and atrophy of unknown etiology. *Duchenne muscular dystrophy* and *Becker type* are both x-linked recessive conditions; about one-third of Duchenne cases represent new mutations ([Martin, 1987](#)). The gene whose dysfunction is responsible for Duchenne muscular dystrophy has been located and its protein product, dystrophin, identified ([Hoffman et al., 1987](#)). Dystrophin is absent from the muscle tissue of boys with Duchenne muscular dystrophy. Duchenne-type dystrophy appears between 2 and 4 years of age, with delayed motor milestones, whereas the Becker type has its onset between 5 and 11 years of age ([Menkes, 1995](#)). Although the Becker type has a slower progression, both lead to wheelchair confinement and a decreased life span. *Fascioscapulohumeral* and *myotonic muscular dystrophies* are autosomal dominant disorders. The fascioscapulohumeral type occurs between 6 and 20 years of age and primarily affects the shoulder girdle and face. The myotonic type occurs from infancy to adulthood and involves distal and facial muscles, cataract development, gonadal atrophy, and myotonia.

Varying degrees of mental retardation of unknown pathogenesis have been reported in Duchenne, myotonic, and congenital muscular dystrophies, but less so in the Becker and fascioscapulohumeral types ([Menkes, 1995](#)). In Duchenne muscular dystrophy, estimates of mental retardation range from as low as 20% to as high as 50%, whereas in Becker's muscular dystrophy mental retardation is less well defined and thought to be about 5% ([Cotton et al., 1998](#); [Melo et al., 1995](#)). With increasing age and physical disabilities, increasing, decreasing, and static intellectual impairment have all been observed. [Whelen \(1987\)](#) reported average IQ but significantly lower verbal fluency and immediate verbal and nonverbal memory. [Sollee and associates \(1985\)](#) noted that IQ deficits in young Duchenne patients are primarily in language and attentional-organizational tasks, not in visual-motor tasks; these impairments improved to average with age. A similar trend was observed in a study that controlled for motor skills ([Cotton et al., 1998](#)). The Duchenne subjects, as compared to a healthy control group, had poorer functioning on neuropsychological tests that measured complex attention, verbal fluency, nonverbal memory, and visuospatial cognition. Results suggested that cognitive abilities in the Duchenne group might be specific rather than global.

In a comparison study of children with Duchenne's muscular dystrophy and spinal muscular atrophy, a more characteristic profile was found for children with Duchenne ([Billard et al., 1992](#)). Their WISC-R verbal IQ was significantly lower, whereas performance IQ was in the average range. Their left-handedness was more prevalent and language-based cognitive abilities, such as reading and verbal memory, were impaired. [Billard and associates \(1998\)](#) further examined the reading abilities and processing skills of three groups of children: Duchenne muscular dystrophy, spinal muscular atrophy, and those receiving mainstream education. The Duchenne children exhibited a reading-age that was significantly lower, and they were substantially impaired in reading single non-words, similar to that seen in dysphonetic dyslexia. [North and coworkers \(1996\)](#) described patients with Becker's muscular dystrophy who had no muscle weakness but presented with intellectual impairment and psychiatric disturbance, including learning disabilities, poor judgment, and depression.

The controversy over the extent of existence of cognitive impairment and the possible extent of CNS involvement in various forms of muscular dystrophy remains. It is questioned whether the absence of dystrophin in Duchenne patients affects the brain. [Kim and coworkers \(1995\)](#) found that dystrophin is deficient in synapses in the brain of Duchenne patients and that this deficiency might be related to cognitive impairment.

Children with all forms of muscular dystrophy are at risk for developing psychiatric disturbance such as anxiety, depression, and dysthymia disorders; the incidence is high regardless of normal or impaired intellectual functioning ([Melo et al., 1995](#)). [Fitzpatrick and coworkers \(1986\)](#) found frequent diagnoses of dysthymic disorder and major depressive disorder in boys with Duchenne, especially older boys. Another study showed that boys with muscular dystrophy, as compared to those with primary psychiatric disorder and chronic fatigue syndrome, related their depression and anxiety primarily to their physical condition ([Wood et al., 1994](#)). Social isolation, depression, and prolonged grief reactions are common; parents exhibit denial, preoccupation with the child, difficulty responding to death issues, guilt over the genetic transmission of the disease, and marital difficulties ([Witte, 1985](#)). The parents' initial expectations of a rapid course are greeted with false hope, because the disease progresses slowly; however, the parents' grief and conflict reemerge as walking becomes more difficult. Communication within families about muscular dystrophy presents difficulties for both parents and child, and the child is often the silent partner in decision-making ([Fitzpatrick and Barry, 1986](#)). Proper management includes education, genetic counseling, facilitation of communication, involvement of the child in making decisions, and social and emotional support such as that provided by the Muscular Dystrophy Association.

## CONCLUSIONS

Neurodegenerative and neuromuscular disorders encompass many diverse diseases with an array of neuropsychiatric effects. There may be no specific neuropsychiatric symptoms (e.g., Becker-type muscular dystrophy), mild intellectual impairment (e.g., neurofibromatosis), depression (e.g., Duchenne muscular dystrophy), severe cognitive disability (e.g., Huntington's chorea), or autism (e.g., tuberous sclerosis). The etiology and pathogenesis for many of these disorders are insufficiently understood, and often treatment is only supportive. For those disorders for which specific treatment is available (e.g., Wilson's disease), the treatment may not reverse some of the neuropsychiatric deficits. As most of these diseases are inherited, genetic counseling is an essential part of treatment. Education about the disorder, enhancement of family communication, and provision of social and emotional supports are beneficial and necessary components of management. Psychotropic medication may be considered for clearly defined symptom alleviation.

### HISTORICAL PERSPECTIVE

Many doubted the existence of depression and mania in children and adolescents for years because it was felt that children, for theoretical reasons such as “immature personality structures,” could not experience extremes of mood ([Schulterbrandt and Raskin, 1977](#)). Yet case reports on despondency and depression in children and adolescents date back to the early 17th century. Melancholia was reported in the middle of the 19th century. In the 20th century, the existence of depression in children was doubted through the 1960s because it was felt that children's immature superego would not permit the development of depression ([Weller and Weller, 1984a,b](#)). However, this thinking changed following the Fourth Congress of the Union of European Pedopsychiatrists in Stockholm, Sweden, in 1970. The theme of this meeting was “Depressive States in Childhood and Adolescence.” As a direct result of this conference, the Union of European Pedopsychiatrists concluded that depression in childhood comprised a significant portion of mental disorders in children and adolescents ([Akiskal and Weller, 1989](#)).

Subsequently, the publication of the book, *Depression in Childhood: Diagnosis, Treatment and Conceptual Models*, by [Schulterbrandt and Raskin \(1977\)](#) increased the awareness of childhood depression in North America. This book was based on findings by a group of clinicians, researchers, and scientists sponsored by the National Institute of Mental Health. They reviewed the existing literature on affective disorders in childhood and came to the conclusion that depression in children and adolescents can be diagnosed using adult criteria if adjusted to assess symptoms in an age-appropriate manner.

The third edition of *Diagnostic and Statistic Manual of Mental Disorders* (DSM-III), DSM-III-R, and DSM-IV have used the same criteria to diagnose depression in adults and children. A few minor adjustments were made in the criteria to account for differences in age and stage of development between adults and children. For example, in the criteria for depression, failure to gain expected weight can substitute for significant weight loss in children. Also, the duration of symptoms required to diagnose dysthymia is 1 year in children and adolescents instead of the 2 years required for adults.

### PHENOMENOLOGY OF DEPRESSIVE DISORDERS IN CHILDREN AND ADOLESCENTS BASED ON THE DSM-IV CLASSIFICATION SYSTEM

The DSM-IV diagnostic criteria for depressive disorders are the same for children and adolescents as adults, with small exceptions stated as notations to the criteria. There is evidence to support the use of DSM criteria for major depression in adolescents ([Roberts et al., 1995](#)).

#### Major Depressive Disorder

The DSM-IV defines a *major depressive episode* as a syndrome in which at least five of the following symptoms have been present during the same 2-week period:

1. Depressed mood (for children and adolescents, this can also be an irritable mood)
2. Diminished interest or loss of pleasure in almost all activities
3. Sleep disturbance
4. Weight change or appetite disturbance (for children, this can be failure to achieve expected weight gain)
5. Decreased concentration or indecisiveness
6. Suicidal ideation or thoughts of death
7. Psychomotor agitation or retardation
8. Fatigue or loss of energy
9. Feelings of worthlessness or inappropriate guilt

At least one of the symptoms must be diminished interest/pleasure or depressed mood. The symptoms must cause significant distress or impairment of functioning in social, occupational, or other important areas. The syndrome should not have been precipitated by the direct action of a substance or the result of a medical condition and should not be better explained by bereavement or schizoaffective disorder. Also, a major depressive episode should not be superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or a psychotic disorder not otherwise specified.

The disorder can be rated as mild, moderate, or severe. Also, it can be noted to be with or without psychotic symptoms that can be mood congruent or incongruent. It also can be determined to be in full or partial remission. When the episode has lasted 2 consecutive years, the depression should be diagnosed as chronic.

A depression also may be determined to have melancholic features. Either a loss of pleasure in almost all activities or a lack of reactivity to usually pleasurable stimuli should be present. Additionally, at least three of the following are required:

1. A quality of depressed mood that is distinctly different from the kind felt when a loved one is deceased
2. Depression worse in the morning
3. Waking up 2 hours earlier than usual
4. Observable psychomotor retardation or agitation
5. Significant weight loss or anorexia
6. Excessive or inappropriate guilt

Depressive or manic episodes also can present with *catatonic features* requiring at least two of the following as delineated in DSM-IV.

1. Motoric immobility in the form of catalepsy or stupor
2. Motor overactivity that seems purposeless and not in response to external stimuli
3. Extreme negativism or mutism

4. Voluntary movement peculiarities such as posturing, grimacing, stereotypy, and mannerisms
5. Echolalia or echopraxia

The *seasonality of mood disorders* also can be specified. To diagnose a seasonal mood disorder, there should be a regular temporal relationship between depression and/or mania, and a particular period of the year. A full remission or switching from depression to mania should occur within that characteristic time of the year. An individual should manifest at least two episodes of mood disturbance in the last 2 years. Finally, seasonal episodes should substantially outnumber nonseasonal episodes. It is difficult to diagnose seasonal affective disorder in children, because they experience the recurring universal stressor of starting school every fall. Also, a young child might present with an apparent seasonal depressive disorder but not yet have had any prior episodes. In this situation, a seasonal mood disorder could not be diagnosed because the required three episodes would be lacking. Manic or depressive episodes also can be considered as *postpartum* in women if the onset is within 4 weeks of their delivery according to DSM-IV criteria.

### Dysthymic Disorder

Dysthymic disorder can be diagnosed when there is a depressed or irritable mood that lasts a year or longer (in adults this must be 2 years or longer), and the affected youth is never symptom-free more than 2 months. In addition to a mood disturbance, to diagnose dysthymia at least two of the following symptoms must be present:

1. Appetite change
2. Sleep change
3. Decreased energy
4. Low self-esteem
5. Difficulty making decisions or poor concentration
6. Feelings of hopelessness

Dysthymia should not be diagnosed if there is a major depressive episode during the first year of the disturbance; if there is a history of manic, hypomanic, or mixed episode; if the disorder is during the course of a psychotic disorder such as schizophrenia; or if it is secondary to use of a substance or general medical condition.

Dysthymia is often referred to as depressive personality because it often starts in childhood, adolescence, or early adult life. The condition is chronic. It is called secondary dysthymia if it coexists with anorexia nervosa, anxiety disorder, rheumatoid arthritis, somatization disorder, or psychoactive substance dependence. If the age of onset is prior to 21, it is called early onset. In children and adolescents, predisposing factors include attention deficit hyperactivity disorder (ADHD), conduct disorder, specific developmental disorder, and a chaotic home environment. Children who have dysthymia and subsequently develop a major depressive episode have a so-called “double depression.” [Kovacs and associates \(1984\)](#) report dysthymic children to be at risk for developing depression and mania on follow-up.

### Atypical Depressive Features

A depression also may be identified as having atypical features. Characteristics of this subtype are mood reactivity, exclusion of melancholic and catatonic subtypes, in addition to two or more of the following for a period of at least 2 weeks:

1. Increase in appetite or significant weight gain
2. Increased sleep
3. Feelings of heaviness in arms or legs
4. A pattern of longstanding rejection sensitivity that extends far beyond the mood disturbance episodes and results in significant social or occupational impairment

### Depressive Disorder Not Otherwise Specified

In the DSM-IV, this category includes disorders with features of depression that do not meet the criteria for a specific mood disorder or adjustment disorder with depressed mood. Examples include depressive episode superimposed on residual schizophrenia; a recurrent, mild depressive disturbance that does not meet criteria for dysthymia; or non–stress-related episodes that do not meet the criteria for a major depressive episode. DSM-IV should be consulted for further details as to the diagnostic criteria for depressive disorders not otherwise specified.

## PREVALENCE AND EPIDEMIOLOGY

Varying prevalence rates have been reported for depression. Such differences may result from different populations sampled—community, ambulatory psychiatry patients, pediatric outpatients (nonpsychiatric), or pediatric or psychiatric inpatients. Also, the refinement of structured and semistructured instruments for use in diagnosing child and adolescent psychiatric disorders that occurred in the 1980s made assessment more accurate ([Weller and Weller, 1986](#); [Weller et al., 1984a](#)).

Epidemiologic studies done in the United States have reported the incidence of depression to be 0.9% in preschoolers, 1.9% in school-age children, and 4.7% in adolescents ([Kashani and Sherman, 1988](#)). A study by [Lewinsohn and colleagues \(1993\)](#) of a randomly selected sample of 1,710 Oregon high school students yielded a percentage of female and male high school students with one current or lifetime episode of unipolar depression of 22.3% and 11.4%, respectively. The percentage of female and male students with two or more episodes was 4.9% and 1.6%, respectively. An epidemiologic study conducted by [Garrison and coworkers \(1997\)](#) in southeastern United States in adolescents aged 11 to 16 years found that the 1-year incidence for major depression was 3.3% and that the 1-year incidence of dysthymia was 3.4%.

Studies also have been done in specialized pediatric populations. For example, 40% of patients on a neurology ward with unexplained headaches suffered from depression ([Ling et al., 1970](#)), and 7% of general pediatric inpatients had depression ([Kashani et al., 1981](#)). In samples drawn from psychiatric settings, 28% of patients in a child psychiatry clinic ([Carlson and Cantwell, 1980](#)), 59% of psychiatric inpatients ([Petti, 1978](#)), and 27% of adolescent inpatients ([Robbins et al., 1982](#)) could be diagnosed as depressed. Thus, the occurrence of depression, as these studies indicate, is not rare. It is commonly encountered in psychiatric practice.

## CLINICAL DESCRIPTION

The age of a child and his or her psychological sophistication can play a major role in the depressed child's clinical presentation. Most children do not use language to effectively communicate information until age 7. Thus, it can be more difficult to diagnose depression prior to this age. However, attention to nonverbal communication such as facial expression and body posture can assist in making the diagnosis in younger children in whom verbal communication is not well developed ([Poznanski, 1982](#)). [Spitz and Wolf \(1946\)](#) and [Bowlby \(1960\)](#) have described anaclitic depression in institutionalized children who were separated from their primary caretakers. The children had listlessness, withdrawal, weeping, refusal to eat, and sleep disturbances. Unfortunately, there is a paucity of well-designed studies of depression in preschool-age children ([Akiskal and Weller, 1989](#)).

As children attend school and begin to better utilize language as a vehicle for exchanging information, they are better able to describe their feelings. Also, the school is another source of information on the child's functioning. As children are in school 6 to 7 hours a day, teachers can observe the child's behavior, as well as compare it to that of their peer group.

As discussed, depression runs in families. Very often at least one of the parents of a depressed child is also depressed. This can present a problem in evaluating a child. The concern is that depressed parents may tend to overreport problems in their children because they are inclined to view everything in a negative fashion ([Weller and Weller, 1990a](#)). Conversely, they also may underreport symptoms in their children when their own symptoms make them more preoccupied with themselves and less aware of things going on around them. School-age children are able to be interviewed and give detailed information as to their emotions and behaviors. Often the child reports sadness, suicidal thoughts, and sleep disturbances that his or her parents are not aware of ([Weller and Weller, 1990b](#)). However, parents may be more likely to report behavioral changes such as irritability, moodiness, “whininess,” and loss of interest. Also, parents often are more aware of duration of symptoms. Thus, it is important to interview both parent and child ([Weller et al., 1984a,b](#)).

Depressed children look sad, are tearful, have slow movements, and speak in a monotone voice, in a hopeless and despairing manner. They describe themselves in

negative terms, such as, "I'm dumb," "I'm stupid," "I'm a bad girl," and "Nobody loves me." Their school performance deteriorates, and they tend to drop out of favorite extracurricular activities such as baseball, soccer, and scouting. Somatic symptoms often occur, the most common being stomachaches and headaches ([Weller and Weller, 1989](#)). [McCauley and associates \(1991\)](#) reported a direct correlation between the frequency of somatic complaints and severity of depression. In late childhood, depression more often includes low self-esteem. The child may report disappointment with self, apathy, irritability, anxiety, and inability to concentrate. Self-endangering behavior and suicide attempts are quite common.

([Carlson and Kashani 1988b](#)) studied the frequency of different symptoms at different ages. Depressed mood, lack of concentration, insomnia, and suicidal ideation occurred equally in all groups. With increased age, there was decreased occurrence of depressed appearance and somatic complaints and increased occurrence of anhedonia, diurnal variation, hopelessness, psychomotor retardation, and delusions. [Ryan and coworkers \(1987\)](#) reported that depressed appearance, somatic complaints, psychomotor agitation, separation anxiety, and phobias were most common in depressed children. Anhedonia, hypersomnia, hopelessness, weight change, and drug abuse were increased in adolescents as compared to children. In adolescence, the clinical picture comes to resemble more that of the adult. Hopelessness and feeling that things will never change are reflected in the increased prevalence of suicide. There is a dramatic increase of suicide attempts and completion of suicide with puberty ([Akiskal and Weller, 1989](#)). Also, the prevalence of depression among females increases at puberty in comparison with males.

Recent research has focused on gender and cultural issues and depression in youth. A prospective, 10-year, longitudinal study of preadolescents into young adults ([Hankin et al., 1998](#)) found that the most critical time for gender difference to emerge was the period between 15 and 18 years. This was the age period when there was a peak in the increase of the overall rates of depression and onset of new cases of depression. The rate of depression increases dramatically for both genders and the rate of depression in females rises to double the prevalence rate for males. No gender differences were noted for depression symptom severity or recurrence. Researchers are beginning to examine the role of culture in juvenile depressives. Several studies have pointed toward the role of stress of acculturation in the increased incidence of depressive symptoms and suicidal ideation among Latino youth ([Hovey and King, 1996](#); [Roberts and Chen, 1995](#)). [Seigel and colleagues \(1998\)](#) in an epidemiologic study of youth (ages 12 to 17 years) in Los Angeles County using the Children Depression Inventory (CDI) found that Latinos reported more symptoms of depressed mood, independent of socioeconomic status, as compared to whites or African-American or Asian-American adolescents. They also found clear social class effects on the report of depression; as income decreased, the average level of depression increased. Clearly, more extensive controlled studies of subpopulations of depressed adolescents are needed. This work is necessary not only to understand the phenomenology of depression in various populations in our country, but also to further develop more appropriate treatment strategies that incorporate consideration of cultural.

## ETIOLOGY AND PATHOGENESIS

### Biological Mechanisms and Hypothesis

#### *Neuroimaging and Electroencephalography*

Increasingly sophisticated neuroimaging techniques have been developed over the past three decades. With neuroimaging, psychiatric disorders can be studied safely and longitudinally in children and adolescents who are at risk for a particular disorder or already have a disorder. Neuroimaging allows for individuals with these disorders to be compared to individuals with normal development ([Hendren et al., 2000](#)). Studies such as magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), magnetic resonance spectroscopy (MRS), and magnetoencephalography (MEG) are best suited to study structural, physiologic, and developmental brain abnormalities in youth and perform repeated measures because they do not involve ionizing radiation or radioactive isotopes ([Hendren et al., 2000](#)). Positron emission tomography (PET) has unique utility as it enables the study of receptor volume and the effect a compound may have on receptors; however, it is problematic to use PET in children and adolescents because it requires complex equipment (a cyclotron) and uses radiation.

Despite a multiplicity of neuroimaging studies in childhood autism, schizophrenia, attention deficit/hyperactivity disorder, and obsessive-compulsive disorder, to date there have been few neuroimaging studies in depressed youth. [Steingard and associates \(1996\)](#) examined 65 hospitalized depressed latency age children and adolescents. (The average age was 13 years. There were 12 children 12 years or younger and 44 adolescents over 12 years.) They used brain magnetic resonance imaging to compare depressed subjects with 18 hospitalized psychiatric controls without a depressive disorder. Depressed youth had a significantly smaller ratio of frontal lobe volume:total cerebral volume, and a significantly larger ratio of lateral ventricular volume:total cerebral volume than controls. The investigators suggest that the alterations in frontal lobe and lateral ventricle volumes is a promising finding and may suggest a role for the frontal lobes in the development of early-onset depression.

[Tutus and colleagues \(1998\)](#) studied adolescents with major depression using brain single-photon emission tomography (SPET), to examine the possible changes in cerebral perfusion and potential association between perfusion indices and clinical variables. The group used technetium-99m hexamethyl propylene amine oxime brain SPET. Fourteen adolescent outpatients (ages 11 to 15 years) with DSM-IV major depression and eleven age-matched normal control (ages 12 to 15 years) were studied. Significant differences between the perfusion index (PI) values of the untreated depressed patients and those of the controls were found, indicating relatively reduced perfusion in the left antero-frontal and left temporal cortical areas. No significant differences in regional PI values were found between the treated depressed patients and controls. Their findings suggest that adolescents with major depression may have regional cerebral blood flow deficits in left antero-frontal and left temporal cortical regions and greater right-left perfusion asymmetry compared with normals. These abnormalities in perfusion indices show a trend toward returning to normal values with improvement in depression, suggesting that they could be a state-dependent marker for adolescents with major depression.

Electroencephalographic (EEG) activity was studied in 16 depressed and nondepressed female adolescent suicide attempters and 22 normal controls ([Graae et al., 1996](#)). Suicide attempters differed from normal controls in alpha asymmetry. Normal adolescents had greater alpha (less activation) over the right than the left hemisphere. Suicide attempters had a nonsignificant asymmetry in the opposite direction. Nondepressed attempters were different than the depressed attempters because they accounted for most of the abnormal asymmetry, particularly in the posterior regions. Attempters with major depression tended to show alpha asymmetry in the anterior sites and nondepressed attempters tended to show alpha asymmetry in the posterior sites. Moreover, the alpha asymmetry over the posterior regions was related to the ratings of suicidal intent but not severity of depression. The alpha asymmetry in the suicidal adolescents was similar to that seen for depressed adults in its abnormal direction but not its regional distribution. The investigators suggested that the EEG asymmetry distinction between the depressed and nondepressed attempters might point toward a behavioral and physiologic separation between the two subgroups of suicide attempters.

The number of neuroimaging studies of adolescents with depression is currently limited; however, the field of neuroimaging in children and adolescents is advancing quickly, and there will likely be more studies of adolescents with depressive disorders in the near future. These studies may help to elucidate possible structural and physiological abnormalities in juvenile depression.

#### *Neuroendocrine Abnormalities*

Neuroendocrine abnormalities have been observed in depressed adults. Several such abnormalities have been studied to determine if they are biological markers of depression. Theoretically, there are two major types of markers, state and trait. A state marker is present or "positive" during an episode of illness and becomes absent or "negative" as the illness remits. The dexamethasone suppression test (DST) is considered a state marker ([Carroll, 1985](#)). The DST is positive in 50% of well-diagnosed endogenously depressed adults. Usually the marker normalizes as response to treatment occurs ([Greden et al., 1983](#); [Leekman, 1983](#)).

Cortisol hypersecretion, as well as dexamethasone nonsuppression, are reported in both prepubertal children and adolescents. [Weller and Weller \(1988\)](#) have reviewed the use of the DST in children and adolescents. Overall, 54% of depressed children and adolescents studied have abnormal DSTs; the abnormality seems more robust in prepubertal children (70% sensitivity) compared with that in adolescents (43%). Possible explanations for this finding include the possibility that prepubertal onset depression is more severe than adolescent-onset depression, and that neuroendocrine systems of prepubertal children are more intact, as they have not yet been influenced by drug abuse or the surge of sex hormones. [Weller and coworkers \(1985\)](#) also have shown that clinical outcome in some prepubertal depressed children is associated with DST results. Children who have normalized their DST at 5 months tended to be clinically well, whereas those with an abnormal DST at 5 months tended to be depressed.

Other biological markers that have been studied in adults, such as growth hormone, have recently begun to be studied in children. An initial study showed that depressed children have hyposecretion of growth hormone in response to an insulin challenge and hypersecretion of growth hormone during sleep ([Puig-Antich et al., 1987](#)). In a review, [Brent \(1992\)](#) reported that similar growth hormone responses could be found in nondepressed children of depressed biological parents, suggesting that these may be related to biological traits predisposing to depression. A more recent study ([De Bellis et al., 1996](#)) examined neuroendocrine changes in prepubertal depressives and examined nocturnal secretion of adrenocorticotropin (ACTH), cortisol, growth hormone (GH), and prolactin in these children compared with controls. Prepubertal depressed children had lower cortisol secretion during the first 4 hours after sleep onset compared with controls. ACTH, prolactin, and GH secretion did

not differ between groups. Lower nocturnal ACTH concentrations in depressed inpatients versus depressed outpatients were found, as well as in depressed sexually abused children versus nonabused children. Lower GH secretion in depressed females than in depressed males was noted. The investigators point out potential differences between nonstimulated (nocturnal) and challenge studies of neuroendocrine secretion, as the nocturnal neuroendocrine studies did not reveal expected group differences. [Dorn and colleagues \(1996\)](#) examined ACTH and cortisol response to ovine corticotropin-releasing hormone (oCRH) tests at baseline and following a cognitive stressor. Boys had higher measures of ACTH than girls, regardless of depression status, and cortisol levels were similar in both groups. The authors suggest that the gender differences in hormone responses may be related to differences in peripheral metabolism of ACTH, resulting in changes in immunoreactivity but not bioactivity or a different set point of the hypothalamic-pituitary-adrenal axis. The pattern of ACTH and cortisol responses to oCRH and 24-hour excretion of free cortisol was normal in adolescents with depression; the authors hypothesize this reflects normal negative feedback mechanisms at this age or that most of these patients suffer from atypical rather than melancholic depression. A study of the nocturnal serum melatonin profile in depressed children and adolescents and a control group found significantly higher melatonin in depressed subjects without psychosis than those with a psychosis and control subjects ([Shafii et al., 1996](#)).

Recent research also has examined possible abnormalities of the neurotransmitter systems. [Nobile and associates \(1999\)](#) has found that human platelet 5-HT uptake, is influenced differentially in nondepressed and depressed children by a common genetic variant of the promoter region of the 5-HTT. Depressed children had decreased transporter activity but this difference was almost entirely sustained by children who carried a specific genotype (the *l* variant for the 5-HTT promoter region). [Birmaher and associates \(1997\)](#) found that before the onset of affective illness, high-risk children had the same pattern of neuroendocrine response to L-5-HTP challenge as did children with major depression. The finding on serotonin in this theory may represent a trait marker for depression in children. The catecholamine theory of depression hypothesizes that norepinephrine levels are decreased in depressed patients. This has been studied by [McKnew and Cytryn \(1979\)](#), who reported that urinary 3-methoxy-4-hydroxyphenylethyl glycol (MHPG) was decreased in depressed children. Replication with larger samples is needed, and recent research in depressed children has focused more on abnormalities of the serotonin system.

#### *Steep Studies*

Studies of depressed adults have found shortened rapid eye movement (REM) latency, increased REM density, abnormal slow waves, and a decrease in sleep efficiency ([Kupfer et al., 1985](#)). In children and adolescents, preliminary studies are contradictory ([Emslie et al., 1990](#); [Puig-Antich, 1987](#)). Additional studies may be necessary to clearly determine what abnormalities of sleep architecture are present in depressed children and adolescents.

#### *Genetic Studies*

Several studies of depressed adults suggest a genetic component in the etiology of affective disorders. Such studies can be grouped in three general categories:

1. Twin studies have found that concordance for affective disorders in monozygotic twins is 76% compared with 19% in dizygotic twins. When monozygotic twins are reared apart, the concordance rate drops to 67%, possibly indicating that environmental factors may play a role in the expression of genetic factors ([Akiskal and Weller, 1989](#)).
2. In studying children of depressed adults, there is increased occurrence of affective disorders compared to other psychiatric disorders ([Weissman et al., 1984](#)).
3. Studies of parents and other relatives of affectively ill children and adolescents have found an increased age-adjusted morbidity risk for affective disorders, compared with the risk to the relatives of affectively ill adults ([Puig-Antich et al., 1988](#); [Strober et al., 1987](#)).

#### *Parent–Child Relation Model*

In this model, depression is conceptualized as resulting from poor parent–child interaction. Depressed adults report low paternal involvement and high maternal overprotection during their early childhood. As children's well being is dependent on the well being of the significant adults in their lives, the importance of environmental influences on affectively ill children cannot be ignored. Poor relationships with parents, siblings, and peers are common in affectively ill children and adolescents. An affectively ill child often has an affectively ill parent. In an ongoing study by [Weller and colleagues \(1990\)](#), affectively ill children have reported abuse or neglect by their affectively ill parent(s). Thus, in evaluating an affectively ill parent, it may be advisable to inquire about the well being of their children. [Hammen and associates \(1991\)](#) reported a significant temporal association between depression in mother and child. According to their findings, children with substantial stress exposure who concurrently had symptomatic mothers were significantly more depressed than those who were exposed to comparable levels of stress only.

In a review of children of depressed adults, [Beardslee and colleagues \(1983\)](#) found that, as infants and preschoolers, these children had higher rates of perinatal complications and cognitive and emotional delays and an inability to separate from their parents. As school-age children, they had depression, hyperactivity, school problems, enuresis, and excessive rivalry with peers and siblings for attention. During adolescence, problems with defiance, rebellion, withdrawal, and conflicts and disagreements with parents were reported. [Weissman and associates \(1984\)](#) reported a threefold increased risk for manifesting a DSM-III diagnosis in children (6 to 18 years of age) of depressed adults. The most commonly observed diagnoses were depression (13%), ADHD (10%), and separation anxiety (10%). Risk factors included both parents being depressed; early onset of illness in the parent; and divorce, separation, or widowhood of the parents. [Keller and colleagues \(1986\)](#) studied children of unipolar depressed parents. Severity and chronicity of parental depression were associated with current impaired adaptation in the child, presence of a DSM-III diagnosis in the child, and marital discord associated with a maladaptive child. In addition, depression in the mother was more strongly associated with psychopathology in their children than was depression in the father.

[Breslau and coworkers \(1987\)](#) studied 333 mother–child dyads. Depressed mothers tended to view their children as more symptomatic and reported increased risk for all psychiatric syndromes. Thus, information obtained from depressed parents about their children may be systematically biased. Again, this indicates the importance of directly interviewing a child and not relying on parents as the sole source of information about the child. Only one study ([Beardslee and Podorefsky, 1988](#)) has reported an optimistic view of children of depressed parents. In this study, 15 of 18 adolescents who were followed for 2½ years were doing well. Those doing well at follow-up were characterized by self-understanding, problem-solving ability, and commitment to relationships, being action-oriented, and having the ability to think and act separately from their parents. Many of these adolescents were caring for their affectively ill parents.

#### *Cohort Effect*

The cohort effect discussed earlier in regard to bipolar illness also applies to depressive illness. Thus, an increase in the incidence of depression in children can be expected in the future owing to this cohort effect.

[Klerman and coworkers \(1985\)](#) and [Gershon and associates \(1987\)](#) have reported a progressive increase in the lifetime cases of major depression over the last 70 years. They report high rates of disorders among relatives, with a younger age of onset and decreased age of onset in successive recent cohorts. The implications are that somehow genetics and environment have interacted to produce an increased incidence and increased severity of mood disorders in succeeding generations.

#### *Sociologic Model*

According to this model, depression is seen as the result of social structures that deprive people of desirable roles. The inability of our social institutions to cope with current social stressors leads to the development of depression in some individuals ([Klerman, 1976](#)).

### **Psychological Theories of Depression in Youth**

#### *Psychoanalytic Theory*

[Freud \(1917/1966\)](#) and [Abraham \(1911/1966\)](#) theorized that depression was due to the real or imaginary loss of a loved object. As it is difficult to objectively study the loss of an imagined loved object, there is little research to substantiate these theories.

#### *Life Stress Model*

This model assumes life stressors or changes in the environment that necessitate readjustments cause depression. Some have theorized that depressive symptoms in children are often a reaction to family turmoil ([Lefkowitz and Burton, 1978](#)). [Poznanski and Zrull \(1970\)](#) reported a high incidence of parental aggression, punitive

discipline, marital discord, and scapegoating or rejection in the families of depressed children.

It is often difficult to know whether the stressor produced the illness or the illness contributed to the manifestation of the stressor. For example, in a depressed child who also has a learning disability, it is incorrect to always assume that one caused the other. Often a biopsychosocial approach in treating the depression alleviates both the depression and coexisting problems.

#### *Behavioral Reinforcement Model*

In this model, it is theorized that inadequate or insufficient positive reinforcers cause depressive behaviors and feelings. Diminished reinforcers produce crying, irritability, and latency of response in young children ( [Ferster, 1973](#)). Limited social skills in depressed children may lead to positive reinforcers being unavailable to them. Social skills training may help alleviate this problem ( [Puig-Antich, 1987b](#)).

#### *Learned Helplessness Model*

In this theory, a depressed person perceives his or her behavior as independent of reinforcers. This perception leads to a sense of hopelessness and subsequently to “giving up” ( [Seligman, 1975](#)). The helplessness is caused by motivational, cognitive, and emotional deficits.

#### *Cognitive Distortion Model*

In this model a negative view of self, the world, and the future (the cognitive triad) are the basic causes of depression; however, it is not clear whether these distorted cognitions are the root or result of depression. Negative view of self (low self-esteem) is very common in children with all types of psychiatric disorders and is not unique to depression. A negative view of the future has been reported in a group of outpatient-depressed children. Although this theory is provocative, well-designed studies to assess its validity are needed.

#### *Self-Control Model*

This model assumes that depressed individuals have deficits in self-reinforcement, -evaluation, and -monitoring. Often they focus on the short- rather than long-term consequences of their actions. They often misattribute personal success to external forces and personal failure to themselves.

### **Assessment**

#### *Structured and Semistructured Interviews*

Diagnostic interviews can be useful in performing a psychiatric evaluation. Structured interviews such as the Diagnostic Interview for Children and Adolescents (DICA) ( [Reich, 2000](#)) and semistructured interviews, such as the K-SADS ( [Chambers et al., 1985](#)) can be used at baseline and follow-up to obtain additional information in a standardized fashion. The Childhood Depression Rating Scale-Revised (CDRS-R) of [Poznanski and associates \(1984\)](#) is a modified version of the Hamilton Depression Rating Scale that rates severity of depression based on information obtained from child, parent, teacher, and clinician. The Childhood Depression Inventory (CDI) ( [Kovacs, 1981](#)), a self-report scale similar to the Beck Depression Scale for adults, is not a diagnostic instrument and should not be used to diagnose depression, as its face validity is poor (i.e., children easily identify appropriate or inappropriate responses). The CDI rates severity of depression.

In a study where the CDI and a DST were performed concurrently, 62% of depressed children had both a positive DST and CDI scores indicative of depression. Only 7% of psychiatric controls and 0% of normal subjects had both tests positive ( [Fristad et al., 1988a](#)). Perhaps the use of both measures simultaneously yields more useful information than either test alone.

#### *Newer Structured Interviews*

The need to provide rapid, accurate, and comprehensive psychiatric diagnoses in children and adolescents in both clinical and research settings has led to the development of “second generation” structured interviews. The Children’s Interview for Psychiatric Syndromes (ChIPS; [Weller et al., 2000](#)) is a concise, comprehensive interview to assess 20 major Axis I psychiatric disorders, including major depression and dysthymia, and psychosocial stressors such as abuse, in youth 6 to 18 years of age using DSM-IV criteria ( [Fristad et al., 1998b](#)). The ChIPS and its parent version, the P-ChIPS, work well both in a clinical setting and in a nonclinical, community sample ( [Fristad et al., 1998b,c,d](#); [Teare et al., 1998a,b](#)). The ChIPS was designed to improve on methodology provided by first generation structured interviews, such as the DICA and the Kiddie-Schedule for Affective Disorders and Schizophrenia. The ChIPS and P-ChIPS are designed to be administered by trained lay interviewers. They require approximately 1 to 1½ hours for the parent and child interviews. It identifies syndromes with a degree of accuracy similar to the DICA, an existing structured interview with proven reliability and validity. The ChIPS sensitivity was superior to DICA’s sensitivity although the DICA’s specificity was higher than that of the ChIPS ( [Teare et al., 1998a](#)). The ChIPS and P-ChIPS have been effectively used in a large, inner-city psychiatric outpatient setting. The interview has also been used effectively in a minority population (Rowan et al., 1998, [1999](#)). Thus, the ChIPS can be used in busy clinic setting or private office to maximize resources and provide a quality control for diagnoses. Depressive disorders, one of the most common diagnoses in clinical psychiatric settings and a major health concern in children and adolescents, can be efficiently and accurately diagnosed through the ChIPS for both clinical and research purposes.

#### *Laboratory Studies*

A child should always have a medical evaluation as part of a complete psychiatric evaluation. Organic etiologies that might mimic a depressive disorder must be ruled out ( [Table 62.1](#)). Conditions thought to mimic depressive disorders fall into several major general categories: infections, medications, endocrine disorders, tumors, neurologic disorders, and miscellaneous disorders. Initial work-up should include a complete blood count (CBC) with differential, to rule out infection and anemia. Electrolytes, BUN, creatinine clearance, creatinine, and urine osmolality should be assayed to rule out kidney disorders. Liver function tests should be performed. Thyroid function tests (T<sub>3</sub>, T<sub>4</sub>, and TSH) are necessary to rule out thyroid disease and are also a necessary part of a lithium work-up. EEG evaluation may be needed for patients with a history or presentation suggestive of seizure disorder or episodic behavior. Also, an ECG must be done prior to starting a tricyclic antidepressant ( [Table 62.2](#)).

Medication	Neurochemical/Genetic	Endocrine	Infection	Other
Tricyclic antidepressants	Serotonin	Diabetes	Atypical mycobacteria	Acromegaly
MAOIs	Pheochromocytoma	Cushing’s disease	Tuberculosis	Diabetes insipidus
SSRIs	Subarachnoid hemorrhage	Adrenal pheochromocytoma	Brucellosis	Cocaine
Antipsychotics	Cardiac arrhythmias	Hypothyroidism	Chlamydia	Amphetamine
Antibiotics	Malaria	Hyperthyroidism	Coccidioidomycosis	Opium
Anticonvulsants	Botulism	Hyperparathyroidism	Chlamydia	Sickle cell anemia
Antipsychotics		Hypoparathyroidism	Atypical mycobacteria	Hypernatremia
Antipsychotics			Atypical mycobacteria	Hypernatremia
Antipsychotics			Chlamydia	Hypernatremia
Antipsychotics			Chlamydia	Hypernatremia
Antipsychotics			Chlamydia	Hypernatremia
Antipsychotics			Chlamydia	Hypernatremia

**Table 62.1. Conditions Mimicking Depression in Children and Adolescents**

self-perception. If the perception of low competence is not correct, therapy can enhance realism in self-perception.

### *Play Therapy*

Play therapy can provide a route of nonverbal communication in younger children or children who are developmentally delayed (especially, speech delayed). Particular attention should be paid to repetitive, reckless activity and issues of loss and retrieval. Play therapy also provides a way of discharging stress via motor activity. Displaced aggression with toys and the acting out of omnipotent fantasies through sadistic or dangerous superhero themes also may be observed in play therapy. Play therapy can be done individually or with a group. It provides the children an opportunity for success. The child is allowed to express feelings and eventually deal with them. The therapist also provides a healthy model for identification.

### *Insight-Oriented Therapies*

The prepubertal child (6 to 12 years) usually is resistant to the lifting of defenses, does not understand the concept of “going back in order to go forward,” and often prefers outside solutions rather than intrapsychic solutions; however, insight-oriented therapies may be successfully employed in older children. Indications for insight-oriented psychotherapy include nonpsychotic depression, behavior problems owing to intrapsychic conflict rather than conduct disorder, adequate intelligence, and achievement of formal operational thinking. Therapy typically starts with a supportive phase, progresses to empathy, and eventually goes to a collaboration/self-observing phase. The therapist gives verbal interpretations of anxiety and affect, as well as of impulsive acts. During the course of therapy, the focus goes from current relationships with significant others to transference relationships.

Play therapy or talk therapy may be used in prepubertal children. If play therapy is to be used, the child is assigned his or her own cubicle to keep play materials that are not to be shared with others. Useful play items include paper, pencil, crayons, scissors, string, tape, doll family, animals, fences, and two or three cars. The onset of puberty may be traumatic to depressed children. Usually, there is a feeling of increased internal and external pressures. Often there is anxiety about distorted body image and complaints of loneliness and isolation. The therapist needs to be more flexible with adolescents, because frequent cancellations are common. Adolescents often prefer same-sex therapists, and it is important for the therapist to avoid being perceived as a peer. The therapist needs to be active, frank, and able to express herself or himself on values if asked. Limits must be set on dangerous behaviors. In late adolescence, the therapist can be less active and more of an observer.

### *Behavioral Therapies*

The necessity for response-contingent positive reinforcement is emphasized in this therapy. With children, therapy often focuses on skills, especially interpersonal skills, so that reinforcement can be elicited.

### *Life Stress Model*

The focus of therapy is either resolving or accepting life stressors that have led to depression. An example might be a child who has an adjustment disorder with depressed mood in response to the separation or divorce of the parents. In this model, the therapist helps the child to accept the decision of the parents to separate or divorce.

### *Cognitive Psychotherapy*

It is assumed that irrational beliefs and distorted cognitions are the essence of the depression. Thus, the therapist challenges the distorted cognitions and encourages the patient to practice alternate behavior. Depressive cognitions include a negative view of self, the world, and the future. Usually the depressed child or adolescent personalizes failure, magnifies negative events, and minimizes positive events and attributes. Possible predisposing factors include early parental loss, a parent with negative cognitions (e.g., a depressed parent), or a parent with rigid rules. The therapist focuses on identifying and correcting cognitive distortions and helps the patient reevaluate his or her thinking. Therapy is active and time limited. Initially, the goal is symptom relief, but eventually, the goal is to alter depressive beliefs. This therapy may be most useful in mildly depressed children. Normal intelligence and at least the beginning of formal operational thinking are necessary; therefore, cognitive therapy is of limited use in preadolescents. Younger children often have cognitive deficits rather than errors. However, 7- to 12-year-old children can misinterpret, distort, self-blame, and feel guilt and self-anger.

A diary may be helpful in cognitive therapy. Parents can serve as “checkpoints in younger children.” A 10-point scale—where 10 is the best you ever feel and 1 is the worst you ever feel—can be used by children. Pictures of sad and happy faces to identify feelings can be used to self-monitor. Parents can be involved in planning the activities that will occur as part of the therapy. However, children should be given choices as to the activities, and contingent reinforcers should be used. Assignments should be graded in difficulty and progress from an easy to a difficult task, in order to allow success. “Think aloud” is a technique that can be used with the parents' prompting. The strategies employed by the therapist may include persuasion, challenging cognition, examining evidence, exploring alternative explanations, and determining consequences. Children and adolescents may need shorter sessions than adults. Some noncompliance should be tolerated. Therapists should maintain ongoing family contact and be sure not to assign complex homework to those who are learning disabled.

[Trautman and Rotheram \(1986\)](#) have described a modified format for cognitive therapy to be used in adolescents. Formal operational thinking is associated with the ability to conceive of contradictory explanations for a given event. Thus, the first step is to identify feelings, measure their intensity, and compare one feeling experience with others. An antecedent affect leads to a belief that may lead to consequences for the child. The therapist must be very active in engaging the adolescent, emphasize “collaborating” with the patient, involve the family, develop a problem list, and use the subjective units of distress scale (SUDS). “The feeling thermometer” may be used with adolescents; the adolescent identifies the best and worst things that have happened to him or her. Homework is assigned concerning three problems that the adolescent had in 1 week, and eventually, the therapist helps the adolescent come up with alternative thoughts. Adolescents are taught to be assertive and use self-instructed thoughts. A list of instructions is developed to be used for crisis situations.

An advantage of cognitive therapy for adolescents is that it is flexible and allows the therapist to move readily between the roles of teacher, confidant, role model, collaborator, and expert. However, cognitive therapy works best in mildly depressed adolescents. It is less effective in severely depressed adolescents, who may need adjunctive medication management.

### *Group Therapy*

Group therapy is useful in developing social skills in depressed children. It allows children to express feelings in a safe and supportive environment. It requires an energetic and empathic therapist.

### *Parent Training*

The purpose of parent training is to teach parents to manage specific problem behaviors and to appropriately use positive or negative reinforcers. Parents also are taught to communicate with their children in an age-appropriate manner. In particular, parents learn how to talk and listen to their children.

### *Family Therapy*

[Poznanski and Zull \(1970\)](#) described lack of generational boundaries, severe marital conflict, projection of parental feelings onto the child, rigid or chaotic rules, and disengaged or enmeshed relationships in the families of depressed children. The family therapist discourages rejection and encourages increased affection and communication among family members. Also, other family members who are concurrently depressed and require treatment may be identified.

### *Remedial Education*

Depression is frequently associated with decreased academic performance. The aim of remedial education is to increase interaction with teacher and peers. Paper and pencil tasks (passive tasks) are discouraged, and more oral and manipulation tasks (active tasks) are encouraged. Rapid academic gains occur as depression lifts ([Quay and Werry, 1979](#)).

### Out-of-Home Placement

Removal from the home sometimes is necessary for short periods of time if home is chaotic, especially when a parent is concurrently depressed. Possible placements include a foster home for the less disturbed children, a group home for moderately disturbed children, and a residential home for the most disturbed children.

### Recent Research in Psychotherapy for the Treatment of Depression in Youth

Recent research on effective therapies for depressed youth have focused on cognitive-behavioral therapy, systematic behavioral family therapy, individual nondirective supportive therapy, group therapy, and interpersonal psychotherapy with adolescents.

A comparison study of cognitive-behavioral therapy (CBT), systematic behavioral family therapy (SBFT), and individual nondirective supportive therapy (NST) for the treatment of major depression was conducted at Western Psychiatric Institute in Pittsburgh, Pennsylvania. Subjects were 107 adolescents (13 to 18 years) in an outpatient clinic with Beck Depression Inventory score of 13 or more. The CBT in this study was adapted from the adult CBT approach of Beck, to the specific developmental needs of adolescents. Systematic behavioral family therapy in this study was a combination of functional family therapy and a problem-solving model of family therapy developed by Robin and Foster. The NST therapists in this study avoided giving advice, setting limits, or teaching specific skills. The goal was to establish, maintain, and build rapport; provide support; and aid the patient in affect identification and expression of feelings. In the active phase of treatment, which included 12 to 16 sessions provided over 12 to 16 weeks, CBT appeared more efficacious for treatment of major depression than SBFT or NST, and resulted in more rapid and complete treatment response ([Brent et al., 1997](#)). Continued depression was predicted by clinical referral to the study compared to those who responded to an advertisement without a referral. This was in part mediated by hopelessness. A higher level of self-reported depression predicted clinical remission. An initial higher level of interviewer-rated depression predicted poorer functioning. CBT's performance continued to be robust, even with adverse predictors ([Brent et al., 1998](#)).

A 2-year follow-up of rapid response to treatment (decline of >50% in Beck Depression Inventory from pretreatment to the beginning of the second session of psychotherapy) indicated that rapid responders showed better outcome at the acute phase of treatment, 1 year, and for some measures, 2 years of follow-up. Subjects were most likely to respond rapidly or not at all in the NST. This research group suggested that milder forms of depression may benefit from initial supportive therapy or short trials of more specialized forms of psychotherapy ([Renaud et al., 1998](#)). Predictors of a need for additional treatment were severity of index depressive episode, comorbid dysthymia in the acute phase, severity of depressive symptomatology, presence of disruptive disorders, and family problems in the follow-up phase ([Brent et al., 1999](#)). On 2-year follow-up of the CBT, SBFT, and NST groups, there were no long-term differential effects of the three psychotherapies. Twenty-one percent were depressed during at least 80% of the follow-up period. Severity of depression at baseline and presence of self-reported parent-child conflict at baseline and in the follow-up period predicted lack of recovery, chronicity, and recurrence of depression ([Birmaher et al., 2000](#)).

[Clark and associates \(1999\)](#) examined the effects of acute and maintenance group CBT for 123 adolescent (ages 14 to 18 years) with major depression or dysthymia. Adolescents were randomly assigned to one of three 8-week treatment groups: (a) 16 2-hour adolescent group CBT sessions; (b) adolescent group CBT with a separate parent group; or (c) a wait list control group. Subjects who completed CBT groups were assigned to one of three situations: (a) assessment every four months with "booster" sessions designed to address three factors in the maintenance of treatment gains: self-monitoring, lifestyle changes, and high levels of social support; (b) assessment only every 4 months; and (c) assessment every 12 months for a 2-year follow-up. The 8-week CBT treatment groups both had higher recovery from depression than the wait list group. Rates of recurrence during the 2-year follow-up period were lower than that reported for treated adult depression but booster sessions did not reduce the rate of recurrence. Booster sessions did appear to accelerate recovery among subjects who were still depressed after the 8-week CBT trial.

[Clarke and colleagues \(1995\)](#) have also investigated a group cognitive therapy intervention targeting a sample of high school students at risk for unipolar depressive disorder. One hundred and fifty adolescents with elevated scores on the Center for Epidemiologic Studies—Depression Scale (CES-D) but not with diagnosable depression on the Schedule for Affective Disorders and Schizophrenia for School-Age Children were randomized to a 15-session cognitive group prevention intervention or a usual treatment group. The cognitive group adolescents were taught cognitive techniques to "identify and challenge negative or irrational thoughts that may contribute to the development of future affective disorder." The average age of the subjects was 15 years. The sample was predominantly white and mostly female. The investigators reported that their cognitive group intervention showed a significant advantage over the control group; the total incidence of unipolar depressive disorder was approximately half that of the control group on 12-month follow-up.

[Mufson and colleagues \(1994\)](#) have studied the acceptability and efficacy of interpersonal psychotherapy for depressed adolescents (IPT-A). Interpersonal psychotherapy for depressed adolescents was investigated in two phases. In Phase I, a small group of five adolescents were enrolled in ITP-A therapy and treatment was modified to meet the treatment needs of the adolescents and was standardized into a manual. In Phase II, 14 depressed outpatient adolescents entered a 12-week open trial of ITP-A. Twelve of the 14 adolescents had major depression, one had dysthymia, and one adolescent had depression, not otherwise specified. All 14 adolescents were minorities. Average age of girls was 14 years and average age of boys was 15 years. They were rated at weeks 0, 2, 4, 8, and 12 with the Beck Depression Inventory, Hamilton Rating Scale for Depression, Symptom Checklist, and Social Adjustment Scale Self-Report. There was a significant decrease in depressive symptomatology and significant improvement in functioning over the 12-week course of treatment.

### Psychopharmacologic Treatment

With the introduction of new classes of antidepressants in the 1990s, research on antidepressants in children and adolescents shifted away from the tricyclic agents, and began to focus on the selective serotonin reuptake inhibitors (SSRIs). The first controlled study to demonstrate the efficacy of an antidepressant in youth was by [Emslie and associates \(1997\)](#). He randomized 96 latency age children and adolescents ages 7 to 17 years with nonpsychotic major depression in outpatient treatment to an 8-week trial of 20 mg of fluoxetine or placebo. The study was double-blind and further controlled via a 1-week, single-blind placebo run-in. Primary outcome measures were global improvement of the Clinical Global Impression Scale and the Children's Depression Rating Scale-Revised. There was significantly greater improvement in fluoxetine treated subjects; 56% of the fluoxetine group was much or very much improved, compared to 33% of the placebo group. There was no clear difference in responsiveness to fluoxetine or placebo based on age or sex. Complete remission occurred in only 31% of fluoxetine-treated patients and 23% of the placebo-treated patients. In this study, fluoxetine was considered superior to placebo for the acute phase treatment of major depression in children and adolescent outpatients with severe, persistent, nonpsychotic major depression.

There is a preliminary report of a second double-blind placebo-controlled trial of an SSRI reporting positive response in depressed adolescents. This study examined the efficacy of paroxetine, imipramine, and a placebo in the outpatient treatment of 275 adolescents ages 12 to 18 years with major depression. The study used up to 40 mg of paroxetine or up to 300 mg of imipramine over an 8-week trial. Paroxetine demonstrated significantly greater improvement compared with placebo in HAM-D total score, HAM-D depressed mood item, K-SADS-L depressed mood item, and CGI score. The response to imipramine was not significantly different from placebo for any measure ([Keller et al., 2001](#)). A third double-blind, placebo-controlled study, of venlafaxine and psychotherapy or placebo and psychotherapy administered over 6 weeks to 33 latency age children and adolescents ages 8 to 17 years with major depression showed a significant improvement over time; however, the improvement could not be attributed to venlafaxine. The investigators did find a low-side effect profile for the study medication. This study used a relatively low dosage of venlafaxine and the trial was shorter in duration than the Emslie or the Keller studies, which may have contributed to the lack of demonstrated efficacy.

There have been several promising open trials of SSRIs in youth. An 8-week open study of nefazodone in 28 children and adolescent outpatients ages 7 to 17 years led to a significant reduction in symptoms of major depression in 69% of the children and 89% of the adolescents ([Findling et al., 2000](#)). Nefazodone was generally well tolerated in this open trial. An open trial of sertraline ([Ambrosini et al., 1999](#)) in 53 adolescent outpatients with major depression had positive results. Subjects were treated for 10 weeks in the acute phase and if they responded they were treated for an additional 12 weeks. At 6 weeks, 65% of subjects were significantly improved and at 10 weeks, 84% were significantly improved. Significant improvement occurred early on and was maintained for 22 weeks. Maximal response in clinician ratings occurred by the tenth week of treatment. Furthermore, sertraline was generally well tolerated. [Nobile and coworkers \(2000\)](#) completed a 3-month open trial of paroxetine treatment in a small number of children and adolescents with dysthymia. Seventy-one percent of subjects had a satisfactory response. Overall, controlled trials of these antidepressants are necessary to further determine safety and efficacy.

The SSRI antidepressants appear to have a low side effect profile. Thus, they have a distinct advantage over tricyclic antidepressants (TCAs) with fewer anticholinergic side effects, limited cardiovascular toxicity, and a wide therapeutic index ([Leonard et al., 1997](#)). The side effects of all of the SSRIs are similar. The most common side effects are nausea, vomiting, diarrhea, agitation, disinhibition, jitteriness, headache, insomnia, and tremors ([Leonard et al., 1997](#)). It is unclear why the SSRIs, to date, have demonstrated better efficacy than the tricyclic antidepressants. The majority of positive studies of SSRIs have been done with outpatient

children or adolescents. Studies of tricyclic antidepressants in youth were generally done on inpatients. Although there has been a reduction in inpatient length of stay in the past 10 years, leading to more adolescents being treated as outpatients, it is possible the population as a whole studied with SSRIs was "less sick" or less depressed. Some studies, such as the [Emslie study \(1997\)](#), excluded psychotic major depression, symptoms of bipolar disorder, or a family history of bipolar disorder. Another possible explanation for the specificity of positive treatment response with SSRIs is that because there is a differential maturation of brain regulatory systems, serotonergic and tricyclic antidepressants may vary in their capacity to alter aberrant neuroreceptor and neurotransmitter function in juvenile depressives ( [Strober et al., 1999](#)).

A definitive way to carry out the psychopharmacologic treatment of a depressed child or adolescent does not yet exist. Several treatment approaches have been suggested, such as the Texas Children's Medication Algorithm Project ( [Hughes et al., 1999](#) ) and the medication strategy suggested by [Wagner \(2000\)](#). Commonly, an SSRI is suggested as a first medication and if this trial fails, a second SSRI may be tried. If there is again a medication nonresponse, other monotherapies, such as venlafaxine, bupropion, mirtazapine, or a tricyclic antidepressant, may be tried. Alternatively, augmentation with lithium, buspirone, or another antidepressant may be considered. If the patient remains nonresponsive, a combination of certain antidepressants might be used, and if the youth continues to remain significantly depressed, an MAOI and then electroconvulsive therapy (ECT) might be employed. More research is needed before the clinician can recommend a length of time a depressed child or adolescent should remain on antidepressants after symptoms resolve, or how long to taper the medication before it is completely discontinued.

There have been multiple controlled studies of TCAs. (For a description of treatment response to TCAs in depressed prepubertal children, please refer to [Table 62.4](#).) Yet none of these studies have shown efficacy in the treatment of major depression in youth. Moreover, there have been several reports of sudden death potentially related to the TCA desipramine ( [Elliott and Popper, 1990](#); [Riddle et al., 1991](#) ). Thus, the use of TCAs for treatment of depressed youth has decreased since the advent of newer classes of antidepressants. However, the use of TCAs in prepubertal and adolescent patients is reviewed here for several reasons. First, knowledge of TCA studies in depressed juveniles is important from a historical perspective. These were some of the first medications available to treat depressed children and multiple controlled studies have been done. Second, as previously stated, there may be a role for treatment with this class of antidepressants if a juvenile fails to respond to other classes of antidepressants. As noted in the following, there has been evidence for efficacy in open trials. Third, knowledge of response to TCAs in depressed young persons may guide the development of future medications for depression in youth.

Author	Drug	Site (inpatient)	N	Improvement (%)	Duration of Treatment (Wk)

**Table 62.4. Treatment Response to Tricyclic Antidepressants in Depressed Prepubertal Children**

Although controlled trials have failed to show the efficacy of TCAs in youth, there is evidence for efficacy in open trials. TCAs may have some use if trials of other medications, such as SSRIs or atypical agents, fail. The therapeutic role of tricyclic antidepressants for depressed children and adolescents needs to be seriously weighed against lethality of overdose, the issues of possible sudden unexplained death, and the availability of safer and easier to monitor medications ( [Geller et al., 1999](#) ). Imipramine has been available for decades and has been frequently prescribed to treat childhood enuresis. [Weller and Weller \(1984b\)](#) reviewed the use of TCAs in depressed children. At that time, well-designed open trials of TRCs were examined. When data from all the open trials were combined, the overall response rate was 75%, and response rates ranged between 46% and 100%. The authors suggested that future studies include plasma drug monitoring to determine equivalency of treatment ( [Table 62.4](#) ).

There are two published double-blind placebo-controlled studies of imipramine in depressed children. The first study, by [Puig-Antich and associates \(1987\)](#), included 38 children in both the inpatient and outpatient setting. Twenty-two received placebo and 16 received imipramine. Imipramine was started at 1.5 mg/kg per day and increased to 5 mg/kg per day. The mean dose was 136 mg (4.35 mg/kg). Response rate was 56% in the imipramine treated group and 68% in the placebo-treated group. Those who responded to imipramine had higher plasma levels (284 ng/mL) than those who did not respond (145 ng/mL). [Preskorn and colleagues \(1987\)](#) used plasma level monitoring and DST results to study response to imipramine in 22 moderately to severely depressed prepubertal inpatients. The laboratory physician adjusted the plasma imipramine levels to be between 125 and 250 ng/mL. Children responded to imipramine better than placebo. When DST results were examined, depressed children with a positive DST responded better to imipramine than placebo, but those with a negative DST responded equally well to imipramine and placebo.

An important consideration when using tricyclic antidepressants is that they have the potential to cause cardiotoxicity. Thus, a child or adolescent's electrocardiogram (ECG) should be monitored throughout TCA treatment. [Elliott and Popper \(1990/1991\)](#) suggest that at a minimum clinicians obtain an ECG at baseline, at about 3 mg/kg per day and at a final dose not to exceed 5 mg/kg per day. Prolongation of the P-R interval should not exceed 0.21, and the QRS changes should not exceed 30% of baseline. Other limits that should not be exceeded include a heart rate of 130, a systolic blood pressure of 130, and a diastolic blood pressure of 85 ( [Ryan, 1990](#) ). Dosage adjustment with plasma monitoring may be needed to ensure compliance and avoid toxicity if these parameters are exceeded. [Preskorn and colleagues \(1988\)](#) reported increased neurotoxicity in children who had plasma levels higher than 500 ng/mL.

Monoamine oxidase inhibitors (MAOIs) have been suggested to be helpful in treating so-called atypical depression in adults. Monoamine oxidase inhibitors have been used sparingly in children and adolescents but they have been used in youth who have not responded to TCAs, before newer classes of antidepressants became available. The major problem with MAOIs is the necessity of a tyramine-free diet, which requires abstinence from chocolate, chicken livers, pepperoni, bologna, sausage, aged cheese, and Chianti wine, among other foods. Most adolescents are too impulsive, lack the discipline, or simply do not want to follow these dietary restrictions to make the use of MAOIs feasible. [Ryan \(1988b\)](#) treated 23 adolescents who had not responded to TCAs with an MAOI; 74% responded. Of these, 57% had a good response and were able to comply with the diet.

At this time many new antidepressants are under study, and much more research on antidepressants in the treatment of depression in youth is needed. Most moderately to severely depressed children and adolescents may be considered for medication treatment. Before starting medication, side effects, as well as anticipated beneficial effects, should be explained to the parent or guardian and the youth. The parent or guardian should also be notified before obtaining informed consent that the Food and Drug Administration (FDA) has not approved these medications for use in depressed children. Literature on effective pharmacologic treatments for depression in youth is continually changing and practitioners who prescribe medication for childhood depression may be kept updated on new studies through review of well-known psychiatry journals, as well as the more recently available journal and newsletters on pediatric psychopharmacology ( [Rowan, 2000](#) ).

#### Electroconvulsive Therapy

Electroconvulsive therapy (ECT) can be effective when other measures fail in severe depression ( [Bertagnoli and Borchardt, 1990](#) ); however, the data concerning safety and efficacy in children and adolescents are sparse. As stated earlier, the [American Psychiatric Association has published specific guidelines for obtaining consent and for the indications and administration of ECT \(1990\)](#). Two psychiatrists who are experienced in treating children and are not otherwise involved with the case should concur with the recommendation for ECT prior to the initiation of treatment.

#### Outcome and Follow-Up Data

[Weissman and colleagues \(1999\)](#) did a 10- to 15-year follow-up of 83 subjects with prepubertal-onset major depression, 44 control subjects with anxiety disorder and without major depression, and 91 normal controls. They found the clinical outcome of children with prepubertal depression includes a high risk of suicide attempts (threefold increased compared to normal controls and twofold compared to the anxiety control group) and bipolar disorder. [Pine and associates \(1998\)](#) prospectively

studied the longitudinal associations between adolescent and adult depressive and anxiety disorders. They found that adolescent anxiety or depressive disorders predicted a twofold to threefold increased risk for adulthood anxiety or depressive disorders. [Pine and colleagues \(1999\)](#) also studied the subclinical symptoms of major depression in adolescence and found that they strongly predicted an adult episode of major depression.

[Lewinsohn and associates \(1999\)](#) followed adolescents with major depression into adulthood age of 24 years. The study included several control groups. Major depression in adulthood was significantly more common in the adolescent group with major depression than either a nonaffective psychiatric and a no disorder control group. Adolescents with major depression had a high rate of nonaffective disorders in young adulthood but did not differ from adolescents with nonaffective psychiatric disorder. This study documented the significant continuity of major depression from adolescence to young adulthood. Major depression in childhood not only appears to confer a risk for major depression in adulthood, but also appears to be a particularly serious form of affective illness, as they converted to bipolar disorder more frequently than adults do ([Kovacs, 1996](#)). Although there appears to be a positive short-term outcome for these youth, they appear to have recurrent episodes of depression relatively early in their lives ([Kovacs, 1996](#)), as well as a higher switch rate to bipolar disorder. Overall, outcome is poor, as might be expected; however, there is some reason to believe that the course of depression in children and adolescents may improve in the future. Newer classes of antidepressants and an interest in rigorously studying several forms of psychotherapy in youth may lead to more effective acute and long-term treatments in juvenile depressed patients and better outcomes.

A complicating factor in the assessment and treatment of this disorder in children and adolescents is the frequent occurrence of comorbidity. [Kovacs and coworkers \(1984, 1988\)](#) reported that 79% of depressed prepubertal children had at least one other Axis I diagnosis: 38% had dysthymia, 33% anxiety disorder, and 7% conduct disorder. A follow-up study of depressed children found that 36% developed conduct disorder as a complication of depression ([Kovacs et al., 1988](#)). [Kashani and Sherman \(1988\)](#) studied depressed adolescents. In this report, 75% had comorbid anxiety, 50% oppositional disorder, 33% conduct disorder, 25% alcohol abuse, and 25% drug abuse. Those with onset of depression in childhood or adolescence are at risk to develop multiple episodes on follow-up ([Kovacs et al., 1984](#)) and often require rehospitalization ([Asarnow et al., 1988](#)). [Harrington and associates \(1991\)](#) reported that for depressed children to have comorbid conduct disorder was prognostically favorable for the outcome of depression in adulthood but not for conduct disorder. These patients had a similar likelihood of developing antisocial personality as adults when compared with patients who had conduct disorder without depression but who were much less likely to have depression as adults when compared with a group of patients who were depressed but did not suffer from conduct disorder. These findings suggest that depression may represent an early feature of conduct disorder rather than a separate comorbid illness. In a prospective longitudinal study of the course of depression in children and adolescents, [McCauley and associates \(1993\)](#) reported poorer overall outcome to be associated with increased levels of stress in the family environment.

---

#### CASE ILLUSTRATION: PREPUBERTAL DEPRESSED CHILD

B.J., an 11-year-old boy, was admitted to the children's inpatient unit with a chief complaint of, "Nothing is working out for me." He had been failing in school for the last year, although he had previously been a B student. He complained of trouble sleeping (middle insomnia). His parents had not bought new clothes for him for the last 2 years "because he had not outgrown his old ones." He looked very sad, cried easily, and thought his peers were making fun of him because he was "ugly and stupid." He had started refusing to go to school, because he felt very tired in the morning and wanted to sleep more. His mood usually improved by the afternoon. His mother had found a note written by B.J. that said he was planning to jump in front of a car on a busy street "to end my misery," and then listed to whom his belongings should be given after his death. Neither B.J. nor his parents could identify any stressors.

His mother had a history of numerous depressive episodes that had responded to antidepressants. Her first episode of depression occurred at age 10 when she was hospitalized on a general pediatric service for aches and pains and being tired all the time. B.J.'s maternal grandmother had received ECT for depression that occurred after B.J.'s mother was born.

Initially, B.J. was treated with individual and family therapy. However, because of his severe vegetative symptoms, he was given imipramine, and he responded within 10 days.

---

#### CASE ILLUSTRATION: ADOLESCENT DEPRESSION

Shelly was a 14-year-old girl hospitalized because she was refusing to take a bath, had no energy, was sleeping 16 hours a day, and had dropped out of school. She had made multiple suicide attempts. These attempts involved taking her mother's antidepressants, overdosing with alcohol and drugs, and trying to jump off the roof of a five-story building. She was quite annoyed that people would not let her die. She saw no hope for the future because, "Life is a bummer." She rarely interacted with anyone on the unit during a 3-day observation period.

Her parents gave a three-generation history of bipolar illness in their family. Lithium was recommended because this child was thought to be at high risk for suicide and mania; however, her physician refused to give lithium to the child because "it deposits in the bones." She was started on a tricyclic antidepressant and thiothixene 1 mg twice daily and discharged. A week after discharge, she was found in another state trying to "conduct business." She was admitted to a psychiatric hospital and treated with lithium carbonate and had a fairly good response. Her physician was now willing to consider lithium because Shelly had push of speech and flight of ideas and was very grandiose and hypersexual.

---

## RESEARCH DIRECTIONS

Although there has been a dramatic increase in the number of studies of depressed children and adolescents in the past two decades, more research is needed. Further studies are needed to assess risk factors that may predict depression, and such studies must be done in a prospective longitudinal manner. In regard to treatment, additional studies are needed not only to determine if pharmacologic treatment is helpful but also to identify subgroups that may be most responsive to pharmacologic intervention. With the changes in FDA regulations, there has been an increase in efforts to perform double-blind and placebo-controlled studies in children and adolescents. The first studies demonstrating some positive effect of medication in childhood depressive disorders were published in the past 5 years. Much more research is needed, though, before the most effective somatic therapies and treatment algorithms for the treatment of juvenile depressions can be determined. Controlled studies assessing the effectiveness of the various psychotherapies in childhood depression also are needed. Studies using neuroimaging appear promising and may revolutionize our understanding of depressive disorders in youth. Research on neuroendocrine factors and sleep architecture need to be expanded and replicated. The elucidation of the human genome, which has received so much attention in the news, may focus attention on genes that are expressed in childhood onset depressive disorders one day. Both preclinical and clinical research has accelerated over the past decade; we may begin to see significant progress in the areas of prevention and treatment of childhood depression as pieces of the puzzle are gradually worked out.

major depressive episode occur over the same period. Also, the absence of a major depressive episode, a mixed episode, or a manic episode during the first year of the disturbance is required. [Klein et al. \(1986\)](#) reported that 24% of the offspring of bipolar patients and 0% of the offspring of control subjects had cyclothymia as detected by the General Behavioral Inventory, which had excellent correlation with the interview-derived diagnosis.

*Bipolar disorder not otherwise specified*: In DSM-IV, this diagnostic classification includes disorders that have manic features or hypomanic features that do not meet the criteria for any specific bipolar disorder as described previously. Examples of these disorders would include a manic episode that was superimposed on schizophrenia or a delusional disorder or recurrent hypomanic episodes, but with no intercurrent depression.

For all the preceding categories, the diagnoses should not be made if the disturbance can be explained by schizoaffective disorder or (excepting bipolar disorder, not otherwise specified) superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified. Further information and explanation of the diagnostic criteria for bipolar disorders and details regarding diagnostic subtypes can be obtained from DSM-IV.

## HISTORICAL NOTE

Mania in children has been reported by several prominent psychiatrists over the years, including [Esquirol \(1845\)](#), [Kraepelin \(1921\)](#), [Kasanin \(1931\)](#) and [Bleuler \(1934\)](#). Kraepelin believed that mania was rare in children but that the incidence increased by adolescence. He reported that approximately 0.5% of his manic patients had their first episode at age 10 years or younger. However, some child and adolescent psychiatrists, such as [Kanner \(1960\)](#) and [Anthony and Scott \(1960\)](#), doubted mania's existence in children. Anthony and Scott developed and applied very stringent criteria to diagnose mania in a study of psychiatrically ill children. They concluded mania was very rare in children. However, they went on to describe a patient who appeared manic as a child and who subsequently had his mania confirmed when followed up as a young adult.

[Davis \(1979\)](#) developed criteria to diagnose mania in children. However, these criteria were very nonspecific, including minimal brain dysfunction, enuresis, and electroencephalographic anomalies. He called this syndrome *manic depressive variant syndrome*.

Others have diagnosed bipolar disorders in children and adolescents using adult-type criteria adjusted to children's different maturational levels ( [Carlson and Strober, 1978](#); [Weinberg and Brumback, 1976](#); [Weller et al., 1986c](#)). [Weller et al. \(1986c\)](#) conducted an extensive review of all available case reports of psychotic or severely disturbed children by blindly reviewing cases to determine how many, if any, met DSM-III criteria for mania. From 1809 to 1982, 157 case reports were reviewed independently by the authors. In doing so, they noted that 50% of children who satisfied DSM-III criteria for mania had been previously reported as having conduct disorder, attention deficit hyperactivity disorder (ADHD), or schizophrenia. This finding suggests that mania may have been previously underdiagnosed or misdiagnosed in children and adolescents. Several possible explanations may account for the difficulty clinicians may have in diagnosing children and adolescents with bipolar disorder. These include bias against the diagnosis of mania in childhood, the low base rate of bipolar disorder relative to other psychiatric illnesses in children, symptom overlap between bipolar disorder and other, more prevalent childhood psychiatric illnesses, and developmental constraints and variability in symptom expression and presentation.

## PREVALENCE AND EPIDEMIOLOGY

No definitive epidemiologic study to determine the prevalence of bipolar disorder in childhood has been completed. Current estimates of the prevalence of bipolar disorder in childhood are based on small community surveys or retrospective data. [Carlson and Kashani \(1988\)](#) studied a community sample of 150 adolescents, 14 to 16 years of age, from Columbia, Missouri, using structured diagnostic interviews to ascertain a diagnosis of mania. They reported that 14% satisfied criteria for mania if duration was not taken into account, and 7.5% of adolescents met criteria for mania if severity was not taken into account. However, when severity and duration were both taken into account, only 0.6% were diagnosed manic. The prevalence of bipolar disorder during late adolescence is estimated to approximate that in adulthood. Bipolar disorder occurs in 1% of adults. Men and women are equally afflicted. The epidemiologic catchment area studies done on 10,000 young adults 18 to 24 years of age in New Haven, Connecticut, Baltimore, Maryland, and St. Louis, Missouri; reported a prevalence of 0.6% to 1% for manic episodes ( [Robins et al., 1984](#)). Onset of bipolar disorder before puberty is estimated to be rare. In a retrospective study involving adult patients with bipolar disorder, 0.5% reported onset of their illness to have been between 5 and 9 years of age; 7.5% reported onset between 10 and 14 years of age ( [Lish et al., 1994](#)). Furthermore, reports suggest that bipolar disorder before puberty may be more common in boys than in girls ( [Carlson et al., 2000](#); [Geller et al., 1998](#); [Varanka et al., 1988](#)).

Since World War II, the prevalence of mood disorders, including mania and depression as well as schizoaffective disorders, has been increasing ( [Gershon et al., 1987](#); [Klerman et al., 1985](#)). This observation has come to be known as the *cohort effect*. One study describes a parallel increase of affective disorders in children and adolescents ([Ryan et al., 1992](#)). If this trend continues, it can be anticipated that more children and adolescents will manifest mania in the future. Anticipation, a tendency for a disease phenotype to worsen (e.g., to be expressed at an earlier age and to run a more severe course) in consecutive generations is one possible explanation of this phenomenon.

## CLINICAL DESCRIPTION

Manic adolescents often have a clinical presentation similar to that of adults. Symptoms such as elated mood or irritability, push of speech, flight of ideas, grandiosity, sleeplessness, and bizarre behavior, including bizarre attire, typically are observed. Prepubertal children with bipolar disorder most frequently present with symptoms that are considered atypical in adults ( [Biederman et al., 2000](#); [Boring and Kovacs, 1992](#)). Mixed features, rapid cycling, psychosis, high rates of comorbidity, especially with externalizing disorders, and significant functional impairment in social, academic, and occupational spheres are common ( [Carlson, 1990](#); [Carlson et al., 2000](#); [Geller et al., 1998](#); [Kovacs and Pollock, 1995](#); [Sanchez et al., 1999](#)).

[Carlson \(1983\)](#) analyzed in detail how symptom patterns vary by age. She concluded that younger manic children (<9 years of age) present with irritability and emotional lability, whereas older children present with euphoria, elation, paranoia, and grandiose delusions. Hyperactivity, push of speech, and distractibility were present in both age groups. Similarly, [DeLong and Aldershof \(1987\)](#) suggest prepubertal bipolar children begin their illness with cycles in which dysphoria, hypomania, and agitation commonly are intermixed. The extremes of depression and manic excitement appear to become more common with the onset of puberty.

The first controlled phenomenologic study of bipolar disorder in childhood reported that children with bipolar disorder are significantly more likely than children with ADHD to endorse cardinal symptoms of mania, including elated mood, grandiosity, hypersexuality, decreased need for sleep, flight of ideas, racing thoughts, social intrusiveness, and increased goal-directed activity ([Geller et al., 1998, 2000](#)). Reports of mixed mania, rapid cycling, and psychosis were very common in their sample of 93 young children diagnosed with bipolar disorder. Approximately 55% of the bipolar sample endorsed mixed mania, defined as a temporal overlap in the onset and offset of mania or hypomania with major depression or dysthymia ([Geller et al., 2000](#)). Furthermore, 87% of the sample endorsed rapid cycling, defined as four or more mood disturbances a year. Of the children who experienced rapid cycling, 10% reported ultrarapid cycling, with mood disturbances lasting a few days to a few weeks, and 77% reported ultradian cycling, with mood disturbances occurring within a 24-hour period ( [Geller et al., 2000](#)). Sixty percent of the sample endorsed psychotic symptoms. Of these, grandiose delusions were the most common and occurred in 50% of the sample ( [Geller et al., 2000](#)). Approximately 25% of the sample admitted to serious suicidal ideation with intent and plan, which underscores the potential mortality associated with this disorder ( [Geller et al., 2000](#)). Longitudinal studies of children with bipolar illness are needed to determine the evolution of cycling patterns and long-term outcome for these children.

Some suggest that the presentation of mania in prepubertal children resembles that of treatment-resistant, chronically ill adults ( [Biederman et al., 2000](#); [Carlson et al., 2000](#); [Geller and Luby, 1997](#)). Thus, childhood-onset bipolar disorder may represent the most severe form of the adult illness. The question of whether the phenotypic differences reported between childhood-onset and adult-onset bipolar disorder result from developmental variations of the same genotype ( [Geller et al., 2000](#)) or genotypic differences ( [Schürhoff et al., 2000](#)) remains unsettled.

The diagnosis of bipolar illness in adolescence is much less controversial; the phenomenology of bipolar disorder in adolescents more closely resembles that of adult-onset bipolar illness ( [Bowden and Sarabia 1980](#); [Carlson et al., 2000](#); [Carlson and Strober, 1978](#); [Coryell and Norten, 1980](#)). Furthermore, follow-up studies have confirmed the diagnosis in many cases ( [Kimura et al., 1980](#); [Krasa and Tolbert, 1994](#)). Mixed manic features and psychotic symptoms, including mood-incongruent hallucinations, paranoid delusions, and thought disorder, frequently complicate the clinical presentation of mania in adolescence ( [Akiskal, 1995](#); [Ballenger et al., 1982](#); [Bashir et al., 1987](#); [Goodwin and Jamison, 1990](#); [McGlashan, 1988](#); [McElroy et al., 1997b](#); [Rosen et al., 1983](#)). There is evidence that suggests psychotic symptoms are more common in bipolar disorder when onset is in adolescence than when onset is after age 30 years ( [Ballenger et al., 1982](#)).

Bipolar disorder often first manifests itself as depression in childhood ( [Lish et al., 1994](#)). Reports suggest that a bipolar course develops in 20% to 30% of children with major depression ( [Geller et al., 1994](#)). Several risk factors have been associated with the development of a manic episode after an episode of depression,

including (a) a depression characterized by rapid onset, psychotic features and psychomotor retardation; (b) a family history loaded with mood disorders, especially bipolar disorder; and (c) a history of antidepressant-induced hypomania or mania ( [Akiskal et al., 1983](#); [Strober and Carlson, 1982](#)).

---

#### CASE ILLUSTRATION

J.R. was 6 years of age when he was referred for inpatient treatment by a physician in a day hospital program because his behavior could no longer be tolerated. He presented with extreme hyperactivity and push of speech (including profanities and sexual comments in which he invited the female staff to have sex with him). After a careful evaluation, sexual abuse was ruled out. Previous treatment with Mellaril, Thorazine, Navane, Ritalin, Cylert, Dexedrine, and clonidine had been unsuccessful. He was silly and giggly. He made up songs, punned, and had clang associations. He spoke so fast it was hard to follow his thoughts. He believed he was Superman and could fly. He ran in front of cars, thinking he could stop them. An interview with his parents revealed that this child's father had been involved in legal trouble and had been jailed on several occasions. The father had been diagnosed as bipolar by the referring physician, who thought the father was medicating himself with psychoactive drugs. The father had stopped abusing drugs and had started on lithium, with dramatic improvement. His early history was very similar to J.R.'s current clinical presentation. J.R. was given a trial of lithium carbonate, and he responded fairly well. He was easier to manage and direct and was able to attend school.

---

#### CASE ILLUSTRATION

B.J. was 13 years of age when he presented to the emergency department of a pediatric hospital. His chief complaint was "I wanted to take the dog for a walk last night, so I went to Six Flags (an amusement park) to go to the bathroom!" His speech was very difficult to interrupt. He had paranoid thoughts that his friend and classmates were after him and making fun of him. He also talked about "pumping up my BB gun 10 times before pulling the trigger and slashing my wrists because I want to die." He also said he was "wanting to be born over and over again." He was calling his female classmates and asking them to have sex with him and also "wanted to go to the desert to hunt lions." He was refusing to eat and had slept only 2 to 3 hours per night for 3 days. He paced constantly and made fun of the resident in the emergency department. His maternal grandmother had depression and a maternal uncle had been put in detention for behavior similar to this when he was an adolescent.

He reported he came to the hospital to make a death movie, and he was hearing male and female voices telling him to grow up and "to cut it off." When asked what "to cut it off" meant, he replied, "my penis." He had been involved in oral sex for the last month, and he thought this was a punishment. He thought he could fly and make people blind by staring at them. Drug use was denied, and a drug screen was negative. Treatment with Mellaril 200 mg subdued him somewhat. The family refused a trial of lithium carbonate because their pediatrician was worried about its possible long-term side effects.

---

## ETIOLOGY AND PATHOGENESIS

Numerous etiologies have been considered in mania. The major hypotheses are briefly discussed.

### Psychoanalytic Theory

In psychoanalytic theory, mania is a reaction formation to depression. It is described as a defense against depression that involves a defensive projection where the patient focuses on the weaknesses of others to avoid thinking of his or her own weaknesses.

### Biological Theories

#### GENETIC

Although the etiology of bipolar disorder is unknown, studies support that there is a substantial genetic contribution. Twin studies consistently report that monozygotic twins are more concordant for affective illness than are dizygotic twins. [Numberberger and Gershon \(1982\)](#) reported the concordance of mania in monozygotic twins to be 65%, whereas concordance was 14% in dizygotic twins. Likewise, [Bertelsen and colleagues \(1977\)](#) reported the concordance for monozygotic twins to be 67%, whereas concordance for dizygotic twins was only 20%. Concordance rates for monozygotic twin pairs were higher for pairs in which one had bipolar illness (79%) than for pairs in which one had unipolar illness (54%); concordance rates between dizygotic twins pairs were similar for bipolar (24%) and unipolar (19%) illness. Thus, these studies strongly support a genetic contribution to the vulnerability for affective illness.

Current reports involving adoptees with bipolar illness suffer from methodologic difficulties and provide only limited support for the hypothesis that genes rather than environmental or family influences account for a large degree of the risk associated with the development of bipolar illnesses. Results from two small studies were inconclusive ([Von Knorring et al., 1983](#); [Wender et al., 1986](#)). A larger study by [Mendlewicz and Rainer \(1977\)](#) found that 31% of biological parents of adopted manic probands were affected, whereas only 2% of adoptive parents manifested the illness.

Family studies involving adults with affective illness consistently report that the rate of affective illness in relatives of affectively ill adult probands is two to three times the rate in relatives of appropriately selected case control subjects ([Gershon, 1990](#)). A study of the relatives of bipolar subjects by [Rice et al. \(1987\)](#) showed a 1.5% to 10.2% incidence of bipolar disorder, compared with an incidence of 0.2% to 1.8% in relatives of normal control subjects. Furthermore, family studies support at least a partial overlap in vulnerability for bipolar and unipolar affective illness because the most frequent affective disorder in relatives of patients with bipolar illness is unipolar illness ([Gershon, 1990](#); [Rice et al., 1987](#)). A multicenter pilot family study completed by the [National Child Study Institute of Mental Health Molecular Genetics of Psychiatric Disorders Initiative Group \(1993\)](#) reported that the lifetime probability for development of affective disorders (bipolar, major depression, or dysthymia) in children and adolescents is associated with the number of affected parents who had high density of affective disorder in extended families. The corresponding percentages were 16.7%, 23.5%, and 100% for 0, 1, and 2 affected parents, respectively.

There is evidence to suggest that childhood-onset bipolar disorder is associated with greater familial loading for affective illness than adult-onset bipolar disorder ([Todd et al., 1994](#)). In studying the parents of bipolar children and adolescents, several investigators reported an increased incidence of both unipolar and bipolar disorders ([DeLong and Aldershof, 1987](#); [Strober et al., 1988](#); [Varanka et al., 1988](#)). Further, if onset of illness is in the prepubertal years, the rate of bipolar disorder in family members is three times that of those with an onset after puberty ([Strober et al., 1988](#)). Furthermore, recent reports on children of adults with bipolar disorder suggest that a history of early-onset illness increases the risk that bipolar disorder will develop in offspring ([Chang et al., 2000](#)).

To date, linkage and association studies have failed to identify the genes associated with bipolar illness. Detailed genetic studies of well defined bipolar children and adolescents are lacking.

#### NEUROBIOLOGICAL STUDIES

Few studies have examined the neurobiological underpinnings of bipolar disorder in children and adolescents. Preliminary neuromorphometric reports have found enlarged ventricles and increased number of white matter hyperintensities in prepubertal children with bipolar disorder compared with control subjects ([Botteron et al., 1995](#)). Thalamic abnormalities also have been observed in adolescent patients with bipolar illness. A study using magnetic resonance spectroscopy found elevated lipid levels in the frontal lobes and elevations of glutamate in both frontal lobes and basal ganglia of children with bipolar disorder relative to control subjects ([Castillo et al., 2000](#)). There are no published studies examining neuroendocrine or neuroanatomic differences in children and adolescents with mania.

### Familial Environmental and Social Influences

As described earlier, mania tends to run in families. When child-rearing practices of manic parents were examined, many had poor parenting techniques ([Cytryn et al., 1986](#)). The episodic nature of the unreasonable behavior of these parents may be deleterious to the normal development of these children.

## LABORATORY STUDIES

There are no specific laboratory studies that can diagnose bipolar disorder in children and adolescents.

## RATING SCALES

It appears that the diagnostic accuracy for bipolar illness in children and adolescents improves when DSM criteria are applied ([Carlson et al., 1994](#)). Several structured and semistructured interviews may be used to help assess mania in children. The Diagnostic Interview for Children and Adolescents, Revised (DICA-R) (Reich W, Weiner Z, Diagnostic Interview for Children and Adolescents [DICA-R-C], DSM III-R Version, St. Louis, Washington University, Division of Child Psychiatry, unpublished manuscript, 1988), the Diagnostic Interview Schedule for Children (DISC) ([Costello et al. 1982](#)), and the Children's Interview for Psychiatric Syndromes (ChIPS) ([Weller et al., 1999](#)) are structured interviews that have sections to assess bipolar disorders. Several semistructured interviews also may be used, including

the Schedule for Affective Disorders and Schizophrenia for School Age Children (KSADS) ( [Chambers et al., 1985](#)), the Washington University Kiddie and Young Adult Schedule for Affective Disorders and Schizophrenia—Lifetime and Present Episode Version for DSM-IV (WASH-U-KSADS) ( [Geller et al., 1998](#)), and the Interview Schedule for Children (ISC) ( [Kovacs, 1978](#)). With standardized assessment instruments, bipolar disorder can be overdiagnosed if a comprehensive and careful evaluation is not completed.

Clinical rating scales may be used to track the severity of target symptoms of mania. Such rating scales for bipolar disorders are quite underdeveloped at present. [Strober et al. \(1987\)](#) used the Beigel Murphy Scale ( [Beigel et al., 1971](#)) in assessing severity of mania in adolescents, and reported the instrument to be helpful. [Fristad et al. \(1988\)](#) modified the Mania Rating Scale ( [Young et al., 1978](#)) for use in prepubertal manic children. A preliminary study found it was helpful in differentiating manic children from hyperactive children on the total score as well as on most individual items. The Child Behavior Checklist (CBCL) also has been reported to distinguish children with mania from those with ADHD ( [Biederman et al., 1995](#); [Geller et al., 1998](#)). However, the CBCL is not a diagnostically derived instrument, and differences in scores may reflect severity of illness rather than diagnostic differences ( [Carlson and Kelly, 1998](#)).

## DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

In diagnosing a manic episode, other psychiatric and medical illnesses should be excluded. Medical conditions ( [Table 63.2](#)) may mimic mania, and patients with several other psychiatric illnesses sometimes can appear manic. Reports suggest that manic symptoms are common in both nonreferred samples ( [Carlson and Kashani, 1988](#); [Lewinsohn et al., 1995](#)) and psychiatrically ill children ( [Carlson and Kelly, 1998](#)). Manic symptoms in children may be a marker for severe psychopathology and impairment ( [Carlson and Kelly, 1998](#)). Careful diagnostic workup and long-term follow-up often are needed to clarify diagnosis in this age group ( [Carlson, 1998](#); [Carlson et al., 2000](#)).

Head	Endocrine	Neurologic	Toxic	Medications	Other
Encephalitis	Hypothyroidism	Seizures	Toxic	Stimulants	Acetaminophen
Influenza		Head trauma	Gloma	Isoniazid	Digoxin
Spina		Multiple sclerosis	Meningioma	Sympathomimetics	Amphetamines
AD		Stroke			Hallucinogens
		Metabolic disease			Anemia
					Hemodysia

Reprinted from M. M. Zandi, J. R. Costello, & J. Costello (1998). *Journal of Abnormal Child Psychology*, 26, 1-18.

**Table 63.2. Medical Conditions Mimicking Mania in Children and Adolescents**

### Medical Conditions

#### DRUGS

A diagnosis of mania should not be made until the child or adolescent is observed in a drug-free state. Some drugs reported to induce manic states include amphetamines, corticosteroids, sympathomimetics, isoniazid, and antidepressants.

#### ENDOCRINE DISORDERS

Hyperthyroidism may present with a manic-like state.

#### NEUROLOGIC CONDITIONS

Mania has been associated with head trauma, multiple sclerosis, stroke (especially with lesions involving the right hemisphere and the thalamus), and seizure disorders with a left temporal focus. Also, space-occupying lesions such as meningiomas, gliomas, and metastatic lesions in the thalamus have been implicated ( [Wise and Rundell, 1988](#)).

### Psychiatric Conditions

#### ATTENTION DEFICIT HYPERACTIVITY DISORDER

Symptom overlap between mania and ADHD can lead to diagnostic confusion ( [Carlson, 1998](#)). Psychomotor agitation, distractibility, aggression, poor school performance, restless sleep, and sexually inappropriate behavior are symptoms that frequently are associated with both ADHD and mania.

Reports suggest that childhood-onset bipolar disorder frequently is comorbid with ADHD ( [Geller et al., 1995](#); [Wozniak et al., 1995](#)). Age of onset of bipolar illness may be associated with varying rates of comorbid ADHD. [Faraone and colleagues \(1997\)](#) reported that adolescents with childhood-onset bipolar illness had the same rate of comorbid ADHD as children with prepubertal-onset bipolar illness. Both groups had higher rates of ADHD than adolescents with adolescent-onset bipolar illness. Furthermore, [Sachs and colleagues \(2000\)](#) reported that among adults with bipolar disorder, a history of comorbid ADHD was evident only in those with a history of early-onset illness (mean age of onset, 12.1 years).

Cross-sectionally, children with ADHD may appear to resemble those with mania, especially in the prepubertal age range. However, manic children have more affect and are euphoric or irritable. Children with ADHD often have low self-esteem and a much longer duration of symptoms. Psychotic symptoms are common in prepubertal manic children ( [Varanka et al., 1988](#)) but are not typically part of ADHD. The sleep disturbances and overactivation associated with ADHD are chronic and part of the child's baseline behavior. The sleep disturbance associated with mania usually is associated with onset of the mood disturbance. Age of onset for mania usually is after 7 years of age, whereas age of onset for ADHD usually is in the toddler years.

#### CONDUCT DISORDER

Conduct disorder frequently is a comorbid condition with bipolar disorder ( [Kovacs and Pollock, 1995](#)). Many children with mania have unruly, disruptive behavior suggestive of a conduct disorder. However, children with a "pure" conduct disorder do not have push of speech, flight of ideas, or delusions of grandeur. Also, the duration of symptoms is more chronic and less suggestive of an abrupt onset or clearly episodic course. A study by [Weller et al. \(1986c\)](#) found that children who clearly satisfied criteria for mania sometimes were diagnosed as having conduct disorder.

#### DRUG AND ALCOHOL ABUSE OR DEPENDENCY

Children and adolescents with mood disorders sometimes become involved with the use of alcohol or drugs in an attempt to treat symptoms attributable to their mood disorder. Most adolescents have easy access to drugs and alcohol. Special attention should be paid to rule out mania in prepubertal children presenting with drug abuse.

#### SCHIZOPHRENIA

Symptoms such as hallucinations and delusions are common in both mania and schizophrenia. Usually the onset of schizophrenia is insidious, whereas the onset of mania is more sudden. Both schizophrenic and manic adolescents can be delusional, and, at times, it may be difficult to differentiate paranoid schizophrenia from

mania. Assessment of premorbid personality may be helpful in differentiating the two disorders. In schizophrenia there may be either schizoid traits or bizarre conduct disorder, whereas in mania, there may be symptoms suggestive of ADHD or conduct disorder with significant affective symptomatology. A positive family history for bipolar disorder is more common in manic adolescents than in schizophrenic adolescents ( [Strober et al., 1988](#) ).

## TREATMENT

### General Considerations

Once a diagnosis of mania has been established after a thorough assessment, treatment must be planned and implemented. Psychotherapeutic and pharmacologic intervention may be required in children and adolescents. It is difficult to treat a full-blown manic episode on an outpatient basis. Hospitalization often is essential to ensure patient safety. In the hospital, firm limits must be set with the patient. Arguments, challenges, or questions regarding a patient's delusional system should be avoided until the medications take effect and the patient is more amenable to other therapeutic interventions. It is essential to educate parents and children about bipolar illness. Support groups organized through the National Alliance for the Mentally Ill are available in certain communities and can be of help to some patients and their families.

Several baseline laboratory studies need to be done before starting a child on lithium carbonate or any other psychotropic medication that can affect many organ systems. For example, lithium affects the neuroendocrine, central nervous, reproductive, and gastrointestinal systems. A good prelithium workup should include a complete blood count with a differential ( [Table 63.3](#) ). This is needed because lithium can cause neutrophilia, and carbamazepine and divalproex, mood-stabilizing medications sometimes used in lithium nonresponders or rapid cyclers, may cause suppression of white blood cells. Electrolytes, blood urea nitrogen, creatinine, creatinine clearance, urine osmolality, and liver function tests should be performed. Lithium is known to affect serum electrolytes, especially sodium. Also, lithium may affect kidney function tests; hence, a baseline creatinine clearance, as well as urine osmolality, should be determined and repeated periodically if lithium treatment lasts more than 6 months.

**Table 63.3. Pretreatment Screen for Mood Disorders in Children and Adolescents**

Thyroid function tests are required because lithium can alter thyroid function. Hypothyroidism is the most common abnormality. Because a hypothyroid person also may look depressed, baseline measurements of thyroid-stimulating hormone (most sensitive) and thyroxine and triiodothyronine resin uptake should be measured before lithium initiation, and should be repeated periodically throughout treatment. Liver function tests should be done in cases in which medications normally metabolized in the liver are being used.

A pregnancy test and serologic tests (for syphilis and acquired immunodeficiency syndrome) should be performed, especially in sexually active adolescents. Hypomanic and manic people are known for their hypersexuality; they may engage in sexual activity with multiple sexual partners in an indiscriminate manner. Pregnancy must be ruled out because mood-stabilizing agents have been associated with teratogenic effects. Before treating a manic child or adolescent with lithium or other medication, consent from the family and assent from the patient should be obtained, and known side effects should be explained.

### Psychopharmacologic Treatment

There is a dearth of controlled medication trials in children and adolescents with bipolar disorder. However, conventional wisdom suggests acute mania is best managed with an antimanic agent. Adjunctive medications such as benzodiazepines or antipsychotics may be used in the short term to help control symptoms of severe agitation, insomnia, and psychosis. It usually is wise to start medications at a low dose and to titrate them up to the minimally effective dose to minimize adverse effects and maximize compliance. Careful titration is particularly important in younger children because they are particularly prone to experience untoward effects ( [Campbell et al., 1991](#) ). Every effort should be made to manage both the acute and maintenance phase of this illness with as few agents as possible. Antidepressants may be necessary when depressive episodes occur, but use should be closely monitored.

### LITHIUM

Lithium has been extensively studied in adults with bipolar disorder. Furthermore, reports suggest that maintenance treatment with lithium may be effective in reducing the risk of suicide associated with bipolar disorder ( [Tondo and Baldessarini, 2000](#) ). Controlled trials of lithium for the treatment of explosive aggressive behavior in children and adolescents also have been conducted ( [Campbell et al., 1995](#) ). Most reports of its use in children and adolescents with bipolar disorder consist of case reports ( [Geller and Luby, 1997](#) ) and open-label trials ( [Kafantaris et al., 1998](#) ). A randomized clinical trial of lithium for the treatment of bipolar illness in adolescents included 25 adolescents who met DSM-III-R criteria for either bipolar I, bipolar II, or major depressive disorder with adolescent predictors of future bipolar disorder. These youths also had secondary substance abuse. Lithium was not more efficacious than placebo on measures of affective symptoms. No study has examined the efficacy of lithium in prepubertal children with mania, although safety ( [Hagino et al., 1995](#) ) and dosing ( [Hagino et al., 1998](#) ) have been studied.

The most common side effects of lithium are gastrointestinal upset, nausea, overeating, weight gain, enuresis, tremor, and acne. Diarrhea sometimes is an early sign of toxicity. Seizures may occur with lithium overdose. Children and adolescents often tolerate lithium carbonate better than adults. Lithium levels of 0.6 to 1.2 mEq/L are well tolerated. If there is no response at that level, the level might be increased to 1.4 mEq/L with careful monitoring and in the absence of significant side effects. [Weller and colleagues \(1986a, 1986b\)](#) have developed a dosing schedule based on weight, so that a child can be started on lithium and reach a therapeutic level quickly ( [Table 63.4](#) ). Children who have central nervous system impairment or mental retardation may be particularly sensitive to side effects from lithium and may have difficulty achieving a therapeutic effect.

A. Administer dosage according to chart below.  
 B. Take blood levels 12 hours after last dose (8:00 AM before morning dose) every other day (M, W, F) until two consecutive levels appear in the therapeutic range (0.6–1.2 mEq/L). If no clinical improvement is seen, increase dose to reach 1.4 mEq/L.  
 C. Administer Side Effect Rating Scale and Mania Rating Scale weekly.

Weight (kg)	8 AM	Dosage (mg) 12 noon	8 PM	Total daily
15–25	150	150	300	600
25–40	300	300	300	900
40–50	300	300	600	1,200
50–60	600	300	600	1,500

\*CAUTION: In dealing with organically impaired or retarded children, use lower doses. Adapted from Weller (B, Weller SA, Fristad MA, Lithium dosage guide for prepubertal children: A preliminary report. *J Am Acad Child Psychiatry* 25:92–96, 1986.

**Table 63.4. Lithium Protocol**

## CARBAMAZEPINE

Other medications have been less well studied than lithium in manic children and adolescents. Carbamazepine (Tegretol; Novartis, Summit, NJ) has been reported to be as efficacious as lithium in reducing symptoms of acute mania in adults with bipolar disorder ( [Simhandl et al., 1993](#); [Small et al., 1991](#)). Carbamazepine may not be as efficacious as lithium in maintenance treatment ( [Greil et al., 1997](#)). No published study has examined the efficacy of carbamazepine for either the acute or maintenance treatment of mania in children or adolescents. Furthermore, carbamazepine has been associated with the development of mania in children ( [Myers and Carrera, 1989](#); [Reiss and O'Donnell, 1984](#)).

Carbamazepine must be used carefully because it is known to cause bone marrow suppression with clinically significant neutropenia. Often, sore throat and fever are the first warning signs of a seriously low neutrophil count. Carbamazepine usually is started at 100 mg twice daily (15 to 30 mg/kg) and increased every fourth day. Therapeutic plasma levels are 5 to 11 mEq/L; biweekly blood counts to evaluate possible bone marrow suppression should be obtained for 3 months. Furthermore, dosage may require adjustment at 4 to 6 weeks owing to autoinduction of hepatic enzymes.

## DIVALPROEX

There is a substantial body of evidence to support the efficacy of divalproex in the treatment of adults with bipolar illness ( [Bowden et al., 1994](#); [Denicoff et al., 1997](#); [Pope et al., 1991](#)). Support for its use in children and adolescents is limited to case reports and small open-label trials ( [Papatheodorou and Kutcher, 1993](#); [Papatheodorou et al., 1995](#)). Fifteen adolescents and young adults were treated with divalproex sodium for 7 weeks for acute mania; improvement on the clinical severity scale for mania was reported in nine subjects ( [Papatheodorou et al., 1995](#)).

A starting dose of 250 mg twice daily may be used and increased gradually to a dose not to exceed 25 to 60 mg/kg/day. Blood levels between 50 and 120 mg/L are considered effective in adults. However, no controlled studies in children or adolescents have been published. The most common side effects are nausea, vomiting, and anorexia. Because hepatotoxicity has been reported, periodic liver function tests are necessary. Fatal hepatotoxicity has been reported in children; this risk is highest for children younger than 2 years of age and diminishes to close to zero after 10 years of age ( [Bryant and Dreifuss, 1996](#)). More recently, concerns have risen about a possible association between childhood valproic acid use and later risk for polycystic ovary disease in women ( [Irwin and Masand, 1998](#); [Isojarvi et al., 1993](#)). This serious untoward effect has been reported in patients treated for epilepsy, but has not been reported in those treated for bipolar disorder ( [Rasgon et al., 2000](#)). However, caution should be used when prescribing divalproex to any adolescent girl. It is recommended that before starting divalproex in an adolescent girl, a baseline weight, baseline waist/hip measurement, complete menstrual history, and evaluation for hirsutism be obtained.

## LAMOTRIGINE

There is growing support for the efficacy of lamotrigine in the treatment of adults with bipolar disorder ( [Calabrese et al., 1996](#); [Fatemi et al., 1997](#); [Kusumaker and Yatham, 1997a,b](#); [Sporn and Sachs, 1997](#); [Walden et al., 1996](#)). Its use in the treatment of mania in children and adolescents, however, is limited by its age-related association with Stevens-Johnson syndrome ( [Dooley et al., 1996](#); [Mackay et al., 1997](#); [Messenheimer et al., 1998](#)). Its use in the treatment of mania in children, as in epilepsy, is limited to adolescents 16 years of age and older who have failed other therapies.

## GABAPENTIN

Gabapentin has been used in adults in the treatment of acute mania ( [Ghaemi et al., 1998](#); [Knoll et al., 1998](#); [McElroy et al., 1997a](#); [Young et al., 1997](#)). Few studies have been conducted in children and adolescents. One case report recounts a favorable response to gabapentin plus carbamazepine in a 13-year-old boy with bipolar disorder ( [Soutullo et al., 1998](#)). Gabapentin has been reported to worsen aggressive behavior in children treated for seizures ( [Lee et al., 1996](#); [Tallian et al., 1996](#); [Wolf et al., 1995](#)).

## ANTIPSYCHOTICS

A study involving prepubertal children with mania suggests that psychotic symptoms as well as manic symptoms can be effectively managed without the use of antipsychotic agents ( [Varanka et al., 1988](#)). A more recent report involving adolescents with psychotic disorder, however, suggests that lithium alone may not be able to control psychotic symptoms in this age group ( [Kafantaris et al., 1998](#)).

Haloperidol has been effective in the treatment of aggression associated with disruptive disorders in children ( [Campbell et al., 1984](#)). Use of traditional antipsychotics is limited by untoward effects that interfere with compliance, including risk of tardive dyskinesia, weight gain, and sedation. Reports suggest that the novel antipsychotic agents risperidone, olanzapine, and clozapine may be effective in the treatment of mania in children and adolescents ( [Chang and Ketter, 2000](#); [Fras and Major, 1995](#); [Fuchs, 1994](#)). Extrapyramidal symptoms tend to be observed less frequently with these agents than with traditional antipsychotics, but weight gain and sedation continue to pose significant problems. Furthermore, the risk of agranulocytosis associated with clozapine limits its use in this age group.

## Electroconvulsive Therapy

Electroconvulsive therapy (ECT) has been used to treat severe bipolar disorder in children and adolescents. In a literature review, [Bertangoli and Borchardt \(1990\)](#) report that the few systematic studies were done before the early 1950s, and since then only individual cases have been reported. Data concerning safety and efficacy of ECT in children are sparse. A report involving 16 adolescents who received ECT for treatment-resistant bipolar disorder indicated that ECT was effective, well tolerated, and cost efficient in this age group ( [Kutcher and Robertson, 1995](#)). Furthermore, adolescents given ECT for severe bipolar illness do not appear to sustain cognitive impairment at long-term follow-up ( [Cohen et al., 2000](#)). The [American Psychiatric Association \(1990\)](#) has published specific guidelines regarding indications for, procedures of obtaining consent for, and administration of ECT treatments. Before referring children for ECT, two psychiatrists experienced in treating children and who are not otherwise involved with the patient should agree with the recommendation for ECT. ECT may be considered when other modalities of treatment have failed.

## OUTCOME AND FOLLOW-UP DATA

There are no systematic follow-up data on preschool- or prepubertal school-age children with bipolar disorder. Anecdotal reports suggest that these children do not "grow out of it" ( [Poznanski et al., 1984](#)). Several studies report follow-up data on adolescent-onset mania. Reports suggest that compared with adults, adolescents with bipolar disorder have a more prolonged early course and are less responsive to treatment ( [McGlashen, 1988](#); [Strober et al., 1995](#)). Long-term outcome, however, is reported to be similar to that of adult-onset bipolar disorder.

[Landolt \(1957\)](#) found that after 18 years of follow-up, 17% of patients with adolescent-onset of mania recovered, whereas 50% had a poor outcome. Data on the remaining subjects were inadequate to make a decision as to outcome. [Olsen \(1961\)](#) reported on 28 adolescents with a mean age of onset of 15 to 16 years. He divided his group into those who had had an acute onset and those with prior childhood psychopathology. A 25-year follow-up revealed a good outcome for 33% of the acute-onset group, whereas only 15% in the group with prior psychopathology had a good outcome. [Hudgens \(1974\)](#) and [Weiner et al. \(1979\)](#) reported the outcomes for their adolescent patients with mania to be social disability, substance abuse, multiple suicide attempts, and completed suicide. In a 20-year follow-up of adolescents with mania, [Carlson et al. \(1977\)](#) reported that 60% of subjects studied had a good social outcome, 20% had significant impairment, and 25% were chronically ill.

Another study reported good outcome in 35 adolescents with mania ( [McGlashen, 1988](#)). The author divided this sample into two groups: those with onset before 20 years and those with onset after 20 years of age. Patients with the earlier age of onset had more psychiatric symptoms and trouble with the law, and 70% had "psychotic assaultiveness." However, there was no difference in the suicide rate or frequency of hospitalizations between the two groups. Also, those with earlier onset performed significantly better regarding work and frequency of social contacts.

In a naturalistic follow-up study, [Strober et al. \(1990, 1995\)](#) found that adolescents who continued their lithium carbonate treatment had fewer relapses than those who stopped the treatment, which suggests that lithium may play a role in preventing relapses. In this study, only 2 of 54 adolescents failed to recover from their initial

episode over a 5-year period. Furthermore, rate of recovery was influenced by the polarity of the index episode; subjects with depression took longer to recover than subjects who had cycling, mixed episodes, or pure manic episodes.

Adolescents with bipolar disorder are at increased risk for suicide relative to children with other psychiatric illnesses ( [Brent et al., 1988, 1993](#)). Eleven of 54 adolescents with bipolar disorder made serious suicide attempts during 5-year follow-up ( [Strober et al., 1995](#)). Comorbid substance abuse further increases the risk for suicide in adolescents ( [Rich et al., 1986, 1990](#)).

## SUMMARY

Bipolar disorder in children and adolescents is less studied than adult-onset bipolar illness. Historically, several factors have made the diagnosis of bipolar disorder in childhood difficult. These include bias against the diagnosis of mania in children, the low base rate of mania relative to other psychiatric illnesses in children, symptom overlap between bipolar disorder and other, more prevalent childhood-onset psychiatric disorders, and developmental constraints and variability in clinical presentation. The validity and prevalence of bipolar illness in childhood remain controversial. Epidemiologic studies are needed to assess accurately the prevalence of this disorder in childhood. Current consensus is that the incidence of bipolar illness increases with puberty. Reports on the phenomenology of bipolar disorder in children and adolescents indicate that its presentation is highly variable, with a developmental trend toward increasing resemblance to the adult phenotype with increasing age of onset. Diagnostic accuracy seems to improve with adherence to DSM criteria. The course of bipolar disorder in childhood has received only limited study. Available studies suggest that bipolar illness is a relapsing, recurrent illness with substantial morbidity and mortality. Few studies that systematically investigate the use of pharmacologic agents in the treatment of bipolar illness in youth have been published. Justification for the use of mood stabilizers in children is based primarily on adult literature. There is a significant need for additional research in all aspects of childhood-onset bipolar disorder.

Light and its effect on the human body has been the subject of investigation for centuries. Lighting conditions at work, home, and play can affect our behavior ([Wetterberg, 1992](#)). Seasonal rhythms in human behavior have been observed since antiquity, and Kraepelin noted seasonal differences in mood and behavior in the early 1900s. Numerous investigators became interested in the relationship between environmental light and mental illness, and in [1984, Rosenthal and colleagues](#) reported their initial description of a pattern of recurrent depressive symptoms observed in women in their early twenties that they termed *seasonal affective disorder* (SAD). They noted that one-third of adult patients with SAD had onset in childhood, and later described children with seasonal symptoms who complained of sadness, anxiety, fatigue, irritability, changes in appetite, and social withdrawal. These symptoms were associated with seasonal changes in school behavior and academic difficulties, especially in individuals with family histories of mood disorders and alcohol abuse ([Kern, 1990](#); [Mghir and Vincent, 1991](#); [Sher et al., 1999](#)).

The relationship between mood and light has aroused continued interest in general psychiatry, and investigators have only recently begun to pursue the scientific study of SAD in children and adolescents. This chapter reviews the literature regarding the clinical description, epidemiology, and etiology of SAD. Treatment also is reviewed, and future directions for study are discussed.

### CLINICAL DESCRIPTION

Seasonal affective disorder (SAD) was initially included in the [American Psychiatric Association's \(1990\) Diagnostic and Statistical Manual of Mental Disorders](#), third revised edition (DSM-III-R) and was described as a mood disorder modifier, not as a separate diagnostic entity or course specifier ([Bauer and Dunner, 1993](#)). SAD was designated a course specifier in DSM-IV ([American Psychiatric Association, 1994](#)) and was defined as a cyclical pattern of recurrent major depressive symptoms in adults with a seasonal or temporal pattern. It was applied to unipolar, bipolar I, and bipolar II disorders and had a regular, seasonal onset in the absence of psychosocial stressors. In [1984, Rosenthal and colleagues](#) presented their definition of SAD as recurring fall and winter depressive episodes without related stressors. Asymptomatic periods occurred in the spring and summer with two seasonal episodes in consecutive years, one of which met DSM-IV criteria for a major depressive disorder (MDD). Rosenthal et al. excluded any other Axis I pathologic process. To qualify for the seasonal specifier, a pattern of recurrent depression with initiation and termination of symptoms had to occur within a 60-day window from year to year. The remarkable feature, therefore, was the temporal nature of the disorder itself ([Blehar and Rosenthal, 1989](#)). In DSM-IV, the seasonal specifier also requires that full remissions or cycling into mania or hypomania occur regularly throughout the year and that within the last 2 years before the onset of SAD, two major depressive episodes had occurred demonstrating a seasonal aspect to the episodes. Other Axis I diagnoses do not necessarily exclude the application of the seasonal specifier ([Bauer and Dunner, 1993](#)).

The diagnosis of SAD is based on clinical evaluation. The practitioner must consider chief complaint, present and past psychiatric history, family data, and especially the temporal relationship between symptoms, environment, and psychosocial stressors. Patients with SAD usually complain of atypical depressive symptoms, such as increased appetite, carbohydrate craving, increased weight, and increased sleep, that are worse in the evening. These symptoms occur in 65% to 80% of patients with SAD and 15% to 30% of patients with MDD who present as outpatients. Other symptoms include premenstrual difficulties, interpersonal dysfunction, and work distress ([Terman et al., 1989](#)). Patients with SAD may meet criteria for major depression, but the symptoms are described as seasonal ([Pendse et al., 1999](#)).

Onset of SAD typically is in September through November, with hypersomnia, hyperphagia, and excessive fatigue occurring with a change in the amount of natural light. A later onset can occur if the fall is mild and sunny ([Mayor et al., 1991](#)). The most severely symptomatic months for patients are January and February, with remissions usually occurring in April and May. The lifetime prevalence of anxiety disorders in SAD is high—generalized anxiety disorder, simple and social phobia, as well as personality disorders are prevalent. Patients may have unipolar, bipolar I, bipolar II, or dysthymic disorders ([Terman et al., 1989](#)), although most are unipolar ([Sakamoto et al., 1995](#)). Other comorbid conditions include disruptive behavior disorders in children. Patients with SAD complicated by other psychiatric disorders are more severely depressed and can present with suicidal ideation. Two-fifths of SAD patients have pure SAD, two-fifths have complicated SAD, and one-fifth remit over 8 years. There are no data to suggest that having bipolar disorder and SAD worsens the long-term course of the SAD ([Schwartz et al., 1996](#)). In fact, some patients with SAD can become hypomanic secondary to use of a selective serotonin reuptake inhibitor ([Sakamoto et al., 1995](#)).

Seasonal affective disorder symptoms are more frequent with increasing distance from the equator and decrease with short geographic visits to lower latitudes. Symptoms usually are more intense with increasing latitude ([Partonen and Partinen, 1994](#); [Terman et al., 1989](#)). Patients living in an extreme northern latitude show an increase in severity of symptoms ([Rosenthal et al., 1984](#); [Sourander et al., 1999](#)). Geographic location and its impact on day length, daily hours of sunshine, and temperature are other variables that appear to affect patients with SAD.

Most children and adolescents are undiagnosed ([Sourander et al., 1999](#)). In children and adolescents, seasonal symptoms may be due to school pressures and not expressly SAD because it is difficult to eliminate the effects of the academic school year on patients ([Milman and Bennett, 1996](#)). Children show depressed mood of 2 weeks or longer, fatigue, sleep disturbance, carbohydrate craving, headache, school problems, and social withdrawal. Parents report that the children are irritable, tired, have more school problems, seem sad, cannot sleep, and have more somatic complaints, changes in appetite, carbohydrate craving, and increased motor activity. Parents also observe more crying, increased anxiety, social withdrawal, and tantruming. Symptoms that are similar to those of adults in the winter include depressed mood and decreased activity.

Most children do not present with complaints of excessive sleep, which is a commonly reported symptom in adults with SAD ([Swedo et al., 1995](#)). SAD is considered a valid type of mood disorder in children, and one of the major reported symptoms is disruptive behavior. Adolescents have a higher prevalence than children; it is estimated that 1 million adolescents have SAD ([Sourander et al., 1999](#)). SAD is a milder syndrome in children, yet it leads to functional impairment and results in social and academic difficulties at school. The children frequently are unaware of the problem and they perceive the disorder as external, with multiple complaints from teachers and parents ([Rosenthal et al., 1986](#)). It is debated whether pediatric patients with SAD may be predominantly bipolar II or unipolar ([Sher et al., 1999](#)).

The Seasonality Scale Index is a reliable measure to assess patients, yet SAD is a clinical diagnosis and should be made through obtaining a detailed history ([Magnusson et al., 1997](#)). The Seasonal Pattern Assessment Questionnaire is another instrument used in research protocols for identifying patients with SAD, but its psychometric properties are open to question ([Raheja et al., 1996](#)).

### EPIDEMIOLOGY

The lifetime prevalence of SAD is 1% to 2% of the general population, 0.4% to 0.9% in patients with MDD, and 1% in patients with dysthymic disorder. The combined prevalence of SAD and subclinical SAD is 3.1% over 2 consecutive years and 2.4% over 3 consecutive years, with an increased prevalence in twins ([Partonen and Lonnqvist, 1998](#)). [Carskadon and Acebo in 1993](#) and [Swedo et al. in 1995](#) reported that 3% to 5% of school-age children may have SAD. [Sourander et al. \(1999\)](#) observed that SAD occurs in 4% to 12% of adults, 1.9% of 9-year-olds, and 5.5% of 19-year-olds, with an increased prevalence in northern latitudes. The female-to-male ratio has been reported to be 4:1 to 6:1 ([Kasper et al., 1989](#); [Rosenthal et al., 1984](#)), although others have reported the sex ratio to be equal ([Carskadon and Acebo, 1999](#)). Some note up to a 69% frequency of a mood disorder in first-degree relatives of patients with SAD ([Rosenthal et al., 1984](#)). In general, approximately one-third of patients have onset in childhood, with higher rates in girls than in boys ([Sourander et al., 1999](#)). Patients with SAD report increasing symptoms with age and at puberty. Some postulate a relationship between puberty and increased rates of SAD in girls and of temporally related depressive episodes

in adult women during their reproductive years ([Swedo et al., 1995](#)).

## ETIOLOGY

Humans and other mammals have biological functions occurring on an approximately 24-hour cycle that are regulated by hormones through various anatomic structures and pathways in the central and peripheral nervous systems (circadian rhythms). These cycles are manifested in aspects of physiology, such as temperature, hormone production, and sleep–wake cycles. Hormones such as melatonin and cortisol have diurnal rhythms, affect sleep, and are influenced by light and temperature. Without exposure to light, the human body adjusts itself to an approximate 24-hour period, depending on the individual and the environment ([Wetterberg, 1992](#)). Because it is well known that certain mammals hibernate during shortened periods of light and experience seasonal physical changes owing to the environment, it has long been postulated that similar changes in the photoperiod have effects on human physiology and behavior.

Several hypotheses are reviewed in the literature for SAD. The first is the phase shift hypothesis (Lewy and Sack, 1986), which postulates that there is a primary disturbance of delayed timing of circadian rhythms in patients with SAD. Exposure to bright light is thought to terminate the delayed portion of nocturnal melatonin secretion. Others note that dim light also results in delayed melatonin secretion ([Glod et al., 1997](#)). Patients with SAD may have a particular vulnerability to a decreasing photoperiod in the winter months. There appears to be a correlation between later onset of daily light and depressed mood, which suggests that some individuals may have an exaggerated need for environmental light ([Oren et al., 1994](#)). Patients may for some unknown reason be more sensitive to changes in natural light because of biological phenomena or other mechanisms ([Guillemette et al., 1998](#)).

The second hypothesis ([Czeisler et al., 1987](#)) postulates that the amplitude, not the 24-hour phase of circadian rhythms, may be reduced and that light works by increasing the amplitude of hormone production and regulatory functions. There is little evidence that this phenomenon occurs with temperature, yet there is some research that supports this hypothesis with respect to hormonal changes in the human body.

The third hypothesis ([Teicher et al., 1990](#)) suggests that in SAD there is a primary regulatory disturbance, called *entrainment*, which refers to the body's ability to align itself with the environment. It is postulated that a reduction in the degree of entrainment is corrected by bright light. Serotonergic projections to the suprachiasmatic nucleus may control the rhythm, yielding decreased entrainment.

The fourth hypothesis maintains that SAD results from decreased absorption of quanta of light, perhaps due to a retinal pathologic process, and that bright light works by increasing the number of photons of light absorbed. A general change in the photoperiod appears to be mediated by retinal and hypothalamic structures in the central nervous system ([Partonen and Partinen, 1994](#)). Some suggest that bright light works by changing the secretion of melatonin, which is mediated by afferents through the retinohypothalamic tract, suprachiasmatic nuclei, and upper cervical ganglion to the pineal gland, which secretes the hormone ([Oren and Terman, 1998](#)). Melatonin reaches its highest levels at night and decreases during the day, and it is thought that patients with SAD have a greater seasonal change in the pineal gland's secretion of the hormone. Others suggest that the ventrolateral and dorsomedial aspects of the suprachiasmatic nuclei are intimately involved in entraining the circadian clock and that in patients with SAD, these neurons are pathologically misaligned with the environment in the winter months ([Thompson et al., 1990](#)).

Neurotransmitters and hormones also have been implicated in the etiology of SAD. It is unclear if serotonergic potentiation is the cause of circadian rhythm phase shifting ([Terman and Terman, 1999](#)). Noradrenergic projections may be responsible for decreased amplitude and attenuation. Hormones involved in sexual development may modulate the brain's vulnerability to changing season and light schedules ([Swedo et al., 1995](#)). Neuroimaging research in patients with SAD shows decreased metabolic rates ([Cohen et al., 1992](#)). Studies of prolactin, thyroid hormone, and adrenocorticotropic hormone have not clearly defined the pathophysiology of SAD. Estrogens may effect the timing of depressive symptoms and disruptive behavior in children and adolescents, and effect changes in adult women ([Oren et al., 1994](#); [Partonen and Partinen, 1994](#)). Seasonal changes may occur in serotonin levels in fall and winter ([Bick, 1986](#)). Disturbed biological rhythms may be due to impaired transmission of serotonin or other neuropeptides along afferent pathways to the circadian pacemaker. Decreased dietary tryptophan may lead to decreased levels of serotonin, and depressive symptoms ([Partonen et al., 1997](#); [Thalen et al., 1995a, 1997](#)). Other mechanisms suggested include an immune response of peripheral blood lymphocytes, the involvement of visual-evoked responses, changes in rapid eye movement density, serotonin dysregulation, and retinal disease ([Terman et al., 1989](#)). In addition, the dopaminergic system might be involved, and some suggest that a deficiency of dopamine may exist in certain neuroanatomic pathways ([Oren et al., 1994](#)).

## DIFFERENTIAL DIAGNOSIS

Differential diagnosis in SAD includes that of any mood disorder, especially organic mood disorders, dysthymic disorder, cyclothymic disorder, adjustment disorders, substance abuse and dependence, personality disorders, pseudodementia, schizoaffective disorder, and disruptive behavior disorders in pediatric patients. Practitioners also need to consider chronic fatigue syndrome, thyroid disorders, sleep disorders, eating disorders, and depressive disorders related to the menstrual cycle ([Partonen and Partinen, 1994](#)). The evaluation includes a physical examination, neurologic evaluation if indicated, and complete psychiatric history.

## TREATMENT

In general, treatments may include medications, psychotherapy, sleep deprivation, light therapy, dawn simulation, aerobic exercise, and outdoor recreation. Adequate sleep hygiene, dietary modification, and standard interventions for mood disorders are used routinely ([Partonen and Partinen, 1994](#); [Wirz-Justice et al., 1996](#)). The efficacy of psychotherapy in the treatment of SAD has not been studied ([Partonen and Lonquist, 1998](#)). The use of selective serotonin reuptake inhibitors is effective, yet some patients may be reluctant to take medications and elect alternative treatment. Numerous controlled trials support the effectiveness of bright light therapy for the treatment of SAD in adults and patients with atypical depressive symptoms ([Terman et al., 1996](#)). Light therapy also can be used as an adjunct to antidepressant treatment and is efficacious in patients whose symptoms do not meet the full criteria for SAD ([Kasper et al., 1989](#)). Although there are few data in children and adolescents, active treatment with light has been found to be superior to placebo ([Swedo et al., 1997](#)). Phototherapy is now regarded as the treatment of choice, with a response in 1 to 2 weeks, although classic antidepressant therapy is effective as well.

Light therapy can be used at home, in the workplace, during travel, and in the clinic. The treatment occurs with a light “box” placed at eye level approximately 1 meter from the patient for 2 to 6 hours per day with full-spectrum fluorescent light, incandescent light, or cool-white fluorescent light ([Terman et al., 1989](#)). Treatment with a light box is convenient because the patient sits in front of the apparatus on a regular basis and is able to read, study, or work throughout the duration of the exposure to light. Some institutions have separate rooms with permanently installed phototherapy equipment and white walls to maximize reflection ([Partonen and Partinen, 1994](#); [Terman et al., 1989](#)). Treatment usually is well tolerated by patients, with minimal side effects, and the response is more rapid than with antidepressants ([Terman et al., 1996](#)). The efficacy of light therapy has to do with the spectrum of the light, its intensity, and the duration and time of exposure to the light source. These variables are discussed in the following paragraphs.

The wavelength of light, or spectrum, and its relationship to SAD symptoms has been little studied. Light boxes that contain white fluorescent bulbs are common. Most protocols use full-spectrum fluorescent light bulbs that emit small amounts of ultraviolet (UV) light. The amount of UV transmission varies with the source (incandescent bulbs emit less UV light), and the length of exposure to UV light is an important factor because UV light has been reported to produce retinal changes. Full-spectrum light with UV is effective on typical and atypical depressive symptoms, whereas UV-blocked light has been noted to be effective only on atypical symptoms ([Lam et al., 1991](#)). Others note no clinical advantage using full-spectrum UV light over light that is UV blocked and suggest that there is no increased clinical efficacy with either source of transmission ([Lam et al., 1992b](#); [Partonen and Partinen, 1994](#)). UV light usually is not necessary in the treatment of SAD and may be blocked during treatment as a precaution in patients with concerns regarding retinal status. Shorter to medium wavelengths of light (blue, green, and yellow) have been shown in some studies to be more effective than longer-wavelength white light ([Lee et al., 1997](#)). White, broad-spectrum light, however, usually is used for a robust clinical response.

The intensity and duration of light exposure are important factors in phototherapy. Bright light usually is more effective than dim light, and intensity has a direct relationship to the response of SAD symptoms. As the intensity of light increases, the classic symptoms of depression, as well as atypical symptoms, respond with increasing frequency. However, atypical symptoms have been noted in trials to respond less aggressively to an increase in the intensity of light ([Lee and Chan, 1999](#); [Levitt et al., 1996](#)). Bright light of 2,500 to 10,000 lux has been found in most studies to be effective as first-line treatment, and removal of the light therapy results in relapse within a 2- to 4-day period ([Rosenthal et al., 1985](#)). Treatment with 2,500 lux for 2 hours each morning for 1 week yields a 67% response rate, and if the patient is treated with 10,000 lux for 30 minutes each morning for 1 week, the response rate increases to 75% to 80% ([Avery et al., 1992](#); [Partonen and Lonqvist, 1998](#)). By the middle of 1987, 24 trials found that bright light of 2,500 lux was more effective than dim light ([Blehar and Rosenthal, 1989](#)). Most researchers recommend 10,000-lux white fluorescent light from a light box for 30 minutes each day for 2 weeks ([Terman and Terman, 1999](#)). A more intense light treatment requires less time of exposure at any time of day, and after 1 to 2 weeks of treatment, sessions can be decreased to 5 days per week. Two hours per day of treatment

with low-intensity light is difficult for some patients, and studies note that a 30- or 40-minute duration of very intense light is as efficacious and improves compliance (Avery et al., 1992; Terman et al., 1989).

The timing of light treatment continues to be a topic of debate, although most studies suggest that morning treatment is more effective than evening (Rosenthal et al., 1985). However, other studies have not reproduced the clear efficacy of morning therapy over other dosing times (Lee et al., 1997; Meesters et al., 1991, 1993b; Schwartz et al., 1996). Dawn simulation (exposing a sleeping individual to light) also has been reported to be effective and has been used in adult and pediatric patients with SAD but is associated with less immediate improvement compared with light box treatment (Avery et al., 1992; Lingjaerde et al., 1998; Meesters, 1998).

The mechanism of light treatment is unclear. Light is thought to effect many biological functions through a variety of anatomic pathways that are involved in circadian bodily rhythms. Bright light is received by the retina and, through the retinohypothalamic tract and the suprachiasmatic nucleus, effects melatonin production in the pineal gland. The duration of melatonin secretion appears to be more important than the amount of melatonin secreted (Rosenthal et al., 1985), and extending the photoperiod with light therapy can change the duration of melatonin secretion (Rosenthal et al., 1984). In general, the greater amount of light in the summer months correlates with increased duration of melatonin secretion, and decreased duration in the winter months correlates with a shorter photoperiod (Wehr et al., 1986). The change in hormonal secretion due to the extension of the photoperiod in patients with SAD alters the phase-response curve and advances circadian rhythms. Light treatment also may decrease urinary output of norepinephrine and its metabolites (Anderson et al., 1992). The effects of light therapy are presumed to be mediated primarily by the eyes, yet little work has been done on how light affects the skin and its production of hormones.

Common side effects of light therapy include irritability, headache, nausea, eyestrain, insomnia, hyperactivity, and "feeling wired." These side effects occur in the beginning of treatment and reportedly increase with the intensity of light used, although other studies are inconclusive. Light-induced mania is rare, as is worsening of depressive symptoms. Side effects may be worse with head-mounted units or light visors, although there is a lack of clinically significant side effects or ocular changes (Terman and Terman, 1999). Short-term side effects are self-limited and there are no known long-term effects (Kogan and Guilford, 1998; Levitt et al., 1993).

Light therapy has been noted in general to be efficacious in children and adolescents in the limited studies available (Sourander et al., 1999; Rosenthal et al., 1986), and treatment protocols are analogous to those in adults. Studies have shown that children respond to light therapy at lower intensities and shorter exposures. SAD symptoms decrease with light treatment, compliance with light therapy is high, and side effects are fewer in the pediatric population (Giedd et al., 1998).

Patients may complain of the inconvenience of sitting in front of boxes routinely, and thus it is important to recommend that patients work the treatment into their normal and daily schedule. Some begin treatment prophylactically and purchase units themselves because there is a low rate of reimbursement by insurance companies despite documented efficacy (Oren et al., 1991b). Predictors of response to treatment include hypersomnia, hyperphagia, and atypical depressive symptoms (Lam, 1994; Lam et al., 1992a; Oren et al., 1992). Comorbid anxiety disorders are associated with a positive response, whereas the response in patients with concomitant personality disorders is not as impressive. The efficacy of light treatment is stable over time, with patients continuing to respond well with subsequent yearly treatments. Most patients continue to do well, experience few side effects, and have a decreased risk for MDD (Oren et al., 1992).

## FUTURE DIRECTIONS

The definition of SAD as a distinct entity, rather than a specifier for recurrent major depression, needs to be reviewed. The prevalence, diagnostic norms, and criteria in children and adolescents require further study. The etiology of SAD and, specifically, biological markers and hormonal mechanisms involved in the disorder, provide ample opportunities for study as treatments, such as light therapy, continue to spark scientific interest. Long-term outcome studies would be beneficial to ascertain whether patients continue to improve over time, and work is needed to compare the efficacy of light treatment with other treatment modalities. Finally, the use of natural, outdoor light in lieu of light therapy and the effect of light spectrum in the treatment of patients with SAD are of great interest.

## RESOURCES

There are many manufacturers now offering a variety of light appliances for personal and institutional use. Companies can be found on the Internet using "seasonal affective disorder," "light therapy," or "light box production" as search engine key words.

[Chapter References](#)

At the beginning of the new millennium, suicidal behavior in children and adolescents continues to be an important mental health problem in the United States and worldwide. Recognition of the high degrees of psychiatric and social morbidities associated with suicidal acts among youth has stimulated extensive development of empirical investigations to identify risk factors for youth suicidal behavior. Notably, in 1999, the Surgeon General of the United States published guidelines for a major national initiative to prevent suicidal behavior among youth ( [U.S. Public Health Service, 1999](#)). The 15 major issues identified in this initiative were classified as awareness, intervention, and methodology. Awareness that suicide is a public health problem for which reduction of stigma and enrichment of community resources for suicide prevention was emphasized. The recommendations included development of a National Strategy for Suicide Prevention involving public and private resources that will improve the recognition and treatment of suicide risk by primary care providers, eliminate barriers in insurance coverage for treatments, educate families about suicide risk, as well as implement effective crisis and peer support programs in schools to eliminate youth distress, use schools and workplaces as referral and access points, and provide support to those who lose a loved one to suicide. Advances of the science of suicide prevention were suggested as occurring through research to identify risk factors, evaluation of suicide prevention interventions, promotion of interagency collaboration to improve monitoring for suicidal behavior, and development of new suicide prevention techniques through reduction of access to lethal suicide methods.

The Surgeon General's report built on the aggressive impetus to eradicate youth suicidal behavior that began in the 1980s with the initiation of innovative research methodologies involving epidemiologic, cross-sectional, psychological autopsy, and longitudinal approaches. Furthermore, numerous scientific papers published in the 1990s have educated health care professionals and the community about the characteristics of this profound mental health problem. This chapter provides an overview of suicidal behavior among children and adolescents that is derived from the information gleaned from these studies.

The concept of suicidal behavior in children and adolescents includes thoughts about causing intentional self-injury or death (suicidal ideas) and acts that cause intentional self-injury (suicide attempt) or death (suicide). Based on research suggesting that the severity of depression, death preoccupations, and general psychopathology are directly proportional to the severity of suicidal behavior, researchers concluded that suicidal behavior among children and adolescents involves a continuum from nonsuicidal behavior to suicidal ideas, suicide attempts, and suicide ( [Brent et al., 1988](#); [Pfeffer, 1986](#)). The complexity of these concepts requires more research, especially with respect to potential differences in various phases of child and adolescent development. The chapter focuses predominantly on fatal and nonfatal suicidal acts, such as suicide and suicide attempts.

## HISTORICAL NOTE

In the early 19th century, when Goethe's classic *The Sorrows of Young Werther* was published, an epidemic of youth suicide occurred. This epidemic was attributed to imitation of the book's hero, who shot himself after the breakup of a love relationship. Subsequently, the book was banned in Europe. In 1910, the Vienna Psychoanalytic Society convened a special meeting to evaluate risk factors for youth suicidal behavior ( [Pfeffer, 1986](#)). This historic meeting was organized because of concern about the significant rise in youth suicide and the anxiety that ensued about how to prevent suicide. Among the participants at this meeting were Drs. Federn, Freud, Rank, Steckel, and Tausk. Sigmund Freud, for example, was concerned that the most significant influence on youth suicide was conflict with loved persons. He proposed that intensive study of specific suicidal individuals would elucidate dynamic aspects of childhood suicidal behavior. Others offered suggestions about how to decrease stresses, such as school pressure, that may enhance risk of youth suicidal behavior. Many advocated the need to develop systematic techniques to study youth suicidal behavior.

A rapid rise in suicide among male 15- to 24-year-olds in the United States began in the late 1960s, peaked in 1977, and has decreased in the last few years. Clusters of youth suicide were recognized in the 1980s. As a result, extensive public attention was directed toward developing suicide prevention methods, particularly in schools. Subsequent research of such school suicide prevention programs redirected the thinking about the most effective and safe strategies for such suicide prevention efforts ( [Shaffer et al., 1991](#)). The importance of developing well conceptualized approaches to decreasing youth suicide was highlighted in the 1986 Health and Human Services–National Institute of Mental Health Task Force Conference on Youth Suicidal Behavior. Participants at these conferences included international research experts on youth suicidal behavior. Recommendations made at the close of these conferences ( [Alcohol, Drug Abuse, and Mental Health Administration, 1989](#)) included the need to:

1. Define suicide and report suicide in national and local databases more consistently.
2. Develop research to identify the multifaceted elements of youth suicidal behavior.
3. Evaluate the efficacy of treatments for suicidal youth and those at risk.
4. Support and plan appropriate suicide prevention methods.
5. Educate those providing health care about identification, treatment, and prevention of youth suicidal behavior.
6. Collaborate in the public and private sectors to prevent youth suicide.

National attention to this major mental health problem was stimulated by the publication in 2000 of the Surgeon General's guidelines to prevent youth suicide ( [U.S. Public Health Service, 1999](#)).

## EPIDEMIOLOGY

The most recent year for complete death records of the United States Vital Statistics is 1998 ( [Murphy, 2000](#)). The age-adjusted rate of suicide for 15- to 24-year-olds was 11.1 per 100,000, a rate less than the rate of 11.3 per 100,000 for all ages. It also is less than the rates of 11.4 per 100,000 in 1997 and 12.4 per 100,000 in 1979 for 15- to 24-year-olds. The age-adjusted suicide rate for 15- to 24-year-olds is in marked contrast to the age-adjusted suicide rate of 0.8 per 100,000 for 5- to 14-year-olds. Notably, the rates for 5- to 14-year-olds have doubled since 1979. Suicide among 15- to 24-year-olds is the third leading cause of death and in 5- to 14-year-olds, it is the sixth leading cause of death. In 1998, among 15- to 24-year-olds, there were 4,135 suicides. In the same year, among the 5- to 14-year-olds, there were 324 suicides.

Suicide rates in the United States in 1998 are highest among white males of all ages. The age-adjusted suicide rates for white males are followed by those for nonwhite males, white females, and nonwhite females. In 1998, age-adjusted male suicide rates per 100,000 among 15- to 24-year-olds involve the following: whites, 19.3; blacks, 15.0; Hispanics, 13.4. These rates are higher than the female rates. In 1998, the 15- to 24-year-old age-adjusted female suicide rates per 100,000 were

as follows: white, 3.5; Hispanics, 2.8; and blacks, 2.2.

Suicide caused by firearms accounted for 56.7% of all firearm injury deaths in 1998. Approximately 12% of all firearm deaths were in youths younger than 20 years of age.

Birth cohort effects have been identified for youth suicide in several countries ( [Klerman, 1988](#)). A birth cohort is defined as a group of people born within a specific period. Reports from Canada, the United States, and Australia suggest that each successive birth cohort has a higher youth suicide rate than previous birth cohorts. In addition, these reports suggest that suicide rates increase as individuals in a cohort age.

Period effects also have been identified for youth suicide rates. Period effects represent trends that are associated with phenomena occurring within specific periods. Notably, there has been a marked increase in suicide rates of 15- to 24-year-olds, specifically among individuals born after World War II ( [Klerman, 1988](#)). These individuals became known as the baby boom cohort. Other psychological problems, such as violence, substance abuse, and severe depression, also were significantly higher in these individuals.

Reliable national data for suicide attempts do not exist because there is no national registry for suicide attempts. However, the epidemiology of suicide attempts among children and adolescents is gradually being elucidated. It is estimated that approximately 8% to 10% of adolescents report a suicide attempt at least once in their lifetime. Approximately 1% of preadolescents in the general community report suicide attempts ( [Pfeffer et al., 1986](#)). The ratio of attempted suicide to suicide in children and adolescents has been estimated to be 50:1 ( [Andrus et al., 1991](#)).

The rates of suicide and suicide attempts for community samples are significantly lower than those found among psychiatric patients. For example, approximately one-third of preadolescent and young adolescent psychiatric inpatients attempted suicide before hospitalization ( [Pfeffer, 1986](#)). Suicide among children and adolescents who had a history of psychiatric hospitalization occurs approximately nine times more often than among children and adolescents in the community ( [Kuperman et al., 1988](#)).

## CLINICAL DESCRIPTION

Suicidal ideation and acts are episodic events that can be clearly defined and characterized to have a discrete onset and duration ( [Pfeffer, 1986](#)). Intent to cause harm to oneself is an essential ingredient in defining suicidal behavior. Suicidal intent may be explicit and strong or it may be ambiguous. Evaluating intentionality often is a difficult clinical task, especially among preadolescents. For example, a 9-year-old boy, who was seriously despondent after his dog died, threatened to stab himself with a knife during an argument with his mother. He denied that he had thoughts of wanting to kill himself but stated that he wanted to upset his mother. In this case, the intent was not clear, but the overt behavior was potentially life threatening. In contrast, a 15-year-old girl ingested 127 aspirin tablets after she broke up with her boyfriend. She wanted to kill herself because she felt she “had nothing to live for.” In this case, suicidal intent was clearly stated.

Because intentionality often is difficult to define in children and adolescents, it is helpful for a clinician to consider that self-injurious acts in children and adolescents are potentially suicidal. This enhances the possibility that a clinician will more readily plan appropriate life-sparing interventions.

Suicidal behavior involves a wish to cause death. However, understanding that death is final is not an essential ingredient in considering a child or adolescent as suicidal. Concepts about death develop in parallel with children's development ( [Pfeffer, 1986](#)). Although appreciation of the finality of death may not occur until adolescence, some suicidal adolescents do not have mature concepts of death. Furthermore, children's concepts of death may vary. For example, a 7-year-old may understand that because his pet bird has died, it will no longer be alive. However, this youngster may not understand that if he dies he will never be alive again. Fluctuations in a child's understanding of death also may occur. A child may realize that death is final at one time but when severely stressed—for example, by the divorce and arguments of his parents—such a child may believe that death is reversible. Using these concepts, it is evident that very young children, such as preschoolers who do not appreciate the finality of death, can be considered to be suicidal if they wish to carry out a self-destructive act with the goal of causing death.

Children and adolescents plan and carry out suicidal acts using a variety of potentially lethal methods. These include shooting, hanging, ingestion, suffocation, stabbing, running into traffic, burning, and drowning. In the last few decades, firearms have been the most common means of youth suicide ( [Brent et al., 1987](#)). Furthermore, young women attempt suicide more frequently than do young men. Women predominantly use methods that involve ingestion of lethal substances to attempt suicide, whereas men use firearms to commit suicide. The differences in suicidal methods used by men and women may account for why suicide is higher among men.

---

### CASE ILLUSTRATION

The following case exemplifies some of the characteristics of a teenage suicidal episode. Sam, a 16-year-old boy, attempted to hang himself in his bedroom but was discovered by his father, who untied the noose. Sam left an extensive note on his desk describing how depressed he felt in the past few months. He had failed two school midterm examinations and was not accepted on the varsity swim team. He was very disappointed about these events. In addition, he had arguments with his girlfriend, who wanted to date other boys. The night of his suicide attempt, Sam attended a party and drank excessively. He became loud and argumentative. His girlfriend reprimanded him about his behavior. She told him that she was ashamed to be with him and returned a bracelet he had given her for her birthday. Sam was in despair about the tensions with his girlfriend. He returned home A.M. and wrote a long note explaining why he wanted to kill himself. After he completed the note, he tried to fall asleep but continued to be very upset. Gradually, he formulated a plan to hang himself on Sunday morning while his family was at church. However, that morning Sam's father did not go to church and discovered Sam in the process of attempting suicide.

---

### CASE ILLUSTRATION

The following vignette highlights suicidal behavior in a preadolescent. Susan was 9 years of age when she took a dose of her mother's antidepressant medication. That day she was with her father, who was drinking heavily. He became angry because she was playing the radio too loudly. He hit Susan with a belt and demanded that she stay in her room. She felt devastated by the harsh discipline of her father and thought that it would be best for her to die. She remembered that she had heard her mother talk about wanting to kill herself, especially after arguments with her father. Susan knew that her mother was depressed and identified with her mother's sadness. She quietly left her room, hoping that her father would not hear her, and went to the medicine cabinet where her mother's medication was kept. She took the 10 pills that were in the bottle and returned to her room. Approximately 1 hour later, her mother returned. She was told by her husband how poorly Susan had behaved and how he had sent her to her room. Susan's mother felt concerned and went to speak with Susan. She found Susan in her bed and very drowsy. After attempts to arouse Susan, her mother called the pediatrician, who advised bringing Susan to the emergency department. On the way to the hospital, Susan told her mother that she had taken her mother's medication and felt that she wanted to die. She was admitted to the pediatric intensive care unit for treatment of the overdose.

---

Both illustrations depict serious suicide attempts in children and adolescents. Both youngsters wanted to die and carried out their planned suicide attempts after experiencing intense stresses, depression, anger, rejection, and criticism. Each youngster could have died if he or she had not been discovered in the process of carrying out the act.

## ETIOLOGY AND PATHOGENESIS

Suicidal behavior is a complex symptom that is influenced by sociocultural factors and by the presence of psychiatric symptoms and psychiatric disorders, stressful life events, and problems in social adjustment. To conceptualize better the components of youth suicidal behavior, a multiaxial approach, similar to that of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) classification for psychiatric disorders, may be used as a model of integrating the multifocal attributes associated with suicidal behavior in children and adolescents. Notwithstanding the fact that suicidal behavior is a symptom and not a psychiatric disorder, the factors involved with the incidence and prevalence of youth suicidal behavior can be outlined in accordance with five axes: (a) primary psychiatric disorders, (b) developmental and personality disorders, (c) biological factors, (d) stress, and (e) social functioning.

An important concern in understanding risk for youth suicidal behavior is that there are few studies of representative community samples of children and adolescents that evaluate the varied manifestations of suicide attempts. Most comparative studies of youth suicide and suicide attempts use psychiatric patients who attempted suicide. As a result, distinctions between suicide and attempted suicide have not been definitively identified. Rather, most studies suggest similarities between youth suicide and suicide attempts.

### Primary Psychiatric Disorders

Studies using psychological autopsy methodology to examine factors associated with youth suicide and cross-sectional research methods with children and adolescents who report suicidal ideation and acts validate the significant correlations of suicidal behavior with mood disorders and disruptive disorders among prepubertal children and adolescents, and the significant relationship of alcohol and substance abuse disorders with suicidal acts in adolescents. The San Diego

Suicide Study (Fowler et al., 1986; Rich et al., 1986) highlighted the comparison of 150 people who committed suicide when older than 30 years of age and 133 who committed suicide when younger. The youth suicide victims had a higher prevalence of drug abuse, noted by the finding that 53% of the younger suicides abused substances. Substance abuse was chronic and prevalent for approximately 9 years among these younger suicide victims. The most frequently abused substances were alcohol, marijuana, and cocaine. The younger suicide victims had a lower prevalence of mood and organic mental disorders. Another psychological autopsy report of 140 adolescent suicide victims and 131 community age- and sex-matched control subjects suggested that psychopathology, especially substance abuse, regardless of whether it was comorbid with mood disorder, distinguished risk for suicide among older versus younger adolescents (Brent et al., 1999). Specifically, this study indicated that adolescents who committed suicide when older than 16 years, compared with those who were younger than 16 years when they committed suicide, had higher prevalence of psychopathology, specifically substance abuse, and higher suicidal intent. This study could not identify why men committed suicide at significantly greater rates than women.

The New York Psychological Autopsy Study (Shaffer, 1988) described psychiatric factors associated with sex differences for 173 youth suicide victims. Using odds ratios, a statistic that defines the likelihood that a given factor will have a specific effect to increase risk for suicide, this study reported that among young men, a history of a suicide attempt (odds ratio = 22.5), presence of major depression (odds ratio = 8.6), and presence of substance abuse (odds ratio = 7.1) were the strongest correlates for adolescent suicide. The strongest correlates for female adolescent suicide were presence of major depression (odds ratio = 49.0) and a history of a suicide attempt (odds ratio = 8.6).

A case-control study (Brent et al., 1993a) comparing 67 adolescents who committed suicide with 67 demographically matched adolescents in the community reported that the presence of major depressive disorder increased risk for suicide by 27 times. Risk was increased nine times by presence of bipolar disorder, 8.5 times by presence of substance abuse, and six times by presence of conduct disorder. Most (82%) of the suicide victims had a mood disorder, and it was notable that when substance abuse coexisted with a mood disorder, there was a 17 times greater risk for suicide. History of previous suicidal thinking or suicide attempts were associated with suicide in this study. Although the suicide rate for young children is low, it has been reported (Hoberman and Garfinkel, 1989) that in a sample of suicide victims involving 21 (3.2%) youth younger than 15 years of age, 208 (31.7%) adolescents, 15 to 19 years of age, and 427 (65.1%) young adults, 20 to 24 years of age, the youngest group had the highest rates of antisocial behavioral, and the adolescents and young adults had higher rates of mood disorders.

Community samples of children and adolescents who attempted suicide have not been sufficiently studied and compared with those who committed suicide. One report of 302 adolescents in the community indicated that of those who made medically serious suicide attempts, approximately 16% had a diagnosis of cannabis abuse or dependence at the time of the suicide attempt, compared with approximately 2% of nonsuicidal adolescents (Beautrais et al., 1999). Other psychiatric disorders comorbid with cannabis abuse or dependence were significant risk factors for suicide attempts. A population-based study of 630 adolescents indicated that for boys, but not for girls, sexual orientation was associated with suicidal intent and suicide attempts (Remafedi et al., 1998). Bisexual and homosexual adolescents had higher risk for suicide attempts. Using data from 1,007 young adults followed for 21 years in the New Zealand Birth Cohort Study, the 2.8% who were classified as being gay, lesbian, or bisexual exhibited greater symptoms of depression, generalized anxiety, conduct disorder, suicidal ideation, and suicide attempts than the other young adults in this longitudinal study (Fergusson et al., 1999). This developmental study clearly suggested that gay, lesbian, and bisexual youth have more extensive psychiatric problems than those without these sexual orientations.

Although studies of children and adolescents who report nonfatal suicidal behavior suggest that mood disorders, particularly major depressive disorder, are significant correlates of suicidal behavior, clear differences between suicidal depressed youth and nonsuicidal depressed youth have not been identified (De-Wilde et al., 1993). In an effort to identify which aspects of major depressive disorder were associated with suicidal behavior, a study of 64 adolescent psychiatric inpatients reported that suicidal ideation or acts were significantly associated with severity of depressed mood, intensity of negative self-evaluation, increased level of hopelessness, poor concentration, and high levels of anhedonia (Robbins and Alessi, 1985). Furthermore, the number of suicide attempts reported was related to intensity of depressed mood, presence of alcohol abuse, heightened negative self-evaluation, and presence of substance abuse. The seriousness of suicidal intent was documented to be associated with increased degree of depressed mood and elevated degrees of negative self-evaluation. Finally, the lethality of suicide attempts was found to be correlated with increased level of depressed mood, elevated negative self-evaluation, intense states of anhedonia, presence of psychomotor agitation, and presence of alcohol or substance abuse.

The findings from another study of 200 adolescent psychiatric inpatients supported the significant correlations of mood disorders and alcohol abuse disorder with suicidal acts. Specifically, this study identified that adolescent boys who had a history of a suicide attempt and alcohol abuse were most likely to report a recent suicide attempt (Pfeffer et al., 1988). In contrast, adolescent girls who were most likely to report a recent suicide attempt had histories of a mood disorder, alcohol abuse, and aggressive behavior. Notably, among adolescent psychiatric inpatients, symptoms of depression and hopelessness accounted for a significant risk of suicide attempts (Dori and Overholser, 1999).

Research with psychiatric patients and youth in the community provided validating information about the significant association of mood disorders and youth suicidal behavior. For example, among child and adolescent psychiatric outpatients with a diagnosis of major depressive disorder, more than 70% reported suicidal ideation or attempts (Myers et al., 1991). Although these suicidal tendencies were recurrent, they did not increase in severity over a 3-year follow-up. Future suicidal tendencies were best predicted by irritability or anger, past history of suicidal thinking or behavior, and older age. Another study used a two-stage approach with self-report surveys and research interviews of 1,542 adolescents, 12 to 14 years of age, who were living in the community (Garrison et al., 1991). Prevalence of moderate to severe suicidal ideation was 4% in boys and 8.7% in girls. Prevalence of suicide attempts was 1.9% in boys and 1.5% in girls. Presence of major depressive disorder imparted an almost seven times greater risk for suicidal ideation and an almost 10 times greater risk for suicide attempts. Another community study interviewed 1,710 older adolescents and reported the significant relation of depression to suicide attempts (Lewinsohn et al., 1993). Furthermore, when the effects of depression were controlled, the greater the number of other risk factors, such as externalizing and internalizing behaviors, lifetime history of psychiatric disorders, school problems, health problems, and gender, the greater the likelihood of reporting a suicide attempt. Aggression, substance abuse, and cigarette smoking were high-risk behaviors noted in community samples. Most studies of community samples use adolescents who attended school. In contrast, when 576 runaway youths were interviewed, 37% reported a history of a suicide attempt (Rotheram-Borus, 1993). Although girls were more likely to have attempted suicide, depression was significantly associated with suicide attempts in boys and girls. These reports substantiate the effects of similar risk factors for suicidal behavior in community and psychiatric patient samples.

Follow-up investigations are important for identifying risk factors for suicidal behavior. In a 5-year follow-up study of 180 consecutively psychiatrically discharged adolescent inpatients, it was observed that approximately 25% of the youths attempted suicide and no one committed suicide in the follow-up period (Goldston et al., 1999). This study pointed out that the first year after discharge was the period of highest risk. The strongest predictor of a suicide attempt was the number of prior suicide attempts. Mood disorder alone was not a predictor of a posthospitalization suicide attempt, but in conjunction with a history of a suicide attempt, mood disorder predicted a future suicide attempt.

### Developmental and Personality Disorders

Although there is evidence that youth with specific developmental disorders that impair their learning skills are at heightened risk for suicidal behavior, research suggests that IQ is not a predictor of youth suicidal behavior. With attention focused on understanding the effects of comorbid psychiatric disorders, it has become apparent that elements related to personality disorders may be significant correlates of youth suicidal behavior. For example, psychiatric symptoms such as impulsivity and intense aggression, which may be indicators for the future development of adult personality disorders such as narcissistic, antisocial, and histrionic personality disorders, have been reported to be positively associated with suicidal behavior in prepubertal children and adolescents. This is illustrated by a psychological autopsy study conducted in Finland (Marttunen et al., 1991) of 53 adolescents who were 13 to 19 years of age when they committed suicide, which highlighted the prevalence of personality disorders. It was reported that 94% had a mental disorder. The most prevalent disorders were mood disorder (51%), alcohol abuse (26%), and personality disorder (32%), especially antisocial personality disorder. A reanalysis of the San Diego Suicide Study suggested strong evidence for high prevalence of comorbidity with depression, substance abuse, and antisocial personality disorder (Rich and Runeson, 1992). Furthermore, 41% of the 133 adolescents in the San Diego Suicide Study had symptoms of a borderline personality disorder. The investigators raise the important question of whether Axis I and Axis II psychiatric disorders are independent in relation to youth suicide.

A report of 453 consecutive Israeli male suicides, 18 to 21 years of age, suggested that an appreciable number (18.6%) had no DSM-III-R Axis I disorders and that approximately 9% had no DSM-III-R Axis II psychopathology (Apter et al., 1993). The most prevalent diagnosis (53.5%) among these suicide victims was major depressive disorder. Notable was the finding that narcissistic or schizoid traits were quite prevalent among youth suicide victims. This report also suggested the importance of focusing on aspects of personality in understanding youth suicidal behavior.

One of the first reports to identify an association between personality disorder and adolescent suicide attempts noted that among 53 adolescent psychiatric inpatients, those with borderline personality disorder had the most frequent and severe suicide attempts (Friedman et al., 1983). In another report, impulsivity and aggression were noted to be associated with suicidal behavior among adolescent psychiatric inpatients (Apter et al., 1998). Higher scores on the subscale of the Kiddie Schedule

for Affective Disorders and Schizophrenia that indicate degree of suicidal tendencies were found for adolescents with conduct disorder than for adolescents with major depressive disorder. It is possible that features of conduct disorder that may predict adult personality disorder may be important links to youth suicidal behavior. Another study reported that adolescent psychiatric inpatients with borderline personality disorder had significant rates of suicidal behavior, specifically among the girls but not among the boys ([Pfeffer et al., 1988](#)).

A study evaluated the prevalence and severity of assaultive behavior, impulsivity, and personality disorders in 37 adolescent psychiatric inpatients who attempted suicide and adolescent psychiatric inpatients without a history of suicidal behavior ([Brent et al., 1993a](#)). Significantly more suicide attempters than nonsuicidal adolescents had symptoms of personality disorder, especially borderline personality disorder. However, no discernible differences were found in prevalence or severity of assaultiveness or impulsivity among the two groups of adolescents.

Although reports of prepubertal suicidal children have not focused on disturbances in personality traits, subgroups of suicidal children have been identified. For example, prepubertal children who report both suicidal and violent behaviors had significant deficits in impulse control ([Pfeffer, 1986](#)). Features of violence, suicidal behavior, and impulsivity may be ingredients for future development of personality disorders. In contrast, a group of prepubertal children were described who were suicidal and not violent. These children were predominantly depressed and had good impulse control. The relationship between indicators of personality disorders and suicidal behavior remains to be identified in this subgroup of suicidal children.

## Biological Factors

Elucidation of biological correlates of suicidal behavior in prepubertal children and adolescents is emerging and appears, in general, to concur with features described for suicidal adults. Positive correlations in adults between suicidal and violent behaviors, impulsivity, and aberrations in neurotransmitter systems, especially those involved with serotonin metabolism and regulation, have been described. [Asberg \(1976\)](#) was the first to report low levels of 5-hydroxyindoleacetic acid (5-HIAA) in cerebrospinal fluid (CSF) of violent suicidal adults. Suicide occurred more frequently among those individuals than among those with higher levels of CSF 5-HIAA. These results were validated in numerous other studies suggesting associations between aberrant serotonin system functioning and  $\alpha_2$ -adrenoceptors in postmortem brain samples, especially frontocortical regions, and low levels of 5-HIAA in CSF samples of suicidal adults. In addition, some studies of suicidal adults report lower levels of homovanillic acid, a dopamine neurotransmitter metabolite, in the CSF of suicidal compared with nonsuicidal adults. Following evidence that brain regions of depressed suicide victims have an altered density of the serotonin 2A (5-HT<sub>2A</sub>) receptors, one study evaluated the allele and genotype frequencies of the 102T/C polymorphism of this serotonin receptor ([Du et al., 2000](#)). This study suggested a significant association between suicidal ideation in adults with major depressive disorder and the 102C allele in the 5-HT<sub>2A</sub> receptor gene.

Research using similar complex methods to study youth is underway. At the 1995 annual meeting of the Society for Biological Psychiatry, Greenhill reported preliminary results of a study of suicidal adolescent psychiatric inpatients with a diagnosis of conduct disorder that found low levels of CSF 5-HIAA in these adolescents. A report of peripheral plasma markers suggested that platelet imipramine binding may be lower in depressed prepubertal children and adolescents with a history of suicidal behavior than among youth with no history of suicidal behavior ([Ambrosini et al., 1992](#)).

Studies of other peripheral markers have suggested significant correlations with suicidal behavior. [Pfeffer and colleagues \(1998a\)](#) were among the first to report the relationship between suicidal behavior in prepubertal children and peripheral serotonin markers. This study of 75 prepubertal psychiatric inpatients and 35 prepubertal, nonsuicidal, community control subjects indicated that whole-blood tryptophan content was significantly lower among inpatient children with a recent suicide attempt than among the nonsuicidal children or the inpatients with suicidal ideation. Furthermore, psychiatric inpatient children with a mood disorder had a significantly higher platelet serotonin content than inpatients without a mood disorder. Another study of nine adolescent psychiatric inpatients with a history of repeated suicide attempts and 10 adolescent psychiatric inpatients without suicide attempts indicated that the suicide attempter adolescents had significantly lower platelet benzodiazepine receptor densities than the non-suicide attempter adolescents ([Soreni et al., 1999](#)). This result was similar to that in adults with generalized anxiety disorder and posttraumatic stress disorder.

Neuroendocrine functioning, especially hypothalamic–pituitary–adrenal (HPA) axis functioning, which is a system associated with stress responses, has been studied regarding associations with suicidal behavior. Elevated levels of plasma cortisol were identified as associated with suicidal behavior in adults. Some reports for youth indicate a possible role for excessive HPA function among suicidal youth. For example, it was reported that an elevated level of plasma cortisol during the dexamethasone suppression test occurred among suicidal compared with nonsuicidal prepubertal child psychiatric inpatients ([Pfeffer et al., 1991b](#)). It also was reported that adolescents who reported suicide attempts during an episode of major depressive disorder had elevated levels of plasma cortisol before sleep onset ([Dahl et al., 1990](#)). This was not observed for adolescents with major depressive disorder who did not have a history of a recent suicide attempt. The role of HPA activity, especially as a potential indicator of response to stress, in the risk of youth suicidal behavior requires additional research.

Approaches using chronobiological methods have yielded important information on the biological correlates of youth suicidal behavior. For example, unlike prepubertal children, adolescents with major depressive disorder who reported a recent suicide attempt had aberrations in sleep architecture before the onset of sleep, compared with no aberrations among depressed adolescents with no history of suicidal behavior ([Dahl et al., 1990](#)). Follow-up assessments of neuroendocrine functioning in depressed adolescents suggest that sleep-related growth hormone secretion may predict future episodes of major depression and suicide attempts. Specifically, a prospective study of 34 depressed and 43 nondepressed adolescents who were followed up in young adulthood suggested that adolescents with at least one episode of major depression during the follow-up and who exhibited at least one suicide attempt secreted significantly more growth hormone during the first 4 hours of sleep ([Coplan et al., 2000](#)).

## Stress

Extensive research results suggest the significant relationship between youth suicidal behavior and stressful life events. Prepubertal children who reported suicidal ideation or suicide attempts had higher rates of cumulative stressful life events than nonsuicidal prepubertal children. The varied types of stressful events include deaths and separations of relatives, births of siblings, illness, hospitalization, and multiple family moves. Similarly, adolescent suicide attempters, compared with depressed nonsuicidal adolescents and normal adolescents, have more lifetime and recent stressful life events.

Family disruptions and discord stemming from excessive arguments and overt violence, loss of relatives due to marital separations or divorce, and problems in family interpersonal relations due to parental psychiatric illness are important aspects of stressful circumstances experienced by suicidal children and adolescents. A comparative psychological autopsy study reported that adolescent suicidal victims, compared with nonsuicidal adolescents, had more exposure to suicidal behavior among relatives or friends ([Shafiq et al., 1985](#)). For example, 60% of the suicide victims, compared with 12% of the nonsuicidal adolescents, had parents or adult relatives with suicidal tendencies. The parents of these suicide victims had more emotional problems and absence from home, and they abused their children more than did parents of nonsuicidal adolescents. This study highlights the importance of identifying youth who may have psychological problems after the suicidal behavior of a relative.

The New York Psychological Autopsy Study reported that a family history of suicide imparted a fivefold greater risk of suicide on adolescent boys and an almost threefold greater risk for suicide on adolescent girls ([Shaffer, 1988](#)). It also was reported that among adolescents who committed suicide and adolescents who reported suicidal ideation or suicide attempts, there was a significantly high prevalence of mood disorders, antisocial personality disorders, and suicide among relatives ([Brent et al., 1988](#)). In one of the first systematic, controlled family studies of prepubertal suicidal children, [Pfeffer et al. \(1994\)](#) reported high rates of suicidal acts, violence, substance abuse, and antisocial personality disorders among first-degree relatives of prepubertal children who reported suicidal ideation or suicide attempts. Family discord also was marked among these suicidal children. Similar results were obtained in a study that followed these prepubertal children into adolescence ([Pfeffer et al., 1998b](#)). It indicated that adolescents who reported a lifetime history of a suicide attempt had higher rates of family discord, suicide attempts of mothers, and parental substance abuse.

Violence, especially physical and sexual abuse, has been described as a strong risk factor for youth suicidal behavior. A report suggested that 159 adolescent suicide attempters evaluated in an urban hospital emergency service, who were compared with a similar number of nonsuicidal adolescents evaluated in the same emergency service, were three to six times more likely to have had contact with the Department of Social Service Registry for suspicion of physical abuse ([Deykin et al., 1985](#)). The Department of Social Service found the estimated proportion of suicide attempts that could be explained by a history of abuse was 12%. This study lends support to the idea that physical abuse is a significant risk factor for youth suicidal behavior. In a community sample of 776 children and adolescents that was followed for 17 years, it was observed that adolescents and young adults with a history of childhood maltreatment were three times more likely to become depressed or attempt suicide ([Brown et al., 1999](#)). Furthermore, the effects of history of sexual abuse conferred an eightfold greater risk for repeated suicide attempts in adolescents and young adults. Among 127 adolescent psychiatric inpatients, a history of childhood abuse was associated with internalizing and externalizing behaviors in suicidal

patients; however, a greater prevalence of internalizing disorders was identified in suicidal adolescents without a history of childhood abuse ( [Grilo et al., 1999](#)).

The effects on risk for suicidal behavior of severe family adversity during childhood, including economic strain, marital disruption, poor parent–child attachment, and exposure to sexual abuse, were highlighted in a 21-year longitudinal study of a community sample of 1,265 children born in New Zealand ( [Fergusson et al., 2000](#)). The effects of these factors on risk for suicidal behavior in late adolescence and young adulthood were mediated by mental health problems and stressful events in adolescence. The strong effects of child maltreatment were highlighted among 335 African-American women who were psychiatric inpatients ( [Thompson et al., 2000](#)). History of physical or sexual abuse, emotional abuse, and emotional and physical neglect combined with a current diagnosis of posttraumatic stress disorder significantly increased the risk for suicide attempts.

Another facet of family disturbance was reported using a follow-back research design to study the relation between prenatal, birth, and neonatal factors and youth suicidal behavior ( [Salk et al., 1985](#)). Fifty-six factors in the prenatal, birth, and neonatal records of 52 adolescents who committed suicide and records of a similar number of matched nonsuicidal control subjects were studied. Respiratory distress for more than an hour after birth, no antenatal care before 20 weeks of pregnancy, and chronic physical disease of the mother differentiated those who committed suicide from those who did not. An implication of this study is that early stress may enhance vulnerability to suicide, especially among adolescents who have a history of severe stress or psychopathology during adolescence. However, the mechanisms leading to such vulnerability require identification.

## **Social Functioning**

Problems with social adjustment involving interpersonal relations with family, peers, and others are important characteristics of suicidal children and adolescents ( [Pfeffer, 1986](#)). Poor social adjustment among suicidal youth is apparent even after a child or adolescent no longer reports suicidal tendencies. This feature, in large measure, accounts for the long-term vulnerability of children and adolescents to suicidal acts.

Social adjustment in children and adolescents is influenced by presence of adequate social supports and predictability of the environmental milieu, especially regarding relationships with parents, siblings, and other helpful adults and peers. Suicidal children and adolescents frequently lack available empathic individuals who could offer guidance and an avenue for the child or adolescent to vent distressing ideas and feelings. An unpredictable social support network combined with a suicidal youth's perceptions of inadequacies in mobilizing social support intensify the suicidal youngster's sense of isolation, anxiety, poor self-esteem, rejection, and hopelessness. Perceived hopelessness is among the significant factors that intensify suicidal risk for youth. Hopeless feelings frequently impair a suicidal youngster's ability to remain motivated to solve problems and cope with adversity.

Specific styles of coping among suicidal children and adolescents limit their flexibility and resourcefulness in coping with intense emotions and in problem solving ( [Pfeffer, 1986](#); [Schwartz et al., 2000](#)). When prepubertal suicidal children encounter ambiguities or difficulties in interpersonal situations, they lack skills to respond with beneficial actions that solve their dilemmas. Rather, suicidal children and adolescents characteristically respond either impulsively or tend to withdraw into states of paralytic rumination or fantasy. Ego mechanisms of defense, empirically studied among suicidal children and adolescents, involve denial of affects or events ( [Pfeffer, 1986](#)). This may account for observations suggesting that suicidal youths' reality testing may be impaired. Another ego defense mechanism is reaction formation, which operates to modify painful affects and distressing thoughts by turning their perception into perception of the opposite. Compensation, another ego defense mechanism among suicidal children, involves risk-taking behavior or overt exaggeration of one's skills. This defense defuses a youngster's sense of inadequacy. Suicidal adolescents also cope by involving specific ego mechanisms that are similar to those observed for suicidal preadolescents. In general, suicidal adolescents turn feelings against themselves, especially aggressive impulses. They also use aspects of reaction formation. These styles of coping are among the important factors that compromise suicidal children and adolescents in maintaining adequate levels of social relatedness. Combined with this, social functioning of suicidal children and adolescents also is impaired by life in an inadequate or unpredictable social milieu.

The role of cultural affiliation rather than ethnic identity as a risk factor for suicidal behavior is an important issue requiring extensive research. To illustrate this, varying rates of suicide within ethnic groups have been observed. A community study of 3,094 Native Hawaiian adolescents indicated that stronger cultural affiliation rather than ethnicity was significantly predictive of adolescent suicide attempts ( [Yuen et al., 2000](#)). Similar concerns have been observed for African Americans, in whom increased suicide rates may be related to migration, cultural affiliation, and changing social supports.

## **LABORATORY STUDIES**

### **Biological Assessment**

There is no distinct biological test to measure risk for youth suicidal behavior. The most fruitful areas of clinical investigation lay in understanding the relation between alterations in serotonin metabolites and neuroendocrine functions and risk for suicidal behavior. However, practical applications have not been determined.

### **Psychological Assessments**

Assessment of youth suicidal behavior involves comprehensive interviews with a suicidal youngster and the parents. Significant issues for assessment are the presence of current and past suicide intent, which involves the balance between the wish to live and the wish to die. It includes appraisal of past and current suicidal ideation and suicide attempts, accessibility of suicidal methods, and underlying risk factors, such as psychopathology, cognitive distortions (e.g., hopelessness), problematic coping styles involving impulsive behavior, and environmental stress factors. Assessment of a suicide attempt should focus on the type of method used, its potential for lethality, the degree of planning, and the likelihood that discovery of the act is possible. These assessments are complicated, especially when interviewing prepubertal children about their suicidal ideation and acts ( [Jacobsen et al., 1994](#)). Some of the aspects that influence the information obtained in a clinical interview are the child's cognitive and emotional state and the degree of parental psychopathology. It is important that clinical interviews be conducted at the time of maximum suicidal risk and repeated subsequently until the risk of suicidal behavior is diminished. The most important aspect of the assessment is to determine the degree of immediate danger for a youngster. If a youngster's situation is unpredictable, consideration of emergency psychiatric hospitalization is warranted.

Essential to the evaluation is to determine the current psychological status of a youngster with respect to type and degree of psychopathology and degree and quality of coping mechanisms, such as adequacy of judgment, degree of impulse control, intensity of hopelessness and helplessness, and ability to communicate. An important clue for an impending suicide attempt is preoccupation with death ( [Gothelf et al., 1998](#)). A youngster may be at lower risk for suicidal acts if he or she has good judgment, high impulse control; low levels of hopelessness and helplessness; and ability to communicate openly and honestly about feelings, worries, and thoughts of suicide. However, it must be appreciated that the status of these variables may change rapidly, so that repeated, comprehensive discussion with a suicidal youngster is necessary.

Assessment of family and environmental conditions is essential. It is important to determine whether a family can provide a consistent, stable environment or whether there is high degree of stress, violence, and psychopathology, as well as unavailability of relatives. Positive social supports are critical in diminishing suicidal risk among children and adolescents ( [Wagner et al., 2000](#)). If an environment does not provide sufficient beneficial social supports, a potentially suicidal child or adolescent needs to be removed from such an environment and placed in a situation, such as a psychiatric hospital, that promotes psychological growth and deters suicidal tendencies.

Clinical assessment may be aided by the use of specialized rating scales that measure suicidal risk factors. A recently developed, reliable and valid screening measurement is the Child-Adolescent Suicidal Potential Index (CASPI), which involves 30 items answered in a yes-no format ( [Pfeffer et al., 2000a](#)). The total score provides an estimate of suicidal risk. Another method involving nonverbal assessment of children and adolescents is the use of human figure drawings ( [Zalsman et al., 2000](#)). All such screening measures should be used in conjunction with in-person interviews to evaluate if the screening risk assessment is valid.

## **DIFFERENTIAL DIAGNOSIS**

The two most significant issues in a differential diagnosis of youth suicidal behavior are to identify whether the destructive act is self-intended rather than accidental, and to identify whether there is a high or low level of risk that an injury will occur. The first issue is a qualitative issue and involves a systematic assessment of intent and the specific circumstances in which a self-destructive act occurred. The second issue is a quantitative one and involves a comprehensive evaluation of the intensity of and interactions among risk factors. Psychiatric issues to be considered are the severity of depressive symptoms, presence of hypomania or manic symptoms, and mixed or rapid cycling states of manic or depressive symptoms. Other symptoms to consider are the severity of irritability, agitation, delusional symptoms, and other psychotic symptoms, including poor reality testing and hallucinations. These issues often are difficult to define distinctly. It is more helpful, in

situations where a definite conclusion cannot be made, to consider a youngster to be suicidal and at significant risk rather than to minimize the clinical condition. By using this approach, a plan for treatment may be conceptualized and implemented rapidly.

## TREATMENT

The most salient acute issue in treatment is to decrease the likelihood that self-inflicted injury or death could occur. Availability of psychiatric services involving outpatient and emergency services and inpatient or residential programs is important in lowering suicidal risk. Psychiatric hospitalization may be recommended if observation and intensive therapeutic intervention are warranted when a child or adolescent manifests an unpredictable condition. The hospital offers an environment with structure and a consistent, high-availability of staff to provide immediate, around-the-clock interventions. Hospitalization also is a way of removing a youngster from an environment that may be too stressful or disorganized. In contrast, outpatient or partial hospitalization should be used when the child or adolescent is not imminently likely to carry out a suicidal act or if there is sufficient family support to identify and respond to a suicidal crisis.

Emergency treatment involves certain principles that should be consistently followed. A suicidal child or adolescent should not be discharged from an emergency service without verification of the patient's clinical condition with the parent and discussion of making unavailable such lethal methods as guns, firearms, or medications ([Kruesi et al., 1999](#); [McManus, et al., 1997](#)) and limiting access to alcohol or drugs. The family's experience with the emergency service staff will affect compliance with future treatments ([Rotheram-Borus et al., 1996](#)).

Psychotherapeutic intervention involves developing a trusting atmosphere for truthful communication. It is essential that a therapist maintain an empathic but objective concept of a suicidal youngster. A therapist's collusion with the perceptions of despair, misery, or hostility of a suicidal child or adolescent impairs treatment progress. Discussion that may elucidate the operation of new and effective coping strategies is essential. This can be achieved by incorporating a cognitive orientation into the treatment process.

Delineation of the motivations for a suicidal act is an important feature of treatment. Such motivations may be conscious or outside the immediate awareness of a suicidal youth. Common motives for enacting suicidal behavior involve despair over loss of a special person such as a breakup with a boyfriend or girlfriend or separation of parents. These situations often are characterized by intense guilt on the youngster's part, who thinks he or she may have caused the loss. Other motivations involve anger or feelings of revenge in response to frustrations, deprivations, or perceived wrongdoing. Often a youngster impulsively threatens suicide in an effort to instill guilt in those who are closely involved in the youngster's life situation. Another motivation is based on psychotic functioning. Some psychotic youngsters feel so demoralized and in such psychic pain that they wish to relieve themselves of the pain by committing suicide. Such a response may be impulsive and occur without warning.

Treatment of suicidal children and adolescents is complex and often requires simultaneous use of multiple modalities. In addition to dynamic, supportive, and cognitive psychotherapy, psychopharmacologic modalities may be indicated. There are no controlled studies of treatment of suicidal children and adolescents, although initial efforts are now underway to develop and study controlled treatment conditions for factors that increase suicidal risk. For example, cognitive-behavioral therapy for depressed adolescents has been more effective than family or supportive therapy ([Brent et al., 1997](#)). However, 2 years after the treatment, there were no differences in outcomes with cognitive-behavioral, family, or supportive treatment ([Birmaher et al., 2000](#)). Interpersonal therapy, which addresses interpersonal conflicts involving loss, interpersonal role disputes, role transitions, and interpersonal deficits, has been found to be more effective for depressed adolescents than a control treatment ([Mufson et al., 1999](#)). This treatment may be helpful for depressed suicidal adolescents with interpersonal conflicts. However, its efficacy with suicidal adolescents has not been studied. Dialectical-behavioral therapy is the only psychotherapy that has been effective in reducing suicidal behavior in adults ([Linehan, 1993](#)). This treatment requires investigation with suicidal adolescents. Family therapy may be useful to decrease family discord and enhance effective family problem solving and conflict resolution. A home-based family intervention with a time-limited framework was found to have limited efficacy for children and adolescents who did not have a major depressive disorder ([Harrington et al., 1998](#)).

Studies of the efficacy of psychopharmacologic treatment of suicidal children and adolescents are needed. Lithium has been found to decrease by almost ninefold the recurrence of suicide attempts in adults with major depression or bipolar disorder ([Tondo et al., 1997](#)). Discontinuation of lithium was associated with a sevenfold increase in suicide attempts and a ninefold increase in rates of suicide ([Tondo et al., 1997](#)). Use of lithium with suicidal children or adolescents requires careful monitoring by a responsible adult because an overdose may be lethal. Other mood stabilizers also may be effective, but studies to demonstrate this are needed. In addition, antidepressants such as selective serotonin reuptake inhibitors may be promising for treating suicidal children and adolescents. Although the efficacy of fluoxetine, which is one of this class of medications, has been demonstrated in depressed children and adolescents ([Emslie et al., 1997](#)), such medications have not been demonstrated to be effective specifically for suicidal children or adolescents. Use of such medications requires consistent and detailed monitoring for possible activation that may be associated with suicidal risk.

Psychopharmacologic treatment to reduce the risk of underlying conditions associated with suicidal behavior involves use of various medications specific to the diagnosis or symptomatology. Caution in use of medications that may disinhibit some children and adolescents, such as psychostimulants, benzodiazepines, or phenobarbital, is required.

Treatment of parents and other relatives may be indicated, especially if such people have a direct influence on a suicidal youngster, and if they have impairing symptoms of psychopathology that contribute to the adverse family milieu. Parental marriage counseling, individual psychotherapy, or focused psychopharmacotherapy may be required for certain relatives. Detailed assessment and treatment of psychiatric symptoms and disorders of family members is necessary to promote a stable atmosphere for the youngster.

Collaborative efforts with other professionals who are involved with a youngster must be organized. For example, it may be essential to consult with the school psychologist or guidance counselor, who may speak with a youngster during school hours. Collaboration with the school may help stabilize a youngster in the school and community environment.

## APPROACHES FOR PREVENTION OF YOUTH SUICIDAL BEHAVIOR

Although rates of suicide among youth in the United States are high, the development of suicide prevention strategies can be inferred by the results of prospective studies of youth suicidal behavior. For example, it is evident from prospective research that prepubertal children and adolescents who report suicide attempts are at significant risk for recurrent suicidal acts ([Pfeffer et al., 1991a, 1993](#)). Prepubertal psychiatric inpatients who attempted suicide are six times more likely to attempt suicide in adolescence than are children in the general community. Prepubertal psychiatric inpatients who report thoughts of suicide are at a fourfold higher risk for attempting suicide within less than 10 years than children in the general community. Adolescent psychiatric inpatients who attempt suicide are at significant risk for a repeat suicide attempt within 6 months of follow-up ([Brent et al., 1993b](#)), and for suicide in less than 10 years ([Pfeffer, 1986](#)). The data on suicidal children and adolescents also are supported by studies showing that prepubertal children who have a major depressive disorder are at risk for suicide attempts in adolescence ([Kovacs et al., 1993](#)) and suicide in young adulthood ([Rao et al., 1993](#)). Suicide prevention efforts should focus on identifying such high-risk children and adolescents and monitoring them repeatedly for early signs of risk for a suicidal act. An important issue is to develop community case-finding approaches by means of screening procedures and referral of those children and adolescents found to be at risk for suicidal behavior. Educating mental health, medical, and school professionals, clergy, and others who are in contact with children and adolescents to identify children and adolescents at risk for suicidal behavior is an important suicide prevention strategy.

Efforts to prevent youth suicidal behavior require public health model strategies in school settings. These may focus on encouraging adolescents to seek help if they recognize symptoms of suicidal risk. New approaches to this are required because evaluations of prior school programs concluded that their efficacy was not adequate to prevent suicide, change adolescents' attitudes about suicide, or enhance help-seeking behavior. Some reports suggested that adolescents who had a history of suicidal behavior were especially upset and had negative feelings about suicide prevention curricula ([Shaffer et al., 1991](#)).

Clusters of youth suicide, notable during the early 1980s in the United States, became phenomena of intensive research investigation ([Gould and Shaffer, 1986](#), [Hafner and Schmidtke, 1989](#); [Phillips and Carstensen, 1986](#)). It became apparent that factors promoting youth suicide clusters involved imitation of suicidal acts. Clusters were defined as incidents of youth suicide that occurred either in the same defined period or the same defined location. Complex research methods determined that there was a significant increase in adolescent suicide within 2 weeks after media presentations of stories of actual or fictional youth suicide. Guidelines for media coverage have been developed and may be useful in decreasing risk for suicide after media presentations ([Gould and Kramer, 1999](#)).

Another aspect of the problem of imitation of youth suicide involved developing methods for communities to respond to a youth suicidal death so that risk for other

youth suicidal acts is lessened. Guidelines were established that included organizing community networks consisting of school professionals, mental health professionals, police, religious leaders, and parents to be available to respond to the community crises of a youth suicide. Organized liaison approaches with the media are essential to promote helpful media coverage of the event and to prevent confusion, fear, and risk for other youth suicidal acts stimulated by the presence of news reporters and presentations of the story of a youth suicide. Focus on other vulnerable youngsters is another aspect of responding to the crisis of a youth suicide. Discussions with friends and acquaintances of the adolescent who committed suicide are helpful. Research suggests that risk for suicidal behavior may be low among friends and acquaintances of an adolescent suicide victim within 6 months of the suicidal death ( [Brent et al., 1992](#); [Hazell et al., 1993](#)). However, the risk for development of a major depressive disorder and posttraumatic stress disorder is high among such friends and acquaintances.

Suicidal behavior involves a legacy that runs in families. Prepubertal children who report suicidal ideation and suicide attempts have higher rates of suicidal acts among first-degree relatives than nonsuicidal children ( [Pfeffer et al., 1994](#)). Research has identified that psychiatric morbidity is significantly greater for children and adolescents who suffered the suicide of a parent or other close relative ( [Cerel et al., 1999, 2000](#); [Pfeffer et al., 1997, 2000b](#)). Programs are needed to identify such bereaved children and adolescents and to offer them targeted intervention to prevent adverse outcomes resulting from the sequelae of a suicide in the family.

Finally, strong evidence suggests that availability of guns and firearms is significantly associated with youth suicide risk ( [Shah et al., 2000](#)). Intense efforts to prevent youth suicide require a national focus to advocate for better restrictions on the availability of guns and firearms, especially to children and adolescents. Furthermore, clinical assessments of suicidal risk among children and adolescents should incorporate inquiry about the presence of such lethal weapons in the home or whether there are other avenues for access to a gun or firearm. Decreasing such accessibility is an important suicide prevention action.

## CONCLUSION

Knowledge about risk for youth suicidal behavior has expanded. As we enter the new millennium, future efforts to investigate suicidal behavior should use new research methodologies that may lead to identification of the interactions between environmental factors and constitutional and biological factors that are associated with risk for suicidal behavior. Such studies may be relevant for developing effective treatment strategies to lower the risk for youth suicidal behavior. Research is needed to understand sociocultural factors involving risk and protective factors for youth suicidal behavior. Such research, when combined with research that focuses on biological factors or psychiatric phenomenology, may be helpful in reducing rates of suicidal behavior among youth.

Depression is a common disorder with a chronic, episodic course marked by frequent recurrence, considerable impairment, and substantial health care costs (Birmaher et al., 1996a,b). According to a study of global mortality and disability associated with 107 disorders, depression ranked fourth in terms of its disease burden (Murray and Lopez, 1997). Although the prevalence of depression is low in prepubertal children (Fleming and Offord, 1990), the rates increase substantially during adolescence (Hankin et al., 1998). The point prevalence of childhood depression is between 1% to 2%, and adolescent depression is estimated at between 4% to 8%, with the average episode lasting between 6 to 8 months (Fleming and Offord, 1990; Kovacs, 1996; Lewinsohn et al., 1993, 1994a). An estimated 20% of adolescents will have a depressive episode by 18 years of age (Lewinsohn et al., 1993). Depression is recurrent, with as many as 40% of children and adolescents experiencing a second episode within 2 years, and nearly 75% within 5 years (Kovacs et al., 1984a,b; Lewinsohn et al., 1994a). Most will experience another episode in their adult life (Kandel and Davies, 1986; Rao et al., 1995), and most cases of recurrent adult depression had their initial onsets during adolescence (Pine et al., 1998). Finally, depression is associated with substantial impairment both during and after the episode, with difficulties in school, interpersonal relationships, occupational adjustment, tobacco and substance abuse, suicide attempts, and a 30-fold increased risk of completed suicide (Birmaher et al., 1996a; Brent et al., 1988a, 1993; Harrington et al., 1990; Riggs et al., 1995; Rohde et al., 1994). Thus, depression is an important public health problem that should be the focus of prevention efforts early in development.

Several reviews of the prevalence, course, outcome, etiology, and treatment of child and adolescent depression and suicide are available (e.g., Birmaher et al., 1996a, 1986b; Garber and Flynn, 2001; Hammen and Rudolph, 1996; and see Chapter 62, this volume). The purpose of this chapter is to describe programs for preventing depression and suicide that target children and adolescents and to review the empirical studies examining their efficacy. [For reviews of prevention of depression in adults, see Gillham et al. (2000) and Munoz (1993)].

### TREATMENT VERSUS PREVENTION

Prevention of mental health problems is important for several reasons. First, the cost of disorder to the individual and society in terms of personal suffering and lost productivity can be extensive. Second, in the long run, prevention may be more cost effective than continued treatment. Third, it is likely that over time there will not be enough mental health professionals available to treat all those individuals in need of services at any given time. (Coie et al., 2000). Thus, services for the prevention of mental health disorders are needed in addition to treatment.

Whereas treatment is concerned with the reduction of symptoms in individuals already manifesting a disorder, prevention is defined as lowering the risk of the onset of new cases of a disorder. With regard to depression, which tends to be episodic, prevention also can involve reducing the recurrence of symptoms after an episode has remitted (Compas et al., 1997; Munoz, 1993). That is, depressed individuals who return to normal functioning become "new cases" if they experience a future episode of clinical depression, and therefore also are candidates for preventive interventions.

Although efficacious psychosocial and pharmacologic treatments for adolescent depression have been demonstrated (Kaslow and Thompson, 1998), any single approach helps only approximately 50% to 60% of those treated (Brent et al., 1997; Emslie et al., 1997). Moreover, chronicity, comorbidity, and parental depression all render efficacious treatments less likely to work well (Birmaher et al., 2000; Brent et al., 1998; Clarke et al., 1992; Emslie et al., 1998). Therefore, prevention of depression, particularly among high-risk individuals, may be more cost effective than waiting for the condition to appear and then trying to treat a full-blown depressive episode. The question is not whether prevention is more or less important than treatment; rather, both prevention and treatment may be appropriate, depending on the particular goals of the researchers and clinicians. "Diverse intervention efforts and a broad portfolio of approaches are central to adolescent mental health" (Kazdin, 1993, p. 136).

### PREVENTION SCIENCE

Because the old distinctions among primary, secondary, and tertiary prevention (Felner et al., 1983) are now considered ambiguous, they have been abandoned. For example, secondary prevention referred to early intervention for new cases as well as interventions for individuals with high levels of symptoms but who did not yet meet criteria for a clinical disorder. The Institute of Medicine (IOM) Report (Mrazek and Haggerty, 1994; Munoz et al., 1996) adopted Gordon's (1983) distinction among three types of prevention. *Universal* preventive interventions target entire groups or populations that have not been selected on the basis of risk. *Selective* preventive interventions target individuals with elevated risk for the disorder. *Indicated* preventive interventions target high-risk individuals who display some early precursor signs of the disorder or symptoms predicting the disorder. Targeted prevention includes both selective and indicated interventions and has been contrasted with universal prevention (e.g., Offord, 1996). Whereas universal interventions that lead to small effects in large numbers of people may have enormous benefits for society (Offord, 1996; Offord et al., 1998), targeted prevention may be more efficient, leading to greater prevention effects for each individual involved.

The science of preventive intervention research involves the careful study of the identification and epidemiology of disorders, etiology, risk, and protective factors, the design and implementation of controlled preventive intervention trials with random assignment and extensive follow-up, and the examination of the generalizability of these interventions in real-world community settings (Coie et al., 1993). The IOM (Mrazek and Haggerty, 1994) suggested that the preventive intervention research cycle is a recursive process in which the results of clinical and field trials are used to inform more basic science concerned with etiology and mechanisms of risk.

### RISK FOR DEPRESSION

Although affective disorders represent a significant psychiatric problem for the general adolescent population, specific subgroups are particularly vulnerable to development of mood disorders and associated problems (e.g., suicide, social isolation). The IOM committee recommended that a risk reduction approach should be taken. This involves targeting populations with elevated levels of known risk factors, reducing risk factors that are malleable, and increasing protective factors such as problem-solving skills, interpersonal relationships, and social support (Beardslee and Podorefsky, 1988; Compas et al., 1997; Petersen et al., 1997). Risk factors that consistently have been found to be associated with mood disorders include being the offspring of a depressed parent, having subsyndromal depressive symptoms, having a personal history of a mood disorder, comorbid disorders, or family dysfunction, and being female (e.g., Brady and Kendall, 1992; Goodman and Gotlib, 1998; Pine et al., 1998; Reinherz et al., 1993). A complete review of all of these risk factors is beyond the scope of this chapter (e.g., Garber and Flynn, 2001; Hammen, 2001; see Chapter 62, this volume); rather, we highlight some of the most likely vulnerability factors for depression during childhood and adolescence.

First, parental depression is one of the strongest risk factors for depression in children ( [Beardslee et al., 1998](#); [Goodman and Gotlib, 1998](#); [Kaslow et al., 1994](#)). Numerous studies have shown that offspring of affectively ill parents are at risk for psychopathology, with the most frequent diagnosis being mood disorders ([Beardslee et al., 1988](#); [Hammen, 1991](#); [Orvaschel et al., 1988](#); [Radke-Yarrow, 1998](#); [Weissman et al., 1987](#)). A meta-analysis showed that offspring of parents with affective disorders are approximately four times more likely to have a mood disorder than are children of nondepressed parents ( [Lavoie and Hodgins, 1994](#)). Life-table estimates suggest that by the age of 20 years, a child with an affectively ill parent has a 40% chance of having an episode of depression, and by 25 years of age this rate increases to 60% ([Beardslee et al., 1993a](#)). Offspring of depressed parents also are at increased risk for high levels of medical utilization, behavior and school problems, suicide attempts, and substance abuse disorders ([Hammen et al., 1990](#); [Kramer et al., 1998](#); [Weissman et al., 1987](#)). In addition, the risk for offspring depression is greater if the parent had an early-onset or recurrent depressive episodes, and if both parents have experienced depressive disorders ( [Warner et al., 1992](#); [Weissman et al., 1987, 1992](#)). Current parental depression also appears to affect the course of adolescent depression, through slower recovery, lower levels of functioning, and poorer response to cognitive interventions ( [Brent et al., 1998](#); [Hammen, 1991](#); [Keller et al., 1986](#); [Weissman et al., 1992](#)). Thus, children of parents with affective disorders are at great risk for psychiatric disorders, especially depression, and therefore, they are a logical and critical population to target for prevention.

Second, one of the strongest predictors of depressive disorders is prior depressive symptoms. [Compas et al. \(1993\)](#) suggested that depressed mood may be a marker of risk for subsequent depressive syndromes. Subsyndromal levels of depressive symptoms significantly increase the risk of having a full major depressive episode in adults ([Horwath et al., 1992](#); [Judd et al., 1997](#)) and adolescents ([Clarke et al., 1995, 2001](#); [Lewinsohn et al., 1999](#); [Pine et al., 1999](#); [Rueter et al., 1999](#)). [Pine et al. \(1999\)](#) reported that having depressive symptoms during adolescence predicted a twofold to threefold greater risk of an episode of major depression in adulthood. [Brent et al. \(2001\)](#) found that adolescents with depression who only partially recovered still had subsyndromal depression and functional impairment, and were at significantly greater risk for recurrence compared with those who recovered fully from their depression. Subsyndromal levels of depression also can have a negative impact on academic/occupational and interpersonal functioning ( [Wells et al., 1989](#)). Thus, targeting individuals with subsyndromal depression for preventive intervention could not only reduce their risk for development of major depressive disorders, but could ameliorate existing levels of distress and dysfunction ( [Munoz et al., 1994](#)).

Third, a prior history of a depressive disorder also is a significant risk factor for subsequent depressive episodes. Children with mood disorders have recurrent depressive episodes during adolescence ( [Emslie et al., 1997](#); [Kovacs et al., 1984a,b](#)) and adulthood ([Garber et al., 1988](#); [Harrington et al., 1990](#); [Weissman et al., 1999](#)), and adolescents have recurrences later in adolescence ( [Lewinsohn et al., 1994b](#); [McCauley et al., 1993](#)) and into adulthood ([Lewinsohn et al., 1999](#); [Rao et al., 1999](#); [Weissman et al., 1999](#)). Recurrence rates have ranged from 45% to 72% over 3 to 7 years ( [Emslie et al., 1997](#); [Harrington et al., 1990](#); [Kovacs et al., 1984b](#); [Lewinsohn et al., 1999](#); [McCauley et al., 1993](#)). Such recurrent episodes are associated with negative functional outcomes in school, work, and interpersonal relationships ([Rao et al., 1999](#)). Moreover, the longer depressive episodes last, the more difficult they are to treat ( [Judd et al., 1998](#); [Thase and Howland, 1994](#)). Preventive interventions may reduce the risk for subsequent episodes of depression as well.

Finally, several other risk factors are known to be associated with the onset of depression, including female sex, negative cognitions, dysfunctional family environments, and comorbidity. The risk of onset increases in girls relative to boys starting during adolescence ( [Hankin et al., 1998](#); [Nolen-Hoeksema and Girgus, 1994](#)). Negative cognitions about the self and future have been found to predict changes in depressive symptoms in children, adolescents, and adults (e.g., [Metalsky et al., 1993](#); [Nolen-Hoeksema et al., 1992](#); [Robinson et al., 1995](#)). Family environments characterized by high levels of discord, criticism, and lack of involvement and supervision increase the risk of depression onset and recurrence, and interfere with recovery ( [Asarnow et al., 1993](#); [Birmaher et al., 2000](#); [Garber et al., 2001](#); [Kaslow et al., 1994](#); [Weissman et al., 1992](#)), and also may predict the occurrence of comorbid conditions such as disruptive disorders and substance abuse ( [Blum, 1987](#); [Fendrich et al., 1990](#)). Finally, comorbid conditions such as anxiety and disruptive disorders are associated with the onset of depression and interfere with the course of recovery from depression ( [Brady and Kendall, 1992](#); [Brent et al., 2001](#); [Hamilton and Bridge, 1999](#); [Reinherz et al., 1993](#); [Sanford et al., 1995](#)).

Identifying factors that are associated with the onset and recurrence of mood disorders, of course, does not necessarily mean that these variables play a causal role in the development of the disorder. Nevertheless, it makes sense to use these factors to help identify individuals who are at the greatest risk for the disorder, and therefore should be the focus of prevention efforts. Moreover, these risk factors also can provide some guidance about the nature of the preventive intervention that might be needed. For example, if the presence of negative cognitions presumably is a risk for the development of depression, then preventions that aim to alter such cognitive styles should reduce the occurrence of depressive symptoms.

## PROGRAMS FOR THE PREVENTION OF DEPRESSION IN CHILDREN AND ADOLESCENTS

Despite the declaration in 1984 that "In general, the onset of clinical depression cannot be prevented" ( [Lobel and Hirshfeld, 1984](#), p. 4), some evidence now exists that psychosocial interventions can reduce the occurrence of depression in youth. Three different groups of investigators have developed programs to prevent depression in children and adolescents ( [Beardslee et al., 1993b](#); [Clarke et al., 1995, 2001](#); [Seligman, 1998](#)). These programs vary with regard to the participant ages, targeted risk factors, and sample selection. Nevertheless, they each have shown some positive preventive effects.

### Clarke's Cognitive-Behavioral Group Preventive Intervention

Clarke and colleagues have developed a cognitive-behavioral intervention for the prevention of depression in adolescents, which is based on the Coping with Depression for Adolescents (CWDA) course used effectively to treat depression in adolescents ( [Clarke et al., 1999](#); [Lewinsohn et al., 1990](#)). This cognitive intervention is derived from the theoretical model of [Lewinsohn et al. \(1985\)](#) and includes many features of [Beck's \(1976\)](#) cognitive therapy. Treatment sessions are conducted in a classlike fashion, with the group leader teaching adolescents methods of controlling their depressed mood through cognitive restructuring techniques. Each adolescent is given a workbook ([Clarke et al., 1990](#)) that contains brief readings, structured learning tasks, short quizzes, and forms for homework assignments. Because it is presented as a class rather than therapy, the Coping with Stress (CWS) course is less stigmatizing than traditional psychotherapy, an issue that is particularly relevant with adolescents.

The intervention approach has been modified from cognitive therapy for depressed adults ( [Beck et al., 1979](#); [Ellis and Harper, 1961](#)) and teaches participants how to identify and challenge negative and unrealistic thoughts. [Clarke et al. \(1990\)](#) simplified these techniques for use with adolescents. Cartoon strips with popular characters (e.g., Garfield the Cat, Bloom County) are used to illustrate both the negative thoughts that contribute to depression, as well as the more realistic counterthoughts that offset the irrational beliefs. Through a series of progressively more advanced exercises, participants are taught how to apply cognitive techniques to their own personal thoughts, with the goal of learning to generate their own, effective counterarguments to unrealistic or excessively negative beliefs.

Using this approach, Clarke and colleagues have conducted a series of prevention studies both in schools and with at-risk offspring of depressed parents. In an early school-based primary prevention program for adolescent depression, [Clarke et al. \(1993\)](#) compared a three-session educational (knowledge-only) intervention in ninth grade health classes (n = 361) to a randomly assigned control condition (n = 261), and found a short-term reduction in depressive symptoms among boys but not girls. However, this effect was not sustained over a 12-week follow-up period. Based on the behavioral model of depression ( [Lewinsohn et al., 1985](#)), a more intensive five-session intervention was developed to train adolescents to increase pleasant activities as a method of preventing depressive symptoms. However, compared with a randomized control group (n = 190), the behavioral intervention adolescents (n = 190) failed to exhibit any persistent reduction in depressive symptomatology ([Clarke et al., 1993](#)).

[Clarke et al. \(1995\)](#) next completed a randomized, controlled trial of a school-based prevention program aimed at reducing the incidence of unipolar affective disorders and symptoms in high school adolescents at risk for depressive disorders by virtue of their having subdiagnostic levels of depressive symptoms, defined as *demoralization* ([Roberts, 1987](#); [Roberts et al., 1990](#)). At-risk ninth grade adolescents were identified by a two-stage screening procedure ( [Kendall et al., 1989](#)) consisting of a schoolwide administration of a self-report screening instrument (Center for Epidemiological Studies-Depression Scale (CES-D), followed by a confirmatory structured diagnostic interview (the Schedule for Affective Disorders and Schizophrenia, Childhood Version) with those adolescents who had elevated screener scores. Adolescents with *Diagnostic and Statistical Manual of Mental Disorders*, third edition-revised (DSM-III-R) major depression or dysthymia were diverted to a nonexperimental treatment group, and the remaining 148 subdiagnostic, demoralized adolescents were randomly assigned to either (a) a 15-session, after school, cognitive-behavioral preventive intervention, modified from the CWDA course (n = 74); or (b) a "usual care" control condition (n = 74). All were followed at 6 and 12 months postintervention. Results indicated that the cognitive-behavioral therapy prevented progression from subsyndromal depression to full-blown major depression in the youth randomized to preventive intervention compared with the control subjects. Total mood disorder incidence rates at a median 13-month follow-up were 14.5% for the cognitive-behavioral therapy intervention group and 25.7% for the control subjects ( [Clarke et al., 1995](#)).

Finally, Clarke et al. (2001) recently completed a study of a cognitive-behavioral preventive (CBP) intervention compared with a usual care group among adolescent

offspring of parents being treated for depression in a large health maintenance organization (HMO). Potential participants were identified by reviewing the HMO pharmacy database and behavioral health records. Those adults in treatment for depression who had children between 13 and 18 years of age were sent letters from their health care providers inviting them to participate in the study. Interested parents were then interviewed to confirm their diagnosis of a mood disorder, and the children were evaluated with regard to their history and current level of depressive symptoms and disorders. A "demoralized" group was identified who had current subdiagnostic levels of depressive symptoms (i.e., a CES-D score <24) or a previous episode of major depression. These 123 adolescents were randomly assigned to either a usual care control condition or the 15-session, group depression prevention program, called the Adolescent CWS course, which is an abbreviated version of the adolescent depression treatment program. Survival analyses revealed a significant advantage for the CBP group (9.3%) versus the usual care group (28.8%) in the cumulative incidence of major depression at the 12-month follow-up. The odds ratio of depression at 12 months was 5.64 (usual care vs. CBP, 95% confidence interval = 1.56 to 20.39) when adjusted for sex, age, CES-D score, and previous depression history. (The latter two were the criteria for inclusion.)

Thus, this CBP intervention appears to be quite promising for the prevention of depression in high-risk adolescents. It is efficiently delivered in a group format and has produced significant change in both depressive symptoms and rates of disorders, although the effects of the intervention showed some waning with time. Future studies need to examine whether this intervention will generalize to more geographically, ethnically, and socioeconomically diverse populations.

### **A School-Based Cognitive–Behavioral Preventive Intervention**

A second cognitive–behavioral depression prevention program has been developed at the University of Pennsylvania ( [Gillham et al., 1995](#); [Jaycox et al., 1994](#); [Seligman et al., 1999](#); [Zubernis et al., 1999](#)). The Penn Optimism Program (POP; Gillham JE, Jaycox LH, Reivich KJ, et al., unpublished manual, University of Pennsylvania, 1990) consists of a cognitive and a social problem-solving component. The cognitive component is based on cognitive–behavioral therapy ( [Beck et al., 1979](#)) and the learned helplessness theory of depression ( [Abramson et al., 1978](#)). Children are taught the cognitive model of emotion and behavior, identifying negative thoughts and thinking styles and disputing negative thoughts by generating alternatives and evaluating evidence for and against them. The social problem-solving component teaches children goal-setting, perspective-taking, information gathering, generating alternative actions, decision-making, and emotion control techniques. Both components use cognitive techniques; whereas the cognitive training section focuses on children's interpretations of problems, the social problem-solving component emphasizes children's actions to solve problems. A third aspect of the program focuses directly on coping with family conflict and other stressors and involves relaxation training, distraction, and seeking social support.

The POP was evaluated in a district-wide, school-based indicated prevention study that targeted 10- to 13-year-old children at risk for depression based on elevated self-reported depressive symptoms or self-reported parental conflict. Intervention groups comprised 10 to 12 children who met in 90-minute group sessions held after school over a 12-week period. Sixty-nine children from one school district were assigned to one of three prevention conditions: cognitive, social problem solving, or combined. They were compared with 49 matched control subjects from a neighboring district similar in demographic characteristics. All participants completed self-report measures of depressive symptoms and explanatory style before the intervention, postintervention, and at 6-month intervals for 3 years of follow-up. Parents and teachers reported on children's internalizing and externalizing behaviors.

Children who participated in the prevention groups reported significantly lower levels of depressive symptoms than control subjects through 2 years of follow-up. At the 2-year follow-up, 44% of control subjects reported moderate to severe levels of depressive symptoms Children's Depression Inventory (CDI) i.e.,  $\geq 15$  compared with only 22% of the prevention group ( [Gillham et al., 1995](#)). The effects on depressive symptoms did not endure beyond 2 years, however ( [Gillham and Reivich, 1999](#)). Significant improvements in explanatory style also were found for the prevention group through the 2-year follow-up period, and change in attributional style appeared to mediate the relation between the preventive intervention and change in depressive symptoms ( [Gillham et al., 1995](#)). Parents reported fewer externalizing symptoms at follow-up, and teachers reported significant improvements in classroom behavior in the prevention group compared with control subjects postintervention ( [Jaycox et al., 1994](#)).

Thus, the cognitive–behavioral prevention program developed at the University of Pennsylvania appears to reduce depressive symptoms in young adolescents over a 2-year follow-up period. Limitations of this study include the lack of random assignment to condition, the lack of assessment of depressive disorders, relatively small sample, and a high rate of attrition over the follow-up period.

Finally, using a similar group cognitive–behavioral prevention program with older adolescents (i.e., college freshmen), [Seligman et al. \(1999\)](#) randomized 231 at-risk college freshmen, with risk being defined as a negative attributional style, into either an 8-week group cognitive prevention program or an assessment-only control group. The prevention group had significantly fewer self-reported depressive symptoms compared with the control subjects at the 3-year follow-up. In addition, the prevention group had significantly fewer episodes of generalized anxiety disorder and a trend toward fewer major depressive episodes. Significant improvement in cognitions (i.e., attributional style, hopelessness, dysfunctional attitudes) mediated the effect of the intervention on depressive symptoms. A particularly important contribution of the studies by the researchers at the University of Pennsylvania has been their examination of mechanisms of change.

### **A Targeted, Family-Based Cognitive–Educational Prevention Program**

Beardslee and colleagues ( [1996](#), [1997a,b,c](#)) developed and evaluated a family based, cognitive–educational intervention for the prevention of depression. This was a selective prevention program in that it targeted nonsymptomatic adolescents who were at risk for the development of depression because of having at least one parent with an affective disorder. This intervention is theoretically compatible with cognitive–behavioral approaches ( [Beardslee and Schwoeri, 1994](#)) and aims to increase family understanding about affective disorders, improve parental focus on their children, and enhance child resilience ( [Beardslee et al., 1992](#), [1993b](#)).

Beardslee et al. ( [1997a,b,c](#)) compared two intervention programs: a clinician-based intervention administered to families on an individual basis, and a lecture program delivered to parents in a group format. The clinician-facilitated intervention consisted of 6 to 10 sessions in which a clinician worked with individual families. Most of the sessions were with the parents, one session was held with each child in the target age range, and a family meeting was held during which the clinician facilitated a family discussion of affective illness. The lecture condition consisted of two small group lectures for parents. Although children did not attend the lectures, parents were encouraged to talk with their children about their affective disorders.

The focus of the clinician-facilitated program was on (a) assessment of all family members; (b) educating parents and children about affective disorders and the potential effects of the illness on relationships with family members, particularly the impact of parental depression on children; (c) teaching information about risks and resilience in high-risk offspring; (d) linking this information to the individual's and family's life experience; (e) improving communication between parents and their children; and (f) enhancing the children's understanding of affective illness to help them develop concrete plans for coping in the future ( [Beardslee et al., 1992](#)). The lecture intervention also provided cognitive information about affective disorder, risks to and potential resiliency of offspring of depressed parents, recognizing distress in children, and enhancing children's adaptive capacities, but without the direct link to the individual experiences of family members.

Parents, recruited from an HMO in the Boston area, were invited to participate if they had at least one child between the ages of 8 and 15 years who had not been treated for an affective disorder, and if at least one parent had experienced an episode of affective disorder in the past 18 months. Thirty-seven families with 52 children were randomly assigned to either a clinician-facilitated, manual-based, psychoeducational preventive intervention or a standardized lecture-group discussion. Parents and children were assessed before the intervention, after intervention, and approximately 1 to 2 years after enrollment (or approximately 9 to 12 months after the intervention). [Beardslee et al. \(1996\)](#) showed that both interventions were feasible and well accepted by high-risk offspring and their depressed parents, had comparable acquisition of cognitive information, and were associated with positive changes in behavior and attitudes in both parents and children, and the degree of upset regarding child-related concerns decreased in both conditions from before to after intervention. Families in the clinician-facilitated group, however, reported significantly more positive behavior changes (e.g., increased communication with spouses and increased talking with their children about depression) and more positive attitude changes (e.g., increased understanding of their children's experience, increased closeness within the family) that were sustained over 3 years.

Positive intervention effects also were found on adolescent functioning both immediately posttreatment ( [Beardslee et al., 1993b](#)) and over a longer follow-up period of 18 months ( [Beardslee et al., 1997c](#)). Participants in the clinician-facilitated condition reported significantly greater levels of clinician-rated and self-reported change than did participants in the lecture condition. Greater parental benefit from intervention in terms of changes in illness-related behaviors and attitudes was associated with significant global change among children, including enhanced understanding of parental illness and improved communication with parents ( [Beardslee et al., 1997a,b,c](#)). In addition, children in the clinician-facilitated intervention reported significantly higher levels of global functioning. No differences were found for depressive symptoms, depressive disorders, behavioral problems, or self-worth, however.

The prevention study of Beardslee and colleagues ( [1997a,b,c](#)) had several strengths, including random assignment to intervention conditions, multiple outcome measures and informants, examination of possible detrimental effects, and evaluation of family functioning and other proposed mediators. A limitation of the study was

that it included a relatively small sample, thereby reducing power to detect differential effects of the interventions. The lack of a no-treatment control group made it difficult to interpret nonsignificant differences between the two conditions. Finally, the fairly short-term intervention might not have been sufficient to address the more chronic and severe consequences of parental depression. Nevertheless, the findings from this program of research indicate that providing parents with factual information about children's risk and resilience, and linking it to family members' affective illness experiences, can produce behavioral and attitudinal changes in parents that translate into more optimal functioning among children ([Beardslee and Gladstone, 2001](#)).

### Other Prevention Programs with Youth

Three other depression prevention studies are worth noting. [Petersen et al. \(1997\)](#) examined the effects of an intervention for preventing depression in a sample of 486 students in seventh grade. The sample was selected for elevated levels of depressive symptoms, stressors, and poor coping skills. Students were randomly assigned to either the intervention or no-treatment control group. The sixteen 40-minute sessions were conducted at the students' schools during the spring of their seventh grade year. Cognitive techniques included reducing irrational thoughts and increasing self-affirming thoughts. Problem-solving techniques included relaxation training, identifying goals, brainstorming about solutions, evaluating the consequences of decisions, and teaching assertiveness and other social skills. Measures of coping, depressive symptoms, and internalizing and externalizing symptoms were obtained before the intervention, immediately postintervention, and at 6- and 12-month follow-ups. Clinical interviews were conducted to assess depressive disorders.

Postintervention, prevention group participants reported fewer internalizing and externalizing symptoms and scored higher on measures of coping compared with control subjects. In addition, a surprising sex difference was found. Postintervention, the prevention group girls reported fewer depressive symptoms than control girls, whereas boys in the intervention group reported higher levels of depressive symptoms than control group boys. Thus, there actually were some short-term negative effects of the intervention for boys. There were no group differences for either girls or boys over the follow-up period, however. In addition, no differences were found between the intervention and control groups regarding clinical diagnoses of depression. Thus, Petersen and colleagues' preventive intervention had only short-term positive effects on reducing depressive symptoms in girls.

Using a longer cognitive-behavioral program, [Hains and Ellmann \(1994\)](#) found somewhat promising results, although their study should be interpreted with caution because of the small sample ( $n = 21$ ) and the absence of a control group at the 2-month follow-up. The stress inoculation training intervention consisted of thirteen 50-minute sessions and included a combination of group and individual sessions. High school students were taught (a) cognitive restructuring techniques for evaluating negative interpretations of problems by considering alternatives and examining the evidence for and against their beliefs; (b) problem-solving skills of generating multiple solutions, considering consequences, and choosing among different options; and (c) relaxation training consisting of deep breathing and progressive muscle relaxation techniques. Assessments of state and trait anxiety, state and trait anger, depressive symptoms, stress, and physical health were conducted before the intervention, postintervention, and at a 2-month follow-up. Records of students' grades and absences from school also were collected at these times. Participants were classified as high or low in emotional arousal based on their baseline scores on trait anxiety and anger.

Among the high-arousal students, program participants reported greater reductions in trait anxiety and depressive symptoms from preintervention to postintervention compared with control subjects, and the gains in the interventions group were maintained at the 2-month follow-up. Students in the wait-list group participated in the intervention between postintervention and 2-month follow-up, and similar postintervention results were found for high-arousal participants. In contrast, no intervention effects were found for the low-arousal group. Finally, no group differences were found with regard to grades or school absences.

Finally, using a large and ethnically diverse urban sample, [Kellam et al. \(1994\)](#) conducted a year-long universal reading enrichment program for first grade children. Children were randomized by classroom to either the regular reading program or the enriched curriculum throughout their first grade year. The enriched curriculum was designed to improve reading achievement by using a group-based assessment of mastery and a flexible corrective process that was tailored to individuals and was flexible in the timing and types of corrective techniques. Reading delays were used as the risk factor in this study.

[Kellam et al. \(1994\)](#) found a significant relation between depressive symptoms and achievement test scores, although the findings differed by sex. In boys who showed a gain in reading achievement at the level of at least the national average, depression fell from fall to spring compared with those whose achievement gain was lower. For girls, there also was a significant relation between gain in achievement and depressive symptoms, although this effect was not different as a function of the intervention. Kellam et al. explained these sex differences by suggesting that girls were more sensitive to teachers' feedback than boys and that girls tended to internalize blame more than boys, thereby maintaining depressive symptoms even in the intervention group.

### Summary and Future Issues

Despite earlier skepticism that depression could be prevented ([Lobel and Hirshfeld, 1984](#)), evidence is increasing that intervention programs can successfully forestall increases in depressive symptoms and possibly delay the onset of depressive disorders, although much more research is needed. Most programs have used combinations of cognitive-behavioral, problem-solving, and stress reduction techniques administered directly to the target children and adolescents in group formats. Less work has been done with families, although Beardslee and colleagues' ([1996, 1997a,b,c](#)) family education program has shown some positive effects. Although Clarke and colleagues ([Clarke et al., 1999; Lewinsohn et al., 1990](#)) did not find a benefit of an added parent intervention component compared with the adolescent-alone intervention, they did not test the effects of a cognitive-behavioral program delivered to the entire family at the same time. Prevention programs that integrate various components, such as cognitive-behavioral and family communication skills training, should be developed and tested. In addition, depression prevention programs should focus on the development and enhancement of competencies and resilience. By so doing, these programs not only can prevent disorder and dysfunction, but can build prosocial skills that may serve a protective function.

Whether conducting efficacy or effectiveness trials, prevention researchers should rely on rigorous experimental methods similar to those recommended for treatment outcome research (e.g., [Chambless and Hollon, 1998](#)), including control groups or alternative interventions, random assignment, large enough samples to achieve adequate statistical power, development and use of intervention manuals, evaluation of treatment fidelity, use of psychometrically adequate assessment measures, attention to the problem of differential attrition across conditions, assessment of possible mediators, use of multiple outcome measures, examination of the clinical significance of the findings, and consideration of possible negative effects of the intervention.

Most depression prevention studies have used a control or comparison group and some form of random assignment. The issue of whether the individual, family, classroom, or school is the unit of randomization needs to be addressed further, and more sophisticated nested analyses need to be conducted. Multiple measures and informants have been used to assess outcomes, although how best to combine this information and how to handle discrepancies across informants is an unresolved issue for the broader field of developmental psychopathology. In general, studies have used self-report measures of depressive symptoms as the primary outcome measure. Although change in self-reported depressive symptoms remains an important goal and should continue to be included in prevention studies, an evaluation of diagnosed depressive disorders also should be conducted. In addition, other psychopathology should be assessed, both because comorbid disorders can affect the impact of the preventive intervention on depressive outcomes, and because some powerful preventive interventions might actually reduce other problem behaviors in addition to depression.

Future prevention researchers will continue to grapple with the question of whether programs should be universal, indicated, or selective. The answer to this depends on the current state of knowledge about risk factors, the specific aims of the investigator, and the resources available. These approaches can be linked hierarchically and sequentially ([Compas et al., 1997](#)). Universal approaches can reach the most individuals, although the intensity of the intervention generally is limited. To show that the intervention has had an effect, it often takes very large numbers, particularly if the goal is to reduce onset of diagnosed depressive disorders. Selective interventions can be added for those individuals who are identified on the basis of some known vulnerability factor(s). Existing programs have shown some success with risk groups identified on the basis of parental history of depression, negative attributional style, stress, and emotional arousal. As more information is obtained about risk factors, and prevention programs are developed specifically to target these variables, it will be possible to provide more cost-effective services to those who are most in need. Because prior depressive episodes and high levels of depressive symptoms also are known predictors of future depression, indicated prevention programs with such individuals probably are the place to begin. Once programs are successful with these highest-risk individuals, prevention programs can be expanded more universally.

The issue of sex differences in the effects of preventive interventions needs to be taken seriously. Several studies have found different outcomes as a function of participants' sex (e.g., [Clarke et al., 1993; Kellam et al., 1994; Petersen et al., 1997; Reivich, 1996](#)), and the direction of these findings has not been consistent across studies. Why are some interventions working better or worse for boys versus girls? How do the children's age and developmental level interact with sex in the different prevention approaches? Does using same- versus mixed-sex intervention groups affect outcomes? The mechanisms underlying why sex moderates the effect of the

intervention on depressive outcomes need to be examined.

Another important issue concerns how enduring are the effects of prevention efforts. Most studies have conducted preintervention and postintervention assessments and then follow-up evaluations for another 2 to 3 years. Although the short-term effects have been encouraging, evidence of long-term effects is lacking. The contribution of booster or continuation sessions should be explored as a possible means of extending the positive initial effects of preventive interventions. Why the effects wane over time needs to be understood. Are participants forgetting what they learned? Do they lose their motivation to implement their acquired skills? Are the interventions just not powerful enough to sustain long-term benefits? What is the impact of development on the long-term effects? A related question is what is the best developmental period in which to intervene to produce the most enduring effects during the period of greatest risk for depression?

Several important practical questions also need to be addressed with regard to implementation of the various preventive intervention programs. For group interventions, what is the best size of the group? Most programs have included 8 to 10 participants in a group. Is that too large? How many therapists are needed? For groups with younger children or with children with comorbid disruptive behaviors, might two therapists be needed? Who are the best therapists? Can teachers, case managers, nurses, or nonprofessionals implement the interventions successfully? The extent to which the prevention program is structured and manualized will partially determine who can best implement it. What are the best settings in which to conduct preventive interventions: schools, psychiatric clinics, pediatric offices, HMOs? Some of this will depend on whether the prevention program is universal, selective, or indicated, although it is possible to execute any of these types of interventions in multiple settings. Finally, what are the essential components of preventive interventions? That is, can these prevention programs be boiled down to the absolute key ingredients so they can be broadly and cost-effectively disseminated? What kinds of innovative methods can be used to reach the most people (e.g., the Internet, public service announcements)?

Another critical and as yet unanswered question is to what extent existing prevention programs are applicable to diverse populations. In general, studies aimed at preventing depression have been conducted with white, middle class samples [although see [Kellam et al. \(1994\)](#) for an exception]. The IOM ([Mrazek and Haggerty, 1994](#)) recommended that external validity of prevention programs when implemented by other investigators and personnel across different settings, samples, and geographic locations should be examined. Moreover, not only are studies needed that test whether interventions generalize to different ethnic and socioeconomic groups, but more basic work needs to be done exploring whether the same or other factors make individuals from different social, economic, and ethnic backgrounds vulnerable to depression. Based on this work, existing prevention programs would need to be revised to reflect and accommodate these sociocultural differences.

Finally, prevention research also needs to investigate the mechanisms that underlie change. Seligman and colleagues ([Gillham et al., 1995](#); [Seligman et al., 1999](#)) have shown that changes in negative cognitions mediate the link between the intervention and reduced depressive symptoms. One of the exciting benefits of prevention studies is that they provide a means of testing theory by allowing an ethical and ecologically valid means of directly manipulating factors that are hypothesized to be part of the causal chain underlying the disorder. Researchers need to use prevention studies as an opportunity to study mechanisms as well as a means of reducing suffering.

## SUICIDE PREVENTION PROGRAMS FOR YOUTH

Rates of suicide and suicide risk behaviors among adolescents have risen dramatically over the last four decades ([Allison et al., 1995](#); [Andrews and Lewinsohn, 1992](#); [Berman and Jobes, 1995](#); [Brent, 1995](#); [Garrison et al., 1993](#); [Lewinsohn et al., 1994b](#); [McIntosh, 2000](#)). In 1956, the rate of suicide among adolescents (15 to 19 years of age) was 2.3/100,000; by 1996, these rates had increased to 9.7/100,000, an increase of 322% ([McIntosh, 2000](#)). Increases also occurred in the rates of suicide among children 10 to 14 years of age (from 0.4 to 1.6/100,000). Suicide is now one of the leading causes of death among adolescents, along with accidents and homicides (*Morbidity and Mortality Weekly Report*, 1998). Moreover, for every completed suicide, there is an estimated 8 to 25 suicide attempts ([Eggert et al., 1995b](#); [King, 1997](#)). The [Centers for Disease Control's \(CDC\) \(1990\)](#) survey of 11,631 high school students found that 27.8% of the students had thoughts of suicide, 16.3% had made a specific plan, and 8.3% had made a serious suicide attempt. Thus, adolescent suicide has become a major public health concern.

The most dramatic increases in rates of suicide among young people 15 to 24 years of age occurred between the mid-1950s and the late 1970s (1977: 13.6/100,000). Although the rate of suicide has remained fairly stable since then, it also has remained high; the average suicide rate between 1990 and 1996 was 13.1/100,000 ([McIntosh, 2000](#)). Furthermore, suicide rates for adolescents (15 to 19 years of age) and children (10 to 14 years of age) have increased consistently since the 1950s. Completed suicide continues to be a much more prominent and concerning problem for boys, whereas girls are responsible for more suicide attempts. When risk rates are computed separately by sex, the suicide rates for boys jump to 20/100,000, whereas the rates for girls are 3.6/100,000 (based on 1996 data; [McIntosh, 2000](#)). The ethnic demography of youth suicide has changed, however. In the past, suicide occurred predominantly in white boys with dramatic peaks in some, but not all Native American groups ([LaFromboise and Howard-Pitney, 1995](#)). In the 1990s, the suicide risk in the United States rose steadily among African-American boys and young men, particularly those living in urban settings, such that rates among this group are now comparable with the those of the white population ([McIntosh, 2000](#)).

### Factors Contributing to Increased Rates of Youth Suicide

Although not conclusive, factors thought to contribute to the dramatic increase in suicide among young people include changes in population density, increased prevalence of depressive, conduct, and substance abuse disorders, increased family instability, increased exposure to stressors, and ready access to firearms ([Berman and Jobes, 1995](#); [Brent et al., 1987, 1991](#)). The 1950s through 1970s mark the "baby boom" period, with dramatic increases in the birth rate in the United States. It is theorized that individuals who are part of large birth cohorts have to compete more for limited resources than members of smaller birth cohorts. There is some support for this theory based on analysis of historical trends, which indicates that members of larger birth cohorts are exposed to increased levels of stress and untoward outcomes such as increased violence and suicide [see review by [McIntosh \(2000\)](#)].

Increases in rates of depressive, conduct, and substance abuse disorders that have occurred since the 1950s affect the adolescents as well as their parents ([Klerman, 1990](#)). This trend certainly influences risk for suicide. Psychological autopsy studies have documented that up to 90% of youth who commit suicide had a diagnosable psychiatric disorder at the time of their death, although only a subset of these young people (33% to 50%) had ever had mental health treatment ([Brent and Perper, 1995](#); [Brent et al., 1988a, 1993a](#)). Alcohol use frequently is associated with youth suicide and seen as a potential trigger because it increases depression and hopelessness while reducing impulse control and problem-solving skills ([Shaffer et al., 1996](#)). Furthermore, parental psychopathology is more common among suicidal youth compared with community control subjects, particularly parental history of depression, substance abuse, or suicide attempts ([Brent et al., 1996](#)). [Brent and Perper \(1995\)](#) demonstrated that parental psychopathology increased a young person's risk for suicide even after controlling for familial transmission of psychopathology.

Exposure to suicide creates an additional risk for suicide. Suicide is more common in young people with a family history of suicide ([Brent et al., 1996](#)). However, suicide also is more likely to occur in young people who have been exposed to suicide through the death of a friend or classmate, or even through the media ([Brent et al., 1988a](#); [Gould et al., 1989](#)). Adolescent suicide also has been characterized by cluster or group suicides, phenomena that are particularly sensitive to exposure to suicide. Cluster suicides occur after exposure to a suicide; for example, the death by suicide of one youth in a high school is followed by the suicides of a number of young people in the community. Group suicides, on the other hand, represent the decision by a group of young people to take their lives together.

Family stability, another key risk factor for youth suicide ([Lewinsohn et al., 1993, 1996](#); [Thompson et al., 2000](#)), has changed dramatically over the last four decades with the marked increase in divorced or working parents. Living with a single parent, living without a parent, and father-absent families have been associated with increased suicide risk behaviors ([Garrison et al., 1991](#); [King et al., 1995](#)). Suicide-vulnerable teens frequently describe parents as unsupportive but also critical and controlling ([Allison et al., 1995](#); [Martin and Waite, 1994](#)). Studies of adolescent suicide risk behaviors indicate that parents tend to be either unaware of their teen's suicidal behaviors or report much lower rates than the teen reports ([Garrison et al., 1991](#); [Joffe et al., 1988](#)). Adolescent suicide attempts occur most frequently during the late afternoon/evening, between school and bedtime, a time that may be unstructured or unsupervised ([Nakamura et al., 1994](#)). In a study of female suicide attempters, 78% of the attempts were precipitated by family fights ([Rotheram-Borun and Trautman, 1988](#)). Parent-child discord has been identified as the most common precipitant for suicide and suicidal behaviors ([Brent et al., 1988b](#); [Hawton et al., 1982](#)).

School stressors, dropout status/truancy, or poor grades also have been linked with suicide risk behaviors ([Gispert et al., 1987](#); [Levy and Deykin, 1989](#); [Lewis et al., 1988](#)). Specifically, lower grades are related to increased risk of suicide attempts ([Garrison et al., 1991](#)), suicides often follow long school absences ([Shaffer, 1988](#)), and negative attitudes toward school capabilities are associated with suicidal ideation ([Butler et al., 1994](#)). [Gould and colleagues \(1996\)](#) concluded that youth who are "drifting" with lack of affiliation to school or work are particularly at risk for suicide.

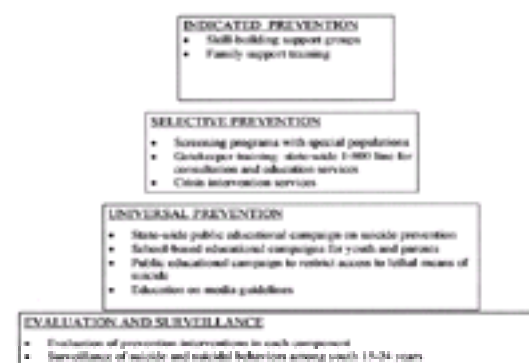

Finally, a number of epidemiologic and case-control studies have documented the relation between access to a firearm and suicide. Suicide is more common, particularly among adolescents, in areas with less restrictive gun control legislation in place ([Sloan et al., 1990](#)) and among those with access to guns in their homes

([Brent and Perper, 1995](#); [Kellermann et al., 1992](#)). Since the early 1980s, firearms have become the most common means of committing suicide among young people. In 1996, gunshot wounds accounted for 62% of all suicides among 10- to 19-year-olds in the United States.

However compelling, these factors do not adequately account for the fact that suicide rates have dramatically increased in boys while remaining stable among adolescent girls. [Berman and Jobes \(1995\)](#) point to the fact that boys are more likely to become involved in substance use and may be more likely to use alcohol when depressed, anxious, or angry. Furthermore, boys more commonly commit suicide when under the influence of alcohol. Others speculate that differences in support systems, coping styles, and willingness to seek help continue to differentiate male and female adolescents ([McIntosh, 2000](#)). Studies of social support and suicide risk reveal that both suicidal and depressed youth endorsed less social support from their family and friendship networks ([Asarnow, Carlson, and Guthrie, 1987](#); [Mazza and Reynolds, 1998](#)). Also, when social support was increased in preventive interventions, suicide risk behaviors and depression decreased ([Eggert et al., 1995a](#)).

### Approaches to Suicide Prevention

As noted earlier, prevention science defines a continuum of approaches ranging from *universal* programs that benefit the general population, to *selective* programs that target at-risk populations, to *indicated* prevention programs that focus on high-risk individuals. [Figure 66.1](#) outlines these approaches as they apply to youth suicide prevention. The CDC (1992) has identified a series of strategies to be used in suicide prevention with the assumption that effective prevention efforts will need to incorporate a number of different strategies simultaneously. These strategies fall into two conceptual categories: (a) those designed to increase recognition of youth at risk and facilitate referral to mental health services, and (b) those designed to address risk factors related to youth suicide. The CDC (1994) also has responded to the contagion aspect of youth suicide by developing guidelines for the media so that coverage of suicide is not sensationalized by glorifying the victim or providing morbid or dramatic details of the death.

**Figure 66.1.** Recommended youth suicide prevention programs and strategies. (Reprinted with permission from Eggert LL, Thompson EA, Randal B, et al.: *Youth suicide prevention plan for Washington State*. Olympia, WA, Washington State Department of Health, 1995.)

The strategies outlined by the CDC include school and community gatekeeper training, educational, screening, and peer support programs, crisis services/hotlines, means restriction, and interventions after a suicide. The 1992 CDC document underscored a series of problems with youth suicide prevention efforts at that time. The central problem was the failure to gather adequate data on efficacy and outcome. The report highlighted related problems such as an over-reliance on general educational programs that appeared to have limited efficacy, inadequate attention to other, more promising strategies such as means restriction, and failure to tie suicide prevention programs into other risk-reducing programs, such as alcohol and drug abuse programs. The limited data on efficacy of these efforts are summarized in the following sections.

### Initial Wave of Youth Suicide Prevention Efforts

The alarming increase in youth suicide in the late 1970s led to the development and implementation of a wave of suicide prevention programs. The most common approach involved a combination of gatekeeper training and general education about suicide. Shaffer and colleagues ([Garland et al., 1989](#); [Shaffer and Garland, 1986](#)) conducted a survey of 435 of these programs. Gatekeeper training efforts were directed toward school personnel, parents, and students through education about suicide that was offered in universal, didactic programs; that is, it was offered to the student body in general. Students were trained as gatekeepers because young people are more likely to talk to a peer than a parent or other adult when feeling suicidal ([Tierney et al., 1990](#)). The programs were designed to increase awareness of suicide as a problem, and to teach students, teachers, and parents how to recognize youth who might be at risk and refer them to appropriate resources. Most programs operated from a model that emphasized suicide as a response to stress rather than focusing on suicide as a sign of mental illness. Many of the programs were quite limited in scope, some providing a single didactic session for the teachers covering warning signs and how to make a mental health referral. Seventy-six percent of the programs were 3 hours in length or less.

[Shaffer and colleagues \(1988\)](#) also conducted an in-depth evaluation of the efficacy of a sample of these school-based programs, including representation of both the stress and mental health models of suicide risk ([Shaffer et al., 1990, 1991](#)). They found that most students, even before exposure to the program, had a good sense of warning signs, felt that disclosure of suicidal ideation should be referred to a responsible adult, and that seeking mental health services was the desirable response. These students in general were positive about the prevention programs, but demonstrated only limited changes in knowledge and attitude about suicide from before to after the intervention assessment. A subset of youth, 5% to 20% of students, however, expressed the view that suicide was a reasonable solution to problems, would not reveal a peer's confidential communication of suicidal ideation or intent, and would not seek mental health help. These students did not demonstrate a significant change in attitudes postintervention. Moreover, students who reported having made a previous suicide attempt reported a negative response to the program. An 18-month follow-up of a subset of these students also failed to demonstrate significant program effects ([Vieland et al., 1991](#)). The investigators questioned the efficacy and cost effectiveness of these brief, universal, school-based, general education programs, particularly those that presented suicide as a response to normal adolescent stressors rather than an indication of significant emotional distress. They argued instead for taking a case-finding approach that would identify youth with emotional problems and facilitate their involvement with appropriate mental health interventions. In a review of suicide prevention efforts, [Shaffer and colleagues \(1991\)](#) emphasized the importance of focusing prevention efforts specifically on adolescent boys who had made a previous suicide attempt or who were depressed.

Other outcome studies ([Spirito et al., 1988](#)) found some support for programs that increased knowledge about suicide warning signs and mental health referral sources, but found no change in the proportion of youth who would ask a teacher, counselor, or parent about how to contact a mental health professional outside of school, and no increase in the proportion of youth who indicated they knew how to get help outside of school. [Spirito and colleagues \(1988\)](#) revealed improvements in coping skills after participation in a program that educated youth about helpful and harmful ways of coping with stress or suicidal ideation—participants were less likely than control subjects to believe social withdrawal was an effective response, reported less engagement in wishful thinking or blaming others, and reported decreased feelings of hopelessness after participation. None of the studies found evidence that programs triggered increases in suicidality among exposed teens, and [Shaffer et al. \(1991\)](#) noted a positive consequence of the programs, in that 3% of the participants identified themselves as in need of help and used the assessment/intervention opportunity to seek help from school personnel.

Although Shaffer and colleagues acknowledged the importance of the gatekeeper training components of these programs, they noted that this aspect of these school-based programs has not been carefully evaluated. In their 1992 report, the CDC cited only two studies that had evaluated gatekeeper training. In each of these studies [see [McConahay \(1990\)](#) and [Tierney \(1988\)](#), reviewed in [CDC \(1992\)](#)], participants who completed a 2-day training program retained the skills at a 6-month follow-up evaluation, but did not report working with increased numbers of suicidal youth. One of these studies ([Tanney, 1989](#)) assessed a gatekeeper training program developed and widely disseminated in Canada, the Foundation Workshop, which evolved into LivingWorks. Based on the realization that few caregivers across multiple disciplines were receiving adequate training in how to recognize and manage suicidal behavior, [Tanney \(1989\)](#) developed a 2-day gatekeeper training workshop that built on the principles of the suicide prevention work of the 1970s. This program involved a 2-day training commitment and covered knowledge and attitudes about suicide as well as skill-building simulations. By the late 1980s, approximately 4,000 caregivers had been trained. Participant evaluations were positive, but systematic program evaluation was not reported.

During the late 1980s, there also was growing attention given to the importance of limiting the access of youth to lethal means of self-harm. The importance of means restriction has been exemplified by the decline in suicide rates in England secondary to changes made in the lethality of cooking gas. Asphyxiation had been the most

common means of suicide in England up to that time; suicide rates declined without evidence of at-risk individuals turning to an alternative means ( [Shaffer et al., 1988](#)). Similarly, as noted previously, the increase in youth suicide in the United States has been linked to the increased availability of firearms. Initial studies documented that suicide was less common, particularly among adolescents and young adults, in areas where more restrictive gun control laws were in effect ( [Brent and Perper, 1995](#); [Sloan et al., 1990](#)). As summarized by [Brent and Perper \(1995\)](#), firearms are found more common in homes of suicide victims than either psychiatric or community control groups, if a firearm is in the home there is an increased risk of its being used in a suicide regardless of storage method, and suicide victims seldom purchase a firearm or seek a firearm outside the home ( [Kellermann et al., 1992](#)). These findings as well as the rising numbers of accidental and violent child deaths secondary to firearms led to an educational campaign directed at pediatricians to increase their awareness of the risk of firearms in the home and to increase the likelihood that primary care providers would ask about firearms and educate parents about the risks and need for safe management of firearms. Again, program evaluation data are not available.

Crisis centers/services and hotlines that offer 24-hour-a-day access have been a mainstay of suicide prevention efforts for decades. These programs assume that many suicides are impulsive acts prompted by problems that may seem overwhelming in the moment but that are manageable if the person can get immediate and easy access to appropriate social and emotional support. This premise is particularly applicable to suicide in youth who, as revealed by psychological autopsy studies, are typically emotionally distressed individuals who make an impulsive suicidal act when faced with a stressful event that makes them emotionally aroused (e.g., angry or anxious) ( [Shaffer and Craft, 1999](#)). Studies of the efficacy of crisis services or hotlines suggest that adolescents find them more accessible than traditional mental health services, and young adult white women are the group most likely to make use of these services (CDC, 1990; see reviews by [Shaffer et al., 1988, 1989](#)). Most adolescents or college students who had contact with these services were not involved in other mental health services at the time of contact and most felt satisfied with the help they received, but girls were more likely than boys both to contact a crisis line and feel that the contact was useful. A subset of young people, however, reported that the response given was not helpful to them. Data on whether telephone hotlines lead to an actual reduction in suicide frequency appear mixed. Evidence of a reduction in suicide rates among young white women was revealed in a study of suicide rates in the United States comparing counties with and without suicide prevention centers ( [Miller et al., 1984](#)). [Leenaars and Lester \(1995\)](#) examined the association between the presence of suicide prevention centers in a community and changes in suicide rates in Canada during 1985 to 1991. No statistically significant trends emerged.

[Shaffer et al. \(1988\)](#) concluded that hotlines continue to be an important part of the suicide prevention armamentarium because of the need for immediate access to help. They argued that increased public education about the availability of services geared particularly at young men and better training of crisis line workers would improve their usefulness. Furthermore, they reported that compliance with follow-up treatment recommendations was greater when the crisis line worker actually made an appointment for the caller and contacted the caller if the appointment was not kept ( [Shaffer et al., 1988](#))

### Youth Suicide Prevention Efforts: 1990s

Prevention science in general underwent considerable growth and refinement during the 1980s and early 1990s, leading prevention specialists to recommend guiding principles for the next phase of prevention projects that included the need to test theory-based causal models, target high-risk populations, include a developmental framework, focus on both risk and protective factors, address risk broadly (e.g., address related problems such as substance abuse), be comprehensive enough to address effectively the complex issues underlying risk, and include rigorous attention to methodologic issues such as sampling, measurement, and statistical analyses ( [Coie et al., 1993](#); [Eggert et al., 1995a](#)).

In response to the limitations of prior suicide prevention efforts, several alternative school-based suicide prevention programs were developed and evaluated. [Ciffone \(1993\)](#) examined a brief universal program offered in health class to all sophomores in a school district near Chicago, in light of the concerns raised by Shaffer et al. ( [1988, 1990](#)). This program was similar to those included in the Shaffer evaluation in that it was brief, school based, and universal. The program differed, however, in that it made a clear link between suicide and mental health problems. Students participated in a before and after (30 days after completion) program assessment using tools similar to those used in Shaffer and colleagues' evaluation, but no random assignment to intervention/no intervention was included. Posttest results revealed that after participating in the group, significantly more young people indicated a willingness to seek help from an adult if a peer talked to them about suicide, seek help from a friend themselves if they had thoughts of self-harm, or seek help from a mental health professional. Furthermore, significantly more youth endorsed understanding the association between mental health concerns and suicide. However, 55% of the subset that viewed suicide as a possible solution to problems at baseline did not change their view after the intervention. Although concluding that the brief, universal, school-based suicide prevention program was useful for most participants, the investigator emphasized that programs need to state clearly that suicidal behavior is a symptom of mental health problems that in turn can be effectively treated.

More extensive suicide prevention programs also were developed. [Klingman and Hochdorf \(1993\)](#) tested a 12-week cognitive-behavioral suicide prevention program with 237 eighth grade students in Israel. This program combined elements of gatekeeper training and general education about suicide with peer support program elements designed to reduce risk factors associated with suicide, such as poor coping skills. It also increased students' awareness of, and ability to respond to, peers in distress. Students were randomly assigned to the intervention program or a control group, which was an education program to control for attention effects. The index program was administered to groups of 18 in 50-minute interactive sessions over a 12-week period. The program followed a three-phase intervention model beginning with an education component geared to help teens understand the nature of distress and the role feelings and thoughts can have in maintaining distress. The second phase focused on the acquisition of coping skills, including positive self-talk, empathy training, help-seeking behavior, and training in how to identify suicide risk in peers. The third phase involved rehearsal and implementation, which was built into every session and extended through homework assignments. Results revealed significant reductions in suicidality among students who participated in the program compared with control subjects; this difference was most evident among the boys. Suicidality was measured by the Index of Suicide Potential adapted for use with young adolescents in Israel. Posttest evaluations also revealed improvements in awareness of distress, coping skills, and information regarding youth suicide, including risk signs and support resources for program participants, compared with control subjects.

Another program was conducted with Israeli high school students. [Orbach and Bar-Joseph \(1993\)](#) developed an introspective, emotion-oriented program that encouraged students to discuss their own experiences while also learning coping and problem-solving strategies as a way to protect them from self-destructive behaviors. A "self-help and peer-help" approach was emphasized. Participants were 11th grade students in six high schools; five were general education programs and one was a special program for conduct-disordered youth. Across the 6 schools, 393 students were randomly assigned to either the program or control group. The suicide prevention program was administered over 7 weekly 2-hour sessions. Preintervention and postintervention measures were given to assess suicidal potential, ego identity, and coping. In four of the six schools, students in the experimental group demonstrated a significant decrease in suicidal tendencies compared with control subjects, with girls showing a bigger decline than boys. In three of the six schools, students who participated in the program also provided evidence of significant improvement on the measures of ego identity, cohesion, and coping. No changes in hopelessness were observed. Both Israeli programs were well accepted by participants; in the high school study ( [Orbach and Bar-Joseph, 1993](#)), the students in the conduct-disordered class indicated that the program was too revealing but also demonstrated a significant decline in suicide potential at posttest. Neither of these programs has been replicated, however. This limits our ability to understand the implications of this work in relation to more general suicide prevention efforts across cultural contexts.

A culturally specific suicide prevention program has been tested in the Zuni Pueblo ( [LaFromboise and Howard-Pitney, 1995](#)). Zuni leaders initiated a suicide prevention program that focused on life and social skills training in hopes of increasing high school students' ability to cope with factors that increased risk for suicide. The Zuni Life Skills Development curriculum was administered to an unselected group of 69 students during their language arts class, with three classes per week over 30 weeks. Fifty-nine students in the same school served as a no-intervention control group; students were not randomly assigned to conditions. A multimethod assessment approach that included self-report measures, behavioral observations, and peer ratings was used to evaluate suicide vulnerability, hopelessness, self-efficacy, and ability to engage in effective problem solving when presented with a suicidal situation involving a peer. Pretest and posttest (at 8 months) assessments revealed that the students exposed to the curriculum had more positive scores than the no-intervention group on measures of suicide probability and hopelessness. In addition, the intervention group showed greater ability to perform problem-solving and suicide intervention skills on the behavioral observation but not the peer rating outcome measures.

Each of these investigative groups points to the fact that their findings differed significantly from the results reported by Shaffer et al. ( [1988, 1990](#)) regarding the initial wave of suicide prevention programs. The investigators emphasized that their interventions were more comprehensive than earlier programs and focused on alternative responses to suicide rather than presenting suicide as a normative response to stress. School-based suicide prevention programs continue to be controversial, however, in part because many still follow a stress-related model, assume a universal rather than indicated prevention approach, and assess changes in attitudes rather than actual suicide-related behaviors ( [Mazza, 1997](#)).

Another group of researchers has developed and tested a series of programs, the Reconnecting Youth Prevention Research Programs, designed to reduce suicidal potential among high-risk high school students by providing a combination of social support with skills training. [Eggert et al. \(1995a\)](#) began working with youth at risk for dropping out of high school. Evaluation of these young people revealed that they differed from typical adolescents not only in terms of school attendance and

grades, but 40% endorsed more depression and suicide risk as defined by previous suicide attempt or high suicidal ideation (Eggert et al., 1994b). They then evaluated the efficacy of an in-depth assessment protocol, the Measure of Adolescent Suicide Potential (MAPS) (Eggert et al., 1994b), versus a one- or a two-semester school-based program Reconnecting Youth (RY) that incorporated social support and life skills training to decrease depression and suicidal risk behaviors, improve school performance and attendance, and decrease drug involvement. Participants were students identified as at risk for high school dropout because of low grades and poor attendance and who also endorsed depression or suicide risk behaviors on a second screen. The program was administered as a "for credit" class in the student's high school schedule and was delivered in small groups of 12 participants with teachers selected for their ability to be supportive and to help students form into a supportive and effective prosocial working group. Additional core components included regular monitoring of mood, school behaviors, and drug use as well as skills training in four areas: self-esteem enhancement, decision making, personal control (anger, depression, stress management), and interpersonal communication. The one- versus two-semester programs differed in that the second semester expanded students' involvement in activities at school to increase their school bonding, and extended the use of skills learned in the first semester to a broader range of situations in the students' lives. The MAPS is a 2-hour, computer-assisted interview followed by a crisis intervention/social connection protocol to ensure the safety of the suicide-vulnerable youth. In that component, students who revealed significant suicide risk were connected with a school counselor for additional in-school services, and parents were notified. One hundred five students were compared across the three experimental conditions as well as with a contrast group (n = 202) of nonrisk students from the same high schools.

This study used a three-group repeated-measures design; trend analysis served to assess patterns of change for youth in the three study conditions across three points in time (baseline, 5 months, and 10 months). All groups showed significant declines in suicide risk behaviors, depression, hopelessness, stress, and anger, as well as increases in self-esteem and network social support, suggesting that the MAPS assessment was effective for decreasing suicidal behaviors and related emotional distress factors. Increased personal control was observed only in the experimental RY groups and not in the MAPS-only condition. This study demonstrated the efficacy of the RY prevention classes and the therapeutic potential of MAPS. More recent work has explored the mediating effects of the RY prevention program (Thompson et al., 2000). It was hypothesized that intervention effects would be influenced by the direct and mediating effects of teacher social support on peer group support and perceived personal control. Personal control was enhanced by teacher and peer group support and in turn contributed to reduced depression and suicide risk behaviors. A structural equation model was used to test the direct and mediating effects of RY teacher social support on peer support and personal control, thereby, on suicide risk behaviors and depression. As hypothesized, teacher social support directly enhanced peer group support, with a stronger effect evident in the intervention groups versus the control (MAPS) group. Peer group support enhanced personal control and thereby indirectly decreased depression and suicide risk behaviors, and personal control mediated the link between intervention and depression in the two-semester RY group.

Based on these findings, Eggert and colleagues developed a condensed version of the RY class, Coping and Support Training (CAST), which included the key elements of peer group and teacher support, monitoring, and skills training. CAST is administered in groups of 6 to 8 students, with 10 sessions over a 5-week period. Eggert and colleagues (Randell et al., 2001; Thompson et al., 2001) then tested CAST versus the MAPS only (now referred to as Counselor's CARE, or C-CARE) versus "usual care" control subjects using a larger sample of suicide-vulnerable youth. The impact of the three groups on reduction of suicide risk behaviors and improvement of individual mediators (personal control, problem solving coping, and self-esteem) and family mediators (family support, family goals met, and family distress/conflict) was tested using repeated-measures design (preintervention, post C-CARE at 4 weeks, and post CAST at 10 weeks). Subjects were 460 suicide-vulnerable youth randomly assigned to one of the three groups (C-CARE, CAST, and usual care/control). Findings revealed significant decreases in suicide risk behaviors and emotional distress indicators for all three groups. Significant intervention effects were reported for the posited personal mediators (increased personal control and problem-solving coping) and posited family mediators (increased family support and family goals met) as well.

These results provided preliminary support for the brief C-CARE and CAST models. The CAST intervention was superior only in enhancing the posited mediators of personal control, problem-solving coping, family support, and family goals, effects that appear related to specific skills training in CAST. Given the efficacy of these brief intervention models, the RY group currently is testing Counselor's Care in contrast to C-CARE paired with Parents' Care (P-CARE) a brief parent intervention (Randell BP, personal communication, 2001). P-CARE provides a structured intervention for parents of suicide-vulnerable youth that is delivered in two home visits. Parents are given gatekeeper-like training in how to recognize suicide warning signs and ask their teens about suicide while showing care and concern. A second home visit provides training in communication and problem-solving skills. Results are not yet available from this ongoing project.

### **Additional Suicide Prevention Approaches**

In addition to the development and testing of specific preventive intervention programs, a broader level of responses to the issue of suicide prevention has been evident since the early 1990s. Grossman and Kruesi (2000) have categorized recent youth suicide prevention strategies into public health, grassroots, means restriction, gatekeeper training, mental health, hospital safety, and community action approaches. The following sections review findings on the current status of these various strategies.

#### *PUBLIC HEALTH*

The public health approach focuses on reducing suicide. This is clearly stated in the U.S. government's *Healthy People 2000* (U.S. Department of Health and Human Services, 1999) and 2010 campaigns as well as the active writing and public speaking campaign highlighting the need for a public health approach to suicide prevention, which the former Surgeon General, Dr. David Satcher, has actively pursued (Satcher, 1998).

#### *GRASSROOTS*

Complementing these efforts has been the growth of grassroots programs, which on both the state and local level have pulled together relatives of those who have committed suicide with academic and governmental institutions. These initiatives, as represented in the work of Suicide Prevention Advocacy Network, a nonprofit organization begun by the parents of a young woman lost to suicide in 1996, have been very active in promoting a national suicide prevention initiative and bringing the need for suicide prevention to the attention of politicians and policy makers (Grossman and Kruesi, 2000).

#### *MEANS RESTRICTION*

Growing out of the initial studies demonstrating the strong connection between ready access to a firearm and rates of completed suicides, efforts have expanded to educate the public in general, and parents of at-risk youth specifically, about firearms. These efforts have included a task force on handguns and youth suicide as well as an educational campaign sponsored by the American Academy of Pediatrics that focused on increasing awareness among pediatricians of the need to ask about access to firearms and educate about firearm safety as part of routine pediatric practice. Only a few studies have explored the efficacy of education campaigns. Brent et al. (2000) reported on compliance with the recommendation to remove firearms from the home among parents of 106 adolescents with major depression who were participating in a treatment of depression research project. Parents who reported having firearms in the home were educated about the strong risk of suicide among depressed youth and the increased risk of suicide given the presence of a firearm, and were encouraged to remove the firearms. Only 26.9% of the families followed through with this request, even though they were compliant with the many other demands of the research study. The authors concluded that the brief educational intervention used was not adequate and emphasized the need for education that includes a variety of firearm storage options and is directed specifically at the parent who is the primary gun owner. Another study (Kruesi et al., 1999; McManus et al., 1997) investigated education about means restriction provided in emergency departments (EDs). They found that although only a few centers (14%) documented providing means restriction education to parents of youth brought for care after a suicide attempt by drug overdose, education resulted in a significant increase in parents who secured medications.

#### *GATEKEEPER TRAINING*

Several programs since the early 1990s have focused on increased gatekeeper training efforts, typically in conjunction with other prevention strategies. A comprehensive training program has been developed and extensively used in Canada, the LivingWorks Applied Suicide Intervention Skills Training (ASIST) (Ramsey et al., 1996). This training program has been tested in two comprehensive youth suicide prevention initiatives, one in the state of Washington (Eggert et al., 1999) and the other in Australia (Turley and Tanney, 1998; Turley et al., 2000a, 2000b)

Based on a statewide needs assessment, Washington State implemented a three-pronged youth suicide prevention program, including a public education campaign, gatekeeper training for adult caregivers, and enhancements to existing crisis services. These efforts provide important information about how best to spend limited public health dollars. Gatekeeping training was done first with adult caregivers and then with high school students in four demonstration projects. Compared with extensive public education campaigns, gatekeeper training of both youth and adults resulted in greater gains in the desired program outcomes of increased public awareness about youth suicide prevention, knowledge of suicide warning signs, and ability to initiate prevention steps. Finally, enhancement of crisis services was the

most challenging aspect of the program. Training of crisis services workers was effective in increasing competencies in assessing level of suicide risk, but enhancing access to youth-friendly crisis services was difficult given the limited funding and high use of existing services.

In 1995, the Australian Commonwealth provided funding for field trials of two gatekeeper training programs developed by LivingWorks ASIST, a 1- to 3-hour Suicide Aware program and the 2-day Suicide Intervention workshop. These programs use a "train the trainer" model. Initially, 70 individuals were trained, who in turn completed 2,870 Suicide Intervention workshops and 3,972 Suicide Aware trainings. Thus, the program was highly successful in creating opportunities to increase suicide awareness in the target communities. Efficacy of the Suicide Intervention workshops was assessed by self-report measures administered before, immediately after, and 4 months after program completion. Targeted outcomes were gatekeepers' readiness to help a person at risk, suicide assessment and intervention knowledge, and attitudes and beliefs affecting the gatekeepers' suicide prevention role. Measures of readiness to help (self-report of comfort, competence, and confidence), intervention knowledge (19-item Intervention Knowledge questionnaire), and intervention beliefs (Suicide Beliefs Questionnaire assessing two factors: willingness to help and optimism–pessimism about effective outcome) all increased significantly from preworkshop to postworkshop assessments, and gains remained stable at the 4-month evaluation. Although the longer-term follow-up data were encouraging, only 30% of the initial sample and only subsamples of the overall group completed the Intervention Knowledge and Suicide Beliefs questionnaires ( [Turley and Tanney, 1998](#)). To assess further the efficacy of the workshop, a more comprehensive assessment was completed on 91 participants to determine changes in their capacity to identify evidence of suicide risk, accurately estimate level of risk, demonstrate knowledge of the intervention process, and identify and articulate a plan of action. A comparison group of 40 individuals from similar professional/support role backgrounds who did not attend the workshop also was included. Capacity to apply information/skills presented in the workshop was assessed using two videotaped simulations; participants were rated by evaluators on their response to the simulations in terms of understanding of issues, assessment of risk, and knowledge about how an effective intervention strategy might be applied. The experimental and control groups did not differ at baseline, but at the postworkshop assessment the experimental group demonstrated significant gains in their self-declared readiness to make a suicide intervention and in their competencies as reflected in responses to the simulations, whereas the contrast group demonstrated no change. The investigators concluded that this evidence supports the efficacy of the ASIST approach, but acknowledged the need for longer follow-up evaluations that assess the effectiveness of these programs on actually altering rates of suicide (Tanney B, personal communication 3/23/2001).

Another program, Community Action for Youth Survival, combined gatekeeper training with means restriction and postvention efforts ( [Grossman and Kruesi, 2000](#)), and targeted school and health care professionals. Evaluation of the program indicated that participants reported increases in knowledge of suicide prevention practices that were retained over a 4- to 5-month period and that led to changes in their practices with teens. For example, they were more likely to make follow-up plans for at-risk youth and to talk with parents about means restriction. Efforts to disseminate the program nationwide through an interactive educational CD-ROM suggest that this approach alerts viewers to the problem of who then needs direct training ( [Grossman and Kruesi, 2000](#)).

## MENTAL HEALTH

Studies continue to provide modest support for the efficacy of suicide prevention hotlines. [Becker \(1997\)](#) examined the effectiveness of suicide prevention center telephone interventions in reducing the suicidality of a sample of 129 participants, ranging in age from 14 to 66 years. Evaluative data were obtained at the beginning and end of the telephone intervention and again 1 week later. Findings revealed significant reduction in suicidality both at the end of the call and over the 1-week follow-up period. Unlike prior studies, no sex differences were found. Similarly, [Turley et al. \(2000a\)](#) evaluated the results of an active campaign to promote Lifeline Australia and enhance the competency of the phone counselors. Calls regarding suicide made up 4% to 8% of the calls made across the 42 call centers and increased 41% during the active campaign, but declined gradually when the campaign ended. A follow-up study of a subset of callers revealed overall satisfaction with the counselor's response; most of the callers sampled in the follow-up study reported following the options for further care suggested by the counselor.

However, in a review of 14 studies examining whether suicide prevention centers have an effect on suicide rates, [Lester \(1997\)](#) found that only seven studies provided support for a preventive effect. Methodologic differences and limitations across projects make it difficult to come to a final conclusion, but Lester argued that suicide prevention centers have a small positive effect on reducing rates of suicide. It appears that concerns similar to those raised by [Shaffer et al. in 1988](#) remain in relation to crisis telephone services ( [Seeley, 1997](#)). These include the need for better training and supervision of the staff and volunteers providing these services, and the need for policies guiding hotlines in the legal and ethical issues of suicide prevention and crisis intervention services ( [Seeley, 1997](#)). Even with these drawbacks, however, suicide prevention scholars continue to include crisis and telephone hotline services as one of the important elements in youth suicide prevention efforts ( [Goldney, 1998](#)). Because of the impulsive nature of most youth suicidal behavior, the ready access to a care provider who can serve as a deterrent remains a critical component of prevention services.

Other programs that fall in this category include emergency department (ED)- and hospital-based programs for youth who present with suicidal ideation or attempts. As stated previously, suicide attempts are common among adolescents. Moreover, youth that make a suicide attempt are at increased risk for future attempts as well as for eventually committing suicide ( [Shaffer and Piacentini, 1994](#)). There are, however, few systematic studies of the treatment of suicidal adolescents, in part because these youth and their families frequently fail to follow through with the treatment recommendations made and appointments scheduled at the time of the suicide gesture ( [Trautman et al., 1993](#)).

[Rotheram-Borus and colleagues \(1994\)](#) have developed and tested a two-part intervention designed to decrease risk of repeated suicide gestures/completed suicide among Hispanic adolescent girls who present in an ED/clinic having made a suicide gesture. The first component of their program is ED based and includes training of ED staff; an educational video for parents and teens to view while in the ED aimed at increasing their understanding about youth suicide, the need for treatment, and what to expect from treatment; and an on-call therapist who works with the family while in the ED and helps with their transition to outpatient treatment. The second component is a six-session, cognitive–behavioral treatment program developed for working with suicidal youth and their families. The program, Successful Negotiation/Acting Positively (SNAP), is designed to increase positive feelings and problem-solving skills among family members while also demonstrating that therapy can be an effective tool so as to increase the probability that these families will seek help again when problems arise. The first component, directed at the family's initial contact in the ED, has proven more effective than standard ED care as reflected in reports of greater declines in depression and suicidal ideation and greater adherence with participation in follow-up treatment among girls in the specialized ED care, as well as more positive attitudes regarding treatment among their mothers ( [Rotheram-Borus et al., 1996](#)). Furthermore, recent data suggest that both the suicidal adolescent girls and their mothers who were exposed to the specialized ED care continued to report lower levels of depression at the 18-month follow-up assessment than did those who received traditional ED care. The specialized ED care was particularly associated with a decline in distress among mothers of highly symptomatic girls. Number of therapy sessions attended post-ED visit did not affect outcome, but the efficacy of SNAP *per se* has not been fully evaluated because all subjects were included in this component of the program ( [Rotheram-Borus et al., 2000](#)).

Finally, in the mental health arena, screening youth to increase identification and referral of youth with mental health problems has been recommended as a more effective approach to suicide prevention than universal, school-based education programs ( [Shaffer and Craft, 1999](#); [Shaffer et al., 1988](#)). Screening programs, however, have not been implemented yet because of the complex issues involved. Given the fluctuating nature of adolescents coupled with the fact that at least some key disorders that should be screened for, such as depression, are episodic, there are questions about how best to determine the timing and frequency of screening as well as concerns over ensuring that services are readily available for youth if a screening program were initiated ( [Hayden and Lauer, 2000](#)).

## Future Directions in Suicide Prevention

[Berman and Jobes \(1995\)](#) recommended that as we move forward, suicide prevention must be viewed from a broad approach that includes primary, secondary, and tertiary prevention efforts. At each of these levels, they suggest strategies for addressing individual predisposition, social milieu, and "proximal agents," which refers to efforts to educate caretakers about the risks associated with firearms as well as medications. [Table 66.1](#) summarizes their approach. One example of this kind of broad-based perspective has been developed and tested in the Dade County School District ( [Zenere and Lazarus, 1997](#)). Their program involves a comprehensive model of suicide prevention adopted by the school board and administration, with components that range from a comprehensive curriculum integrated into the district's health education program beginning in kindergarten to trained school-based crises teams. The curriculum addresses several themes: self-awareness development, decision-making skills, drug information, and development of positive alternatives and assertiveness, conflict resolution, and stress management skills. Suicidal behavior is not formally introduced until the 10th grade, when it is discussed as one unit of a life management skills class that all students take for one semester. The focus is on prevention strategies. The program was evaluated by comparing school district data on the number of students who completed or attempted suicide from 1980 to 1988 with the same data from 1989 to 1994, the first 4 years in which the program was operating. [Zenere and Lazarus \(1997\)](#) reported a decline of 67% in the average annual number of suicides as well as a significant decline in known suicidal attempts. Rates of suicidal ideation, however, declined during the first 2 years of the program and then returned to levels seen at the time of the program's inception. The investigators found that during the second 2 years of their study (1992 to 1994), the highest levels of suicidal ideation were reported by students in grades 6 to 8, and attempts were most common in students in grades 7 to 9, suggesting that the presentation of specific suicide prevention material should be in early middle school rather than 10th grade.

	Primary Prevention	Secondary Prevention	Tertiary Prevention
Primary prevention	Depression management Algebra management Cognitive-behavioral therapy Problem-solving training Coping enhancement Critical thinking skills Help-seeking training Relaxation Counseling Outpatient treatment	Depression management Early detection/initial of parents Coping skills Supportive therapy Family therapy Case finding Cognitive therapy Cognitive-behavioral therapy Crisis intervention programs Case management follow-up	Gun safety training for parents and adolescents Suicide awareness among health care providers Parent/teen/peer educator education Medication limited Subsistence skills Decrease access to guns
Secondary prevention	Psychiatric treatment Substance abuse treatment	Psychiatric treatment Crisis intervention programs Case management follow-up	Substance abuse treatment Psychophysics for diagnosis Neuroleptics for psychosis

**Table 66.1. A Conceptual Model of Prevention Strategies**

In sum, suicide prevention requires the broad-based approach outlined in this review. It is critical that ongoing efforts address not only suicidal or risk-taking thoughts and behaviors *per se* but the myriad of individual, environmental, and societal risk factors that contribute to the suicide vulnerability of today's youth. Protective factors also must be activated—hence the importance of enhancing social problem-solving and emotion regulation skills as well as the young person's sense of personal competence and access to family support. The next generation of youth suicide prevention efforts must continue to draw on a wide range of prevention strategies that include universal, selective, and indicated prevention approaches.

[Chapter References](#)

Anxiety disorders in children and adolescents are a prevalent, understudied, and perhaps underreported phenomenon. Estimates are that 10% to 20% of school-aged children exhibit symptoms of social withdrawal, anxiety, isolation, hypersensitivity, depression, and self-consciousness ( [Anderson et al., 1987](#); [Bernstein et al., 1990b](#); [Costello, 1989](#); [Kashani and Orvaschel, 1988](#); [McGee et al., 1990](#); [Orvaschel and Weissman, 1986](#); [Werry, 1986](#)). Anxiety disorders are associated with a negative impact in multiple domains such as low self-esteem, social isolation, inadequate social skills, and problems in academic work ( [Klein and Last, 1989](#); [Strauss et al., 1989](#)). Youth with anxiety disorders often experience debilitating physical symptoms such as headaches, stomachaches, and irritable bowel syndrome ( [Livingston et al., 1988](#)). Not only do child anxiety disorders have the potential to persist over time ( [Cantwell and Baker, 1989](#); [Keller et al., 1992](#)), but there is evidence that they tend to worsen over time ( [Strauss et al., 1988](#)). The presence of anxiety disorders in childhood also may confer a general risk for other forms of psychopathology, both concurrently, as well as later in life ( [Barlow et al., 1996](#); [Cole et al., 1998](#)). These observations highlight the importance of addressing these problems in children.

For most forms of psychopathology, knowledge about and research evidence from work with adults is better developed than that with children and adolescents. The temptation often is to extrapolate downward the information gained from work with adults. As is discussed shortly, with certain forms of anxiety, this has turned out to be an appropriate strategy, whereas with other forms of anxiety it has been less effective for understanding the problems as they affect youth. Until the publication of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) in 1994 ( [American Psychiatric Association, 1994](#)), the study of childhood anxiety disorders was separate and fairly disconnected from the study of adult anxiety. At that point, separation anxiety disorder (SAD) became the only anxiety diagnosis specific to children alone, while the other childhood anxiety disorders were integrated into the lifelong “adult” diagnoses.

This approach to anxiety disorders “across the life span” makes sense in the context of increased efforts to identify early risk factors for anxiety. However, the practice of extrapolating down adult-derived conceptualizations to fit children (and thereby integrating these two separate fields) often fails to recognize the developmental trajectory that may underlie both children's pathology, as well as the more normative aspects of their development. This point is particularly salient when considering anxiety in children and adolescents because there are age-appropriate, nonpathologic manifestations of fear and anxiety that change over the course of development.

In the first section of this chapter, anxiety is broadly defined and an overview of developmental considerations for examining both normative and pathologic forms of anxiety in youth is offered. General epidemiologic data regarding prevalence, incidence, typical demographic features, and patterns of comorbidity are presented. The following are considered: SAD, social phobia, generalized anxiety disorder (GAD), specific phobias, panic disorder with and without agoraphobia, and school refusal [obsessive–compulsive disorder (OCD) and posttraumatic stress disorder (PTSD) are covered in separate chapters]. This is followed by an overview of treatment, including pharmacologic and psychosocial treatment studies. A discussion of etiologic theories of child anxiety disorders is beyond the scope of this chapter. Traditionally, these include biological risk factors, psychosocial risks, and learning theories. The reader is referred to [Chapter 25](#) for a review of these theories.

### DEFINITION AND DEVELOPMENTAL PERSPECTIVE

Anxiety may be broadly defined as “emotional uneasiness associated with the anticipation of danger” ( [Livingston, 1991](#)). In contrast to many other forms of psychopathology, anxiety is considered a normal emotion throughout development and plays both a protective and adaptive role ( [Eisen and Kearney, 1995](#); [Labellarte et al., 1999](#)). Fear usually is considered a normal reaction to a real or imagined danger or threat (e.g., fear of the dark in a young child) ( [Eisen and Kearney, 1995](#); [Morris and Kratochwill, 1991](#)). Indeed, neuroethologic models suggest that anxiety is necessary for “survival of the species” ( [Leckman and Mayes, 1998](#)). It is not uncommon to see fears as well as isolated subclinical anxiety symptoms develop and change over time in most children and adolescents, and transitory fears and anxieties are widely accepted as part of normal child development ( [Bernstein et al., 1996a](#); [Craske, 1997](#); [Last et al., 1996](#); [Silverman and Nelles, 1990](#)). These may include fears of harm to self or others, excessive worry about a particular situation, or separation anxiety ( [American Academy of Child and Adolescent Psychiatry, 1997a](#); [Bell-Dolan et al., 1990](#)).

A great deal of research has investigated developmental patterns of normal fear in children and adolescents ( [Evans et al., 1997](#); [Gullone, 2000](#); [Ollendick, 1983](#); [Ollendick et al., 1985](#); [Reed et al., 1992](#)). Results suggest that certain fears and anxieties are more common at some ages than others, although not as a function of age exclusively. Beginning in infancy, young children are fearful of stimuli in their immediate environment. By 12 months of age, fears begin to include strangers, strange places, and heights. In the preschool years, children become fearful of being alone, the dark, animals, and imaginary creatures. Once children enter school, it is common to see fears of supernatural phenomena, evaluative or social situations, and bodily injury/illness or natural disasters.

Because many childhood fears play a normal, adaptive, and protective role, the distinction between normal and abnormal child anxiety is not always clear ( [Bernstein et al., 1996a](#); [Klein, 1994](#)). The extent to which irrational fears or worries cause significant distress or impairment in academic or social functioning is important. The timing of symptoms also must be considered in a developmental context (e.g., mild separation anxiety means something different in a young child than in an older adolescent). In addition to using these factors to help differentiate normal from pathologic anxiety, it also is important to acknowledge that several symptoms associated with anxiety disorders may be present in individuals who do not qualify for anxiety diagnoses. In fact, some researchers and clinicians have supported the use of dimensional diagnostic systems as opposed to the categorical system provided in DSM-IV as a means of capturing the level of symptomatology present in a given individual.

Anxiety researchers also make distinctions among anxiety, fears, and phobias. In contrast to fears, phobias involve excessive, specific, persistent fear of a stimulus as well as significant avoidance or distress ( [American Academy of Child and Adolescent Psychiatry, 1997a](#)). Phobic reactions are disproportionate to the demands of the situation, impervious to reasoning, and often occur outside the normal developmental period of a fear (e.g., fears of monsters in an older child). Unlike fears and phobias, anxiety is more diffuse and lacking in specificity ( [Kendall et al., 1991](#)). Although some amount of anxiety is normative and adaptive in many situations, anxiety “disorders” involve irrational fear or worries that cause significant distress or interference in functioning.

There are many different types of anxiety symptoms and diagnoses. Notably, symptoms of anxiety also are seen in psychiatric and medical conditions in addition to those officially categorized as anxiety disorders ( [Table 67.1](#)). Anxiety symptoms and diagnoses present with a range of cognitive, behavioral, and physiologic symptoms. These include excessive fears and worries that can fall in a number of categories, including phobic avoidance, panic attacks, social or stimulus specific fears, and generalized vigilance/anticipatory anxiety ( [Table 67.2](#)).

Disorders usually first diagnosed in infancy, childhood or adolescence
Separation anxiety disorder
Selective Mutism
<b>*Adult diagnoses that include children</b>
Generalized anxiety disorder
Social phobia
Specific phobia
Obsessive-compulsive disorder
Posttraumatic stress disorder
Acute stress disorder
Panic disorder with and without agoraphobia
Anxiety disorder due to a general medical condition
Substance-induced anxiety disorder
Anxiety not otherwise specified
<b>Other disorders with anxious features</b>
Hypochondriasis
Somatization disorder
Adjustment disorder with anxious mood

**Table 67.1. DSM-IV Anxiety and Anxiety-Related Disorders**

Cognitive	Behavioral	Physical
Fearful	Restless	Cardiovascular (e.g., racing heart)
Nervous	Clingy	Respiratory (e.g., difficulty breathing)
Stressed	Dependent	Skin (e.g., sweating)
Fretful	Shy	Musculoskeletal (e.g., stiff neck)
Self-defeating	Withdrawn	Gastrointestinal (e.g., irritable bowel)
Difficulty concentrating	Reluctant	Headache
Inattentive	Avoidant	Dizziness

**Table 67.2. Signs and Symptoms of Anxiety**

## PREVALENCE AND EPIDEMIOLOGY

Overall, anxiety disorders are considered to be one of the most common psychiatric diagnoses in children and adolescents (Albano et al., 1996; Bernstein and Borchardt, 1991). In community samples, anxiety disorders have been shown to occur in 5% to 18% of children (Benjamin et al., 1990; Costello and Angold, 1995). In preadolescent children, the prevalence is 0.3% to 12.9%, depending on the disorder (Anderson et al., 1987; Craske, 1997; Kashani et al., 1989). For adolescents, prevalence ranges are from 0.6% to 7%, depending on the disorder (Bell-Dolan and Brazeal, 1993; Lewinsohn et al., 1993). Specific phobias, SAD, and GAD tend to be the most prevalent.

There is very limited information available with regard to sex, age, socioeconomic status (SES), and ethnicity as they relate to child anxiety disorders. With regard to sex, in general community samples, girls outnumber boys in terms of number of fears (Craske, 1997). This may, in part, be the result of socialization and parent modeling. In terms of anxiety diagnoses, in community samples, girls outnumber boys except in the diagnosis of OCD (American Academy of Child and Adolescent Psychiatry, 1997a). However, there appears to be less of a sex differential for children and adolescents in clinical settings (Last et al., 1992; Strauss and Last, 1993).

With regard to age, SAD has an earlier age of onset than the other anxiety disorders (Last et al., 1992). Younger children with SAD also tend to have more symptoms and different symptoms than older children (Francis et al., 1987). In contrast, older children with GAD have been shown to have more symptoms than younger children with GAD (McGee et al., 1990). These limited data also parallel the normative developmental trajectory presented earlier. There are no current data describing the relationship between age and other anxiety disorders.

Research on the connection between SES and ethnicity and their relationship to child anxiety has focused mostly on normal fears. For example, lower SES children have been shown to have more fears and more intense fears than higher SES children (Gullone, 2000). Some authors also have found differences in the development of normal fears in cross-cultural studies (Dong et al., 1994; Neal et al., 1993). For example, African-American children report fewer concerns about school- or embarrassment-related fears than white children. It also has been suggested that there may be some connection between SAD and lower SES (Last et al., 1992; Velez et al., 1989). There also may be higher rates of GAD in middle and upper class white children (Last et al., 1987a). Finally, African-American children may be less likely to present for treatment for school refusal (Last and Perrin, 1993). Again, we have no research with regard to SES and other anxiety disorders. Clearly, further study is needed to understand better these important issues.

## COMORBIDITY

As with adults, anxiety disorders in youth frequently occur simultaneously with each other and with other types of psychopathology. Rates of comorbidity among anxiety disorders tend to be somewhat lower in the general population—39% in children (Anderson et al., 1987; Kashani et al., 1990) and 14% in adolescents, (McGee et al., 1992)—than in clinic samples (50%) (Last, 1987). After comorbidity with another anxiety disorder, depression is the most commonly reported comorbid condition among youth with anxiety disorders. In their review of the relationship between anxiety and depression in children and adolescents, Brady and Kendall (1992) found that 15.9% to 61.9% of children identified as anxious or depressed had the other disorder as well. Differential diagnosis among anxiety and other childhood disorders is a significant concern as well. (This issue is discussed in detail for each specific disorder addressed later in this chapter.)

Anxiety disorders also can occur with externalizing disorders such as attention deficit/hyperactivity disorder, conduct disorder, and oppositional defiant disorder. One group of researchers has reported that approximately 20% of cases with an anxiety disorder also meet criteria for an externalizing disorder (Last et al., 1992; Last et al., 1987b). Epidemiologic data support the conclusion that anxiety and behavior disorders co-occur at beyond chance levels (Anderson et al., 1987; McGee et al., 1990).

## GENERAL ASSESSMENT ISSUES

In addition to a standard psychiatric assessment, a comprehensive anxiety evaluation should pay careful attention to a number of specific issues. These include (a) whether the anxiety is stimulus specific, spontaneous, or anticipatory; (b) the degree of avoidance in daily life caused by the anxiety symptoms; (c) social and familial context and reinforcers of symptoms; (d) temperament, quality of attachment, stranger/separation responses, and childhood fears; (e) medications or medical disorders that may cause anxiety symptoms; and (f) family history of anxiety disorders (American Academy of Child and Adolescent Psychiatry, 1997a).

Useful guidelines for both a general child psychiatric examination as well as an assessment specific to child anxiety can be found in the American Academy of Child and Adolescent Psychiatry's "Practice Parameters for the Psychiatric Assessment of Children and Adolescents" (American Academy of Child and Adolescent Psychiatry, 1997b) and "Practice Parameters for the Assessment and Treatment of Children with Anxiety Disorders" (American Academy of Child and Adolescent Psychiatry, 1997a). The medical workup for an anxious child should include a review of visits to physicians for the presenting symptoms, medications (prescription, over the counter, herbal and health supplements) taken by the patient that could produce anxiety symptoms, and physical conditions that may mimic anxiety disorders (e.g., documented hypoglycemic episodes, hyperthyroidism, cardiac arrhythmias, caffeineism, pheochromocytoma, seizure disorders, and migraine) (American Academy of Child and Adolescent Psychiatry, 1997a).

Once it has been established that a child or adolescent may be experiencing fear or anxiety beyond that expected for someone of his or her age or developmental level, the clinician must begin a more careful review of symptoms. In doing so, there are several issues that may be encountered. Children and young adolescents may be less likely to recognize that their fear response is excessive or to describe themselves as in "distress." In addition, children and young adolescents may show their anxiety in very different ways than adults (e.g., crying, tantrums, irritability, somatic complaints). Finally, children and young adolescents may have difficulty

reporting on their experiences. It is crucial to use developmentally appropriate questioning and examples and to seek additional sources of information (e.g., parents, observational measures).

A comprehensive clinical assessment also might include a structured or semistructured psychiatric interview to confirm anxiety diagnoses and other comorbid disorders. In addition, clinician rating scales, self-report scales, parent-report measures, and observational measures may help to determine the specific nature and severity of anxiety symptoms. The overall goal of these assessment measures should be to (a) provide reliable and valid assessment of symptoms across multiple domains, (b) discriminate symptom clusters, (c) assess severity, (d) incorporate multiple observations (e.g., parent and child), and (e) be sensitive to treatment-related changes in symptoms (March et al., 1997; Stallings and March, 1995).

### Diagnostic Interviews for Child and Adolescent Anxiety Disorders

A number of general diagnostic interviews for children and adolescents include sections/modules on anxiety disorders. These include the Schedule for Affective Disorders and Schizophrenia for School Age Children—Epidemiologic Version (K-SADS-E) (Orvaschel, 1995), the Schedule for Affective Disorders and Schizophrenia for School Age Children—Present and Lifetime Version (K-SADS-PL) (Kaufman et al., 1997), the Diagnostic Interview for Children and Adolescents—Revised (DICA-R) (Reich, 1997), and the National Institute of Mental Health Diagnostic Interview Schedule for Children (DISC) (Schaffer et al., 1996). Only the Anxiety Disorders Interview Schedule for DSM-IV—Child Version (ADIS-IV) (Silverman and Albano, 1996) is designed specifically to evaluate anxiety disorders in youth.

### Clinician Rating Scales

A number of clinician rating scales have been developed to assess child and adolescent anxiety disorders (Greenhill et al., 1998). These measures allow for clinician ratings of general symptoms of anxiety (e.g., social phobia, specific phobia, GAD). Symptoms of OCD and PTSD usually are not included. Many of these instruments are based on composite interviews of both child and parents, and include the Hamilton Anxiety Rating Scale (HARS) (Hamilton, 1959), the Pediatric Anxiety Rating Scale (PARS) (Riddle and Greenhill, 1997), and the Anxiety Rating Scale for Children—Revised (ARSC-R) (Bernstein et al., 1996b).

### Self-Report Measures

A number of self-report measures have been developed to assess the severity of both generalized anxiety and fearfulness in children and adolescents. In addition, many instruments exist that measure the severity of symptoms specific to individual disorders (e.g., social anxiety, posttraumatic stress reactions, obsessions and compulsions). Examples of general self-report measures include the Multidimensional Anxiety Scale for Children (MASC) (March et al., 1997), the Revised Children's Manifest Anxiety Scale (RCMAS) (Reynolds and Richmond, 1978), the State-Trait Anxiety Inventory for Children (STAIC) (Spielberger, 1983), and the Screen for Child Anxiety-Related Emotional Disorders (SCARED) (Birmaher et al., 1997), which also has a parent-report version. A number of more specific measures of anxiety deserve brief mention. These include the Fear Survey Schedule for Children—Revised (FSSC-R) (Ollendick, 1983), the Social Anxiety Scale for Children—Revised (SASC-R) (LaGreca and Stone, 1993), and the Social Phobia and Anxiety Inventory for Children (SPAI-C) (Beidel et al., 1995).

## SPECIFIC DISORDERS

### Separation Anxiety Disorder

#### DEFINITION AND CLINICAL DESCRIPTION

Separation anxiety disorder is the only childhood anxiety disorder retained in DSM-IV under “Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence” (American Psychiatric Association, 1994). The essential clinical feature of SAD is tremendous fear and anxiety regarding being apart from home or from primary attachment figures. The anxiety must be inappropriate for the child's age and developmental level and must last at least 4 weeks. It is particularly important to distinguish normal from abnormal separation anxiety, given that such anxiety is an age-appropriate phenomenon from approximately 7 months to 6 years of age (Albano et al., 1996; Bernstein and Borchardt, 1991; Rabian and Silverman, 1995). The reported prevalence of SAD is in the range of 2.4% to 5.4% in most studies (Anderson et al., 1987; Benjamin et al., 1990; Bowen et al., 1990; Costello, 1989).

Children with SAD may show distress when separation is anticipated or occurs, or will try to avoid separation situations altogether. Distress may take the form of terror or autonomic arousal. Children with SAD often resist separation by clinging, crying, begging, or complaining of somatic distress. The underlying fear is that harm may come to the attachment figure or the child, resulting in permanent separation. School refusal and excessive somatic complaints are the most common reason for parents and children to seek treatment.

#### DEVELOPMENTAL PERSPECTIVE

Separation anxiety disorder is found most often in prepubertal children, but can be diagnosed at any age before 18 years (Albano et al., 1996; Kashani and Orvaschel, 1988). As noted earlier, the distress or impairment in functioning related to separation must be greater than what would be considered developmentally appropriate. Subclinical SAD symptoms are thought to be relatively common in nonclinical samples (Bell-Dolan et al., 1990). Francis and colleagues (1987) found that the age of the child did differentiate both the specific symptomatology and the total number of symptoms in clinical samples of youth with SAD, with younger children showing more symptoms and greater distress.

#### DIFFERENTIAL DIAGNOSIS/COMORBIDITY/RELATED SYMPTOMS

The differential diagnosis of children presenting with difficulty separating from parents, avoidance of school or other situations involving separation, or excessive distress on separation should include, in addition to SAD, a number of anxiety as well as other disorders. The primary focus of the fear in SAD must be related to the threat of or actual separation from primary attachment figures. Occasionally, OCD may present looking like SAD, but usually other symptoms of OCD would be present.

Children with SAD often may be diagnosed with other comorbid anxiety disorders, as well as depression (Last et al., 1987b). Overanxious disorder (now GAD in DSM-IV), as well as specific phobia appear to be the most common comorbid anxiety problems (Last et al., 1987a). Children with SAD often present with a number of specific fears (e.g., monsters, the dark, animals), even if the fears are not serious enough to warrant a phobic diagnosis (Last, 1989). In addition, SAD is the most common anxiety diagnosis in samples of depressed prepubertal children (Keller et al., 1992; Kovacs et al., 1989). Other related features include somatic complaints (Last, 1991) as well as decreased participation in extracurricular activities and time spent with friends (Albano et al., 1996). Academic performance also may be affected because of preoccupation with separation during the school day, or refusal to attend school.

#### COURSE AND OUTCOME

There is not a great deal of research with regard to the long-term course of SAD (Cantwell and Baker, 1989; Keller et al., 1992). However, SAD is seen in general as having a variable course, with possible exacerbations at times of stress or transition. In some children with SAD, there appears to be complete recovery with little residual impairment. This may be particularly true for children in whom the disorder develops at younger ages (Black, 1995). Others may have a chronic course characterized by periodic exacerbations and recurrences or more persistent symptoms.

A later age of onset, comorbidity with other psychiatric disorders, family psychopathology, and missing more than 1 year of school may be associated with increased rates of chronic illness (Black, 1995). Moreover, if the anxiety symptoms interfere with the normal tasks of developing self-esteem and peer relationships, later developmental stages may be affected. Ongoing somatic complaints also may develop into a consistent pattern throughout childhood and adolescence and lead to multiple medical evaluations. Many authors have suggested that childhood SAD is a risk factor for the development of panic disorder or agoraphobia as an adolescent or adult (Battaglia et al., 1995; Biederman et al., 1993; Gittelman and Klein, 1984; Moreau and Follet, 1993). Children with SAD also may be at increased risk for depressive disorders and social phobia as adults (Black, 1995). Children of parents with panic disorder have more than a threefold increase in the risk for SAD (Weissman et al., 1984).

## TREATMENT

Individual, family-based, and group cognitive-behavioral treatment (CBT) appear to be successful in the treatment of SAD. Historically, individual psychodynamic psychotherapy has focused on mastering issues of separation, autonomy, self-esteem, and achieving age-appropriate independent behaviors. Parents may play an important role in the treatment, as they are encouraged to understand both the child's need for security and for independent behavior. It is important to explore each parent's own issues related to separation that may be unconsciously being played out with their own children.

Although there are no CBT programs designed specifically for treating SAD, a number of studies have successfully used CBT strategies to treat children with SAD as well as other anxiety disorders (i.e., GAD, social phobia and specific phobia) ([Barrett et al., 1996](#); [Cobham et al., 1998](#); [Dadds et al., 1997, 1999](#); [Kendall, 1994](#); [Kendall et al., 1997](#)). A systematic combined treatment program (CBT plus imipramine) was developed by Bernstein and colleagues ([Bernstein et al., 2000](#)) to treat children with school refusal (with comorbid anxiety and major depressive disorder), and this is discussed subsequently.

Specific treatment strategies have included (a) exposure (gradual exposure, systematic desensitization using relaxation); (b) contingency management (positive reinforcement, shaping, extinction); (c) cognitive strategies (problem solving, coping thoughts, self-talk); (d) modeling (demonstration of appropriate behaviors); and (e) family treatment (parent anxiety management, teaching parents to serve as cotherapists) ([Francis and Beidel, 1995](#); [Labellarte et al., 1999](#)). From a clinical perspective, the specific strategies used may vary slightly based on the child's SAD symptoms (e.g., avoidance vs. anticipatory distress) and developmental level. However, a combination of systematic desensitization with positive reinforcement (and cognitive strategies in older children) often is quite effective. For example, children are encouraged gradually to spend time apart from parents (e.g., going in another room, upstairs, to school) and are rewarded with stickers/prizes for successful efforts ([Francis and Beidel, 1995](#); [Labellarte et al., 1999](#)).

In general, psychotherapeutic interventions usually are initiated for SAD before pharmacotherapy is invoked. Children with significant distress and functional impairment who have not responded to specific psychotherapeutic interventions might be considered. Pharmacotherapy would be used only as an adjunct to behavioral or psychotherapeutic interventions. A child with SAD who had comorbid GAD or other anxiety disorders might benefit from the addition of medication to the multimodal treatment plan. Specific medication considerations are reviewed at the end of this chapter.

### Specific Phobia

#### DEFINITION AND CLINICAL DESCRIPTION

Specific phobia is a marked and persistent fear of circumscribed objects or situations (phobic stimuli), such as animals, blood, heights, closed spaces, or flying, such that the child/adolescent either avoids the stimulus whenever possible or endures it with intense anxiety ([American Psychiatric Association, 1994](#)). These fears are unrelated to fears of embarrassment in public or performance (as in social phobia) or fears of having a panic attack (as in panic disorder). Exposure to the phobic stimulus almost immediately provokes a significant anxiety response that may include a panic attack.

The fear must have persisted for at least 6 months and interfere with the person's normal routine, social relationships, or academic functioning, or there must be marked distress about having the fear. Children, unlike older adolescents and adults, may not realize that the fear is excessive or unreasonable. The reported prevalence rates of specific phobia range from 2.4% to 3.3%, with a higher prevalence usually reported for girls than boys ([Anderson et al., 1987](#); [Bird et al., 1988](#); [Kashani and Orvaschel, 1990](#); [Kashani et al., 1989](#)). However, there has been far more research conducted on the epidemiology of "normal" childhood fears.

Behaviorally, children with specific phobia may show avoidance either on exposure or in anticipation of exposure to the feared stimulus. They also are likely to scream, cry, or seek comfort in attachment figures. The cognitions of phobic children tend to focus on the belief that an encounter with the feared stimulus will result in harm to self or others (e.g., fearing being bitten by a dog or stung by a bee). Phobic children also tend to exhibit significant anticipatory anxiety. Physiologic symptoms in children with specific phobias may be somewhat consistent with panic-like symptoms such as increased heart rate, sweating, hyperventilation, shakiness, and upset stomach.

#### DEVELOPMENTAL PERSPECTIVE

Although much has been written on the natural history of "normal childhood fears," there is less research targeting clinical populations of children with specific phobia. It is generally believed that childhood phobias tend to parallel the onset of "normal" developmental fears with regard to age of onset and focus of the fear. Phobias of animals, darkness, blood, insects, and injury typically begin before age 7 years and have not been clearly linked to a traumatic event at onset ([Albano et al., 1996](#); [Marks and Gelder, 1966](#)). Other childhood phobias occur across a wide range of ages, with elevations between the ages of 10 and 13 years ([Strauss and Last, 1993](#)). Much of the work in this area, however, comes from retrospective studies of adults with specific phobia ([Liddell and Lyons, 1978](#); [Ost, 1987](#)).

#### COURSE AND OUTCOME

Specific phobias often begin in childhood and must be differentiated from normal developmental fears. There is some indication that childhood phobias improve over time without treatment; however, many children continue to have phobic symptoms even if they do not meet full diagnostic criteria ([Agras et al., 1972](#); [Ollendick, 1979](#)). Retrospective reports from adults also suggest some retention of phobic symptoms over time, with many adults reporting symptom onset for their phobias in childhood ([Ost, 1987](#)).

#### DIFFERENTIAL DIAGNOSIS/COMORBIDITY/RELATED FEATURES

In making a diagnosis of specific phobia, it is necessary that the fear not be related primarily to another anxiety disorder (e.g., fears of separation in SAD, fears of social humiliation in social phobia, or fears of having a panic attack in panic disorder). However, specific phobias commonly are comorbid with other anxiety disorders. Anxiety that is more generalized and diffuse may be better characterized as GAD. In addition, the clinician must be careful to differentiate the repetitive and ruminative quality of some phobias from obsessive fears associated with OCD or reexperiencing symptoms in PTSD.

## TREATMENT

The empirical literature for childhood specific phobias lags behind similar work in other childhood anxiety disorders. However, graduated *in vivo* exposure in combination with contingency management and self-control strategies appear to be the most promising treatment approaches to date ([Morris and Kratochwill, 1998](#); [Silverman et al., 1999b](#)). The exposure component involves gradual contact with progressively more distressing phobic stimuli. Exposure also can be presented imaginally as a starting point for treatment. The contingency management techniques involve modification of contingencies that relate to the child's phobic/avoidance behaviors (e.g., reinforcement and extinction). Finally, self-control strategies focus on self-evaluation and self-reward (e.g., cognitive coping strategies). A study by [Silverman and colleagues \(1999b\)](#) compared the relative efficacy of an exposure-based contingency management treatment and an exposure-based self-control treatment with an education support control group. Results showed substantial improvement for children in both of the exposure-based groups.

In general, the behavioral techniques are the first-line therapeutic intervention for most simple phobias. Pharmacotherapy has not been shown to be effective for specific phobias, and this is reviewed at the end of the chapter.

### Social Phobia

#### DEFINITION AND CLINICAL DESCRIPTION

Social phobia is a persistent fear of one or more social situations in which a person is exposed to unfamiliar persons or to scrutiny by others ([American Psychiatric Association, 1994](#)). Exposure to the feared social situations provokes anxiety, fear of embarrassment, and often panic attacks. Commonly feared situations include speaking in front of others, attending social gatherings, dealing with authority figures, performing in public, and speaking to strangers. Children and adolescents with social phobia avoid anxiety-provoking situations (resulting in interference in functioning) or endure them with marked distress. In addition, children and adolescents

may not recognize that their fear is excessive or unreasonable.

Social phobia has been estimated to occur in approximately 1% of children and adolescents ( [Anderson et al., 1987](#); [Kashani and Orvaschel, 1990](#); [McGee et al., 1990](#)). However, studies suggest that the prevalence is much higher in older populations and may be the most common anxiety disorder affecting adults ( [Kessler et al., 1994](#)). As a result, it is believed that social phobia in children and adolescents likely is underdiagnosed and undertreated because these children are labeled as “shy” rather than recognized as having clinical impairment ( [Albano et al., 1996](#)). In clinic samples, the prevalence of social phobia has been reported to be 14.9% ( [Last et al., 1992](#)). Children and adolescents with social phobia commonly fear that others will find some fault with them, considering them weird, unattractive, or stupid, or that they will do or say something foolish or embarrassing ( [Beidel et al., 1999](#)). Somatic symptoms are common and include racing heart, sweating, blushing, tremulousness, lightheadedness, and gastrointestinal distress ( [Beidel et al., 1991](#)). Socially phobic children and adolescents often have great difficulty in a number of school situations, and negative cognitions tend to focus on excessive concerns about embarrassment, negative evaluation, and rejection.

Although it is not fully described in this chapter, selective mutism also deserves mention. Selective mutism is characterized by persistent failure to speak in one or more major social situations when speaking is expected, despite speaking in other situations. Although selective mutism is not classified as an anxiety disorder in DSM-IV, research strongly suggests that it may be primarily a manifestation of social anxiety ( [Black and Uhde, 1995](#); [Black et al., 1992](#)). Shyness, fear of embarrassment, and social withdrawal are commonly seen in children with selective mutism. Systematic descriptions of children with selective mutism have revealed that nearly every child also meets criteria for either social phobia or avoidant disorder ( [Black and Uhde, 1995](#); [Dummit et al., 1997](#)). Despite early assumptions, children with selective mutism are not likely to have a history of early trauma or to be particularly oppositional ( [Black and Uhde, 1995](#)). The disorder is diagnosed in children who fail to speak in specific social situations for at least 1 month (not limited to the first month of school) and when the disturbance significantly interferes with educational or social functioning. For a comprehensive description of the assessment of a child with selective mutism, the reader is directed to other sources ( [Leonard and Topol, 1993](#)).

#### DEVELOPMENTAL PERSPECTIVE

Social phobia is most commonly diagnosed in adolescents, although cases of social phobia have been diagnosed in children as young as 8 years of age ( [Beidel and Turner, 1988](#)). Last and colleagues ( [Last et al., 1992](#); [Strauss and Last, 1993](#)) note the average age of onset in clinic-referred samples to range from 11.3 to 12.3 years. Social phobia may look quite different in younger and older children and adolescents ( [Beidel, 1998](#)). For example, younger children may have frequent tantrums or appear very “clingy” with parents or caretakers. They may refuse activities in school. Older children and adolescents are likely to shy away from family or social gatherings and peer relations altogether.

#### COURSE AND OUTCOME

Although research evidence is limited, it appears that when childhood social phobia goes unrecognized, there are significant and long-term negative consequences ( [Beidel and Morris, 1995](#)). As noted earlier, social phobia may result in school refusal behavior, premature termination of formal education, or failure to enter the workforce. In older adolescents, there is likely to be significant interference in occupational development or dating relationships.

#### DIFFERENTIAL DIAGNOSIS/COMORBIDITY/RELATED FEATURES

In making a diagnosis of social phobia, it is necessary to clarify the nature of the core fear as being specific to interactions with or performance in front of others. Children and adolescents with social phobia usually present differently than children with panic disorder (where the focus of fear is the panic attack itself), GAD (where social fears may be one of many disruptive fears), or specific phobia (where the fear is of objects or situations that do not involve social interaction). Making a differential diagnosis can be more complicated with SAD ( [Beidel and Morris, 1995](#)). Although there is a clear distinction between distress over separation from primary attachment figures and distress over approach or interaction with others, the reasons for avoidance in certain situations (e.g., school) are not always clear. The practitioner also must be conscious of obsessions or compulsions that may be fueling social avoidance (e.g., fear of contamination or harm coming to others) rather than the constellation of social fears that comprise social phobia.

Clinical correlates include depressed mood, higher trait anxiety, and increased substance use concerns ( [Beidel and Morris, 1995](#); [Strauss and Last, 1993](#)). Studies suggest that children and adolescents with social phobia have significantly poorer social skills than nonpsychiatric children ( [Beidel et al., 1999](#)). Many children and adolescents also may be perceived as oppositional because of their refusal to participate in developmentally appropriate activities.

#### TREATMENT

As noted earlier, a number of studies have successfully used CBT strategies in more generalized child anxiety treatment programs ( [Barrett et al., 1996](#); [Cobham et al., 1998](#); [Dadds et al., 1997, 1999](#); [Kendall, 1994](#); [Kendall et al., 1997](#)). These controlled treatment studies usually have included children with social phobia, as well as other anxiety disorders. Results from these studies tend to support the use of individual, family-based, and group CBT over comparison treatments ( [Beidel and Morris, 1995](#)). Interventions combining social skill-building as well as anxiety reduction techniques appear necessary for maximally successful outcome ( [Beidel et al., 1999](#)). [Beidel and colleagues \(2000\)](#) reported on 67 children with social phobia who were randomized to either a specific behavioral treatment program (designed to enhance social skills and decrease social anxiety) or an active but nonspecific intervention. Those who received the specific behavioral intervention were significantly improved across multiple dimensions, and the gains were maintained at 6 months' follow-up.

Pharmacotherapy should not be used as the sole intervention for children with social phobia. Medication might be part of a multimodal treatment plan, particularly after an intensive behavior intervention has been tried. Of the different medication options, the selective serotonin reuptake inhibitors (SSRIs) are the most likely first agents to consider. This is based on systematic efficacy studies of SSRIs in adults with social anxiety (e.g., paroxetine) and the most recent controlled trial of fluvoxamine in the successful treatment of social phobia in children and adolescents ( [Walkup et al., 2001](#)).

There is a small literature on the use of SSRIs in the treatment of children with selective mutism. In general, a behavioral treatment plan should be initiated first. If the child does not make sufficient progress, then adjunctive medication with ongoing behavioral treatment is considered. In an open study ( [Dummit et al., 1996](#)) 21 children with selective mutism were treated with fluoxetine, and 76% were improved. Improvement at week 9 was inversely correlated with age, suggesting that it is harder successfully to treat the child who has been symptomatic for a long time ( [Black and Uhde, 1994](#); [Dummit et al., 1996](#)). [Black and Uhde \(1994\)](#) reported that in 16 children with selective mutism who were treated in a double-blind, placebo-controlled study, fluoxetine was superior to placebo.

### Generalized Anxiety Disorder

#### DEFINITION AND CLINICAL DESCRIPTION

Generalized anxiety disorder is characterized by excessive and uncontrollable worry— *excessive* meaning that the worry is out of proportion to the facts of the situation, and *uncontrollable* meaning that once the individual starts worrying, he or she finds it very difficult, if not impossible, to stop. Therefore, the distinction between developmentally appropriate worry and the worry experienced by individuals with GAD is based less on the subject of the worry and more on the persistence and unrealistic nature of the worries in GAD. To be classified as having GAD, a youth needs to display a pattern of excessive worry that interferes with daily functioning and lasts for at least 6 months. Using these criteria, youth prevalence estimates range from 2.7% to 4.6% ( [Costello, 1989](#)).

Most often, the worry associated with GAD is not confined to one topic area. Typical worries for children and adolescents with GAD include worries about competence, approval, and appropriateness of past behavior. Future events and new or unfamiliar situations also are common foci for worries. There also may be excessive concerns about punctuality. Children with GAD often are seen as overly conforming and perfectionistic, and may be seen by adults as rigid or oppositional. Children and adolescents with GAD frequently seek reassurance from others, although this reassurance usually provides only fleeting relief from the oppressive worries.

Patients also are expected to present with symptoms of motor tension and vigilance, although in children only one such symptom is required to establish the diagnosis, whereas in adults three physical symptoms are required. Somatic complaints such as headaches, abdominal pain, and difficulties sleeping are common. Phenomenologically, patients report feeling keyed-up or on edge and feeling as if they are unable to relax. Particularly in children, irritability often is associated with the worry such that when more worried the child is more irritable.

## DEVELOPMENTAL PERSPECTIVE

Generalized anxiety disorder has only recently (beginning with DSM-IV) been diagnosed in children. Previously, children predisposed to excessive worry typically were classified as having overanxious disorder. Although children previously described as having overanxious disorder may not be identified with the current criteria, empirical evidence suggests that replacing overanxious disorder with GAD has had little impact on the identification and treatment of children whose anxiety is typified by excessive worry ([Kendall and Warman, 1996](#); [Tracey et al., 1997](#)). One advantage of the new system is that it facilitates study of the developmental progression of this pattern of symptoms.

Currently, we know very little about how or if the nature of the symptoms of GAD change throughout childhood and into adulthood. However, preliminary evidence suggests that the one developmental consideration included in the DSM-IV criteria for GAD (requiring fewer somatic/physical symptoms in children than in adults) may not be warranted ([Pimentel et al., 2000](#)). There is some evidence for the consistency of GAD presentations across middle childhood ([Tracey et al., 1997](#)). Also, in childhood, GAD is equally common in boys and girls, but starting in adolescence it is more common in girls ([Werry, 1991](#)). Finally, caution must be used in making inferences to children younger than 7 years of age because there is some evidence that cognitive changes that occur at approximately 7 or 8 years of age have an impact on worry processes ([Vasey et al., 1994](#)).

## DIFFERENTIAL DIAGNOSIS/COMORBIDITY/RELATED SYMPTOMS

The symptoms associated with GAD can be caused by an underlying medical condition. It is particularly important to investigate potential medical causes when autonomic symptoms predominate. Gastrointestinal problems, hyperthyroidism, pheochromocytoma, hypoglycemia, and lupus should all be considered if suggested by the history or physical examination. Excessive use of caffeine or other stimulants, particularly among adolescents, also should be ruled out before assigning the diagnosis of GAD.

A diagnosis of GAD is appropriate only when the focus of the worry is unrelated to worry better captured by another anxiety disorder. GAD can be differentiated from the other anxiety disorders in a number of ways. It can be differentiated from the anxiety associated with social phobia because the child with GAD would worry about their performance even if not being evaluated by others, whereas the child with social phobia would worry only when fearing negative evaluation by others. In children, it can be difficult to differentiate worry in GAD from obsessions associated with OCD because children with obsessions are less likely to report them as feeling ego-dystonic, and because children's worries may be seen as less reality based in the eyes of adults. Finally, when the anxiety that a child presents with is short lived and of relatively mild intensity, and when it follows a specific stressor, a diagnosis of adjustment disorder with anxious mood is more appropriate than a diagnosis of GAD.

## COURSE AND OUTCOME

Many, if not most, individuals with GAD report having been anxious for much of their lives, with anxiety most often beginning in childhood. This observation is consistent with the belief held by some that GAD is better conceptualized as a temperamental characteristic (trait) than as a major mental disorder. Also consistent with this belief is evidence that GAD most typically follows a chronic but fluctuating course, with symptoms worsening at times of stress. Obviously, for the symptoms to meet criteria for a disorder, there must be significant distress or interference.

## TREATMENT

A comprehensive assessment of the child should yield a targeted treatment plan that may use individual or family psychotherapeutic interventions. For some, a dynamic insight-oriented psychotherapeutic intervention may be successful. For many, CBT interventions are needed.

Cognitive-behavioral interventions designed for use with children and adolescents individually, as well as interventions that incorporate the family and interventions with groups of children, have been useful in treating GAD ([Barrett et al., 1996](#); [Cobham et al., 1998](#); [Kendall, 1994](#); [Kendall et al., 1997](#)). These interventions use cognitive restructuring techniques to target anxious cognitions, and relaxation training to target physiologic arousal. Behavioral experiments and *in vivo* exposure to anxiety-producing stimuli are used to reduce avoidance behaviors. Group treatments incorporate peer modeling to enhance skill building; similarly, family treatments focus on teaching parents to be effective models for their children. All approaches entail the use of positive reinforcement to increase desirable behaviors and reduce avoidance.

Few controlled trials exist for medications for children with GAD. The SSRIs have become increasingly more popular as first-line medications based on adult studies and one large, controlled trial in children. The Research Unit on Pediatric Psychopharmacology (RUPP) study ([Walkup et al., 2001](#)) reported that fluvoxamine was superior to placebo for children with GAD. A more detailed review of this study is provided at the end of the chapter.

## Panic Disorder With or Without Agoraphobia

### DEFINITION AND CLINICAL DESCRIPTION

Diagnosing children with panic disorder has been a much-debated topic (e.g., [Kearney and Silverman, 1992](#); [Nelles and Barlow, 1988](#)). As in adults, panic disorder refers to the experience of unexpected panic attacks accompanied by persistent apprehension about their recurrence or behavioral modifications in daily routine as a result of the attacks. A panic attack is a discrete period of intense fear or discomfort that is characterized by the presence of at least four somatic or cognitive symptoms. Somatic symptoms include shortness of breath, accelerated heart rate, chest pain, choking sensations, dizziness, tingling or numbing sensations, hot/cold flashes, sweating, trembling, and nausea. Cognitive symptoms include fear of dying, going crazy, and losing control. Panic attacks are typified by their abrupt onset, with all or most symptoms reaching their peak within 10 minutes.

Panic disorder may or may not be accompanied by agoraphobic avoidance. Agoraphobia is anxiety about being in places or situations in which escape might be difficult or embarrassing, particularly if one should experience a panic attack. Typical situations that are feared or avoided are being outside alone, being in a crowd, standing in line, bridges, modes of travel, shopping malls, and movie theaters. Agoraphobia usually results in a pervasive pattern of avoidance, but occasionally may result in the youth being able to endure to feared situation with intense distress, or only in the presence of a companion.

One of the main reasons that researchers have questioned the phenomenon of panic disorder in children and adolescents is a reliance on a cognitive theory of panic disorder that suggests that panic attacks and panic disorder result from "catastrophic misinterpretation" of bodily (i.e., somatic) sensations ([Clark, 1986](#)). Proponents of this model suggest that children and younger adolescents are not cognitively capable of making the kinds of internal, catastrophic attributions that characterize spontaneous panic attacks ([Nelles and Barlow, 1988](#)). They state that notions of external causation (e.g., "My heart is racing because I don't like my teacher") dominate children's cognitive responses, thus precluding the cascade of events that precipitates a panic attack.

Despite the controversy, given evidence from numerous case studies of panic attacks and panic disorder in children and adolescents ([Alessi and Magen, 1988](#); [Alessi et al., 1987](#); [Ballenger et al., 1989](#); [Biederman et al., 1997](#); [Hayward et al., 1989](#); [King et al., 1993, 1997](#); [Last and Strauss, 1989](#); [Moreau et al., 1989](#); [Vitiello et al., 1990](#)), the debate has turned more recently from questions of whether children and adolescents experience panic attacks and panic disorder, to questions about the phenomenology of panic attacks and panic disorder in children and adolescents. Estimates from community samples are that from 35.9% to 63.3% of adolescents have experienced panic attacks, with 0.6% to 4.7% of adolescents experiencing symptoms sufficient to meet DSM-IV diagnostic criteria for panic disorder. Although retrospective reports from adolescents and adults suggest that at least some subset of panic cases have their onset in childhood, there are as yet no reliable estimates as to the prevalence of the disorder in prepubertal children.

The most commonly reported symptoms among adolescents with panic attacks appear to be trembling, dizziness/faintness, pounding heart, nausea, shortness of breath, and sweating ([Kearney et al., 1997](#); [King et al., 1997](#)). Cognitive symptoms are reported less frequently than somatic ones ([King et al., 1997](#)). The most commonly avoided settings included those involving large groups of people unknown to the patient (e.g., restaurants, crowds, auditoriums) ([Kearney et al., 1997](#)).

## DEVELOPMENTAL PERSPECTIVE

Despite recent research, there still is some resistance to the idea that panic disorder is anything but very rare in children. For example, [Last and colleagues \(1992\)](#) suggest that the panic symptoms that occur before adolescence are most often an associated feature of another anxiety disorder. Panic attacks themselves, not even full-blown panic disorder, also are more likely in older children and adolescents ([Hayward et al., 1992](#)).

#### *DIFFERENTIAL DIAGNOSIS/COMORBIDITY/RELATED SYMPTOMS*

The most difficult distinction required when diagnosing panic disorder in youth is the difference between an unexpected panic attack, as required for a diagnosis of panic disorder, and situationally cued attacks that are typical of other anxiety disorders. This task becomes especially challenging given the cognitive predisposition of children, as described previously, to attribute their experiences to external, identifiable, situational factors. Careful noting of patterns in the circumstances surrounding attacks helps with this distinction because panic attacks occurring in the context of another anxiety disorder occur primarily in the presence of the target stimulus. In addition, presence of pervasive apprehension about having a panic attack supports the diagnosis of panic disorder rather than the diagnosis of panic attacks in the context of another anxiety disorder.

Panic attacks can be caused by a variety of medical conditions, including hyperthyroidism, hyperparathyroidism, vestibular dysfunctions, seizure disorders, and cardiac conditions. When panic is accompanied by palpitations, a discussion with the pediatrician as to the need for electrocardiography and cardiac consultation is encouraged. Appropriate laboratory tests and physical examinations should be used to rule out these causes before assigning a diagnosis of panic disorder.

#### *COURSE AND OUTCOME*

Although more direct research with children and adolescents is required, many researchers agree that the modal age of onset for panic disorder is in mid-adolescence, especially after age 14 years ([Von Korff et al., 1985](#)). Very little is known about the course and outcome for children and adolescents with panic disorder with or without agoraphobia. Based on retrospective reports of adults with these disorders, however, it appears likely that untreated, these disorders will persist into adulthood.

#### *TREATMENT*

Empirically supported psychosocial and pharmacologic interventions for panic disorder in youth have not been fully developed nor tested. However, preliminary evidence from a small, multiple-baseline–design study by [Ollendick \(1995\)](#) supports the efficacy of CBT for use with adolescents with panic disorder with agoraphobia. In this study, breathing retraining, applied relaxation, cue-controlled relaxation, positive self-instruction training, and cognitive coping procedures were applied in an interoceptive conditioning exposure paradigm. After teaching the adolescents the necessary coping skills, the adolescents were exposed to anxiety-provoking situations until their anxiety dissipated (up to 4 hours). Panic attacks were eliminated, agoraphobic avoidance was reduced, and self-efficacy for coping with future attacks was increased for all adolescents. Treatment gains were maintained at 6-month follow-up.

Currently, there are no systematic trials of the treatment of panic disorder in children. In adults, SSRIs have become the pharmacotherapeutic treatment of choice, and several SSRIs have approved indications for the treatment of panic in adults (see the discussion at the end of the chapter on medications for the anxiety disorders).

#### **School Refusal**

##### *DEFINITION AND CLINICAL DESCRIPTION*

School refusal is not a separate DSM-IV diagnostic category, and children with this symptom likely represent a heterogeneous group. [King et al. \(1995\)](#) have suggested the following criteria for clinically significant school refusal: “1) Severe difficulty attending school, often resulting in prolonged absence; 2) Severe emotional upset, including excessive fearfulness, temper outbursts, or complaints of feeling ill when faced with the prospect of going to school, 3) Staying home with the parent’s knowledge when the youngster should be at school; 4) Absence of antisocial characteristics such as stealing, lying, and destructiveness” (p. 3). These criteria highlight the need to differentiate school refusal behavior from truant behavior and cases in which other diagnostic categories (e.g., conduct disorder) may be more appropriate.

Some children outright refuse to leave home, whereas others may get part way to school only to rush home in distress, and still others make it to school only to spend much of the day in the nurse’s office, or only to make frequent calls home. When fear is maintaining the school refusal behavior, clinical reports suggest that fear may be of a variety of situations or specific events. Clinical reports also indicate that when school refusers are faced with attending school, they evidence marked physiologic changes, including muscular tension, breathing irregularities, headaches, stomachaches, and pallor ([Granell de Aldaz et al., 1987](#); [King et al., 1995](#)). Excessive dependency on the parent, and parents who present as overprotective and anxious themselves also are common. Reviews suggest that school refusal occurs in 1% of all school-aged children and in 5% of clinic-referred children ([Burke and Silverman, 1987](#); [King et al., 1995](#)).

##### *DEVELOPMENTAL PERSPECTIVE*

The nature of school refusal behavior is likely to change with age, as is the nature of the precipitating events. For example, fear of separation is more common in younger school refusers, whereas fear of teachers or other children is more common in older children; social-evaluative fears also are more common in older children. As children get older, and as the problem potentially becomes more entrenched, it becomes harder for parents physically to force children to attend school, so it is more common for older children with school refusal never to make it to school, rather than to go to school and spend time in the nurse’s office.

##### *DIFFERENTIAL DIAGNOSIS/COMORBIDITY/RELATED SYMPTOMS*

Children and adolescents with school refusal behavior most frequently meet diagnostic criteria for another major mental disorder. Among the most common diagnoses that accompany school refusal behavior are SAD, specific phobia, social phobia, and major depression ([King et al., 1995](#)). In addition, when there is acute avoidance of any situation, a consideration of abuse needs to be explored.

##### *COURSE AND OUTCOME*

Acute onset is more common in younger children (often following a change in routine school attendance such as an illness, move to new school, or a vacation). [Ollendick and Mayer \(1984\)](#) found that the onset of school refusal behavior coincides with entry into school and transitions from elementary to middle school (in the United States, between 5 and 6 years of age, and 10 and 11 years of age). In general, the longer the pattern of school refusal persists, and the more entrenched the pattern becomes, the harder it will be to treat successfully ([King et al., 1995](#)).

##### *TREATMENT*

Several randomized clinical trials have tested the efficacy of CBT interventions for children with severe school refusal behavior. One study ([King et al., 1998](#)) used a manual-based multicomponent treatment program to provide coping skills training and exposure to children, and to provide training to parents and teachers in behavior management strategies. Using the outcome criterion of 90% school attendance, this study found that 88.23% of the treated children had improved, whereas only 29% of the children assigned to a wait list condition had achieved this criterion. Another study ([Last et al., 1998](#)) compared a CBT intervention with a psychosocial placebo control condition. The CBT consisted of graduated *in vivo* exposure and cognitive restructuring training. The placebo control therapy included educational presentations, supportive psychotherapy, and a daily diary assignment to record thoughts and fears. Contrary to expectations, there were no differences in the efficacy of these two approaches. Posttreatment, both groups showed improvements in school attendance and other related outcome measures. Regardless of treatment received, younger children and children with higher rates of school attendance before treatment showed the greatest improvements after treatment.

Another approach is [Kearney and Silverman’s \(1990\)](#) prescriptive treatment approach, which tailors the components of CBT to specific features of children’s school refusal behavior. They identify the motivating conditions and look at removing the negative consequences associated with attending school (e.g., aversive social experiences) and the positive consequences of being at home (e.g., special time with a parent or friends). Open results are promising, but controlled trials are needed

([Kearney and Silverman, 1990](#)).

Until the early 1990s, with the intensive study of OCD, school refusal had been the most studied anxiety in children. The first controlled trials in children with anxiety problem were completed with school refusers. The original four placebo-controlled trials of tricyclic antidepressants for separation anxiety or school refusal reported contrasting results that have been attributed to issues of diagnostic heterogeneity, comorbidity, drug dosage, and absence of control of concurrent therapies ( [Berney et al., 1981](#); [Bernstein et al., 1990a](#); [Gittelman-Klein and Klein, 1971, 1973](#); [Klein et al., 1992](#)). Gittelman-Klein and Klein ( [1971, 1973](#)) reported that children receiving imipramine (100 to 200 mg/day) were significantly more successful (81%) in returning to school than those on placebo (47%). [Klein et al. \(1992\)](#) attempted to replicate their study but found that children who had failed behavioral treatment and who were then randomized to either imipramine or placebo did not significantly differ in outcome. [Berney and colleagues \(1981\)](#) reported that low-dose clomipramine (40 to 75 mg/day) was not superior to placebo in the treatment of 51 children (9 to 14 years of age) with anxiety symptoms (44% had comorbid depressive symptoms). In 1990, [Bernstein et al. \(1990a\)](#) reported that a comparative study of imipramine, alprazolam, and placebo in children did not show significant differences between active medication and placebo. Both alprazolam and imipramine were associated with greater improvement on some rating scales, but this did not approach significance.

In their 2000 landmark study, Bernstein and colleagues used an adapted version of [Last and colleagues' \(1998\)](#) manual to test the efficacy of CBT plus imipramine (CBT+IMI) versus CBT plus placebo (CBT+PBO) treatments for adolescent school refusers with comorbid anxiety and major depressive disorder. Sixty-three subjects entered, and 47 completed, this 8-week, randomized, controlled trial. School attendance improved significantly for the CBT+IMI group but not for the CBT+PBO group. At 8 weeks, 54% of the CBT+IMI group were in remission (defined as 75% school attendance), compared with 17% of the CBT+PBO group. They reported that CBT+IMI was significantly more efficacious than CBT+PBO in improving school attendance and in decreasing symptoms of depression ( [Bernstein et al., 2000](#)). This study was the first combined systematic treatment study completed in children and adolescents with an anxiety disorder, and provides a model for combined psychosocial and drug treatments.

As an aside, school phobias may develop in patients after the addition of a neuroleptic. This phenomenon was initially reported with haloperidol and pimozide and is likely pharmacologically mediated ( [Linet, 1985](#); [Mikkelsen et al., 1981](#)). Most recently, this was reported with an atypical neuroleptic, risperidone ( [Hanna et al., 1999](#)).

## GENERAL TREATMENT ISSUES

[Kendall \(1994\)](#) estimated that fewer than 20% of youth receive the necessary treatment for their anxiety disorder. This is due in part to the fact that children and adolescents with anxiety disorders are more “internalizing,” so their behavioral problems (and distress) may not be as obvious to others. In addition, many may wish to hide their symptoms from others. Despite the difficulties with providing treatment for all of the youth in need, researchers are beginning to document which interventions are efficacious for treating anxiety disorders in youth.

The American Psychological Association (Division 12) ( [Chambless et al., 1996](#); [Task Force on Promotion and Dissemination of Psychological Procedures, 1995](#)) has instituted a uniform set of criteria for standardizing the process of evaluating the empirical support for treatment efficacy. Following these criteria, treatments can be judged as well established, “probably efficacious,” or experimental. To be considered well established, treatments must have been shown to be more effective than pill placebo or alternate treatment, or equivalent to an established treatment in two or more group-design studies. Alternatively, positive outcomes from nine or more single-case studies that describe the sample carefully and use treatment manuals to compare the treatment with another treatment can be used as evidence. “Probably efficacious” treatments have been shown more effective than a no-treatment control group in two studies, or in two studies *from the same investigator* have been shown to be superior to an alternate treatment or equivalent to an established treatment. Alternatively, results from three or more single-case studies using treatment manuals and well described samples may be used as evidence. Any treatment that has not attained probably efficacious status is considered experimental.

Similarly, sophisticated evidence-based medicine guidelines offer another model for assessing the empirical treatment literature for psychiatric disorders. The reader is directed to the text by Sackett and colleagues and to the excellent “User’s Guide” series in the *Journal of the American Medical Association* ([Guyatt and Rennie, 1993](#); [Sackett et al., 1997](#)). Evidence-based models allow for the assessment of combined treatments in a multidisciplinary biopsychosocial model.

In two meta-analyses reviewing treatment outcome results for diverse psychotherapeutic procedures (i.e., psychodynamic, nondirective, family systems, behavioral, and cognitive-behavioral therapies), Weisz and colleagues ( [1987, 1995](#)) concluded that regardless of client age, therapist experience level, or target problem, behavioral treatments were more effective than nonbehavioral treatments. Based on this conclusion, [Ollendick and King \(1998\)](#) focused their application of the criteria for establishing empirically supported treatments for child anxiety disorders on behavioral and cognitive-behavioral procedures. To date, imaginal and *in vivo* desensitization, filmed and live modeling, and CBT that uses self-instructional training have all attained probably efficacious status when used to treat phobias in youth. Participant modeling and reinforced practice are considered well-established for treating phobias in youth.

For other anxiety disorders, CBT interventions with and without family involvement have achieved probably efficacious status ( [Ollendick and King, 1998](#); [Piacentini, 2000](#)). The bulk of the data that support this conclusion comes from Kendall and colleagues’ “Coping Cat” treatment manual ( [Kendall, 1994](#); [Kendall et al., 1997](#)) and from manuals derived from this approach (e.g., “Coping Koala” by Barrett and colleagues ( [Barrett et al., 1996](#)). These procedures entail using cognitive techniques to identify anxious feelings and thoughts and to recognize somatic symptoms of anxiety. Cognitive strategies also are used to cope with anxiety, as are behavioral techniques, including exposure, modeling, relaxation training, and contingent rewarding. Follow-up data from the “Coping Cat” manual suggest that treatment gains are maintained for as long as 1 to 3 years after treatment ( [Kendall and Southam-Gerow, 1996](#)). Group CBT with and without family components also has achieved probably efficacious status for treating anxiety disorders in general ( [Piacentini, 2000](#)).

Researchers also have begun to investigate patient characteristics that may influence treatment outcome in such a way as to help clinicians choose among “probably efficacious” treatments. Support has been found for the belief that when parental anxiety is present, interventions that involve the family directly are more efficacious than individual treatment for the child ( [Cobham et al., 1998](#)).

Even if parents are not participating in family therapy *per se*, parental involvement in treatment may be crucial to the success of the child’s treatment ( [Siqueland and Diamond, 1998](#)). First, parents can help children practice and generalize the skills learned in CBT. Next, parents’ beliefs and attitudes about their own and their child’s ability to cope with anxiety can help or impede treatment success. Finally, increased independence in their child may cause fear or uncertainty in parents. In response to such factors, some authors have included parental anxiety management and family management as components in manualized CBT for child anxiety ( [Barrett et al., 1996](#); [Cobham et al., 1998](#)).

In 1999, a systematic review concluded that no definitive data exist in support of the efficacy of psychopharmacologic agents in the treatment of anxiety disorders in youth (excluding OCD) ([Labellarte et al., 1999](#)). [Of note, the first and only large, systematic psychopharmacologic study of non-OCD anxiety disorders was published subsequently in 2001 ([Walkup et al., 2001](#))]. In a review of the “best available” evidence to date, [Labellarte and colleagues \(1999\)](#) concluded that methodologic flaws, such as failure to use standardized ratings scales to measure outcome and inclusion of subjects with poorly defined primary diagnoses, weakened the ability to draw empirically sound conclusions. In fact, the authors concluded that none of the studies completed to date met the minimal criteria for adequacy of pediatric psychopharmacologic trials proposed by [Riddle and colleagues \(1998\)](#).

One methodologic flaw that has the potential to skew conclusions is that in most of the pharmacologic studies published to date, a drug agent is viewed as the “primary” change producer, to the exclusion of considering the effect that concurrent procedures may have on treatment outcome ( [Kearney and Silverman, 1998](#)). This means that many studies that on the surface appear to be testing the effects of a pharmacologic agent alone are in fact testing a poorly operationalized combination of medication and psychotherapy. Following from this, it will be crucial to make explicit the procedures used in drug trials, in addition to prescribing and distributing the medication. A second and perhaps more important conclusion is that well controlled studies that explicitly examine the efficacy of combined treatment conditions are sorely needed, and until the study by Bernstein and colleagues was published in [2000](#), none existed. No treatment has yet attained “well-established” status for treating anxiety disorders in general (Ollendick and [King, 1998](#); [Piacentini, 2000](#)). Recent work comparing a CBT intervention with a nonspecific control treatment weakens the case for granting CBT procedures “well-established” status because the outcome from the CBT was equivalent to that from the nonspecific treatment control condition ( [Silverman et al., 1999a](#)). Supporters of CBT are quick to point out that the procedures used in the nonspecific treatment control condition in this study may have overlapped too much with some of the integral elements of the CBT. In addition, the target symptoms in the anxious children in this study were specific phobias, which may be more easily treated than other forms of anxiety in children. Further research comparing interventions with alternative treatment control procedures will clarify this issue.

## Overview of Pharmacologic Interventions

Studies of the specific classes of agents are reviewed briefly because they appear in other chapters of this text. The reader is referred to several excellent comprehensive reviews of pharmacologic treatment of pediatric anxiety disorders ([Riddle et al., 1999](#); [Velosa and Riddle, 2000](#)).

## BENZODIAZEPINES

Benzodiazepines, because of their sedative, muscle-relaxant, and anxiolytic properties, have been used to treat anxiety in children in small open and controlled trials.

[Bernstein and colleagues' \(1990a\)](#) comparative controlled study of alprazolam (mean daily dosage of 1.4 mg/day), imipramine, and placebo in children with school refusal did not show a significant difference between either medication over placebo. In the treatment of overanxious or avoidant disorder, 30 children and adolescents were randomized to either alprazolam (mean dosage 1.6 mg/day, range 0.5 to 3.5 mg/day) or placebo in a double-blind fashion. After 4 weeks, 88% of the completers on alprazolam improved, versus 62% on the placebo, but this was not statistically significant ([Simeon et al., 1992a](#)). [Grae and colleagues \(1994\)](#) reported a double-blind, placebo-controlled, crossover trial of clonazepam (0.5 to 2 mg/day) versus placebo in 15 children with mainly SAD. There was no difference in outcome between the clonazepam and the placebo groups.

Benzodiazepines may be a logical choice in the treatment of anxiety associated with medical procedures. In 13 pediatric patients who received low-dose alprazolam (0.125 to 1 mg) in an open fashion before bone marrow aspiration and spinal taps, there was a decrease in anticipatory and acute situational anxiety ([Pfefferbaum et al., 1987](#)). A double-blind placebo study of 0.2 mg/kg of oral midazolam in prepubertal children undergoing laceration repair showed a significant decrease in anxiety on active medication ([Hennes et al., 1990](#)). Currently, midazolam is available only as a parenteral injection solution.

In summary, benzodiazepines sometimes are used on a short-term basis for symptomatic treatment of anxiety. Typically, a SSRI would be the logical choice for an anxiety disorder requiring ongoing medication treatment, but a benzodiazepine might be initiated in conjunction with the SSRI if the anxiety was severe ([American Academy of Child and Adolescent Psychiatry, 1997a](#)).

## BUSPIRONE

No large, controlled trial of buspirone in children and adolescents has been published. Buspirone has been reported to be useful in the treatment of anxiety in two small open studies ([Kutcher et al., 1992](#); [Simeon et al., 1992b](#)). Buspirone (up to 50 mg/day for up to 9 weeks) has been used in an open fashion in 25 prepubertal children with anxiety and depression. The condition in six children worsened, and only three had sufficient benefit to continue on the drug after the end of the study ([Pfeffer et al., 1997](#)). Further study is required before conclusions can be made concerning its safety and efficacy in children with anxiety disorders.

## BETA BLOCKERS

Beta-adrenergic blocking agents (beta blockers) have not been systematically studied in children, although they occasionally have been used for children and adolescents with anxiety disorders or aggressive disorders. Beta blockers sometimes are prescribed to block the physiologic symptoms of anxiety in adults with performance anxiety or panic disorder. None of these agents has been studied in children, so because of the absence of data, they should not be considered until other options have failed ([American Academy of Child and Adolescent Psychiatry, 1997a](#)).

## TRICYCLIC ANTIDEPRESSANTS

The controlled trials of a tricyclic antidepressant for school refusal are reviewed earlier in the chapter. [Bernstein and colleagues' \(2000\)](#) report of CBT+IMI being effective for school-refusing adolescents suggests that such therapy should be considered for the school-refusing child with anxiety and depression. The increasing literature on the SSRIs ([Walkup et al., 2001](#)), and their preferable side effect profile over the tricyclic antidepressants, suggest that a SSRI should be chosen over a tricyclic antidepressant as the initial treatment.

## SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Small open trials of children with mixed anxiety disorders showed promise for the SSRIs. [Birmaher et al. \(1994\)](#) reported a favorable response to fluoxetine in 21 children with anxiety disorders (social phobia, overanxious disorder, or separation anxiety) treated in an open fashion. Eighty-one percent showed a moderate to marked improvement in anxiety symptoms on a mean dose of 25 mg (range, 10 to 60 mg). [Fairbanks and colleagues \(1997\)](#) reported an open trial of fluoxetine for 16 children and adolescents with mixed anxiety disorders. During the 6- to 9-week trial, all patients had significant improvement in general functioning. The mean length of time for treatment response was 5 weeks. As reviewed earlier, there is a small open literature on the use of SSRIs in the treatment of selective mutism ([Black and Uhde, 1994](#); [Dummit et al., 1996](#)).

The first large-scale, systematic study of a SSRI was completed in 128 children and adolescents 6 to 17 years of age with either social phobia, SAD, or GAD ([Walkup et al., 2001](#)). Initially, 153 children were evaluated and underwent 3 weeks of open treatment with supportive psychoeducational therapy. Five children's condition improved with brief psychoeducation, and they did not go on to medication therapy. One hundred twenty-eight children were assigned to either fluvoxamine or placebo for 8 weeks. The fluvoxamine was increased every week by 50 mg to a maximum of 300 mg/day for adolescents and 250 mg/day for children younger than 12 years of age. The average dose of fluvoxamine was  $2.9 \pm 1.3$  mg/kg, and the average last dose was  $4 \pm 2.2$  mg/kg. Five children in the fluvoxamine group discontinued treatment because of adverse effects, and one withdrew for adverse effects in the placebo group. Abdominal discomfort was significantly more prevalent in the fluvoxamine group than in the placebo group, and there was a trend toward a greater frequency of increased motor activity in the fluvoxamine group. The children in the fluvoxamine group had greater reductions in symptoms of anxiety and higher rates of clinical response than the children in the placebo group. On the Clinical Global Impression Scale, 48 of 63 (76%) children in the fluvoxamine group had a response to treatment, compared with only 19 of 65 children (29%) in the placebo group ( $p < .001$ ). The authors conclude that fluvoxamine is an effective treatment for children and adolescents with social phobia, SAD, or generalized anxiety.

## FUTURE DIRECTIONS/CHALLENGES TO RESEARCH

The release of the first large, controlled efficacy study of a non-OCD childhood anxiety disorder has had an important impact on the field. It does not mean that pharmacologic treatment is the most effective intervention for anxiety disorders. The study exemplifies the need for the next step in research, the combination of disorder-specific CBT and medication. Are medications more effective than CBT, or is CBT more effective than medication? Is the combination of CBT plus medications more effective than either alone? As we move into the next century and develop specific treatments, the next challenge is to study unimodal versus combined treatments in a multidisciplinary framework.

A 20-year retrospective of obsessive-compulsive disorder (OCD) certainly points up how much has been learned about OCD, but even more how much the study of OCD has advanced our understanding of the brain. It seems only fitting that study of obsessions and compulsions would lead investigators to understand basic brain structures and functions. After all, obsessions are among the oldest mental symptoms for which there are detailed descriptions, and a history of OCD reads like a history of psychiatry itself. Obsessions and compulsions were depicted as possession by the devil in 1467 in *Malleus maleficarum* (Kramer and Sprenger, 1928) and were described in the “Obsessi” of Paracelsus. In the 1600s, pious texts tell of extremes of religious doubting and “scrupulosity” or excessive devotion (Hunter and MacAlpine, 1963). Pioneers of psychiatry such as Esquirol (1838), Maudsley (1895), Freud (1909, 1953b), and Janet (Pittman, 1987) took up this troubling and fascinating disorder. At each time, the concept of OCD reflects the prevailing philosophy of thought, motivation, and free will.

The current *zeitgeist* features four discoveries that have promoted the explosion of OCD research since the 1980s. First came the discovery that medications that inhibit serotonin (5-HT) reuptake are effective for many patients with OCD. Subsequently, powerful techniques for observing structures and measuring regional brain activity under various circumstances were applied to understand how this happens. During this time, other investigations focused on the prevalence of OCD. By using even more reliable methods, it now appears that OCD is neither as rare as was first thought nor as common as the initial studies reported. Moving from pathophysiology to etiology, the fourth series of discoveries directed our attention to the genetic transmission of OCD. The effort to understand OCD has deepened our understanding of the prevalence, course, etiology, and pathology of these symptoms and along the way has broadened our knowledge of the neuroanatomy of voluntary functions and the heritability of complex behaviors.

## DEFINITIONS

*Obsessions* are unwanted thoughts, images, or impulses that the person realizes are senseless or unnecessary, intrude into his or her consciousness involuntarily, and cause functional impairment and distress. Despite this lack of control, the sufferer still recognizes that these thoughts originate in his or her own mental process. Because they arise in the mind, obsessions can take the form of any mental event—simple repetitive words, thoughts, fears, memories, pictures, or elaborate dramatic scenes.

*Compulsions* are actions that are responses to a perceived internal obligation to follow certain rituals or rules; they also cause functional impairment. Compulsions may be motivated directly by obsessions or by efforts to ward off certain thoughts, impulses, or fears. Often children report compulsions without the perception of a mental component. Like obsessions, compulsions are often viewed as being unnecessary, excessive or senseless, and involuntary or forced. Persons suffering from compulsions often elaborate various precise rules for the chronology, rate, order, duration, and number of repetitions of their acts.

These definitions reflect three critical concepts with relevance to the differential diagnosis. A most essential criterion is functional impairment as a consequence of symptoms. Two others carry from the classic definitions of Jaspers (1963) and Maudsley (1895): Persons feel that they are being forced or invaded by the symptoms, and they possess insight into the senselessness or excessiveness of their thoughts or acts. The validity of requiring patients to view their acts as unnecessary or their thoughts as senseless was challenged after observations that this objectivity may be inconstant. Insel and Akiskal (1986) and Lelliott and coworkers (1988) report on severely impaired patients who at times doubt the need to perform their rituals or who think their behaviors are senseless and who, at other times, are convinced of their necessity to the point of near or actual psychotic proportions. The criteria for OCD set out in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) (American Psychiatric Association, 2000) (Table 68.1) have been modified such that awareness of the senselessness or excess of the symptoms must be present only at some phase of the illness. For children, this criterion is dismissed altogether.

**A. Obsessions or compulsions:**  
Obsessions or compulsions (1, 2, 3, and 4):  
1. Recurrent and persistent ideas, thoughts, impulses, or images that are experienced at some time during the disturbance as intrusive and unwanted and cause marked anxiety or distress.  
2. The thoughts, impulses, or images are not simply excessive worries about real-life problems.  
3. The person attempts to ignore or suppress such thoughts, impulses, or images or to neutralize them with some other thought or action.  
4. The person recognizes that the obsessive thoughts or impulses or the compulsive acts are a product of his or her own mind (not imposed from without, as in thought insertion).  
**Compulsions:** (5 and 6)  
5. There are repetitive behaviors or mental acts that the person feels driven to perform in response to an obsession or according to rules that must be applied rigidly.  
6. The behaviors or mental acts are aimed at preventing or reducing distress or preventing some dreaded event or situation; however, these behaviors or mental acts either are not connected in a realistic way with what they are designed to neutralize or prevent or are excessive.  
**B. At some point the person has recognized that the obsessions or compulsions are excessive or unreasonable.** (Note: This does not apply to children.)  
**C. The obsessions or compulsions cause marked distress, are time consuming (take more than 1 hour a day), or significantly interfere with the person's normal routine, occupational (or academic) functioning, or social activities or relationships.**  
**D. If another Axis I disorder is present, the content of the obsessions or compulsions is not restricted to (e.g., preoccupation with death in the presence of an anxiety disorder; hoarding or repetitive checking with appearance in the presence of body dysmorphic disorder; preoccupation with having or sexual abuse in the presence of hypochondria; or guilty ruminations in the presence of a major depressive disorder).**  
**E. This is not the direct effect of a substance (e.g., a drug of abuse, a medication) or a general medical condition.**

Table 68.1. DSM-IV Criteria for Obsessive-Compulsive Disorder

Few studies differentiate between childhood-onset and adolescent-onset OCD. Therefore, in this chapter, “child,” “childhood,” and “children” are used to signify children *and adolescents*. Some studies have sampled adolescent subjects only. When this is so, the more exclusive term is employed.

## PREVALENCE AND EPIDEMIOLOGY

The prevalence of OCD in childhood or adolescence should be understood in the context of the prevalence of subclinical obsessions or compulsions in this segment of the population. [Evans and coworkers \(1997\)](#) have sent out mailings to parents of children less than 6 years old and find that urges to make things “just right” and preoccupations with symmetry and rules are very common in this unselected population. These concerns decline as children enter grade school age. To learn about the prevalence of obsessive or compulsive symptoms and to compare prevalences across development, [Zohar and Bruno \(1997\)](#) used self-report measures for a study of 1,083 children attending grades 4, 6, and 8. As predicted, many children confirmed the presence of some features. Sixty percent of fourth graders reported preoccupations with guilt about lying and engaging in checking behaviors, and 50% reported contamination and germ fears. By eighth grade, rates for these concerns declined to 40%, but 60% of eighth graders reported worries about cleanliness, and 50% noted intrusive rude thoughts. Mean scores across the age range in this population on the Maudsley Obsessive Compulsive Inventory were 11 to 12.5 out of a possible 30; like the findings of [Evans and coworkers \(1997\)](#) in a younger population, rates of behaviors and symptoms declined over time. A subgroup of eighth graders had high symptom scores (greater than two standard deviations from the mean) and reported high levels of anxiety. The authors suggest that this small group (4%) represents a clinically at-risk group because the large number of symptoms and the elevated state and trait anxiety are such a contrast to the decline in both in their ages.

Nearly 20 years after the Epidemiologic Catchment Area (ECA) survey ([Robins et al., 1984](#)), there continue to be important disagreements over the most reliable prevalence rate for OCD. Significant disparities and varied methods have yielded figures between 0.5% and 3%. Because it is safe to conclude that child and adult OCD are the same disorder, adult epidemiologic reports are relevant to understanding rates for children and adolescents.

The early work ([Rudin, 1953](#)), using weak methods by current standards, reported a prevalence of 0.05% for adult OCD. The scarcity of OCD was predominant until 1984, when ECA survey reported surprising prevalences of 1.2% to 3.29% ([Robins et al., 1984](#)). Subsequent examination of these high rates uncovered weak concordances for OCD. Among all the diagnoses in the ECA study, the concordance between diagnoses derived from lay interviewers and trained clinicians for OCD were the poorest ([Anthony et al., 1985](#); [Helzer et al., 1985](#), [Nestadt et al., 1994](#)). Lay interviews employing the Diagnostic Interview Schedule rely on simple “yes” or “no” responses to queries about the presence of broadly defined obsessions or compulsions. These are not reliable measures for actual *clinical cases* of OCD. [Helzer and coworkers \(1985\)](#) go on to say that results from community surveys, in which many subjects cluster at the “threshold of the diagnostic definition,” are unreliable because the response to a single probe carries too much weight. [Karno and coworkers \(1988\)](#) have reanalyzed ECA data, and prevalence rates are sustained despite the flawed method. False-negative results balanced false-positive results.

In an effort to learn more about this problem, [Nelson and Rice \(1997\)](#) used ECA methods and interviewed a community sample at two intervals separated by 12 months. The 1-year stability of the diagnosis of OCD was “very low.” Only 20% of subjects who reported “ever having symptoms” at time 1 reported “ever having symptoms” at time 2. These investigators concluded “the Diagnostic Interview Schedule diagnosis of obsessive-compulsive disorder possesses extremely limited validity.”

[Stein and coworkers \(1997\)](#) employed a different measure (the Comprehensive International Diagnosis Interview) and DSM-IV criteria. Again, rates derived from lay interviews revealed that 22% to 25% of adults expressed having obsessions or compulsions. However, when clinicians reviewed lay interviews, the rates dropped sevenfold (to 0.7%). These investigators also examined rates of “subclinical OCD” in which criteria were met for symptoms, but not impairment in DSM-IV. Rates for this subclinical syndrome were roughly equivalent to rates of clinical OCD (0.6%). Stein and coworkers, concluded, like [Karno and coworkers \(1988\)](#) and [Nestadt and coworkers \(1994\)](#), that lay interviews lead to many false-positive diagnoses.

The first prevalence rates reporting childhood clinical data ranged from 0.2% ([Berman, 1942](#); [Hollingsworth et al., 1980](#)), to 1.2% ([Judd, 1965](#)) (1.2%). [Flament and coworkers \(1988\)](#) conducted a rigorous study to discover the general adolescent population prevalence. Screening employed a modified Leyton Obsessional Inventory (LOI), and this was followed by direct clinical interviews of subjects with a high score. This produced a point prevalence of 0.35% and a lifetime prevalence of 0.40%. Weightings, such as those used in the ECA study, generated point and lifetime prevalence rates of 1% and 1.9%, respectively ([Flament et al., 1988](#)). Of the 18 adolescents diagnosed with OCD, 12 (67%) reported that symptoms resulted in high subjective interference, yet global assessment scores averaged 67 (“generally functioning pretty well”). To ascertain prevalence in a nonclinical population further, [Zohar and coworkers \(1992\)](#) performed detailed clinician-rated evaluations of 562 consecutive 16- to 17-year-old male and female inductees to the Israeli army. The OCD prevalence rate was 3.6%. Fifty percent of patients were identified as having “obsessions only.” This latter figure was substantially higher than that reported from clinical populations and casts doubt on the validity of the diagnoses generated by this method. Rates for compulsions compared favorably with those of [Flament and coworkers \(1988\)](#), however.

Overall, it appears that OCD is certainly more prevalent than was believed in the 1950s, but it is not as common as was first reported by the ECA. Adult epidemiologic studies offer prevalence rates of OCD from 0.5% to 3%. However, studies that rely on lay interviews and the Diagnostic Interview Schedule are likely to be unreliable. In addition, rates will change as different diagnostic criteria are employed ([Nestadt et al., 1994](#), [Stein et al., 1997](#)). Current valid studies place the prevalence closer to 1% ([Bebbington, 1998](#); [Stein et al., 1997](#)). Prevalence studies employing only structured or nonclinician interviews have a high risk of being unreliable and unsound.

Valid studies suggest that the sex distribution of OCD continues to reflect clinic samples—males and females are equally affected. Male patients appear to have an earlier age of onset ([Rasmussen and Tsuang, 1986](#); [Swedo et al., 1989a](#)). [Noshirvani and coworkers \(1991\)](#) report that male and female patients are equally represented in their sample, but 35% of male subjects have their onset between the ages of 5 and 15 years, compared with 20% of cohort females. Generally, symptoms exist an average of 5 to 8 years before patients reach clinical attention ([Flament et al., 1988](#); [Jenike, 2001](#)). [Noshirvani and coworkers \(1991\)](#) suggest that male patients tend to have a longer duration of illness before they seek treatment, yet the ECA study ([Karno et al., 1988](#)) shows that subjects with OCD have rates of medical and mental health service use roughly equal to those of persons with other disorders.

## CLINICAL DESCRIPTION

The variety of obsessions and compulsions that can be expressed by the human mind and body is unlimited. The typical pattern is for the patient to experience both obsessions and compulsions. It has been presumed that few persons have only one or the other ([Riddle et al., 1990b](#); [Swedo et al., 1989a](#)) but, as noted earlier, having only obsessions may be more common ([Zohar et al., 1992](#)). At any moment, most patients experience multiple obsessions or compulsions; over time, changes in the objects and contents of symptoms develop ([Rettew et al., 1992](#)). Although the repertoire of obsessions can range widely, certain contents are reported more frequently, and development may influence content. Reports of adolescents suggest that the most common categories of obsessions are concern over dirt and germs, fears of an ill fate befalling loved ones, exactness or symmetry, and religious scrupulousness ([Swedo et al., 1989a](#)). Bodily functions, lucky numbers, sexual or aggressive preoccupations, and fear of harm to oneself are less common. In adults, the frequency of these categories is similar, except aggressive and sexual obsessions are more common ([Dowson, 1977](#); [Rachman and Hodgson, 1980](#); [Rasmussen and Tsuang, 1986](#)).

Although a compulsion can be created from any action, only a few are common. An adolescent clinical cohort ([Swedo et al., 1989a](#)) displayed (in descending order of frequency) cleaning rituals, repeating actions (doing and undoing), and checking rituals most commonly. Many fewer subjects reported rituals to protect themselves from illness or injury, ordering maneuvers, and counting behaviors. In adults, the most common compulsions are checking and cleaning ([Rachman and Hodgson, 1980](#); [Rasmussen and Tsuang, 1986](#); [Welner et al., 1976](#)). Slowness ([Rachman and Hodgson, 1980](#)), counting ([Rasmussen and Tsuang, 1986](#)), or doing things by numbers ([Welner et al., 1976](#)) each has been reported as third most common.

Several investigators ([Baer, 1994](#); [Leckman et al., 1997](#); [Summerfeldt et al., 1999](#)) suggest that obsessions and compulsions should no longer be viewed as separate entities. In what promises to be important contributions to OCD research, factor analyses of symptoms in independent studies point to a more meaningful, “multidimensional” way of clustering symptom patterns. Rather than just one homogeneous entity or as “two factors” (obsessions or compulsions), here are strong reasons to consider that OCD may be better viewed as composed of four subtypes. The most rigorous work has identified the following: (a) aggressive, sexual, religious, and somatic obsessions with checking compulsions; (b) symmetry obsessions with counting, arranging, ordering, and repeating compulsions; (c) contamination obsessions with cleaning and washing; and (d) hoarding obsessions with hoarding and collection compulsions ([Baer, 1994](#); [Leckman et al., 1997](#); [Summerfeldt et al., 1999](#)). These investigators propose that course, genetic risk, neuropathology, and treatment may be different among these subgroups and bear further scrutiny. For example, [Alsobrook and coworkers \(1999\)](#) find that a major gene locus model is more strongly supported in families in which the proband has symmetry and ordering symptoms than in probands with other factor symptom clusters. Nevertheless, a 5-HT reuptake inhibitor treatment study has failed to support differences in response among three of these four subtypes ([Mataix-Cols et al., 1999](#)). Several other caveats are suggested by [Summerfeldt and coworkers \(1999\)](#), including the possibility that “more-than-four” factor models may also be viable, that various items have been excluded in the analyses that have been performed to date, and that problems may occur with using “lifetime” ratings because these are subject to recall bias. Moreover, longitudinal studies demonstrate that symptoms

change over time; persons do not belong to one subgroup exclusively over the course of their illness ( [Rettew et al., 1992](#)).

Children with OCD are more selectively impaired than the general clinical population. Academic achievement and extracurricular functioning are often preserved, although the quality of peer relationships may be variable ( [Riddle et al., 1990b](#)). Studies with adults point to significant impairment in social and role function ( [Koran et al., 1996](#)). In the study by Koran and coworkers, moderate to severe illness was correlated in a linear way with social impairment. Clinical studies of children entering treatment programs have consistently demonstrated average intelligence quotients, although the selection bias of these cohorts must be considered in interpreting these data.

It is hard to convey how limiting OCD can be. On the surface, children and adolescents appear to function well and seem relatively well adapted to their lives. However, severe symptoms often envelop the patient and his or her family completely ( [Koran et al., 1996](#)). It is common to learn of washing rituals that consume 4 hours of scrubbing daily, dissolve an entire bar of soap each session, leave the patient's hands worn raw and macerated, and raise monthly water bills dramatically. Counting or ordering compulsions can waste half a day and can lead to complete obstruction. Rituals repetitively executed from night to early morning may curtail sleep to a few hours. Checking or cleansing rituals can produce physical injury such as skin lacerations, ulcers, and chemical burns.

The family's reaction to the patient's symptoms is crucial. Several common response patterns may produce delays in evaluation and treatment of childhood OCD. Although patients are embarrassed and secretive about the content of, and the limitations imposed by, their symptoms, serious impairments rarely elude family members. Parents may delay obtaining treatment as a result of a false hope that symptoms will extinguish if everyone acquiesces and aids in performing the activities. This kind of family assistance does not relieve the child's anxiety. Many parents have difficulty extricating themselves from aiding in rituals. Children may extort, implore, or otherwise compel their parents to collaborate; the patient and parent become pathologically entwined in rituals. Parents may not understand that their child suffers from a serious disorder despite adequate development in other domains. In addition, the child's claims that the thoughts or acts are ridiculous or unnecessary may instill false security in parents who think that "it's just a phase." Parents with subclinical obsession- or compulsion-like behaviors may be unable to recognize symptoms in their child and may unwittingly minimize the child's impairment. Reassurance from clinicians and pediatricians who are unfamiliar with the disorder may result in mistaking severe symptoms for "normal" reactions. It is a frightening and painful moment when parents recognize that their child is ill and has lost control of his or her thoughts and actions.

## ETIOLOGY AND PATHOGENESIS

### Genetic Studies

There is ever-stronger evidence that genetic transmission confers vulnerability to OCD in some persons. Elevated concordance rates are observed among monozygotic compared with dizygotic twins ( [Carey and Gottesman, 1981](#); [Rasmussen and Tsuang, 1986](#)), and higher rates for OCD are seen among first-degree relatives of clinically ascertained patients ( [Nestadt et al., 2000a, 2000b](#); [Nestadt et al., 2000b](#); [Pauls et al., 1995](#)).

The initial family studies did not find elevated rates of OCD in first-degree relatives ( [Black et al., 1992](#); [Hoover and Insel, 1984](#); [McKeon and Murray, 1987](#)). However, after the ECA study, methods changed, and rates began to climb. [Lenane and coworkers \(1990\)](#) report that 30% of 46 adolescent probands had a first-degree relative with OCD. OCD was reported in 17% of parents and the age-corrected rate for siblings was 35%. [Riddle and coworkers \(1990b\)](#) report that 10% of parents from a cohort of 21 clinic patients with OCD were diagnosed with OCD. Twenty-five percent had subthreshold symptoms of obsessions or compulsions. In contrast to studies that relied on questionnaires or telephone inquiry, [Pauls and coworkers \(1995\)](#) directly examined relatives of 100 persons with OCD and of a control group of 33 psychiatrically unaffected persons. The rate of DSM-III-R defined OCD among relatives of patients with OCD was 10% versus 2% of the unaffected probands' relatives. There were also significant differences in rates of obsessive-compulsive traits (or subclinical OCD), with 8% of OCD probands' relatives affected and 2% of the relatives of those in the control group. Combining the subclinical and clinical threshold groups, 18% of OCD probands' relatives were affected compared with 4% of the control relatives. Like Pauls and coworkers, [Nestadt and coworkers \(2000b\)](#) blindly evaluated 343 relatives of 80 adults with OCD and obtained a control sample of 300 relatives of 73 persons ascertained by random number dialing. Patients with OCD were obtained from clinic rosters. Most family members were interviewed directly, and all family members were required to participate for a family to be included. Using a threshold of "definite" DSM-IV criteria, 11.7% of relatives of persons with OCD were affected compared with 2.7% of control relatives. When "probable and definite" OCD were included, then the rates climbed to 16% versus 6%. An additional finding of [Pauls and coworkers \(1995\)](#) and [Nestadt and coworkers \(2000a\)](#) was that earlier age of onset was associated with greater "familiarity" (greater likelihood of OCD among relatives). [Nestadt and coworkers \(2000a\)](#) performed an elaborate study employing segregation analysis of 80 families and a control group. The model of an autosomal dominant pattern of transmission with familial residual effects provided the best fit to the data.

Reports of elevated rates of OCD among patients with Tourette's syndrome ( [Pauls et al., 1986](#)) and of tics and a family history of tics among OCD probands ( [Grados et al., 2001](#); [Green and Pittman, 1986](#); [Leonard et al., 1992](#)) suggest that some cases of OCD may arise from the same genetic origin as Tourette's syndrome ( [Pauls and Leckman, 1986](#)). Reevaluation of the National Institute of Mental Health cohort and their relatives in a 2- to 7-year follow-up lends support to this hypothesis ( [Leonard et al., 1993](#)). Fifty-seven percent of 54 probands had a lifetime history of tics, 15% met criteria for Tourette's syndrome, and 22% had chronic multiple tics. Among their relatives, 14% had lifetime diagnoses of tics. Using a control group, [Grados and coworkers \(2001\)](#) have found that tics and OCD are significantly more likely in relatives of probands ascertained for OCD. Even more provocative are findings that "any tic disorder" is equally likely in relatives of probands with OCD whether the proband has a lifetime history of tics or not. An additional finding is that those relatives with tics and OCD have an earlier age of onset when compared with those relatives with only OCD.

### Neuropsychological Processes

Neuropsychological investigations of OCD provide some support for frontal lobe dysfunction, although this has not been unequivocal. There appear to be significant problems in frontal lobe functions affecting visual-spatial integration, reasoning, and memory in studies performed on adults with chronic OCD ( [Hollander et al., 1990](#)). This does not hold true for adolescents or children, however. [Flor-Henry and coworkers \(1979\)](#) studied 11 subjects with adult-onset OCD by employing age- and sex-matched controls to find frontal deficits, especially in the dominant lobe. These investigators propose that associated dominant temporal and parietal dysfunction stem from the failure of frontal inhibitory responses. Others ( [Insel et al., 1983a](#)) could not confirm frontal lobe findings. [Behar and coworkers \(1984\)](#) found signs of immaturity among 16 adolescent subjects on two measures reflecting frontal lobe function. The performance of six subjects on another test suggested "neurodevelopmental immaturity." Neurologic soft signs, such as synkinesia, were seen in five of the seven adolescents. [Cox and coworkers \(1989\)](#) suggested deficits in regulatory functions localized to the frontal lobe, although they did not confirm dominance of the frontal hemisphere. Few measures supported right-left hemispheric differences. The group underscored that findings were independent of impairment from OCD, and this implies a stable deficit unrelated to severity. [Beers and coworkers \(1999\)](#) examined 21 drug-naive children with new-onset OCD using a neuropsychological battery and found no abnormalities.

### Structural and Functional Neuroimaging

#### STRUCTURAL NEUROIMAGING

##### Computed Tomography

Computed tomographic views of adolescents with OCD or patients with OCD whose onset was in adolescence suggest ventricular enlargement independent of sex, age, duration, and types of symptoms ( [Behar et al., 1984](#)). [Luxenberg and coworkers \(1988\)](#) employed quantitative scanning in male patients with adolescent-onset OCD and a never-ill control group. In the OCD cohort, decreased mean volumes were seen in caudate nuclei bilaterally. Values of normal control subjects and those with OCD overlapped considerably, but pooled mean differences were consistent with a hypothesis of basal ganglia changes in OCD.

##### Structural Magnetic Resonance Imaging

When Garber and coworkers compared magnetic resonance imaging scans of adults with OCD and healthy controls, abnormalities in frontal cortex, cingulate gyrus, and lenticular nuclei were seen ( [Garber et al., 1989](#)). Past medication treatment or family history did not significantly influence findings. Kellner and coworkers did not discover significant structural differences between patients with OCD and normal controls (1991), but [Calabrese and coworkers \(1993\)](#) reported increases in the size of the caudate nuclei. A subsequent study reported that left caudate nuclei volumes exceeded those on the right ( [Calabrese et al., 1993](#)). [Jenike and coworkers \(1996\)](#) studied 10 female patients with OCD and a control group by magnetic resonance imaging. Increased opercular and whole cortex volumes were noted as well as a decrease in total white matter. In a parallel study, Alward and coworkers (1996) failed to find any differences in 24 adults with OCD when compared with a control

group.

## FUNCTIONAL NEUROIMAGING

### Cerebral Blood Flow and Single-Photon Emission Tomography

[Zohar and coworkers \(1989\)](#) measured regional cerebral blood flow (rCBF) changes using single-photon emission tomography with xenon-133 inhalation. Subjects who were stressed specifically to increase anxiety displayed *decreased* temporal rCBF. This pattern was sustained as the stressful stimuli were changed to induce higher levels of anxiety.

There are no published studies of single-photon emission tomography in children with OCD, but two adult studies reported increases in medial-frontal rCBF ([Hoehn-Saric, et al., 1991](#); [Machlin et al., 1991](#)). Rubin and coworkers examined rCBF with xenon inhalation and technetium uptake (1992). Xenon studies did not reveal differences between adults with OCD and normal controls, but with technetium uptake, increased activity in the orbitofrontal cortex was observed with significantly decreased bilateral activity in the head of the caudate ([Rubin et al., 1992](#)), a phenomenon previously noted by others ([Machlin, et al., 1991](#)).

### Positron Emission Tomography

Positron emission tomography has emerged as one of the most powerful tools to extend our understanding of OCD. The first wave of studies examined regional glucose use in the brains of persons with OCD compared with controls ([Baxter et al., 1987, 1988](#); [Martinot, 1990](#); [Nordahl et al., 1989](#); [Perani, 1995](#); [Swedo et al., 1989](#)). Taken together, these studies report increased activity in orbital gyri and the caudate nuclei. There are differences among the studies regarding increased activity in the anterior cingulate gyrus. [Rauch and coworkers \(1994\)](#) scanned individuals with OCD while provoking them with a feared stimulus; increased activation in the right caudate, orbital, thalamic, and anterior cingulate gyrus was observed.

Initial comparisons of patients with OCD and depressed adults suggest bilateral increased glucose metabolism in the orbital gyri ([Baxter et al., 1987, 1988](#); [Nordahl et al., 1989](#)) and the head of the caudate nuclei ([Baxter et al., 1988](#)). Baxter and colleagues propose that the orbital gyri may be specific for tension and anxiety in OCD. [Swedo and coworkers \(1989b\)](#) scanned adults with both current OCD and documented adolescent onset; they found increased bilateral prefrontal and anterior cingulate gyri activity. Other observations of elevated caudate nuclei activity ([Baxter et al., 1988](#)) are not confirmed. Increased metabolism in premotor and midfrontal regions is reported in patients with obsessional slowness ([Sawle et al., 1991](#)).

Subsequent work has examined regional brain metabolic changes after behavioral or pharmacologic treatment. [Benkelfat and coworkers \(1990\)](#) scanned eight patients after clomipramine treatment and found that medication decreased left caudate and orbital frontal activity. [Baxter and coworkers \(1992\)](#) studied adults before and after treatment with fluoxetine or cognitive-behavioral therapy. Responders displayed decreased right caudate nucleus glucose metabolism; no changes appeared in treatment nonresponders and never-ill controls. Swedo and coworkers found that adults with childhood-onset OCD exhibit decreased fronto-orbital metabolism associated with medication-related or spontaneous improvement in OCD severity ratings ([Swedo et al., 1992](#)).

### Functional Magnetic Resonance Imaging

Breiter and coworkers used functional magnetic resonance imaging (1996) in 10 subjects who were studied during provocation of symptoms. Their results point to elevated activity in the medial orbitofrontal, lateral frontal, and anterior cingulate gyri and in the insular cortex, caudate nucleus, lenticular nuclei (putamen and globus pallidus), and amygdala.

### Functional Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy is a noninvasive technique for studying brain function using magnetic fields. It measures the effects on unbalanced elements of specific perturbations generated by a magnetic field. In particular, magnetic resonance spectroscopy measures the influence of tiny local magnetic forces exerted by nearby nuclei on elements subsequent to magnetic perturbation. It has been applied to learn the density and activity of glutamate and *N*-acetyl-aspartate (a measure of neuronal destruction or injury) in the brain. One study explored the density of *N*-acetyl-aspartate in 11 drug-naive pediatric subjects and reported decreased *N*-acetyl-aspartate levels in the medial thalamus ([Fitzgerald et al., 2000](#)). A subsequent study of the same 11 subjects found elevated glutamate levels in the caudate nucleus bilaterally ([Rosenberg et al., 2000](#)). Furthermore, after paroxetine treatment, levels of glutamate in the caudate nuclei were equivalent to those in normal controls ([Rosenberg et al., 2000](#)).

## SUMMARY OF STRUCTURAL AND FUNCTIONAL NEUROIMAGING

Taken together, the results of most structural studies suggest differences between patients with OCD and never-ill controls in frontal cortex and in caudate nuclei. These findings are further supported by more detailed, functional studies showing elevated activity in orbitofrontal, lateral frontal, and cingulate gyri and in the caudate and lenticular nuclei (putamen and globus pallidus). More recent work has focused on glutamate receptors in the caudate and decreased neuronal activity in medial thalamus. Drawing on other neuroanatomic studies and these findings, a broad consensus has emerged that functional defects in a corticostriothalamocortical circuit underlie OCD.

## Neurochemistry: Serotonin and Dopamine

### SEROTONIN

Several lines of evidence lend support to the importance of 5-HT in the pathophysiology of OCD. Agents that affect 5-HT reuptake inhibition (SRIs) have been the most effective medication treatments for persons with OCD. Decreased cerebrospinal fluid concentrations of 5-hydroxyindoleacetic acid, the primary metabolite of 5-HT in the central nervous system, have correlated with clinical response to SRIs. Substances that increase serotonergic transmission, such as *L*-tryptophan and lithium, also have been successful in augmenting serotonergic medication in unresponsive patients. In addition, drug-naive children with OCD treated with paroxetine, a highly selective SRI, showed reductions in caudate nucleus volumes after successful treatment ([Gilbert et al., 2000](#)). The decrement in caudate nucleus volume was correlated with clinical improvement ([Gilbert et al., 2000](#)).

However, studies of various indirect measures of 5-HT in patients with OCD have produced equivocal findings. Adolescents with OCD were found to have normal 5-HT platelet levels when compared with healthy volunteers ([Flament et al., 1987](#)), and adults with OCD showed tritiated imipramine binding and 5-HT uptake similar to those in normal control subjects ([Insel et al., 1985](#)). A cohort composed of adolescents and adults with OCD displayed a substantial decrease in tritiated imipramine binding but no differences in 5-HT uptake ([Weizman et al., 1986](#)). Moreover, when patients who are successfully treated with SRIs for depression or OCD undergo tryptophan depletion, depression reemerges in depressed patients, but obsessive-compulsive symptoms do not reappear in those with OCD ([Barr et al., 1994](#)).

"Pharmacologic probes" that are putatively specific for 5-HT, such as metachlorophenyl-piperazine (MCP), tryptophan, fenfluramine, and metergoline yield contradictory results ([McDougle, 1999](#)). MCP elevated temperature, obsessive-compulsive symptoms, and anxiety in one study ([Zohar and Insel, 1987](#)) and did not affect OCD symptoms or create physiologic responses in another ([Charney et al., 1988](#)). In yet another study ([Hollander et al., 1992](#)), oral MCP reportedly increased symptoms in 55% of subjects. Symptom exacerbation with MCP predicted nonresponse to a selective SRI ([Hollander et al., 1992](#)). MCP administered after 3 months of clomipramine treatment did not evoke acute elevations in obsessive-compulsive symptoms that initially were seen in the subjects with untreated OCD ([Zohar et al., 1988](#)). Metergoline, a specific 5-HT agonist, decreased symptoms only slightly ([Zohar and Insel, 1987](#)). Fenfluramine did not produce increased symptoms ([McDougle, 1999](#)). Unresponsiveness to tryptophan depletion, MCP, and metergoline administration implies that other transmitter systems are relevant in OCD ([Charney et al., 1988](#)).

### DOPAMINE

A contributing role also has been proposed for dopamine ([McDougle, 1999](#); [Rapoport and Wise, 1988](#)). There are several lines of support for this hypothesis. First, increased metabolism in basal ganglia regions, which are rich in dopaminergic neurons, is observed on positron emission tomography scanning in persons with OCD. Second, OCD symptoms are often observed in disorders affecting basal ganglia (e.g., Sydenham's chorea, exposure to toxic agents, trauma). Third, dopaminergic

blocking agents (such as pimozide, haloperidol, risperidone, and olanzapine) have been used with some success to augment treatment in patients who are unresponsive to SRIs ([McDougle et al., 1994](#)). There is also evidence that fluoxetine, paroxetine, and clomipramine exert dopaminergic and serotonergic activity ([Austin et al., 1991](#); [Baldessarini and Marsh, 1990](#)).

### Neuroendocrine Studies

When compared with a matched sample of normal controls and subjects with Tourette's syndrome, a cohort of adults with OCD, who did not have a personal or family history of tic disorders, displayed significantly elevated cerebrospinal fluid levels of oxytocin. This is all the more interesting in view of findings of low cerebrospinal fluid oxytocin in patients with Tourette's syndrome who exhibit OCD. [Leckman and coworkers \(1994\)](#) point out that cognitive and behavioral symptoms of OCD are similar to the behavioral effects of oxytocin (e.g. cognitive, grooming, affiliative, and reproductive behaviors) that have been observed in animals. However, a subsequent trial of intranasal oxytocin ([Epperson, 1996](#)) to treat OCD did not produce discernible effects. However, the investigators acknowledge that only small amounts of oxytocin cross the blood-brain barrier.

### Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections

It is now appreciated that some children develop obsessive-compulsive symptoms after streptococcal infection. Estimates are that this may be an important mechanism in 10% to 20% of children developing OCD. Typically, symptoms arise along with tics, and this phenomenon may be related to obsessive-compulsive symptoms seen in Sydenham's chorea ([Leonard et al., 1999](#); [Swedo et al., 1993](#)). Swedo and coworkers propose that this represents an autoimmune disorder caused by the cross-reaction of streptococcal bacteria and basal ganglia structures ([Swedo et al., 1998](#)). Several lines of evidence support this hypothesis. Scanning data suggest that increased basal ganglia volumes are associated with pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS), just as they are in OCD, tic disorders and Sydenham's Chorea ([Giedd et al., 2000](#)). [Hallett and coworkers \(2000\)](#) infused basal ganglia structures in rats with sera from boys who had both a PANDAS history and the presence of antineuronal antibodies or with sera from healthy boys without antineuronal antibodies. It appeared that the rats infused with sera from affected boys developed stereotyped behaviors, whereas those infused with normal sera did not. However, [Singer and coworkers \(1999\)](#) also looked at antineuronal antibodies and found them both in boys with Tourette's syndrome and in normal control subjects. Although patients with Tourette's syndrome had higher median levels, these investigators did not find any correlation among mean levels of antibodies, clinical severity, symptom types, history (age of onset or suddenness), or evidence of streptococcal infection ([Singer et al., 1999](#)). In addition, there was no correlation between symptom severity or duration and basal ganglia size in a study of children diagnosed with PANDAS ([Giedd et al., 2000](#)). Preliminary data support the efficacy of immunologically curbing treatments such as intravenous immunoglobulin or plasmapheresis ([Perlmutter, 1999](#)).

Several cautionary notes are in order. First, it is very common for children with tic disorders (and perhaps OCD) to report an abrupt onset and to experience exacerbation of symptoms with infection. [Singer and coworkers \(2000\)](#) report that more than 50% of patients with tic disorders report this finding, and 11% report exacerbation of symptoms within 6 months of streptococcal infection. Furthermore, it appears that an autoimmune mechanism is relevant only when the pattern of acute onset is observed. When [Peterson and coworkers \(2000\)](#) compared a cohort of children with "ordinary" OCD to normal controls, children with attention deficit hyperactivity disorder, and children with tic disorders, they found no correlation with antistreptolysin O, Anti-DNAase B, or basal ganglia volumes and OCD. Furthermore, it appears that treatments with immunoglobulin or plasmapheresis are not helpful for patients with OCD who do not exhibit the infection-related onset and exacerbation of PANDAS ([Nicolson et al., 2000](#)). Although an autoimmune mechanism would predict particularly high rates of illness among relatives of individuals with PANDAS, it is interesting that a family study did not show rates greater than those seen for all OCD ([Lougee et al., 2000](#)). In addition, the number of first-degree relatives with childhood-onset symptoms was the same as in studies of ordinary OCD probands and their families.

### Corticostriothalamocortical Circuit

There is a reinforcing relationship between learning about serious mental disorders and our understanding of the neural networks operating in the central nervous system. From the study of disorders we learn about the development, functional interconnections, and neurotransmitter circuitry of the central nervous system. In turn, this new knowledge about the brain further extends our understanding of the pathophysiology of brain disorders, our ability to treat symptoms, and our understanding of the relationships among disorders. OCD is a paradigm of this reverberating process. Once it was shown that medication could improve OCD ([Thoren et al., 1980](#)), the way was opened to identifying biological mechanisms that predispose to it, precipitate it, and maintain it. In turn, this has advanced our general understanding of neural networks.

The current understanding of OCD integrates neuropsychological, anatomic, neurochemical, and electrophysiologic findings ([Baxter, 1999](#); [Baxter et al., 1992](#); [Insel, 1992](#)). It posits the existence of somatotopically organized connections in distant brain structures arranged into corticostriothalamocortical circuits that subserve planning, execution, and termination of voluntary movements. In 1990, [Alexander and coworkers \(1990\)](#) proposed the existence of "basal ganglia-thalamocortical circuits." They suggested that a "lateral orbitofrontal circuit" projecting to ventromedial sectors of the caudate, the substantia nigra, and the globus pallidus may be impaired in OCD. There were doubts about how separate these circuits could be. Subsequent positron emission tomography findings led Baxter and coworkers ([1992, 1999](#)) to propose an "orbital-basal ganglia-thalamic circuit" similar to Alexander's.

This "basic model" ([Baxter, 1999](#)) puts forth that frontal cortical and limbic structures have excitatory effects on striatal structures through glutamatergic efferents. These striatal structures, including the caudate nucleus, putamen, nucleus accumbens, and olfactory tubercle, project to the internal and external globus pallidus. From the internal globus pallidus, inhibitory efferents using g-aminobutyric acid have tonic activity at the thalamus. Consequently, *increased* striatal activity *decreases* inhibitory activity (or creates disinhibition) at the thalamus. Increased activation of thalamic nuclei produces excitatory transmission to cortical structures and then movement.

However, this basic model has required modification in two ways. The first modification introduces separate *direct* and *indirect* pathways between the striatum and the thalamus. The direct pathway is so termed because efferents pass *directly* from the striatum to the thalamus, thus exerting a disinhibiting (activating) effect. Conversely, the *indirect pathway* sends various efferents to subthalamic nuclei that, in turn, send efferents to both the globus pallidus externa and the globus pallidus interna. The indirect pathway "moderates" activity in the thalamus ([Baxter, 1999](#)).

The second modification proposes two parallel systems from the striatum, one related to the dorsolateral region and the other the ventromedial region. Input to the ventromedial region is largely from limbic structures, whereas dorsolateral regions receive input from the dorsal cortex. From the striatum, both direct and indirect systems send information to the thalamus. Activation of the dorsolateral system can produce either disinhibition or inhibition of the dorsal thalamus through the direct or indirect system, respectively. Activation of the ventromedial pathway only results in inhibition of the dorsal thalamus ([Baxter, 1999](#); [Peterson et al., 1999](#)). Balance in the activity between the dorsolateral and ventromedial striatal systems is crucial in maintaining control. In OCD, increased tone in the pathway from limbic cortex to ventromedial striatum excessively activates the direct pathway, decreases inhibition, and produces symptoms (overactivation) ([Baxter, 1999](#)). With treatment using SRIs, afferents to the ventromedial pathway are attenuated at the level of the striatum; direct pathway tone decreases relative to the dorsolateral system, and equilibrium is restored. [Baxter \(1999\)](#) hypothesizes that behavioral treatment works by increasing tone in the dorsolateral system relative to the ventromedial system; increasing tone in dorsolateral system restores the balance.

This model is compatible with the variety of neurochemical findings. First, it accounts for the efficacy of SRIs. 5-HT selectively activates g-aminobutyric acid and reduces glutamatergic output from limbic efferents to the ventromedial caudate. Consequently, serotonergic augmentation substantially reduces activation in the ventromedial system.

The relationship between 5-HT and dopamine adds another important dimension. [Baxter \(1999\)](#) proposes that dopaminergic inputs distributed throughout the caudate nucleus have downstream effects on the thalamus. There is a gradient of D1 and D2 receptors across the caudate. Higher concentrations of D2 receptors are observed in the dorsolateral caudate and decrease as one moves toward the ventromedial region. Conversely, a lower concentration of D1 receptors in the dorsolateral caudate increases as one moves toward the ventromedial region. Blockade of D2 receptors would have a greater effect on dorsolateral circuitry and produce a decrease in both direct and indirect pathway activity. This too would also change the balance in activity between the dorsolateral and ventromedial regions.

### Psychoanalytic Theories

Psychoanalytic theories of OCD have not been subjected to rigorous, systematic scientific research. However, a rich anecdotal literature exists and is important for its historical value. In it, we can also see the seeds for later biological investigations. Freud observed obsessions and compulsions early in his investigations into the unconscious ([1953a](#)). Anna Freud proposed that the failure of two ego functions promoted obsessional neuroses. Fusion of sexual and aggressive drives from the id

ordinarily permits the infant to contain destructive, annihilating drives and to maintain attachment to the caretaker. Synthesis creates harmony out of “opposing strivings” before they reach consciousness (Freud, 1966). Her hypothesis is particularly interesting in light of the importance we now attach to the frontal lobe in inhibiting or modifying of sexual and aggressive impulses and our appreciation of impairment in frontal lobe function in OCD. Anna Freud offered that the consequence of these ego deficits was that patients with obsessional neuroses are unsuccessful in their mastering ambivalence, resolution of sexual and aggressive urges, and “intrasystemic contradictions” in the id, such as feelings of love–hate, masculinity–femininity, and so on (Freud, 1966). She also commented on the primacy of constitutional and environmental contributions. She also described characteristic defenses of undoing, intellectualization, reaction formation, and isolation that are so prominent in OCD.

## DIFFERENTIAL DIAGNOSIS

Table 68.2 offers a partial list of disorders in which obsessions or compulsions are seen. Although rare, some specific brain disorders (“organic brain syndromes”) display OCD characteristics (Drummond and Gravestock, 1988; Frye and Arnold, 1981; McKeon et al., 1984).

Anorexia nervosa
Body dysmorphic disorder
Delusional disorder (all types)
Depression
“Fear of AIDS”
Hypochondriasis
Obsessive-compulsive personality disorder
Organic mental disorder*
Panic disorder
Pervasive developmental disorder
Phobias
Posttraumatic stress disorder
Schizophrenia
Schizotypal personality
Somatization disorder
Somatiform disorders
Trichotillomania
Tourette’s syndrome

\*Specifically arising from central nervous system trauma, tumors, toxins.

**Table 68.2. Disorders Manifesting Obsessions or Compulsions**

The DSM-IV handles disorders comorbid with OCD by requiring that the content of the obsessions not be “restricted” to any coexistent disorder. Although this eliminates some difficulties, it creates others; sometimes it is not easy to discern how “related” or “unrelated” a symptom is. The DSM-IV combines a heterogeneous group of disorders and comorbid features (Leonard et al., 1993; Swedo et al., 1989a) under the term OCD on the basis of presence of a single symptom. Many disorders and comorbid symptoms of different origins are subsumed under this one label. Therefore, clinicians are obliged to conduct thorough diagnostic assessments to detect all the coexisting conditions that are active along with OCD (Towbin et al., 1987). Neglecting to do so leads one to miss findings that are relevant to treatment. Similarly, if research studies are to be generalizable and valid, investigators are obliged to provide comprehensive descriptions of their sample subjects (Towbin et al., 1987). Moreover, care should be taken not to equate *subclinical* obsessions and compulsions and OCD, especially in adolescents. Most subclinical phenomena appear to be stable features that do not interfere with development and functioning (Flament et al., 1988).

Overlapping symptoms sometimes create confusion between obsessive-compulsive personality disorder (OCPD) and OCD. Most patients with OCD do not exhibit OCPD, but some data suggest that OCPD may be more common among patients with OCD than in the general population, particularly among those who have hoarding symptoms (Frost et al., 2000). Although persons with OCPD may have rigid routines, needs for orderliness, hoarding behaviors, and indecisiveness, they usually do not experience these as ego-dystonic. Their compulsive behaviors do not cause them anxiety and, ordinarily, do not result in impairment. Impairment in OCPD is a product of patterns of beliefs or behaviors, not isolated symptoms. OCPD often undergoes phases of exacerbation and remission, and particular characteristics may escalate when a patient is stressed. Conversely, patients with OCD generally are not emotionally cold, unexpressive, stingy, or especially rigid about moral or ethical matters. Furthermore, hoarding, list making, and rigid scheduling behaviors are uncommon among compulsions reported by patients with OCD (Rasmussen and Tsuang, 1986). Adding to the complexity, Samuels and coworkers (2000) systematically assessed OCD probands and relatives against a control group. Compared with controls, OCD probands and their relatives showed elevated rates of OCPD. This may be hypothesized to reflect a “spectrum” of OCD to OCPD conditions, which display vertical transmission.

Differentiating psychosis from an overvalued idea in a patient with OCD can be vexing. Some patients with OCD precariously balance between delusional conviction and insight. At times, they may believe that they are right to engage in compulsive behaviors, but at other times they are aware that their urges are senseless (or excessive) and a product of their minds. The DSM-IV permits the diagnosis of OCD in the presence of when schizophrenia or delusional disorders. Comorbid syndromes like these can frustrate attempts to discover whether the patient possesses insight (the ability to understand that their obsessions originate in their minds and are not imposed by external sources). The absence of insight carries a poorer prognosis and should influence treatment strategies. Clinicians should carefully search for other comorbid diagnoses when patients have little or no insight.

*Fear of acquired immunodeficiency syndrome (AIDS)* consists of obsessional fears and preoccupations about contracting AIDS (Fisman and Walsh, 1994; Wagner and Sullivan, 1991). Although blood tests permit a positive diagnosis of AIDS, a clinician cannot give a diagnosis of hypochondriasis confidently to those with negative or equivocal serologic results. The long incubation period and high risks to adolescents who do not practice safe sex means that those with “fear of AIDS” constitute a group whose concerns can be neither completely refuted nor confirmed. Many cases straddle the boundary between subthreshold obsessions and OCD.

## EVALUATION

### Clinical Evaluation

The critical first step in the treatment of children with OCD is evaluation. Children often feel embarrassed about their symptoms and underreport impairment. Frequently, children fear that their symptoms are bizarre and “crazy.” They are most likely to describe symptoms to a clinician who resists confrontation, conveys acceptance, and respects privacy; it takes time for the patient to reveal his or her fears fully. Consequently, assessment usually cannot be completed in one meeting (American Academy of Child and Adolescent Psychiatry, 1998).

An adequate evaluation of OCD must sample multiple sources. It is desirable to gather history from the patient alone, from his or her parents alone, and from the family together. Helpful information can be obtained from teachers on academic performance, peer relationships, areas of impairment, and tasks presenting special challenges. Siblings may provide valuable information on family responses to the patient.

The objectives of individual meetings are to estimate the extent of impairment, the developmental level attained by the patient, and the associated diagnoses and symptoms that are hampering progress. The clinician needs to learn about the patient's strengths and weaknesses, fears and aspirations, achievements and disappointments. Impairment created by symptoms often permeates home, school, work, peer relations, and self-image. This dictates assessing the patient's adjustment in each of these domains. Although it may be tempting to use meetings with the patient to overpower denial, root out secrets, and unmask obsessions, fostering a relationship is crucial. It is a common mistake to become entangled in an effort to root out symptoms and conquer the patient's concealment.

A family may provide information on the extent to which symptoms interfere with the patient's life, but the family also may unwittingly perpetuate them. OCD is a familial disorder in several ways; it has immediate influences on a family's use of time, its emotions, and energies, and it is an enduring family feature genetically and psychologically. The aims of the family evaluation are to characterize the prevailing family dynamics and to identify the manner and extent of effect on the patient's family. This means learning the significance of the patient's symptoms to the parents, how the parents understand their child, and the family's responses to the patient's behaviors. These aims are most readily accomplished with direct observation and in interaction with the family. A critical question is whether concomitant family treatment may be needed to change patterns of communication, to alter affiliations, and to clarify sources of conflict. When parental psychopathology aggravates the patient's condition, parental treatment may be necessary.

Meeting with parents alone provides time to educate them and to learn sensitive information from them. Information about the parents and their marriage, parental disappointment, concern, and frustration about their child or each other, and potentially confidential information about family history or about their own symptoms

should be obtained without the patient. A second major aim of the meeting with parents alone is to teach and reassure them about their child's illness. They may fear that their child is psychotic or untreatable, feel guilty that they have caused their child's condition, or fear that the clinician is going to blame them for their child's difficulties or compete with them for their child's affection. Meetings are opportunities to reassure and solidify a collaborative relationship with parents.

Creating an arena where symptoms and stresses can be discussed and monitored may not be conducive to achieving a thorough overview of all the domains of strength and difficulty. Standardized instruments are more effective for general assessment and screening. Standardized instruments may not convey the quality of difficulties or the impact of symptoms on the patient and others, but they do review certain behaviors or domains. They also permit the clinician to assess severity in comparison with clinical populations. Two instruments have been used with children and may assist a general clinician in this way: the self-report LOI ([Berg et al., 1986](#); [Cooper, 1970](#)) and the clinician-rated Children's Yale–Brown Obsessive Compulsive Scale (CY-BOCS) ([Goodman et al., 1989](#); [Scahill et al., 1997](#)).

### Laboratory Studies

There are no pathognomonic laboratory findings in OCD. Appropriate laboratory evaluation follows from the findings of the history, physical, mental status, and psychological examination. An electrocardiogram, complete blood count with differential, and baseline blood chemistries, including electrolytes, as well as liver function tests, blood urea nitrogen, and creatinine may be necessary before commencing somatic treatment. Measures of serum copper for Wilson's disease are unnecessary in the absence of psychotic symptoms or physical findings of tics or chorea. Computed tomography or magnetic resonance scanning is warranted only when focal neurologic findings are discovered. Electroencephalography is indicated only when other features suggest a seizure disorder.

Psychological tests can provide a detailed picture of intellectual function, severity of acute stressors, and characteristic defensive structures in patients with OCD. Standardized intelligence tests, such as the Wechsler Intelligence Scales for Children, third edition or the Differential Abilities Scale for younger children, are appropriate. The role of projective tests, such as the Rorschach, Thematic Apperception Test, or Draw-a-Person Test to identify sources of stress is more equivocal. The Adolescent Multiphasic Personality Inventory may be useful in identifying current characteristic defense patterns.

Severity measures of obsessions and compulsions are discussed below. In addition, the parents-on-child version of the Child Behavior Checklist ([Achenbach and Edelbrock, 1983](#)) or the Behavior Assessment System for Children can help to discover other maladaptive behaviors.

## TREATMENT

Various treatments have been applied to children with OCD, although only behavioral approaches and medications have been systematically studied. Adjunctive family treatment and individual psychotherapy are often necessary. There is a role for inpatient hospitalization under some circumstances.

### Family Support and Illness Education

Whichever modalities will be used, the clinician's relationship with the patient is paramount. First, most children with OCD are apprehensive and secretive. They are anxious about treatment and their symptoms. The relationship with the clinician can reassure and absorb much of the anxiety in a way that promotes discussion and treatment. Second, many patients are uneasy discussing their thoughts or rituals because the content is scatological or sexual. Patients must feel that the clinician will understand the distress they experience and can be trusted with the unacceptable content of their symptoms. Third, when treatments require a lengthy trial period or cause increasing anxiety, the relationship with the clinician must be sturdy if treatment is to be sustained. Fourth, because treatment usually does not produce a cure, most patients have a chronic course. The relationship established with a clinician may be long and must be capable of sustaining both parties over years.

After the diagnosis is established, it is critical to sit with the patient and his or her parents to review the causes, nature, and course of illness. The clinician should explain the relevance of comorbid features for interventions and prognosis. This may need repetition at other times during the course of treatment. It is helpful to the family and patient to understand the likely chronic nature of OCD, the objectives of treatment to reduce the interference that symptoms impose on the patient's life, and the primacy of supporting optimal development. It may be unrealistic to expect that symptoms will disappear. Furthermore, it is important to assist the family to learn how they can best support the patient and discover what supports they need to sustain them for the long term. At the same time, clinicians have every reason to be encouraging and optimistic that symptoms can be reduced.

### Behavioral Therapy

The consensus is that behavioral treatments, particularly cognitive–behavioral therapy, are the first line of intervention for children and adolescents when symptoms are mild to moderate ([March et al., 1997](#)). Behavioral treatments have been systematically investigated for adults ([Foa et al., 1985](#); [Marks et al., 1980](#)) and children ([de Haan et al., 1998](#); [March, 1995](#); [March et al., 1994](#)) with OCD. There are many reports of single case studies without control groups ([Wolff and Wolff, 1991](#)). Behavioral techniques such as self-observation, extinction, operant conditioning, and modeling have been used with adolescents ([Wolff and Wolff, 1991](#)). The preliminary studies suffered from design flaws such as those that plagued the early pharmacologic research ([Towbin et al., 1987](#)). The combination of *flooding and response prevention* appears to produce favorable results with adults and adolescents who suffer from compulsions ([Steketee et al., 1982](#)). This method uses direct and imaginary exposure to the feared object or event, followed by thwarting any opportunity to engage in symptom reactions. A patient with contamination fears about garbage would thrust his or her hand into a filled garbage can and be restricted from washing for a period of hours. Reported rates of improvement are near 90% in achieving moderate to complete improvement ([Foa et al., 1985](#)) and correlate with neuroanatomic changes ([Baxter et al., 1992](#)). *Graduated exposure with response prevention* is a modification of this technique, which is less threatening to children and adolescents ([March et al., 1994](#); [Wolff and Wolff, 1991](#)). [March and coworkers \(1994\)](#) employed a cognitive–behavioral method with exposure and response prevention to treat 15 children, of whom nine (60%) achieved at least a 50% reduction in symptoms that was sustained for 18 months. De Haan and coworkers found exposure with response prevention to be as effective as clomipramine treatment (1998). Despite many design shortcomings, evidence suggests that behavioral interventions can be useful in the treatment of OCD ([Rapaport and Inhoff-Germaine, 2000](#)). Clinicians who are trained and experienced in applying these techniques achieve the best results.

### Pharmacologic Treatment

#### SINGLE-DRUG TREATMENT

Treatment with a single agent has been shown to be effective in nearly 50% of patients with OCD. Early systematic investigations of medication were plagued by problems in diagnosis and measurement that made it difficult to generalize and interpret the findings ([Towbin et al., 1987](#)). Today, it is widely known that various SRIs appear to be useful in the treatment of OCD. Although the claims for efficacy are ubiquitous in advertisements and media, they may mislead patients to conclude that everyone with OCD will be healed by medication. It is helpful to inform patients at the outset that reliable studies have shown that 40% to 50% of drug-naïve patients experience a reduction of 25% to 40% severity in symptoms. This is important when obtaining consent before treatment and in helping patients understand why they may continue to experience symptoms after a course of treatment.

The choice of agents should take into account not only OCD, but also whether other psychopathology is present. The choice of medication for OCD should consider the presence of coexisting panic disorder, psychotic or schizotypal features, depression, or Tourette's syndrome.

To determine whether a patient has responded to a medication, it is crucial that sufficient doses be given for a sufficient duration. Most studies suggest that an adequate trial has been offered when the patient receives either the maximum allowable dose or the maximum dose that a patient can tolerate for no less than 12 weeks. Gradual dose reductions are necessary to avert withdrawal reactions when discontinuing those medications with shorter half-lives such as fluvoxamine, paroxetine, and sertraline.

The most thoroughly studied medications in the treatment of OCD are potent SRIs, which also affect other neurotransmitter systems. Blinded, placebo-controlled trials in children have been conducted with clomipramine ([DeVeugh-Geiss et al., 1992](#); [Flament et al., 1985](#); [Insel et al., 1983a](#)), fluoxetine ([Fontaine and Chouinard, 1986](#); [Riddle et al., 1990a](#)), fluvoxamine ([Price et al., 1987](#), [Riddle et al., 1996](#); [Riddle et al., 2001](#)), and sertraline ([Alderman et al., 1998](#); [Chouinard et al., 1990](#); [March et al., 1998](#)). Open trials with paroxetine ([Rosenberg et al., 1999](#)) and with citalopram ([Pallanti et al., 1999](#); [Thomsen, 1997](#)) have also been reported. With the advent of new U.S. federal government rules requiring safety and efficacy studies in children, clinicians can look forward to seeing more of these agents approved for use in children. There have been few “head-to-head” comparisons of these agents, and so there is little to guide the clinician in making first choices among these agents. [Mataix-Cols and coworkers \(1999\)](#) attempted to predict the outcome to placebo or active agents by stratifying the cohort according to factor-analyzed subgroups (see earlier). Their results suggest that the hoarding group is less likely than other subtypes to respond to SRIs. The other factor groups are not different

from one another in their responsiveness to SRIs.

In adolescent patients, clomipramine has been studied most ([DeVeugh-Geiss et al., 1992](#)). Initial studies reported an average 46% symptom reduction. Response rates were noted in 74% of patients ([Flament et al., 1985](#)). These results correlate with the findings from adult trials, in which an average 30% reduction occurred ([Insel et al., 1983b](#)). The improvement occurred in a broad variety of patients in both studies and was independent of symptom type, age of onset, or response to previous medications. [Flament and coworkers \(1987\)](#) find that response correlates with platelet 5-HT concentration and monoamine oxidase activity; lower 5-HT concentration is associated with greater symptom severity, and high 5-HT concentrations appear to predict clinical response to clomipramine. The specificity of serotonergic effects of clomipramine in the treatment of OCD symptoms is suggested by two studies. In a double-blind, placebo-controlled investigation of desipramine versus clomipramine ([Leonard et al., 1989](#)), desipramine was no more effective than placebo in reducing OCD symptoms in adolescents. Later, a double-blind substitution study ([Leonard et al., 1991](#)) suggested substantially higher relapse rates in patients taking desipramine compared with clomipramine.

Side effects of clomipramine can be problematic. Anticholinergic side effects, including dizziness, xerostomia, blurred vision, postural hypotension, tachycardia, sedation, and constipation can occur and can generate noncompliance. Side effects are less likely when one starts with very low doses and gradually increases the medication until symptoms decline. The maximum recommended dose is 5 mg/kg per day or 250 mg per day. One should obtain electrocardiograms and liver function studies at 3-month intervals for the first year of treatment and then at 6-month intervals.

In adults, fewer side effects are reported with fluoxetine than with clomipramine ([Pigott et al., 1990](#)). Double-blind, placebo-controlled trials with children suggest that fluoxetine is effective in controlling OCD symptoms ([Riddle et al., 1992](#)). Doses beginning with 5 mg per day and increasing gradually to a maximum of 60 mg per day are most commonly used. Of the reported side effects, the most frequent are agitation, insomnia, anorexia, dizziness, xerostomia, and increased anxiety. Fluoxetine also may cause a disturbing akathisia. Concerns about suicidal ideation and aggression have also been raised ([King et al., 1991](#); [Riddle et al., 1991](#)).

Sertraline was reported to be safe and useful in an open trial ([Alderman et al., 1998](#)) and then superior to placebo in a multisite, double-blind, placebo-controlled trial of 187 patients ([March et al., 1998](#)). Doses up to 200 mg per day were provided by a flexible strategy. Using a definition of 25% or greater reduction in symptoms, 42% of patients taking sertraline were judged to be "responders." The response rate on placebo was 26%. Thirteen percent of patients taking medication discontinued treatment subsequent to the trial because of side effects. The most common ill effects were insomnia, nausea, agitation, and tremor. There were no effects on vital signs or cardiac function.

Fluvoxamine has a single-ring structure. Side effects resemble those of fluoxetine and include nausea, lethargy, and insomnia ([Riddle et al., 2001](#)). Doses beginning at 25 mg per day and increasing gradually up to a maximum of 5 mg/kg per day or 300 mg per day have been employed ([Apter et al., 1994](#); [Price et al., 1987](#)). [Apter and coworkers \(1994\)](#) conducted an open trial in 14 adolescents. [Riddle and coworkers \(2001\)](#) performed a multisite, double-blind, placebo-controlled trial of fluvoxamine employing doses up to 200 mg per day in 136 children and adolescents with OCD; active treatment produced a mean 25% (or greater) decline in CY-BOCS scores over 10 weeks. Overall, 42% of patients were deemed responders.

#### AUGMENTATION STRATEGIES

It can be readily seen that between 40% and 50% of persons with OCD without associated diagnoses may not respond to adequate trials of SRIs. The response to one SRI agent does not predict the response to another, and side effects of one agent may not predict side effects of another. For this reason, it is important to offer adequate doses for a sufficient period of at least two agents before moving on to augmentation strategies. When one is combining agents with selective SRIs, particular attention should be directed to the metabolic pathways of the agents employed. Drug-drug interactions based on inhibition of the cytochrome P-450 system can lead to toxicity and side effects. Before one adds any prescription medication to a selective SRI agent, there are excellent and reliable website resources that can be consulted, such as the one maintained by David Flockhart, M.D., Ph.D., at Georgetown University in Washington, DC ([flockhad@gusun.georgetown.edu](mailto:flockhad@gusun.georgetown.edu)).

Although the use of polypharmacy is generally to be avoided, when adequate trials of two agents fail, an augmentation strategy may be necessary. [McDougle and coworkers \(1994\)](#) find that patients with Tourette's syndrome, tics, or a family history of tics who are refractory to single-drug SRI treatment may benefit from the addition of dopaminergic blocking agents, such as haloperidol or pimozide. In addition, a few SRI-refractory patients with OCD who did not have tics or a family history of tics also improved with addition of dopaminergic blocking agents. This work was extended to risperidone in blinded, placebo-controlled trials ([Fitzgerald et al., 1999](#), [McDougle et al., 2000](#)) and olanzapine in open trials ([Weiss et al., 1999](#)). This step was conceptually important, too. Dopaminergic inhibition in the corticostriatohalamocortical circuit may be critical to successful 5-HT facilitation.

There are only scanty data on adding lithium ([Rasmussen, 1984](#)) or triiodothyronine. Buspirone can increase serotonergic activity in conjunction with SRIs, but there was no evidence of benefit using buspirone augmentation in OCD ([Grady et al., 1993](#); [Markovitz et al., 1990](#)). Small-scale studies suggest that addition of clomipramine to a selective SRI may be warranted ([Figueroa et al., 1998](#)). Care must be taken to monitor electrocardiographic changes and cardiovascular side effects closely. Clonazepam has been useful to add for high levels of comorbid anxiety or panic ([March and Leonard, 1996](#)), but sedation and memory problems may be encountered. Serious toxicity results from taking fluoxetine with L-tryptophan, and this combination is discouraged ([Steiner and Fontaine, 1986](#)).

#### Psychodynamic Psychotherapy

Psychodynamic psychotherapy may be indicated when children have conflicts, associated with their obsessions or compulsions, that interfere with their optimal development. The use of psychodynamic psychotherapy for patients with OCD does not mean that a clinician has determined that the symptoms have a psychodynamic origin. Psychodynamic treatment has a role in the treatment of reactions or conflicts that accompany OCD. Examples of these concerns may include insecurities related to family dysfunction or divorce, damage to self-esteem, inappropriate expectations, perfectionistic strivings that do not respond to pharmacologic or behavioral treatment, regulation of sexual or aggressive impulses, and the impact of a potentially chronic illness during the developmental years. Moreover, patients may adopt defenses that obstruct their recovery. Psychotherapy geared to diminishing the impact of these impediments can reduce the stress experienced by patients and can promote their treatment.

#### Partial Hospital and Inpatient Treatment

In most cases, it is unnecessary to hospitalize patients to evaluate their symptoms thoroughly. However, patients and their families do encounter crises. Examples are when symptoms spiral completely out of everyone's control, the family's capacity to support the patient is thoroughly depleted, symptoms are dangerous, or a course of adequate treatment fails. Although these circumstances can pressure clinicians to initiate additional interventions quickly, it should be remembered that, usually, crises emerge from chronic strains that accumulate over time. Initiating treatments without a sufficient understanding of these strains may undermine subsequent therapy.

In a crisis, the patient may benefit from partial (or day-treatment) hospitalization and, in the event this does not prove sufficiently helpful, inpatient treatment. These are constructive alternatives to precipitous changes in outpatient treatment. Partial or inpatient hospitalization can reduce the burden on parents to manage and contain uncontrollable symptoms and can reduce the impossible demands on the patient to improve instantly. It reduces the risk of intervening improperly. The primary objectives of hospitalization are to provide rapid, objective assessment of the severity of the patient's impairment outside the home, to facilitate simultaneous initiation of psychological, family, and pharmacologic treatments, and to diminish symptoms by reducing stresses and anxiety.

#### OUTCOME AND FOLLOW-UP DATA

The outcome of an episode of OCD can range from complete, permanent remission to relentless decline. Points along this continuum include complete remission with discrete recurrent episodes, partial remission (chronic low to moderate symptoms), and partial remission punctuated by severe flare-ups ([Goodwin et al., 1969](#)). Studies of patients who are self-referred for treatment do not provide conclusions about outcome that are generalizable to other patient groups. [Rasmussen and Tsuang \(1986\)](#) suggest that, in adults, "continuous" illness with fluctuating severity is most common (84%), and a deteriorating course is next most common (15%). Others ([Rachman and Hodgson, 1980](#)) report 2-year spontaneous remission rates of 65%. [Mawson and coworkers \(1982\)](#) followed their treatment cohort of 40 patients over 2 years and discovered greater than 80% improvement on all measures for the 37 subjects available. However, when hospitalized patients are sampled, the rates of those who are rated "greatly improved" declines to 30% ([Goodwin et al., 1969](#); [Welner et al., 1976](#)).

It has been challenging to obtain reliable longitudinal clinical data. This gap shrank with the study of [Skoog and Skoog \(1999\)](#) on the natural history of 251 adult patients over 30 years. In this sample, 29% had their onset of OCD before age 20, 40% between ages 20 and 29 years, and 32% after age 30. This finding

corresponds to [Black's \(1974\)](#) report of 40% with onset before age 20, and an average age of onset in the early 20s. The ECA data also reflect this; the mean onset was 20.9 to 25.4 years of age ([Karno et al., 1988](#)). Departing from reports of others ([Rachman, 1985](#)), Skoog and Skoog reported that the most common course of illness was intermittent (i.e., remission of symptoms between episodes) (56%), although chronic illness (unremitting, constant severity) was common (27%), as was an episodic course (single episode lasting 5 years or less) (17%).

There is one prospective study of a nonclinical adolescent cohort. [Berg and coworkers \(1989\)](#) resampled a public high school adolescent cohort of 46 subjects 2 years after they were identified with either OCD (n = 16) or "subclinical" obsessions or compulsions (n = 10). Initially, of the students with elevated LOI scores, only one had sought treatment. Two findings emerged at follow-up. First, those with "subclinical" obsessions and compulsions did not worsen; only one of 10 developed OCD. Second, only five of 16 (31%) initially diagnosed with OCD met criteria 2 years later. Furthermore, the mean LOI interference scores of those diagnosed OCD diminished by 30%, beneath the cutoff for clinically significant impairment. The authors suggest that this could reflect actual improvement or methodologic unreliability. The most likely predictors of an OCD diagnosis after 2 years were previous diagnosis of OCD and the presence of another psychiatric diagnosis with OC features. This finding supports the concept of OCD as a heterogeneous disorder with waxing and waning symptoms. The 69% recovery rate approaches the spontaneous adult remission rate proposed by [Rachman and Hodgson \(1980\)](#) and [Goodwin and others \(1969\)](#).

In a prospective study of an adolescent clinical cohort, [Swedo and coworkers \(1989a\)](#) evaluated 27 adolescents who participated in clinical trials of clomipramine at the National Institute of Mental Health. Two to 5 years after successful clinical trials, 25 subjects (92%) continued to have depression or anxiety, despite improvement in OCD. [Bolton and coworkers \(1983\)](#) reviewed the outcomes of 15 adolescent inpatients and outpatients 9 to 48 months after family and behavioral treatment. A "good" response to treatment occurred in 66%. [Leonard and coworkers \(1993\)](#) reviewed records of 54 adolescents at 3.5 years (range, 2 to 7 years) after treatment. Although 94% had some symptoms, 57% did not meet criteria for OCD; only 19% were worse than on initial evaluation. Seventy percent remained on medication. Poor response to medication, presence of tics, and parental psychopathology predicted a poorer outcome ([Leonard et al., 1992](#)).

## FUTURE RESEARCH

OCD research reflects the exciting possibilities in this new millennium. Already we have come a great distance. We now know the prevalence of this disorder, have learned the limitations of screening instruments for ascertaining internalizing disorders, have demarcated a boundary between ordinary defenses and pathology, and have discovered potentially meaningful subtypes. Newer imaging techniques have illuminated structural relationships and have linked neurochemical and anatomic findings in meaningful ways. Family study methods have provided important clues to patterns of transmission, and genetic linkage studies are under way.

OCD continues to provide opportunities to discover answers to basic, far-reaching questions. Among these are the basic relationships between genetic endowment and environmental experience ([Hyman, 2000](#)). Purer agonists and antagonists that act at specific subtype sites may uncover more details of 5-HT physiology, relationships among brain structures, and complex frontal, basal ganglia, and thalamic pathways. The lines of inquiry in genetics are already charted. Products of these genes can reveal the molecular biology of OCD and can provide clues about the relationships among anatomy, physiology, and psyche. While learning about these genetic sites, risk and protective factors contributing to severity and outcome can be studied and understood.

We continue to be optimistic about clinical care. Interest in OCD has produced well-informed clinicians with greater diagnostic and treatment skills. Self-help organizations, such as the OC Foundation (P.O. Box 9573, New Haven, CT 06535), have informed the public and are lessening the isolation and embarrassment of many persons with OCD. As organizations and clinicians educate the public, persons who fear treatment or who have been disappointed in previous efforts are now receiving treatment and achieving some relief. The use of specific behavioral techniques, behaviorally and dynamically informed family treatments, psychotherapy, and medications offer improvement for a majority of seriously ill patients. Nevertheless, we cannot sit back now. Our pharmacologic treatments, even with augmentation, are still not sufficiently effective for up to 40% of OCD sufferers, particularly those with prominent hoarding symptoms. It is apparent that many persons with OCD continue to suffer in secret. Epidemiologic studies remind us that most persons with OCD have not sought consultation or treatment. There are too few clinicians schooled in the specific techniques of cognitive-behavioral treatment, and there is a tendency to neglect this intervention. Continued vigorous effort to inform the public and to assist primary care clinicians in recognition of OCD is still needed. As we learn more about neural circuitry and brain chemistry, there is a realistic basis to be hopeful that new and better treatments will become available in the next 5 years. Moreover, preventive measures can reduce the risk of developing OCD and severity of symptoms once genetic factors are known.

[Management](#)  
[Assessment](#)  
[Treatment](#)  
[Summary](#)  
[Chapter References](#)

Physical symptoms and complaints are exceptionally common in children and adolescents ([Campo and Fritsch, 1994](#); [Fritz et al., 1997](#)), with *somatoform disorders* representing the severe end on a continuum in which medically unexplained physical symptoms are associated with significant distress and functional impairment. The common feature of somatoform disorders is the presence of physical symptoms suggesting an underlying medical condition, but a general medical condition either is not identified or does not fully account for the symptoms or the degree of functional impairment ([American Psychiatric Association, 1994](#)). Psychiatrists are most likely to be involved in the less common, more extreme cases; most children who present with distressing physical symptoms are seen by primary care physicians, who manage them with varying degrees of enthusiasm and success. The term *somatization* has been used descriptively to refer to the experience of physical symptoms when medical evaluation reveals no explanatory disease or pathophysiologic process sufficient to explain the symptoms or their impact on the individual ([Kellner, 1986](#); [Lipowski, 1988](#)). Lipowski's definition of somatization is generically useful: "the tendency to experience and communicate somatic distress and symptoms unaccounted for by pathologic findings, to attribute them to physical illness, and to seek medical help for them" ([Lipowski, 1988](#)). In addition to its descriptive uses, the term has also been employed to refer to a presumed psychological mechanism of symptom production, as well as the operative term in the categorical diagnosis of *somatization disorder*, a relatively specific diagnostic entity characterized by multiple medically unexplained physical symptoms across numerous different organ systems ([American Psychiatric Association, 1994](#)).

The diagnostic criteria for the somatoform disorders are established for adults and are applied to children for lack of a child-specific research base and a developmentally appropriate alternative system. Available research has not applied the categories of somatoform disorder to children and adolescents, but instead has focused on the presenting, medically unexplained symptoms ([Campo and Fritsch, 1994](#)). Although there is reason to suspect a continuity between pediatric somatization and adult somatoform disorders, definitive longitudinal studies have not been performed. However, data do suggest that medically unexplained physical symptoms such as recurrent abdominal pain (RAP) in childhood are predictive of adult emotional disorders ([Campo et al., 2001](#); [Hotopf et al., 1998](#)).

This chapter is based directly on published reviews ([Campo and Fritsch, 1994](#); [Fritz et al., 1997](#)) and chapters ([Campo and Garber, 1998](#); [Campo and Reich, 1999](#)), and it synthesizes the available literature addressing somatization in children and adolescents as categorized within the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) ([American Psychiatric Association, 1994](#)) as somatoform disorders, such as somatization disorder, conversion disorder, pain disorder, hypochondriasis, and body dysmorphic disorder (BDD), as well as important related conditions including vocal cord dysfunction (VCD), reflex sympathetic dystrophy, and functional RAP. [Campo and Fritsch \(1994\)](#) and [Garralda \(1992\)](#) reviewed the current literature in depth regarding somatization in children and adolescents. The term *somatization* is employed in this chapter descriptively because the categorical diagnosis of somatization disorder as defined by the DSM-IV provides diagnostic criteria more appropriately used for the adult population than for children and adolescents. Because the pediatric literature is sparse, adult studies are cited when relevant. A generic model addressing management is then presented based on a collective review of treatment approaches employed across specific disorders characterized by pediatric somatization.

### NOSOLOGY

Seven specific somatoform disorders are described in the DSM-IV: somatization disorder; undifferentiated somatoform disorder; conversion disorder; pain disorder; hypochondriasis; BDD; and somatoform disorder, not otherwise specified ([American Psychiatric Association, 1994](#)). *Somatoform disorders* are defined by the presence of physical symptoms that suggest a physical disorder but are not fully explained by the presence of a general medical condition, the direct effects of a substance, or another mental disorder ([American Psychiatric Association, 1994](#)); the symptoms must cause distress or functional impairment and should not appear to be voluntarily or intentionally produced. The diagnosis of somatoform disorder can be quite subjective, because the diagnostician must make a judgment about whether a particular physical symptom is caused by a physical disease or disorder. Furthermore, the examiner must also infer the patient's sense of control over the production of the symptom. Pediatric somatoform disorders are distinguished from *factitious disorders* and *malingering*, in which physical symptoms are voluntarily fabricated, feigned, or intentionally produced ([American Psychiatric Association, 1994](#)). Another distinction is made from *psychological factors affecting medical condition*, in which psychological factors have an adverse effect on a general medical condition ([American Psychiatric Association, 1994](#)). Physical symptoms are also included in some of the criteria used to diagnose specific anxiety and depressive disorders. Different diagnosticians may conceptualize particular symptom constellations such as irritable bowel syndrome, chronic fatigue, or fibromyalgia differently, with some considering such syndromes representative of a disease process and other considering the associated physical symptoms medically unexplained. Diagnosis may thus be influenced by clinician training and experience, as well as by the site of initial presentation ([Barsky and Borus, 1999](#)), findings suggesting that the diagnosis of somatoform disorder in children and adolescents is likely to be relatively unreliable in its current form. Unfortunately, studies addressing the reliability or validity of the diagnosis of somatoform disorder *per se* in children and adolescents have not been performed. It has also been argued that several of the somatoform disorders are best conceptualized as personality disorders ([Bass and Murphy, 1995](#)). Character traits are viewed as evolving rather than firmly established in childhood, so many child and adolescent psychiatrists are reluctant to diagnose personality disorders or to label presumed enduring patterns of health-related behaviors such as described in the somatoform disorders.

### Somatization Disorder

The diagnosis of *somatization disorder* is rooted historically in early diagnostic conceptualizations of "Briquet's syndrome" or "hysteria" and refers to a recurrent disorder beginning before the age of 30 years and characterized by multiple and diverse somatic complaints associated with medical help seeking or significant functional impairment. The French physician Briquet described patients with multiple medically unexplained physical symptoms and suggested that most of these patients developed symptoms and associated disability before the age of 20 years, with early onset associated with an especially poor prognosis ([Mai and Merskey, 1980](#)).

The diagnostic criteria for somatization disorder are quite specific, requiring a history of pain in at least four different body sites, at least two gastrointestinal symptoms, one sexual or reproductive symptom, and one pseudoneurologic symptom other than pain ([American Psychiatric Association, 1994](#)). The criteria are based on the work of psychiatric researchers in the Midwest, and earlier editions of the DSM employed elaborate symptom counts from an extensive list of physical symptoms ([Cloninger, 1994](#)). Current DSM-IV criteria are an empirically based simplification aiming to address the core features of the disorder. Given the requirement for at least one sexual or reproductive symptom, the diagnosis is difficult to make in children, but children meeting diagnostic criteria for earlier formulations of the diagnosis have been reported ([Kriechman, 1987](#); [Livingston and Martin-Cannici, 1985](#)).

### EPIDEMIOLOGY AND PREVALENCE

Although the actual diagnosis of somatization disorder is rare, recurrent complaints of somatic symptoms are quite common in the pediatric population. Children and adolescents meeting the diagnostic criteria set forth in the third revised edition of the DSM (such as DSM-III-R) have been identified ([Kriechman, 1987](#); [Livingston and Martin-Cannici, 1985](#)), but the use of such strict diagnostic criteria probably limited the prevalence of the diagnosis. In a general population survey, [Offord et al.](#)

(1987) found recurrent distressing somatic symptoms to be present in 11% of girls and 4% of boys ages 12 to 16 years. Garber et al. (1991) evaluated somatic symptoms in 540 school-age children and reported that children endorse various somatic complaints that may be symptoms of somatization disorder. Headaches, fatigue, sore muscles, abdominal distress, back pain, and blurred vision are commonly reported symptoms across ages and sexes, with approximately 1% of children and adolescents endorsing the threshold 13 symptoms required for the DSM-III-R diagnosis of somatization disorder. No pediatric studies have been reported with the DSM-IV criteria, which require at least four pain symptoms, two gastrointestinal symptoms, one sexual symptom, and one pseudoneurologic symptom to be present. In summary, the rarity of the diagnosis of somatization disorder in children and adolescents probably reflects developmentally inappropriate criteria more than the possibility that the disorder arises *de novo* only in adulthood.

Age and gender are important variables in pediatric somatization. Somatization is more likely in older children and in adolescents ( Campo et al., 1999), but methodologically sound longitudinal studies are lacking ( Campo and Fritsch, 1994). Girls may also be more consistent in somatic symptom reporting than boys (Walker and Greene, 1991a, 1991b). Low socioeconomic status and low levels of parental education have been associated with pediatric somatization ( Aro et al., 1987; Campo et al., 1999; Steinhausen et al., 1989), but the impact of social and cultural factors needs to be examined more critically.

#### DEVELOPMENTAL CONSIDERATIONS

Somatic symptoms and expression of pain in children appear to follow a developmental sequence. Prepubertal children may experience affective distress as somatic sensations. RAP (see later) and headaches appear to be the most prominent physical complaints in the prepubertal child ( Belmaker et al., 1985; Faulk and Nicol, 1986; Garber et al., 1990). Headache and RAP are frequently reported painful somatic symptoms, with 10% to 30% of school-age children and adolescents reporting symptoms at least weekly (Garber et al., 1991; Larson, 1991; Tamminen et al., 1991). Limb pain, aching muscles, fatigue, and neurologic symptoms increase with age (Walker and Greene, 1989; Walker and Greene, 1991a). Polysymptomatic presentations may be more common with increasing age (Offord et al., 1987). Conversion symptoms are quite rare before the age of 6 years (Grattan-Smith et al., 1988; Lehmkuhl et al., 1989; Leslie, 1988; Volkmar et al., 1984), but they become somewhat more common in later childhood and adolescence (Stefansson et al., 1976). Pseudoneurologic or conversion symptoms are more prevalent in girls across all ages (Goodyer and Mitchell, 1989), but complaints of recurrent pain occur equally in boys and girls until late childhood and puberty, after which female symptom reporting predominates (Garber et al., 1991; Oster, 1972; Walker and Greene, 1991b). Bass and Murphy (1995) propose that somatization may reflect temperamental or personality traits, given its persistent course, long duration, and early age of onset.

#### GENETIC AND FAMILY FACTORS

Few studies are available exploring the genetic contributions to the development of somatization disorder. Wender and Klein (1981) note that antisocial personality disorder, somatization disorder, attention deficit hyperactivity disorder, and alcoholism cluster in families more than expected by chance. A twin study by Torgersen (1986) explored the links of somatoform disorders in monozygotic and dizygotic same-sex twins born between 1910 and 1955 in Sweden. Twelve subjects were found to meet the criteria for somatization disorder. Of the 12, no monozygotic or dizygotic co-twins were diagnosed with somatization disorder. Both monozygotic and dizygotic co-twins were diagnosed with conversion disorder, pain disorder, generalized anxiety disorder, obsessive-compulsive disorder, and depression. Only three of the 12 co-twins were without concomitant psychiatric disorder. Somatizing children have been found to share similar physical symptoms with family members (Garber et al., 1990; Kriechman, 1987; Walker and Greene, 1989; Walker and Greene, 1991b). In addition, anxiety and depression have been found to be more common in the families of somatizing children. Parents of children with RAP report significantly more psychiatric symptoms than parents of well controls. The presence of family members with chronic physical illness may be associated with increased somatic symptoms in the children (Wasserman et al., 1988; Zuckerman et al., 1987). A pilot study involving family members of subjects with somatization disorder revealed that family members had more illnesses, used illness for stress reduction, reported more substance abuse and legal difficulties, and appeared more dysfunctional than the control families ( deGruy et al., 1989).

#### PSYCHOSOCIAL CONTRIBUTORS TO DEVELOPMENT OF SOMATIZATION

Sexual abuse experienced in childhood has been found to be associated with somatization disorder in adulthood ( Kinzl et al., 1995), and it is suggested to lead to an increase report of subjective physical complaints in children and adolescents ( Friedrich and Schafer, 1995). Adolescents with histories of physical and sexual abuse have been found to score higher on measures of somatization than adolescents without histories of abuse ( Atlas et al., 1995). A pattern of adult chronic somatization has been associated with lack of parental care coupled with a history of childhood illness ( Craig et al., 1993; Craig et al., 1994).

#### Undifferentiated Somatoform Disorder

Children and adolescents with multiple somatic complaints across numerous different body locations insufficient to justify a diagnosis of somatization disorder are more likely to meet diagnostic criteria for *undifferentiated somatoform disorder*, a somatoform disorder characterized by the presence of one or more physical complaints (e.g., individual symptoms of fatigue, urinary, or gastrointestinal distress) lasting at least 6 months ( American Psychiatric Association, 1994). *Neurasthenia* is a diagnosis made in Europe, but not included in the DSM-IV; the disorder has a long tradition in Western medicine and is characterized by persistent and troubling complaints of fatigue after mental effort or minimal physical effort, as well as at least two symptoms from a list that includes muscular aches and pains, dizziness, headache, sleep disturbance, inability to relax, irritability, and dyspepsia ( Wessely, 1990). Children with so-called neurasthenic symptoms of sufficient duration would be diagnosed with undifferentiated somatoform disorder.

#### Conversion Disorder

*Conversion disorder* is the somatoform diagnosis made when the clinician is confronted by one or more deficits or symptoms affecting voluntary motor or sensory function that suggest a neurologic or other general medical condition, and psychological factors are judged to be associated with the symptoms or deficits ( American Psychiatric Association, 1994). The presence of psychological factors is inferred from an association of the symptom with a significant psychological stressor such as family conflict, bereavement, or psychological trauma. Presenting symptoms classically resemble neurologic dysfunction (paralysis, paresis, anesthesia, paresthesia), follow the psychological stressor by hours to weeks, and may cause more distress among parents or physicians than within the patient (*la belle indifférence*). Symptoms frequently reported in children and adolescents include pseudoseizures, apparent paresis, paresthesia, and gait disturbances ( Grattan-Smith et al., 1988; Leslie, 1988; Spierings et al., 1990; Thomson and Sills, 1988). Symptoms are usually self-limited but may be associated with chronic sequelae such as contractures or iatrogenic injury (Fritz et al., 1997). There are four subtypes of conversion disorder in the DSM-IV, based on whether the symptoms presented are primarily motor, sensory, nonepileptic seizures, or mixed.

#### PREVALENCE AND EPIDEMIOLOGY

Because of the need both to specify a psychological association and to exclude medical or cultural causations, conversion disorder cannot be accurately diagnosed using only interview-based epidemiologic methods. Pseudoneurologic symptoms, or symptoms suggestive of a neurologic disorder in the absence of demonstrable neurologic disease, nevertheless appear to be unusual in community samples of children and adolescents in most modern Western cultures ( Garber et al., 1991; Rutter et al., 1970; Stefansson et al., 1976). One retrospective chart-review study of an Iowa medical population identified conversion disorder in as few as 11 patients between 9 and 20 years old out of 220,306 patients of all ages seen during a 2-year period ( Tomasson et al., 1991). Conversion disorder does appear to be more common among girls than boys across all age groups (Spierings et al., 1990; Steinhausen et al., 1989). Conversion disorder seems to become increasingly common in tertiary referral centers and pediatric neurology services, where nonepileptic seizures, faints, falls, and abnormalities of gait or sensation are the most commonly reported symptoms (Goodyer and Mitchell, 1989; Grattan-Smith et al., 1988; Leslie, 1988; Maloney, 1980; Spierings et al., 1990; Steinhausen et al., 1989; Volkmar et al., 1984). Higher prevalences have also been reported in some non-Western clinical settings ( Chandrasekaran et al., 1994).

#### DEVELOPMENTAL CONSIDERATIONS

Conversion disorder is quite unusual in very young children, in whom the diagnosis should provoke considerable skepticism unless there has been an exceptionally careful medical workup. Preschool-age children may at times limp or refuse to walk after a minor injury for a few hours or days, and the symptom may elicit increased attention on the part of parents and other caretakers, but it is often difficult to determine the degree to which such behavior may be associated with stress or psychological factors. Conversion disorder, although still relatively rare, becomes more common with increasing age into later childhood and adolescence ( Campo and Fritsch, 1994). *La belle indifférence*, an apparent lack of concern by the patient for his or her primary symptom, is not invariably seen among children and adolescents and is reported in as few as 8% of cases (Spierings et al., 1990).

The eventual association of conversion disorder with a diagnosable physical disease or injury is variable ( Grattan-Smith et al., 1988; Spierings et al., 1990).

Psychiatric comorbidity in children and adolescents with conversion disorder is poorly studied. A study by [Bowman and Markand \(1996\)](#) of adults diagnosed with pseudoseizures used the Structured Clinical Interview for DSM-III-R and found high rates of psychiatric comorbidity, particularly with other dissociative disorders (91%) and affective disorders (64%). In a retrospective chart-review study of patients of all ages, [Tomasson et al. \(1991\)](#) found significantly higher rates of major depressive disorder, panic disorder, and substance abuse in adults diagnosed with somatization disorder than in those with conversion disorder.

The course of conversion disorder is thought to be brief, and most cases reported resolve within 3 months of diagnosis ([Leslie, 1988](#)). The time to diagnosis is variable and ranges from weeks to a year, or more, during which time the child may be subjected to numerous diagnostic tests and unsuccessful medical interventions. Recurrence of symptoms is thought to be exceptional and may foreshadow the emergence of a polysymptomatic somatization disorder.

#### GENETIC AND FAMILY FACTORS

There is little in the way of firm evidence of a genetic contribution to the development of conversion disorder *per se*. However, family factors are thought to play a prominent role in the expression of the illness and the persistence of symptoms. Conversion disorder may present with symptoms that mimic those of a close friend or relative, a finding reported in one-fourth to one-half of children in two case series ([Grattan-Smith et al., 1988](#); [Spierings et al., 1990](#)). The relationship between conversion disorder and parental psychopathology is poorly delineated; however, [Grattan-Smith et al. \(1988\)](#) identified two broad patterns of disturbance among families of children with conversion disorder: anxious families preoccupied with disease and disorganized and chaotic families. [Turgay \(1990\)](#) suggests that poor family functioning and denial may prolong time to recovery, but such hypotheses remain untested.

#### NONEPILEPTIC SEIZURES AND PSEUDOSEIZURES

The most commonly reported conversion symptom in the recent child and adolescent psychiatric literature is the *nonepileptic seizure* or *pseudoseizure*, an event that resembles an epileptic seizure in the absence of electroencephalographic abnormalities or characteristic epileptic clinical course. Case series of conversion disorder previously cited report frequencies of pseudoseizure in clinical samples of conversion disorder between 15% and 50%. Although epilepsy may be difficult to distinguish from pseudoseizures, clinical distinctions have been proposed and reviewed by [Stores \(1999\)](#). More technologically sophisticated methods to distinguish seizures from pseudoseizures include videoelectroencephalography ([Cohen et al., 1992](#); [Duchowny et al., 1988](#)) and measuring of "postictal" elevations in serum prolactin levels ([Fisher et al., 1991](#)), although the latter technique may be of questionable utility. However, obtaining a "normal" electroencephalographic recording does not exclude the presence of a seizure disorder, and documentation of a seizure disorder does not exclude the possibility of a pseudoseizure ([Lancman et al., 1994](#)).

#### Pain Disorder

*Pain disorder* is diagnosed when pain in one or more anatomic sites of sufficient severity to warrant clinical attention and to cause significant distress or functional impairment is the focus of clinical attention ([American Psychiatric Association, 1994](#)). The three subtypes of pain disorder are as follows: *pain disorder associated with psychological factors*, in which psychological factors are judged to play the predominant role in the causation or persistence of the pain; *pain disorder associated with both psychological factors and a general medical condition*, in which psychological factors and a general medical condition are judged to interact significantly in the development or maintenance of pain; and *pain disorder associated with a general medical condition*, in which psychological factors appear to play no more than a minimal role. The third subtype is not considered a mental disorder and is coded on Axis III. The pain disorder diagnoses are considered *acute* if less than 6 months in duration and *chronic* when lasting 6 months or more. Recurrent complaints of pain have been associated with an increased risk of psychopathology, functional impairment, family difficulties, and higher health and mental health service use in a large sample of children evaluated in the primary care setting ([Campo et al., 1999](#)). The cause of pain, affective suffering, disability, and handicap are all components of pain and are best evaluated independently given the complexity of their associations. For example, such an approach allows the child with pain driven by an "organic" cause and with an associated psychologically determined handicap to be recognized and prescribed comprehensive treatment.

Even though pain is a universal human experience, it has proven surprisingly hard to define. The International Association for the Study of Pain's definition is now widely accepted: "pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." The definition highlights the complexity, the psychological aspects, and the subjective nature of pain. Pain must always be assessed through self-report, because no direct or objective measurement technique exists. Thus, dealing with pain in infants and young children is especially problematic because of their limited self-reporting abilities. The task of determining when a pain syndrome warrants diagnosis as a psychiatric disorder can be somewhat daunting, given the potential for subjectivity inherent in such judgments. A developmental perspective is essential. Pain responses in infants younger than 3 months appear reflexive, with negative affect more consistently accompanying pain after 3 months of age. More observable fear and avoidance of pain-provoking situations and common words for pain ("booboo") develop in infants 6 to 18 months of age; children 18 months and older begin to localize pain, to use the word "hurt," and to recognize pain in others ([McGrath and McAlpine, 1993](#)). Preschoolers exhibit coping strategies, such as seeking hugs or using distraction, to alleviate pain. However, their preoperational cognitive abilities lead to magical thoughts about pain and prohibit understanding a painful procedure as being potentially beneficial. School-age children can clearly specify levels of pain intensity and can link psychological feelings to pain. With formal operations comes an increasingly complex and abstract idea of pain, its causes, and its course. Clinical studies show that the pain threshold increases with age, and younger children are more sensitive to pain from medical procedures than children who are more than 7 years old ([Fradet et al., 1990](#)). Cultural differences in pain expression and pain behavior have been reported in the past, but the existing literature lacks studies that do not confound ethnicity, socioeconomic status, or acculturation levels. Although cultural factors need further investigation, several studies find similar pain responses in Hispanic and white children ([Pfefferbaum et al., 1990](#)).

The diagnostic process for somatoform disorders frequently entails the quantification of children's pain. Because direct, physiologic measures of pain are lacking, four alternative approaches to assessing the response to pain are employed. With infants, associated indicators of distress are useful, either behavioral (body movement, facial expression) or physiologic (heart rate, respiration). Observational scales, completed by either parents or professionals, can be reliable measures of overt distress ([Manne et al., 1990](#)). Direct scaling techniques, in which children pick the face that matches how they feel out of a graduated series, allow pain to be systematically rated and compared over time by children as young as 5 years of age ([Bieri et al., 1990](#)). Finally, pain questionnaires have been developed for children of school age and older to quantify pain ([Varni et al., 1987](#)). Self-report of pain experiences is highly desirable whenever possible, especially when parental objectivity may be compromised. Adolescents may hide their pain from parents or, alternatively, may exaggerate it in their parents' presence; in neither case does parental report provide accurate information. The repeated use of a scale or questionnaire is frequently useful to judge the effectiveness of interventions over time.

Family influences on pain are not well documented, although clinical wisdom and some evidence suggest that disability (reduction of activity) and handicap (social role impairment) associated with pain may aggregate in families ([Palermo, 2000](#)). [Osborne, Hatcher, and Richtsmeier \(1989\)](#), although not specifically using the DSM-IV categorization, report that children whose pain is unexplained and, presumably, more psychologically determined, have more family members as "pain models" than children whose pain is related to a purely organic cause. Adolescents with pain syndromes leading to school absences may experience more maternal reinforcement of illness behavior than matched controls who have pain but who attend school ([Dunn-Geier et al., 1986](#)). Overall, there is scant empirical evidence regarding the impact of parental pain on children, the determinants of handicap when pain exists, and the potential mechanisms of transmission of pain experiences within families.

#### RECURRENT ABDOMINAL PAIN

Recurrent abdominal pain (RAP) has been defined as at least three episodes of abdominal pain occurring over a period of at least 3 months that are severe enough to affect the activities of the child ([Apley and Naish, 1958](#); [Scharff, 1997](#)). The condition is common and affects 10% to 25% of school-age children and adolescents ([Alfven, 1993](#); [Faul and Nicol, 1986](#); [Garber et al., 1991](#); [Hyams et al., 1996](#); [Oster, 1972](#); [Zuckerman et al., 1987](#)). Approximately 2% to 4% of pediatric office visits may be consequent to abdominal pain ([Starfield et al., 1984](#)). RAP is more common with increasing age into adolescence ([Hyams et al., 1996](#)) and in girls ([Alfven, 1993](#); [Eminson et al., 1996](#)). The gender ratio is equal in early childhood ([Faul and Nicol, 1986](#); [Zuckerman et al., 1987](#)), but girls predominate in later childhood and adolescence ([Mortimer et al., 1993](#)). Most cases of RAP are medically unexplained, particularly in the absence of clues such as weight loss, bleeding, fever, other systemic symptoms, or laboratory abnormalities ([Boyle, 1997](#)). Some have nevertheless speculated that so-called "functional" RAP may result from gastroesophageal reflux, gastritis, small bowel dysmotility, or carbohydrate malabsorption ([Murphy, 1993](#)). RAP is most often considered to be a functional gastrointestinal disorder in the absence of explanatory structural or biochemical abnormalities ([Drossman et al., 1990](#)). Many patients meet criteria for irritable bowel syndrome, which is characterized by RAP or discomfort in which the symptoms are relieved by defecation or are associated with changes in stool frequency or consistency.

RAP is commonly comorbid with symptoms of anxiety and depression and with other somatic symptoms such as headache ([Abu-Arafeh and Russell, 1995](#); [Egger et al., 1999](#); [Garber et al., 1990](#); [Hodges et al., 1985](#); [Mortimer et al., 1993](#); [Walker et al., 1993](#); [Wasserman et al., 1988](#); [Zuckerman et al., 1987](#)). RAP is associated with functional impairment such as school absenteeism ([Garber et al., 1990](#); [Hyams et al., 1996](#); [Walker et al., 1993](#)), as well as a greater risk of unnecessary medical

investigations and procedures. [Walker et al. \(1993\)](#) compared children with RAP to controls with respect to life events, emotional and somatic complaints, family illness behavior, and functional disability; children with RAP had significantly more emotional and somatic complaints, and their families rewarded illness behavior more than families of healthy controls, but no differences were found in rates of negative life events or in levels of family functioning. RAP may thus be associated with a family model of illness behavior and may develop in a climate in which somatic and emotional distress is more likely to be experienced and expressed by both parents and children.

Early follow-up studies reported persistence of abdominal pain into adulthood for one-third to one-half of affected children ( [Apley and Hale, 1973](#); [Christensen and Mortensen, 1975](#); [Stickler and Murphy, 1979](#)). Children who complain of stomachaches at the age of 4 years are three times as likely to have similar complaints on follow-up at age 10 than peers ( [Borge et al., 1994](#)). More recent studies suggest that childhood RAP is predictive of emotional disorder in adulthood ( [Campo et al., 2001](#); [Hotopf et al., 1998](#)). Adult studies have suggested that visceral hypersensitivity may be a component of functional abdominal pain, as evidenced by reports of increased awareness of balloon distention in all segments of the gastrointestinal tract compared with normal controls ( [Zigheboim and Talley, 1993](#)). This visceral hypersensitivity may be related to the cognitive distortions previously described as somatosensory amplification by [Barsky et al. \(1988\)](#).

## REFLEX SYMPATHETIC DYSTROPHY

Although more commonly seen among adults, complex regional pain syndrome—reflex sympathetic dystrophy may also occur in children and adolescents. Typically, the condition presents with chronic, painful swelling in an extremity, decreased skin temperature, cyanosis, delayed capillary refill, and limitation of functioning. In adults, complex regional pain syndrome—reflex sympathetic dystrophy commonly follows injury of the involved extremity; however, in children and adolescents, the history of prior injury is less consistent. Moreover, in contrast to adults with this condition, children show decreased uptake during radionuclide imaging in the affected extremity ( [Goldsmith et al., 1989](#)).

The pathophysiology of complex regional pain syndrome—reflex sympathetic dystrophy is still undetermined but may be related either to dysregulation of the sympathetic nervous system or to an inflammatory response to injury. Psychological mediators have been proposed and outlined in case series (Sherry and Weisman, 1989; [Silber and Majd, 1988](#)), but the lack of adequate control groups and the potential for investigator biases methodologically limit these studies. In general, there appears to be an association of reflex sympathetic dystrophy with psychosocial stressors; however, it remains possible that findings of “parental enmeshment” may be a consequence of the effects of chronic pain on family functioning rather than a causative factor.

## Hypochondriasis

*Hypochondriasis* refers to the persistent, preoccupied fear that one has a serious disease. This fear is likely based on misinterpretation of the threat associated with one or multiple physical symptoms, it persists despite appropriate medical workup and reassurance, and it must be present for at least 6 months ( [American Psychiatric Association, 1994](#)). Hypochondriasis is associated with dissatisfaction regarding medical care, “doctor shopping,” deteriorating interpersonal relationships, and the risk of iatrogenic complication from excessive or repeated diagnostic procedures in adults ( [Barsky, 1992](#)). Hypochondriasis can be an independent disorder (primary hypochondriasis) or part of another underlying psychiatric disorder (secondary hypochondriasis). The adolescent who is mistakenly convinced that she is pregnant or the medical student who fears developing a recently studied illness would not be diagnosed with hypochondriasis because of the transient nature of their reactions.

Considerable debate and some research deal with the relationship between hypochondriasis and other psychiatric disorders. Hypochondriasis and obsessive-compulsive disorder often share intense and disabling fears of illness, injury, or contamination, and the lifetime prevalence of obsessive-compulsive disorder in a series of hypochondriacal patients was four times higher (8% versus 2%) than in a comparison group ( [Barsky, 1992](#)). However, in contrast to those with hypochondriasis, patients with obsessive-compulsive disorder view their fears as abnormal, attempt to suppress them, and avoid publicizing their symptoms, which are frequently seen as shameful. Depression and hypochondriasis may overlap, especially when the morbid ideation of depression takes the form of disease phobias.

Little is known and less is reported in the literature about the occurrence of hypochondriasis in children or adolescents ( [Campo and Fritsch, 1994](#)). Although it is reasonable to assume that the disorder would be more common in pediatric than psychiatric settings (similar to the predominance of adult hypochondriasis presenting in medical settings), no data exist regarding the epidemiology in younger age groups. The need for children and adolescents to involve their parents in seeking help for medical concerns may contribute to the rarity with which hypochondriasis is reported in youth. Adolescents' bodily focus means that specific disease fears (of acquired immunodeficiency syndrome or cancer, for example) are not uncommon, although usually at a subsyndromal level. In hypochondriasis, the patient's disease conviction is not of delusional intensity, as in delusional disorder, somatic type. Hypochondriasis is also not diagnosed when the belief or preoccupation is limited to an imagined defect in appearance.

## Body Dysmorphic Disorder

Body dysmorphic disorder (BDD) is defined in the DSM-IV as a preoccupation with an imagined or slight defect in physical appearance causing clinically significant distress or impairment in functioning ( [American Psychiatric Association, 1994](#)). BDD has been described as a disorder in which the sufferer experiences shame and the need for secrecy; thus, it may be missed unless clinicians ask directly about symptoms related to BDD. Parents of children with BDD may seek evaluation after witnessing excessive mirror checking, grooming, and reassurance seeking in their child. From a developmental perspective, preoccupation with appearance can be common during adolescence, but the adolescent with BDD exhibits either clinically significant distress or impairment in functioning. People with BDD often undergo costly and potentially dangerous cosmetic surgeries and dermatologic treatments.

[Phillips et al. \(1995a\)](#) report a virtual absence of psychiatric literature on BDD in children and adolescents despite preliminary evidence suggesting that the onset of BDD occurs in adolescence. To date, no epidemiologic data are available for BDD in children and adolescents. The literature focuses on case reports ( [Albertini et al., 1996](#); [El-khatib and Dickey, 1995a](#); [Phillips et al., 1994a](#); [Sondheimer, 1988](#)), all cases resulting in excessive preoccupation with perceived defects and impairment in functioning. A series of patients with DSM-IV–defined BDD reported a mean age of onset of 16.9±6.9 years ( [Phillips et al., 1995b](#)). The neurobiology of BDD is only now beginning to be studied. Evidence from demographics, features, phenomenology, course, and treatment response suggest the BDD may be related to obsessive-compulsive disorder and the pathophysiology may involve serotonin ( [Phillips, 1996](#)), as suggested by a report by [Albertini et al. \(1996\)](#) of a 6-year-old boy meeting diagnostic criteria for BDD who responded to serotonergic reuptake blockade.

## Somatoform Disorder, Not Otherwise Specified

*Somatoform disorder, not otherwise specified* is diagnosed when symptoms consistent with a somatoform disorder are present, but criteria for a specific disorder are not met ( [American Psychiatric Association, 1994](#)). Examples include unexplained physical symptoms such as fatigue or hypochondriacal concerns that are of less than 6 months' duration.

## VOCAL CORD DYSFUNCTION

Vocal cord dysfunction (VCD) is an often-unrecognized disorder in which spasm of the vocal cords leads to narrowing of the glottis and results in symptoms that mimic acute asthma. Typically, there is a history of asthma unresponsive to very aggressive medical management, including multiple inhaled medications, systemic steroids, and inpatient hospitalization with endotracheal intubation. VCD is differentiated from asthma by the absence of nocturnal symptoms, localization of wheezing to the upper chest and throat, normal blood gases despite extreme symptoms, and significant adduction of the vocal cords when visualized on laryngoscopy ( [Brugman and Newman, 1993](#); [Goldman and Muers, 1991](#)). The prevalence of VCD in children's hospitals is unknown, in part because of clinicians' lack of awareness of the disorder ( [McQuaid et al., 1997](#)). Psychiatrists and psychologists become involved as consultants, often because of suspicion that the symptoms are factitious or intentionally produced (neither is true of VCD). Overt, serious psychopathology is often not identified in patients with VCD or their families, although stress or trauma may be important in the evolution of the disorder. Asthma medications are unhelpful, but speech therapy to reduce tension in the extrinsic laryngeal musculature combined with other psychosocial treatments can be helpful. Psychiatric input regarding the diagnosis, treatment planning, and communication with the family can be important in helping the child return to normal functioning.

## MANAGEMENT

### Assessment

Assessment provides the foundation for treatment and is a particularly critical factor in determining success or failure with an individual patient and family. Both the

content and the process of the assessment are critically important. Most, if not all, children referred for psychiatric consultation for presumed somatization have been evaluated by a primary care physician or even a subspecialist. It is nevertheless the consultant's responsibility to ensure that sufficient medical assessment has been performed, including a careful physical examination. There is no lack of anecdotal and published reports of patients initially believed to suffer from somatoform complaints who were subsequently identified with a physical disease sufficient to explain the presenting symptoms ([Rivinus et al., 1975](#)). The finding that available case series suggest that serious missed disease is relatively uncommon in both presumed conversion disorder and in patients with recurrent pain ([Maisami and Freeman, 1987](#); [Spierings et al., 1990](#); [Volkmar et al., 1984](#); [Walker et al., 1993](#)) should provide little comfort in the individual case unless competent medical assessment has been performed.

The clinician thus should be open to initiating additional medical evaluation if the initial assessment raises concerns about undiagnosed physical disease or if the clinical picture has changed. Previous medical and psychiatric records should be carefully reviewed. Inconsistencies or apparent fabrications in the history can be a clue to the uncommon, but real possibility of malingering, factitious disorder, or factitious disorder by proxy. Medical or psychiatric records hand carried by a parent should provoke suspicion, because record tampering has been reported in some cases of factitious disorder by proxy ([Schreier and Libow, 1993](#)).

Children with unexplained symptoms and their parents often feel misunderstood by their doctors and the professionals involved in their care. They are prone to feel dismissed when a psychiatric referral is suggested and become concerned that the complaints have not and will not be taken seriously. Also of concern is the perhaps more common problem of excessive and inappropriate medical investigations and evaluations performed because of professional anxiety or discomfort associated with the perceived stigma of somatization and psychiatric disorder. Sadly, concerns related to the stigma can serve to motivate patients, families, and clinicians to pursue potentially dangerous and unnecessary medical investigations and treatments. Nonpsychiatric physicians are also likely to be more comfortable with the assessment of physical disease than with the diagnosis and treatment of psychiatric disorder. The clinician must be alert to the powerful influence of anxiety, not only for the patient and family, but also for the clinician. The anxiety experienced by patients and family members in relation to the uncertainties of dealing with subjectively real and frightening physical symptoms can become contagious and may distract otherwise thoughtful professionals from usual sound clinical practice. Unnecessary medical tests and treatments are not only potentially dangerous from a physical perspective, but they may also represent a metacommunication to the family and patient that the clinician expects to find physical disease. This may perpetuate somatization by giving the impression that the clinician fears that a serious physical disease has been missed and can make verbal efforts to reassure the patient and family appear incongruous or deceptive ([Goodyer and Taylor, 1985](#); [Grattan-Smith et al., 1988](#)).

The presence of a physical disease in the child or a family member does not definitively exclude the possibility of pediatric somatization. Chronic physical disease may increase the risk of experiencing symptoms consistent with somatization ([Kellner, 1986](#); [Livingston, 1993](#); [Pilowsky et al., 1982](#)), and unexplained physical symptoms and disability may develop after an acute illness or accident ([Carek and Santos, 1984](#); [Leslie, 1988](#)). Similarly, children with medically unexplained physical symptoms commonly have family members with a history of physical illness. Experience with physical illness may influence vulnerable persons by introducing them to the potential benefits associated with the sick role.

The diagnosis of a somatoform disorder should not just involve the exclusion of serious physical disease, but ideally should be based on certain positive findings that support the diagnosis ([Campo and Garber, 1998](#); [Campo and Reich, 1999](#); [Goodyer and Taylor, 1985](#)). Numerous "clues" to the identification of somatization and the diagnosis of a somatoform disorder have been identified ([Campo and Garber, 1998](#); [Friedman, 1973](#); [Goodyer and Taylor, 1985](#)), including the following: (a) temporal contiguity of the symptom with significant psychosocial stress; (b) a prior history of somatization; (c) social or familial reinforcement of the symptom; (d) a model for the symptom within the family or immediate environment; (e) comorbid psychiatric disorder; (f) apparent communicative or symbolic meaning of the symptom; (g) violation of known anatomic or physiologic patterns by the symptom; and (h) responsiveness of the symptom to placebo, suggestion, or psychological treatment. These clues are clearly less than definitive, with a constellation of clues taken together being most persuasive if not convincing. Clearly, virtually all of the clues mentioned here could be found in association with physical disease. Because somatization is often associated with elevated rates of psychopathology in the identified patient and the family, careful psychiatric assessment is required ([Campo and Garber, 1998](#); [Campo and Reich, 1999](#)). Anxiety symptoms and school refusal are common in children with recurrent pain ([Garber et al., 1990](#); [Hodges et al., 1985](#); [Walker et al., 1993](#); [Wasserman et al., 1988](#)), and depressive symptoms are also commonly associated with pediatric somatization ([Garber et al., 1991](#); [Kashani et al., 1982](#); [Kowal and Pritchard, 1990](#); [Larson, 1991](#)).

Multiple sources of information such as parents, health care providers, other relevant professionals, and the school are key to a comprehensive evaluation. The school is an especially valuable source of objective information. It is exceptionally important to identify any learning skills deficits, because a learning disorder can provide motivation for school avoidance. Physical symptoms may also be employed as "self-handicapping strategies," particularly in perfectionistic and socially anxious children, by providing an ostensible excuse for why a particular child may not be performing up to his or her own expectations or the expectations of others ([Walker et al., 1995](#)).

Careful assessment of the social and family environment is similarly critical. A family history of psychiatric disorder, somatization, or physical illness and disability is important to recognize because of observations that there is often a familial "model" for a given child's symptoms and complaints. Pediatric somatization is commonly associated with separation fears, a sense of parental "overprotection" ([Robinson et al., 1990](#)), and the perception within the family that the child is especially "vulnerable" from a physical or emotional perspective ([Green and Solnit, 1964](#)). The child may have been the result of prolonged efforts for the couple to conceive, or there may be a prior history of trauma for the family associated with medical care, such as the loss of a relative after physicians mistakenly provided reassurance. Inquiring about previous experiences in the health care system is often productive. Other areas relevant to the assessment include possible marital conflict and parent-child relational problems. For example, a focus on the child's physical symptoms may allow the family to preserve its current level of function and may help the parent avoid serious marital conflict by diverting attention to the child's symptoms ([Mullins and Olson, 1990](#)). Other negative life events such as the loss of death of a family member or other close relation may be of critical importance ([Aro et al., 1989](#); [Livingston, 1993](#); [Scaloubaca et al., 1988](#)). Perhaps the most critical environmental issue to consider is that of maltreatment. Although maltreatment can be relevant to the presentation of any child with somatization or emotional and behavioral problems in general, it is particularly important to consider in children with conversion disorder, genitourinary complaints, and chronic, polysymptomatic somatization ([Klevan and DeJong, 1990](#); [Livingston et al., 1988](#); [Rimza et al., 1988](#)).

## Treatment

Treatment needs to be individualized to address the specific problems of a particular child, but therapeutic approaches to the various somatoform disorders share certain common features. A thoughtful generic approach is described by [Garralda \(1999\)](#). Especially with chronic somatoform problems, the child and adolescent psychiatrist will often function as a consultant to the primary care physician who largely manages the case. Somatizing patients and their families think and speak in terms of physical illness, medical problems, and somatic dysfunction and thus resist psychiatric referral, either actively or passively. The psychiatric consultant and primary care physician must coordinate their planning closely if the physician-patient alliance is to be maintained and "doctor shopping" is to be avoided. Working with somatizing patients and their parents can be frustrating for the pediatrician, who experiences critical and dissatisfied responses to conservative management or side effects and new symptoms when an aggressive approach is taken. Comorbid psychiatric disorders are common in somatizing patients and should be diagnosed and treated appropriately. Psychotherapy is often difficult to apply directly with somatizing patients and their families because it may initially seem irrelevant to them. Nonetheless, various types of psychotherapy have been reported as beneficial for some patients, always with the caveats of respecting the patient's somatic language and avoiding premature confrontation that inevitably leads to a sense of misunderstanding. Family cognitive-behavioral therapy for RAP ([Sanders et al., 1989, 1994](#)) has demonstrated higher rates of elimination of pain, lower levels of relapse at 6- and 12-month follow-up, and greater function than with the usual pediatric treatment without psychologic intervention.

## NATURAL HISTORY AND COURSE

As noted previously, current practice is handicapped by the lack of methodologically sound longitudinal studies of groups of children and adolescents with medically unexplained physical symptoms. Furthermore, most available studies have focused only on the presence or absence of the presenting symptom as the sole outcome measure, despite its being clear that other outcomes such as functional status or psychiatric status may be relevant. For example, earlier studies suggest that 25% to 50% of children and adolescents with RAP experience some abdominal pain in adulthood ([Apley and Hale, 1972](#); [Christensen and Mortensen, 1975](#)). More recent follow-up studies report significantly higher levels of abdominal discomfort, other somatic symptoms, internalizing psychiatric symptoms, and functional disability in former RAP patients than in a comparison group ([Walker et al., 1995](#); [Walker et al., 1998](#)), and some studies suggest that pediatric RAP is a better predictor of emotional disorder than physical distress in adulthood ([Campo et al., 2001](#); [Hotopf et al., 1998](#)). Significant physical improvement or complete recovery is reported in 50% to 100% of children and adolescents with conversion disorder in terms of the presenting symptom alone ([Goodyer and Mitchell, 1989](#); [Grattan-Smith et al., 1988](#); [Leslie, 1988](#); [Maisami and Freeman, 1987](#); [Spierings et al., 1990](#)), but data regarding other outcomes are lacking.

## DIAGNOSIS AND ESTABLISHING A FOUNDATION FOR TREATMENT

The diagnostic impression should be discussed directly in the context of a review of the clinician's understanding of the symptoms presented, the time course, the child's temperament, and family environment. Historical details should be clarified, and a shared consensus of the child's presentation should be arrived at together. This establishes the precedent for a partnership in treatment. When a definitive diagnosis of somatoform disorder cannot be made, it is important to acknowledge diagnostic uncertainty. After the diagnosis has been established and reviewed with the patient and family, additional diagnostic evaluation should be avoided in the absence of new clinical information, a change in the clinical picture, or evidence that intervention cannot proceed without the reassurance provided by an additional, relatively low-risk investigation.

Psychoeducation is of value in managing somatoform disorders, and it is a relatively low-cost first-line intervention. Education can be directed at understanding and adhering to a treatment regimen, clarifying when to worry about symptoms and when not to worry, enhancing communication with treating professionals, and using problem-solving coping techniques. Education of the patient and family helps to challenge stigma and to develop hope and positive expectations for recovery. Given the pervasive nature of stigma, it is especially important to educate referring physicians about the dangers of communicating any sense of embarrassment about the diagnosis of somatoform disorder or other psychiatric disorder, because this can contribute to treatment resistance and a wish to perpetuate the search for unrecognized physical disease. Discussing the relationship between mind and body and the false dichotomy implied by separate systems of care of "physical" and "mental" disorders can be useful. Patients and families need to understand that the problem presented by the child is recognized as real and is familiar to experienced clinicians. Explaining the physical symptoms as simple reactions to psychosocial adversity or "stress" may prove unproductive, particularly when clear-cut stressors are not evident or are not appreciated by the patient or family. In addition, a preoccupation with "stress" may inadvertently encourage the patient to avoid uncomfortable and distressing situations, and this is essentially counter to the rehabilitative approach emphasized later.

The importance of a therapeutic partnership or alliance among the child, the family, and the involved professionals must be emphasized, and the roles and responsibilities of each should be carefully defined. The value of close communication and working together to solve the problem should also be discussed directly. The importance of close communication, honesty, and a foundation of trust make the use of placebo or other sham interventions generally unacceptable. From a practical perspective, if suggestion or placebo proves unsuccessful, the clinician then is forced to consider new deceptions or to return to prior efforts to convince the patient that serious physical disease is absent and that symptom removal is not really necessary for a return to function. A simple consultation letter from a consulting psychiatrist to the primary care physician significantly improved the management of adults with chronic, disabling somatization and reduced associated health care expenditures (Smith et al., 1986). The clinician can serve as a bridge to help bring all the involved parties together in a productive alliance to help the child. Medical care is best consolidated by a single physician. Regularly scheduled medical visits can reassure the patient and family that their concerns have not been dismissed. The primary physician may serve as a powerful attachment figure for families when rejection sensitivity and fears of abandonment are prominent. Regularly scheduled visits allow the patient and family to see the physician without the requirement that the child be sick. It is often useful to help define what constitutes a legitimate, medically excused school absence for both the family and the school and to clarify who will be the physician responsible for legitimizing medical excuses. The patient will have to understand that absence from school without the approval of the collaborative treatment team and an appropriate medical excuse will be viewed as truancy, and the school will take the appropriate action. With such a treatment plan, the cooperation of the school can benefit the treatment effort. Once it is clear that any school excuses must come from the primary physician alone, the tendency to "doctor shop," particularly for medical excuses, will be curtailed.

#### REASSURANCE

Reassurance that serious physical disease is unlikely is important for most children and their families (Goodyer and Mitchell, 1989; Grattan-Smith et al., 1988; Maisami and Freeman, 1987; Schulman, 1988). The presenting symptoms should be demystified and helped to appear less threatening by uncoupling the perceived distress from concerns about actual tissue damage. Excessive reassurance can be problematic when obsessional illness worries are present and should be avoided in such circumstances after initial reassurance (Warwick and Salkovskis, 1988). Illness worry can then be framed as a problem to be solved by the child and family.

#### COGNITIVE-BEHAVIORAL INTERVENTIONS

Such interventions have been demonstrated to be successful as components of multimodal interventions for medically unexplained RAP in school-age children (Sanders et al., 1989; Sanders et al., 1994). Cognitive coping skill training, an emphasis on return to usual function, and cognitive-behavioral family interventions have all been employed as core components of treatment programs that also include behavioral interventions and the use of self-management strategies such as relaxation training. Although sample sizes are relatively small, results are encouraging, with significant improvements noted in the treated groups. Cognitive-behavioral therapy combined with serotonin reuptake inhibitors has been reported as helpful for children and adolescents with BDD (Albertini et al., 1996; El-Khatib and Dickey, 1995; Phillips et al., 1995a; Sondheimer, 1988). Supportive psychotherapy (Warwick, 1992), group therapy (Stern and Fernandez, 1991), and individual psychotherapy (Sharpe et al., 1992) have been applied successfully with somatizing adults, although data are lacking regarding the efficacy of these approaches in children or adolescents.

The cognitive-behavioral principle most relevant in the treatment of pediatric somatization appears to be that of taking a *rehabilitative approach*, which encourages the patient to return to usual activities and responsibilities regardless of whether symptoms persist (Dubowitz and Hersov, 1976; Leslie, 1988; Maisami and Freeman, 1987; Schulman, 1988). Such an approach helps patients and families to view the patient's symptoms and the associated disability as challenges to be overcome and shifts emphasis away from the importance of finding a "cure" to that of coping. The *avoidance of homebound schooling* is a corollary of the rehabilitative approach. The patient is treated as an active agent with the strength and wherewithal to live a productive life in spite of the acknowledged subjective distress. Improvement becomes a personal success and an accomplishment. For example, physical therapy has been used in conversion disorder (Leslie, 1988; Maisami and Freeman, 1987). Active coping has been found to be superior to passivity, which has been associated with greater symptoms and disability (Walker et al., 1997). Parents and family members must be helped to understand that it is not cruel or punitive to expect active coping, but actually both kind and therapeutic, given what is known. High expectations communicate parental and professional belief in the fundamental soundness of the child and in the child's ability to overcome adversity now and in the future. This approach directly challenges any long-standing misperceptions that the child is somehow vulnerable or weaker than other children and emphasizes strength and adaptability rather than sickness.

*Behavioral intervention* is a core component of most treatment strategies. Although there are no controlled trials of behavior therapy for pediatric somatization, case reports highlight potential benefits (Campo and Fritsch, 1994; Fritz et al., 1997). Most have emphasized *positive reinforcement* of healthy behaviors and *extinction* or *withdrawal of reinforcement* for symptoms and sick role behaviors (Klonoff and Moore, 1986; Mizes, 1985). Time out from reinforcement has also been applied (Miller and Kratochwill, 1979), but punitive approaches should be avoided. *Negative reinforcement* produces an increase in the frequency of a desired response by removing an aversive event immediately after the desired response has been performed and has been employed by lifting the restrictions theoretically imposed by illness once functional improvement has been demonstrated (Campo and Negrini, 2000; Leslie, 1988). For example, discharge from the hospital may be allowed only when the patient evidences sufficient physical improvement (Leslie, 1988), or persistent bed rest may be imposed with removal contingent on the patient's returning to premorbid function and responsibilities. Similarly, the threat of inpatient psychiatric hospitalization can be removed contingent on the child's maintaining at least minimally acceptable function (e.g., returning to school).

*Self-management interventions* have been reported to be successful in the management of recurrent pain, with specific techniques including *self-monitoring*, *relaxation training* (Masek et al., 1984), *hypnosis* (Elkins and Carter, 1986), and *biofeedback* (Klonoff and Moore, 1986; Mizes, 1985). Relaxation techniques and hypnosis have been reported as helpful in treating headaches, VCD, conversion disorder, and pain syndromes (Brugman and Newman, 1993; Manne et al., 1990). Self-management strategies are likely best employed as part of a multimodal approach (Sanders et al., 1989). Evidence indicates that these techniques are associated with symptomatic relief and by their very nature encourage active coping. Interpersonal and expressive psychotherapies may be useful, particularly in the presence of psychological trauma, but they have not been systematically evaluated.

#### FAMILY AND GROUP INTERVENTIONS

The use of family therapy has been promoted (Mullins and Olson, 1990), but not well studied. Sanders et al. (1994) report on a successful cognitive-behavioral family intervention. Because children presenting with medically unexplained physical symptoms are often considered health impaired or sickly by parents, family health beliefs and any encouragement of illness behavior must be addressed with the goal of reducing anxiety about illness within the family system. Group psychotherapy in the treatment of pediatric somatization has not been evaluated.

#### PSYCHOPHARMACOLOGIC INTERVENTIONS

There have been no systematic studies of psychoactive medications in pediatric somatization (Campo and Garber, 1998). Psychopharmacologic interventions are

nevertheless worthy of consideration in the treatment of persistent medically unexplained pain, gastrointestinal symptoms, or fatigue, particularly in the presence of psychiatric comorbidity or when psychotherapeutic interventions have not been entirely successful. Antidepressant and anxiolytic medications have been shown to reduce somatic symptoms in depressed and anxious adults (Simon et al., 1998). Antidepressant medications appear to be of significantly greater benefit than placebo in the treatment of adult somatoform pain disorders (Fishbain et al., 1998) and medically unexplained physical symptoms in general (O'Malley et al., 1999). Even without other Axis I disorders identified, there is preliminary evidence of the usefulness of selective serotonin reuptake inhibitors in treating adults with BDD or hypochondriasis when obsessive-compulsive aspects are prominent (Kellner, 1992; Phillips, 1996). Comparable work is not available to date for children and adolescents. Pain disorder concomitant with a medical problem improves when analgesics are employed optimally; narcotic adjuvants (nonanalgesics that help relieve pain) may be recommended when narcotics are ineffective or when their side effects are a problem. Tricyclic antidepressants, anticonvulsants such as carbamazepine (Tegretol) or phenytoin (Dilantin), and stimulants such as methylphenidate (Ritalin) or dextroamphetamine (Dexedrine) are demonstrated effective narcotic adjuvants (Lynn, 1990). In some patients who experience physical symptoms predominantly associated with emotional arousal and anxiety, a short course of a benzodiazepine can provide symptomatic relief and can help to reassure the patient and family that emotional distress is operative (Campo and Garber, 1998). As with other interventions, a successful response to treatment can help to reassure the patient and family that the original somatoform diagnosis was correct and can thus allow additional treatment to proceed.

## SUMMARY

Somatization and the epidemiology, diagnosis, and treatment of somatoform disorders constitute one of the remaining frontiers in child and adolescent psychiatry. Definitional ambiguity, theoretical complexity, lack of seminal studies in any domain, and overlapping boundaries with pediatrics have resulted in an area that is poorly mapped and rather forbidding to child mental health clinicians and researchers. Knowledge about somatoform disorders in the young is, thus, at a stage comparable to that of childhood depression in the mid-1980s. Somatoform disorders are conceptually linked to the mind-body split that has plagued Western medicine, and their management highlights the problems associated with parallel systems of care for mental and physical disorders. New ways of conceptualizing the problems posed by patients with physical symptoms that defy traditional medical explanations may prove to be important in the future. Epidemiologic studies are needed comparing numbers, frequency rates, and severity of somatic symptoms in community, pediatric, and psychiatric populations, to provide the empirical base for modified diagnostic criteria. Longitudinal studies of children with somatic symptoms are needed to determine the relationship between childhood presentations and adult disorders. Efforts to explore the nature of comorbidity between medically unexplained physical symptoms and emotional disorders, including from a neurobiological perspective, are likely to be important in the future. Empirical data on treatment efficacy are scant, pointing to the need for creative approaches and systematic follow-up investigations. Changes in medical economics and recognition of the major impact of pediatric somatization on health and mental health service use make it likely that the next 10 years will see rapid progress in our understanding of somatoform disorders in children and adolescents. Important advances such as real inculcation of the biopsychosocial model in medical training, the growing influence of physicians whose backgrounds integrate psychiatry and pediatrics, and the perspective of developmental psychopathology make it quite possible that the next 10 years will see an explosion in empirical knowledge and clinical wisdom regarding somatization in children and adolescents.

There is a certain historical irony in the fact that as psychoanalysis waxed, the diagnosis of *multiple personality disorder*, now called *dissociative identity disorder* (DID), waned, because to observe the phenomenon of DID is to see the unconscious played out before one's very eyes. DID is unbelievable to those who have never seen it. Perhaps it would be more accurate to say that DID is unbelievable to those who have not recognized it, because many, if not most, clinicians have seen it in their child, adolescent, and adult patients but have failed to recognize it. The signs, symptoms, and behaviors that together constitute the disorder are characteristics that we have been taught to associate with other syndromes; hence patients manifesting them are usually given other diagnoses. In the case of DID, it would be safe to say that, for the most part, seeing has been disbelieving.

How can a person have two, three, four, even more different states of consciousness, each relatively independent of the others and often unaware of their existence? Impossible? And yet, the expanding clinical literature attests to the improved ability of clinicians to recognize the syndrome, at least in adults. Our current understanding of the etiology, neurobiology, and treatment of pathologic dissociation supports the validity of DID as an indisputable diagnostic entity. However, for reasons that are elucidated in this chapter, children suffering from DID often go unrecognized, misdiagnosed, and improperly treated.

### DEFINITION

*Dissociation* is defined as the separation of thoughts, feelings, and experiences that are normally integrated into consciousness and memory ( [Maldonado and Spiegel, 1998](#); [Putnam, 1996a](#); [van der Kolk et al., 1996](#)). Absorption, absent-mindedness, and fantasy-proneness are examples of normal dissociative processes. Depersonalization, derealization, somatization, and psychogenic amnesia are examples of dissociative processes that emerge in the presence of trauma and its aftermath. Dissociation is thought to be an adaptational defense against overwhelming physical or emotional trauma. Dissociation enables the person to separate himself or herself cognitively and emotionally from the immediate environment (derealization) and from the body (depersonalization), to deal with unendurable stress. In the aftermath of trauma, psychogenic amnesia enables the victim to maintain self-control through detachment from the experience altogether ( [Maldonado and Spiegel, 1998](#)). Dissociation has been reported to occur frequently during combat, rape, motor vehicle or airplane accidents, and natural disasters such as earthquakes and fires ( [McFarlane and de Girolamo, 1996](#)).

In some cases, the dissociative, anxiety, and amnesic symptoms become so severe and persistent that the victim develops posttraumatic stress disorder (PTSD) or a dissociative disorder, such as dissociative amnesia, dissociative fugue, or dissociative disorder, not otherwise specified (DDNOS). On the continuum of dissociation, its most extreme, pathologic form is DID, which is the focus of this chapter. [Table 70.1](#) describes the manifestations of DID.

- 
- A. The presence of two or more personality states each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self
  - B. At least two of these identities or personality states recurrently taking control of the person's behavior
  - C. Inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness
  - D. Not related to the direct effects of a substance or a general medical condition; note: in children, symptoms not attributable to imaginary playmates or other fantasy play
- 

Adapted from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, DC: American Psychiatric Association, 1994, with permission.

**Table 70.1. DSM-IV Diagnostic Criteria for Dissociative Identity Disorder**

As described in this chapter, childhood manifestations of DID may not be as distinct as the adult manifestations of the disorder. Movement between alternate identity states is frequently subtle and fluid. Thus, identity state switches can be difficult to detect. To enable clinicians to recognize pathologic dissociation in their young patients, [Peterson and Putnam \(1994\)](#) developed a set of diagnostic criteria, resembling those of the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) ([American Psychiatric Association, 1994](#)), that reflect childhood DID ([Table 70.2](#)).

- A. A substance of at least 3 months duration during which either one or two of the following are present:
1. recurrent amnesic periods or missing blocks of time
  2. frequent fugitive states or appearing to be in a state or in another world
- B. Increasing, major fluctuations in behavior that include at least two of the following:
1. dramatic fluctuations in school or work performance and behavior
  2. variations in apparent social, cognitive, or physical abilities
  3. sudden, recurrent shifts in identifiable interests
  4. changes in language, accent, and voice tone
  5. frequent changes in preferences for clothes, food, toys, games, etc.
- C. At least three of the following:
1. refers to self in third person or uses another name to refer to self or parts of self
  2. has vivid imaginary companions
  3. frequently observes observed behavior
  4. exhibits frequent inappropriate sexual behaviors or is sexually precocious
  5. has intermittent depression
  6. has auditory hallucinations from inside the head
  7. has frequent sleep problems
  8. exhibits unprovoked aggressive (anger) and violent behaviors
  9. exhibits other psychotic behaviors
- D. Does not meet the criteria for the adult form of dissociative identity disorder
- Adapted from Peterson, C. Putnam, F.W. Preliminary results of the final test of proposed criteria for dissociative disorder of childhood. *Dissociation* 7 (2): 200, 1996, with permission.

**Table 70.2. Proposed Diagnostic Criteria for Dissociative Disorder of Childhood**

## HISTORY OF DISSOCIATIVE IDENTITY DISORDER IN CHILDREN

The first case of what we would now designate childhood DID was reported by Despine in 1840. Despine described Estelle, an 11-year-old girl who experienced visions, went into trancelike states, was comforted by the voices of angels, and found herself unable to walk. Through the use of hypnosis, or what then was called animal magnetism, Despine was able to bring to light the existence in Estelle of an alternate personality state whose likes and dislikes differed from those of Estelle; while in this state, Estelle was able to walk. By means of hypnosis, and in a relatively brief period, Despine was able to integrate the two identity states and thereby enable his patient to walk once more ([Despine, 1840](#)).

For almost a century and a half, Estelle remained the only reported case of the diagnosis and treatment of DID in a child. Then, in 1979, in a course given under the auspices of the American Psychiatric Association, Kluff described the diagnosis and treatment of an 8-year-old boy who suffered from multiple personality disorder ([Kluff, 1985](#)). Since then, more and more clinicians have reported cases of DID in children and adolescents ([Lewis and Yeager, 1996](#)). Since the early 1990s, we have had the opportunity to evaluate more than 100 children and adolescents with signs and symptoms meeting the criteria for a diagnosis of DID or DDNOS. Four of these children were between 3½ and 4½ years of age at the time of their referrals to the Bellevue Dissociative Disorders Clinic in New York. Thus, gradually, a diagnosis that in the 1980s was practically unknown to child psychiatrists and psychologists has become a recognized entity, having specific, objectively identifiable characteristics as well as specific, effective treatment strategies.

## EPIDEMIOLOGY

Multinational epidemiologic studies ([Mulder et al., 1998](#); [Ross, 1991](#); [Ross et al., 1990a](#); [Vanderlinden et al., 1991](#); [Vanderlinden et al., 1996](#)) indicate that dissociative disorders are not as rare as previously assumed, but they appear to affect between 1% and 6% of adults in the general population, a prevalence rate considerably higher than that of schizophrenia and bipolar mood disorder ([Blazer, 2000](#); [Norquist and Narrow, 2000](#)). The prevalence of dissociative disorders in clinical populations of adults is exceptionally high. Several studies have found that up to 12% of North American adults admitted to general psychiatric inpatient settings meet criteria for DID ([Horen et al., 1995](#); [Latz et al., 1995](#); [Rifkin et al., 1998](#); [Saxe et al., 1993](#)). Studies from the Netherlands ([Friedl and Draijer, 2000](#)) and Turkey (Tutkin et al., 1998) have reported that between 2% and 5% of general psychiatric inpatients meet criteria for DID. In adults, certain psychiatric conditions, particularly substance abuse disorders and eating disorders, have an especially high rate of comorbidity with dissociative disorders ([Berger et al., 1994](#); [Kronson et al., 1990](#); [McCallum et al., 1992](#)).

The prevalence of dissociative disorders in the general population of children is currently unknown. However, findings from a small study we conducted in 1992 (unpublished) to evaluate the validity of a new semistructured interview protocol, the *Bellevue Dissociative Disorders Interview for Children* ([Lewis, 1996](#)), may begin to shed some light on the prevalence of dissociative disorders among ordinary children. Using the new interview protocol, we interviewed a group of 46 “supernormal” children (i.e., children from suburban, largely professional families who had no known histories of harsh corporal punishment, much less abuse) and a group of 24 emotionally disturbed, severely abused children in a residential treatment center. Of the emotionally disturbed children, 10 had severe dissociative symptoms. Of these, seven (six boys and one girl) met DSM-III and DSM-IV criteria for DID. Much to our surprise, of the normal children, one child (2%), a 10-year-old girl, met both DSM-III and DSM-IV criteria for DID.

Several studies of clinical samples of children and adolescents have found high rates of dissociative symptoms. For example, a study of severely abused and neglected child psychiatric inpatients ([Waterbury, 1991](#)) reported that 74% of patients admitted over a 1-year period had dissociative disorders; 23% of them met criteria for DID. [Hornstein and Tyson \(1991\)](#) reported that 5% of children admitted to a general psychiatric inpatient unit over a year's time were diagnosed with a dissociative disorder, including 3% with DID. [Ross \(1996\)](#) reported that 44% of adolescents undergoing evaluations at a general psychiatric facility had some type of dissociative disorder, including 16% with DID. A study of 64 juvenile delinquents ([Carrion and Steiner, 2000](#)) reported that 28% met criteria for a dissociative disorder, including 20% with DDNOS. Apparently, no subject in this study met criteria for full-blown DID. Our especially high rate of DID in the residential treatment sample as compared with the psychiatric hospital samples of other researchers reflects, we believe, the fact that all of our subjects, unlike hospital patients, had histories of extreme physical and sexual abuse and neglect. Clearly, pathologic dissociation is much more common among troubled children and adolescents than has hitherto been appreciated. Therefore, assessment for the presence of dissociative symptoms is essential in the psychiatric evaluations of all children and adolescents.

Estimates of the ratio of adult female to male cases have ranged from 2:1 to 14:1 ([Putnam et al., 1986](#); [Ross et al., 1989a](#); [Stern, 1984](#)). However, these figures are probably skewed because psychiatrically disturbed, aggressive men are more likely than their female counterparts to be channeled to the criminal justice system, and the nature of their psychopathology is less likely to be recognized. Less is known about gender differences in child and adolescent clinical populations. Some authors have hypothesized that the female:male ratio may be equal ([Waterbury, 1991](#)). Indeed, in the Carrion and Steiner study of juvenile delinquents (2000), equal numbers of boys and girls were found to suffer from dissociative disorders. Other investigators suspect that the prevalence of dissociative disorders is higher in girls because girls are more likely to have been abused sexually than boys ([Hornstein, 2000](#)). In our experience, similar numbers of girls and boys with pathologic dissociation are referred to our clinic.

## ETIOLOGY

Derealization, depersonalization, time distortion, alterations in cognition, memory, and somatic sensations, and emotional numbing are common dissociative responses to natural and human-made disasters, physical and sexual victimization, and the witnessing of horrifying events such as torture and homicide ([Classen et al., 1993](#); [Griffin et al., 1997](#); [Shalev et al., 1996](#)). These symptoms reflect a disconnection with the surrounding environment and a lack of integration of trauma with autobiographical memory and self-identity. Dissociation occurs peritraumatically (i.e., at the time of trauma), as well as posttraumatically as a long-term sequelae of traumatic exposure ([Bremner et al., 1992](#); [Ursano et al., 1999](#)). In fact, the severity of peritraumatic dissociation is predictive of who will develop PTSD ([Shalev et al., 1996](#)).

Whereas adults and adolescents may develop PTSD with accompanying dissociative symptoms in response to overwhelming trauma, young children are thought to be at high risk of developing much more complex, pervasive, biopsychological reactions. Children have less mature coping mechanisms with which to tolerate extreme stress; they also have a greater innate capacity to use trance and fantasy to separate mentally from traumatic experiences ([Putnam, 1996b](#); [Pynoos et al., 1996](#); [Roth et al., 1997](#)). In young children, when dissociative mechanisms are repeatedly called into play, the normal development of a coherent, unified sense of self goes awry.

### Physical and Sexual Abuse

When children are the victims of early, ongoing, extreme *physical, sexual, or psychological abuse*, they cannot endure it. Their developmental immaturity, their small size, and their limited strength preclude physical escape. Unlike adults, they cannot rely on the body's fight-or-flight response to propel them to safety. However, it would seem that children's intrinsic abilities to lose themselves in fantasy and role-play have special survival value ([Putnam, 1996b](#)). When they are repeatedly subjected to intolerable pain, children dissociate; that is, they spontaneously remove themselves mentally from their surroundings and in so doing carry themselves to safety. To them, the terrifying event is not even happening; or it is happening to someone else. At these times, sensations, perceptions, thoughts, emotions, and

behaviors become dissociated from consciousness and may later remain unavailable to normal recall.

The exact timing, quality, intensity, and duration of abuse required to engender DID is not known and, perhaps, cannot be ascertained empirically. The very function of dissociation is to block painful experiences from consciousness; the victim therefore would be a poor historian. Sometimes abuse begins so early in life that the capacity to think in terms of words or time is not yet established developmentally. In our study of 12 murderers with DID ( [Lewis et al., 1997](#) ), seven subjects had only fragmentary memories of their histories of extraordinary abuse, whereas four others had no memory of it whatsoever. Old records, interviews with relatives and childhood friends, and scars consistent with floggings and cigarette burns attested to the abuse our subjects could not recall. These kinds of data are especially important because even the experiences that patients with DID recount or seem to relive while they are in dissociated states can be unreliable ( [Yeager and Lewis, 1997](#) ).

An as yet unanswered question is whether physical abuse or sexual abuse has a greater propensity to engender pathologic dissociation, especially DID, in the young child. Although the general consensus is that sexual abuse is the most potent form of trauma giving rise to DID, some studies have indicated that there may be a closer link between physical abuse and pathologic dissociation than has hitherto been appreciated ( [Berger et al., 1994](#); [Carlson et al., 1998](#); [Chu and Dill, 1990](#); [Mulder et al., 1998](#); [Rhue et al., 1995](#) ). The kinds of environments that permit or invite chronic sexual abuse also facilitate other kinds of maltreatment. Although a dose–response relationship between forms and intensities of maltreatment and the development of DID may exist ( [Roth et al., 1997](#) ), it would be difficult to quantify. We have found that children with DID are those who have been placed on heated burners, tied to blisteringly hot radiators, bound hand and foot, brutally beaten, hanged in closets by their wrists, and repeatedly raped and sodomized with all manner of objects. They are the children who have been prostituted, the ones forced to star in pornographic films, and those tortured in bizarre family rituals. They have experienced unspeakable horrors—physical, sexual, and psychological—over extended periods of time.

Retrospective reconstructions by adult patients with DID of the timing of abuse, based on the age at which they recall the first emergence of alternate identity states, place the onset of the disorder well before 12 years of age and usually between the ages of 4 and 6 years ( [Ogawa et al., 1997](#); [Putnam, 1986](#) ). Our own work at the Dissociative Disorders Clinic at Bellevue Hospital indicates that, in most cases, abuse and the dissociative symptoms to which it gives rise begin much earlier than 12 years of age. We have evaluated children 3½ and 4½ years of age with the signs and symptoms of DID well established and with histories suggesting that their disorders have been active for at least a year before clinic referral. Our clinical data indicate that the kind of abuse that generates DID often begins in the very first months and years of life.

A major impediment to the accurate documentation of abuse in children with DID stems from the problem that the very persons on whom clinicians rely to provide a history (i.e., parents) are themselves perpetrators of maltreatment and are therefore unlikely to disclose it. In addition, many perpetrators were themselves victims, dissociate, and consequently are unaware of their own actions. In a remarkable article on the parenting capabilities of 75 women suffering from multiple personality disorder, [Kluft \(1987a\)](#) reported that 16% of the women in his sample were extremely abusive toward their children. In our own study of 11 children with DID or DDNOS ( [Yeager and Lewis, 1996](#) ), parents of nine children exhibited pathologic dissociation. In only one case was the parent aware that she suffered from DID. She was also the only parent to admit to physically abusing her son while she was in an alternate personality state. The other dissociative parents were consciously unaware of how they or others had mistreated their children. In fact, when one of the mothers in this study was in a violent, dissociated state, she asked us to call protective services before she killed her child. We called. The following week, she had no memory of her prior request and berated us for interfering. Only three of these nine families were known to child protective services at the time of our evaluations. This demonstrates how effectively dissociative families are able to keep secret extraordinary abuse.

### **Neglect**

Severe *neglect* is frequently overlooked as a cause of pathologic dissociation. We have evaluated dissociative children who were abandoned by their caregivers to live like animals. Often, they not only had to fend for themselves, but they also had to protect and provide sustenance for younger siblings. It is not known whether severe neglect alone can cause DID because neglect and abuse tend to go together. For example, [Hornstein and Putnam \(1992\)](#) report that 80% of their sample of child and adolescent dissociaters had documented histories of neglect as well as histories of physical and sexual abuse. Findings from a prospective longitudinal study by [Ogawa and colleagues \(1997\)](#) of children living in poverty indicate that neglect during infancy played a significant role in the development of dissociative symptoms during the preschool and elementary school years. Still these children were also subjected to other forms of trauma during the preschool and elementary period.

### **Disorganized Infant Attachment Patterns and Dissociation**

Neglect and maltreatment in infancy have been associated with the development of disorganized–disoriented patterns of attachment to the primary caregiver ( [Carlson et al., 1989](#); [Main and Hesse, 1990](#) ). Maltreated infants may display various peculiar behaviors in the presence of abusive or dissociative parents. Main and colleagues ( [Main and Morgan, 1996](#); [Main and Solomon, 1990](#) ) note that these disorganized–disoriented infants experience apprehension and fear when they interact with the parent. Torn between approaching and fleeing, they “freeze” and go into trancelike states. These behaviors appear to be brief episodes of dissociation ( [Liotti, 1992](#); [Main and Morgan, 1996](#) ). [Main and Hesse \(1990\)](#) postulate that disorganized–disoriented attachment behavior occurs when the child is forced to interact with a parent who is both protector and abuser. Liotti suggests that the need to adapt to such unpredictable parenting engenders dissociative patterns of interaction and, ultimately, may lead to DID ( [Liotti, 1992, 1999](#) ). [Ogawa and colleagues \(1997\)](#), in a prospective, longitudinal study, demonstrate that infants with disorganized attachment patterns, subjected to ongoing abuse during childhood, are more likely than their more securely attached peers to suffer from dissociative pathology in adolescence and early adulthood.

In summary, research to date suggests that extremely aberrant, unpredictable, and abusive parenting, especially during the earliest years of life when the formation of a secure attachment is so important, is at the core of severe dissociative pathology in childhood. Whether all severely maltreated children would develop dissociative disorders is not known. Some infants may be inherently more vulnerable than others to the effects of extreme abuse and neglect.

### **Individual Differences in the Capacity to Dissociate**

Children as a group are able to dissociate more readily than adolescents or adults ( [Putnam, 1996b](#) ). Young children routinely assume different roles and identities, become absorbed in pretend play, and generate imaginary friends and enemies to play out their fantasies. They also exhibit rapid shifts in demeanor, readily fall into brief, trancelike states, demonstrate amnesia for behaviors and events, and engage in denial as a psychological defense more readily than their elementary school-age peers ( [Cramer, 1991](#) ). The capacity to dissociate ordinarily wanes as children reach their teenage and young adult years ( [Ogawa et al., 1997](#); [Ray, 1996](#); [Ross et al., 1989b](#); [Waller et al., 1996](#) ). However, there is good evidence from life span research that recurrent, overwhelming traumas occurring early in life, when dissociative capacity is high, are especially likely to engender dissociative disorders ( [Sanberg and Lynn, 1992](#) ).

Studies of healthy adults, using the Dissociative Experiences Scale (DES), show that people vary in their capacities to dissociate, to disengage from immediate surroundings, and to become absorbed in reverie ( [Bernstein and Putnam, 1986](#); [Ray et al., 1992](#); [Ross et al., 1991](#) ). Whether such individual differences influence the development of pathologic dissociation is unclear. The only study published to date using methods of genetic analysis to investigate genetic contributions to the expression of pathologic dissociation found no evidence of a heritability factor in a sample of 280 monozygotic and dizygotic twin pairs ( [Waller and Ross, 1997](#) ). Rather, one-third to one-half of the variance was attributed to the shared social (abusive) environment, whereas the remainder of the variance was attributed to nonshared environmental factors. Because severe abuse tends to perpetuate itself from generation to generation, so, too, does dissociation. As such, evidence of intergenerational dissociative disorders does not necessarily bespeak genetic heritability ( [Yeager and Lewis, 1996](#) ).

Accumulating evidence suggests that pathologic dissociation is distinctly and categorically different from the normal dissociative continuum. Waller and colleagues, using DES data obtained from normal and clinical adolescent and adult samples, have distinguished two distinct groups or classes of persons, those who experience a range of ordinary dissociative phenomena (e.g., fantasy-proneness and absorption) and those who experience pathologic dissociation (e.g., amnesias, derealization, identity alterations) ( [Waller and Ross, 1997](#); [Waller et al., 1996](#) ). Our own studies comparing the imaginary companions of abused, dissociative children and normal children suggest that these differences in the nature of fantasy life exist early in life ( [Trujillo et al., 1996](#) ). Pathologic dissociation is rare in most other serious neuropsychiatric disorders (e.g., schizophrenia, mood disorders).

### **Hypnotizability and Dissociation**

Pathologic dissociation has been likened by some to self-hypnosis gone awry ( [Maldonado and Spiegel, 1998](#) ). However, whether dissociation and hypnosis are

similar mental processes is currently a subject of debate. Like dissociative capacity, *hypnotizability* varies on an individual basis and throughout the life span; it reaches its height during childhood and declines thereafter ( [Morgan and Hilgard, 1979](#)). Early investigations of the relationship between trauma and hypnotizability suggest that harsh punishment in childhood is associated with increased hypnotizability scores in adulthood ( [Hilgard, 1979](#)). In contrast, several more recent studies on the subject do not support these earlier findings (DiTommaso and Routh, 1993; [Nash et al., 1993](#); [Rhue et al., 1990](#)). In a review of research on the relationship between dissociation and hypnotizability, [Putnam and Carlson \(1998\)](#) conclude that hypnotizability and the tendency to dissociate appear to be weakly correlated. Although the relationship between hypnotizability and dissociation remains uncertain, children and adolescents with severe dissociative disorders look clinically as if they can self-hypnotize and enter into trancelike states more easily than their healthy peers.

### Models of Dissociative Identity Disorder

Numerous different models have been proposed to explain the hallmark of DID, alternate identity states. These range from the supernatural (e.g., demonic possession) to sociologic (e.g., taking on different identities to sidestep societal controls on behavior) to malingering for secondary gain ( [Kluft, 1996](#)). [Putnam \(1996b\)](#) hypothesizes that during the first months and years of life, children lack an integrated personality structure. The infant's responsivity to the environment is organized as a series of discrete behavior states that evolve naturally into a unified sense of self. He suggests that infants who are repeatedly and unpredictably traumatized may fail to integrate these behavioral states and, as a result, develop a discontinuous sense of self-identity. This hypothesis is based on state-dependent learning models. In these models, alternate identity states are thought to evolve when experiences and behaviors occurring in one state of consciousness are bound together as memories disconnected from usual conscious awareness, and they are accessible only in the original psychophysiologic state. Similarly, neural network models ( [Damasio, 1999](#); [Li and Spiegel, 1992](#)) hypothesize that alternate identity states are related to the creation and reinforcement of particular neural networks. These parallel networks are thought to give rise to multiple discontinuous representations of self and multiple autobiographical memory maps. In the absence of further research, the foregoing models remain speculative.

### NEUROBIOLOGY OF TRAUMATIC STRESS AND DISSOCIATION

To date, little research exists on the neurobiology of dissociative disorders. However, we do know that dissociation occurs peritraumatically as well as posttraumatically ( [Bremner et al., 1992](#); [Marmar et al., 1994](#); [Ursano et al., 1999](#)). Therefore, it makes sense to review the studies that have been done on the neurobiology of trauma. The following section reviews briefly the newer research on the neurobiological underpinnings of dissociative states and the neurobiological effects of repeated stress (e.g., child abuse and neglect) on the developing brain.

#### Neural Pathways Mediating the Fear Response

Ordinarily, incoming sensory input is registered by the thalamus and is relayed to the limbic and cortical areas of the brain involved in arousal, attention, emotion, learning, and memory. The thalamus, in turn, receives information from these brain regions and creates a feedback network that modulates an organism's responsiveness to environmental stimuli ( [McCormick, 1992](#); [Turner and Herkenham, 1991](#)). When incoming stimuli are perceived as threatening, however, the amygdala, the limbic structure responsible for initiating the fear response, sounds a "central alarm" ( [Goleman, 2000](#)) through the thalamus and triggers a cascade of stress-related neurochemicals to focus attention, to heighten vigilance, to slow the perception of time, and to stimulate recall of similarly threatening experiences so the organism can determine whether to fight or flee ( [DeWied and Croiset, 1991](#)).

The prefrontal cortex, the seat of executive and metacognitive functions, is believed to be responsible for our ability to distinguish between external and internal models of the world ( [Knight et al., 1995](#)). When a stressful event becomes completely overwhelming, the thalamic–limbic–cortical feedback network is thought to break down, thus causing distortions in both sensory and perceptual processes. Animal research has shown that during exposure to intense stress, extremely high levels of glutamate, dopamine, and norepinephrine are released in the prefrontal cortex to produce a functional lesion, that is, thus effectively shutting down executive function and working memory ( [Arnsten, 1999](#)). Several groups of researchers have hypothesized that, when the prefrontal cortex is unable to integrate diverse sensory, perceptual, cognitive, emotional, and psychomotor processes, a person's distinction between self and surroundings becomes impaired, and this results in dissociation ( [Allen et al., 1999](#); [Chambers et al., 1999](#); [Guralnik et al., 2000](#); [Newport and Nemeroff, 2000](#)). Functional neuroimaging studies of adults with PTSD seem to support this hypothesis. Samples of victims of combat distress, as well as victims of childhood abuse, have demonstrated decreased activity in the prefrontal and parietal cortices and increased activation in the limbic system while they are reliving traumatic experiences ( [Bremner et al., 1999a](#); [Bremner et al., 1999b](#); [Liberzon et al., 1999](#); [Rausch et al., 1996](#); [Shin et al., 1999](#)).

The hippocampus and its surrounding structures, that region of the brain vital for encoding new information as well as for retrieving memories, also seem to be essential for our cohesive sense of self. Electrical stimulation of the hippocampus has been shown to cause depersonalization, derealization, odd visceral sensations, time and space disorientation, and auditory and visual hallucinations ( [Halgren et al., 1978](#)). Furthermore, hippocampal function is exceptionally vulnerable to the effects of acute stress. High levels of endogenous opioids, norepinephrine or epinephrine and corticosteroids, neurochemicals released in response to acute fear or distress, have been found to impair information encoding and retention ( [Lupien et al., 1999](#); [McGaugh, 1995](#); [Newcomer et al., 1999](#)). Chronically high levels of circulating corticotropin releasing hormone in particular appears to be neurotoxic to the hippocampus ( [Brunson et al., 2001](#); [Kaufman and Charney, 2001](#)). High concentrations of glutamate and low concentrations of neurotrophins (essential for neurogenesis) also are thought to contribute to hippocampal atrophy. Hippocampal volume loss has been demonstrated in both combat veterans and sexually abused adults with PTSD ( [Bremner et al., 1995](#); [Bremner et al., 1997](#); [Gurvits et al., 1996](#); [Stein et al., 1997](#)). What is more, these studies report that greater hippocampal atrophy is associated with greater explicit memory deficits ( [Bremner et al., 1995](#); [Bremner et al., 1997](#); [Gurvits et al., 1996](#)) and is also predictive of dissociative symptoms ( [Stein et al., 1997](#)).

#### Conditioning of the Fear Response: A Habit of Mind

Significant prior exposure to excessive stress-related neurochemicals seems to create heightened neurosensitivity not only to extreme stress, but also to benign events. The amygdala, the structure that initiates the fear response, also encodes the emotional component of memories. Together, the amygdala and the hippocampus are responsible for producing what is called the *conditioned fear response* ( [LeDoux, 1993](#)). The conditioned fear response, a form of implicit (i.e., outside of conscious awareness) memory, develops from repeated pairings of painful stimuli with neutral stimuli, such as a sound, a smell, or an environmental context. Eventually, the neutral stimulus alone is able to elicit fear. [Post and colleagues \(1998\)](#) postulate that repeated stimulation of the amygdala by recurrent external and internal (e.g., flashbacks) exposure to trauma may induce seizurelike kindling. At the same time, the anterior cingulate cortex, implicated in extinguishing the fear response, fails to turn it off ( [Hamner et al., 1999](#)). Consequently, the fear response begins to occur autonomously, without any cueing from the external environment or internal world. This hypothesis is supported clinically by the observation that dissociative children and adults often switch reflexively into another identity state the instant the brain registers a word or a sound or a sight that is associated with past traumas. It is also supported empirically by functional neuroimaging studies that demonstrate anterior cingulate hypometabolism in both children and adults with PTSD ( [Bremner et al., 1999a](#); [De Bellis et al., 2000](#); [Shin et al., 1999](#)).

#### Neurobiological Effects of Child Abuse and Neglect

Children are especially vulnerable to the effects of traumatic stress. Unlike the mature brain, the developing brain can suffer profound, potentially enduring neurophysiologic impairment as a result of overwhelming stress, especially when such events occur during critical periods of neural development. Poverty, prior exposure to traumatic stressors, and caregiver emotional instability make the child especially susceptible to the effects of trauma ( [Pfefferbaum, 1997](#)). Evidence is emerging that suggests child maltreatment in particular may cause long-term neurobiological dysfunction. For example, chronic abuse and neglect have been associated with hypothalamic–pituitary–adrenal axis dysregulation in children ( [De Bellis and Putnam, 1994](#); [De Bellis et al., 1994](#); [De Bellis et al., 1999a](#); [Kaufman et al., 1997](#); [Perry, 1994](#); [Putnam and Trickett, 1997](#)).

Severe abuse has electrophysiologic and neuroanatomic sequelae as well. Ito and colleagues report abnormal electroencephalographic findings in the left hemispheres of abused children ( [Ito et al., 1993](#); [Ito et al., 1998](#)). In their magnetic resonance imaging study of maltreated children with PTSD and matched controls, [De Bellis and colleagues \(1999b\)](#) found that, compared with healthy children, abused children had significantly smaller intracranial and cerebral volumes, with enlarged ventricles and excessive cortical cerebrospinal fluid. The extent of neurologic abnormalities correlates with onset and duration of abuse. The possible role of these kinds of neuroanatomic and neurophysiologic changes in severely dissociative children remains to be explored.

#### Psychopharmacologic Analogs of Dissociation

Certain kinds of drugs cause dissociative states in humans. Ketamine, an *N*-methyl-D-aspartate antagonist, is thought to cause dopamine dysregulation, alter

glutamate availability, and thus disrupt cortical–subcortical pathways ( [Chambers et al., 1999](#)). Clinically, it produces dissociative states, cognitive dysfunction, and memory impairment in healthy persons ([Krystal et al., 1994](#); [Zukin, 2000](#)). Subanesthetic doses cause depersonalization, derealization, hallucinations, and distorted sensory, time, body, and identity perceptions ([Curran and Morgan, 2000](#); [Hansen et al., 1988](#); [Jansen, 1990](#); [Krystal et al., 1994](#); [Malhotra et al., 1996](#)). Animal research shows that the long-term use of high doses of ketamine destroys temporal and parietal neurons as well as neurons in the posterior cingulate gyrus, amygdala, and hippocampus ([Wozniak et al., 1993](#); [Zukin, 2000](#)).

Another drug, yohimbine, an  $\alpha_2$ -adrenergic receptor antagonist that indirectly increases availability of brain norepinephrine ( [Starke et al., 1975](#)), has been reported to induce panic attacks, flashbacks, and dissociative symptoms in patients with PTSD but not in healthy controls ( [Southwick et al., 1993](#); [Southwick et al., 1999](#)). These findings are consistent with the hypothesis that, over time, in chronically traumatized persons, the threshold for activation of the fear response is lowered, triggering posttraumatic and dissociative responses to even minor stressors. The foregoing findings provide indirect evidence of possible neurobiological mechanisms involved in pathologic dissociation.

### Neurophysiology and Alternate Personality States

We do not know what happens neurophysiologically when a person with DID switches from one personality state to another. Adult patients frequently manifest staring episodes, stuttering, twitches, eye rolls, and other facial or body movements during transitions between states. Movements appear to be involuntary and outside the patient's awareness. Clinically, these phenomena are observed more rarely in children with DID than in adults.

Studies of the neurophysiologic differences among alternate personality states have been conducted on adults. They include testing of the following: differences in autonomic responsivity such as galvanic skin response ( [Brende, 1984](#); [Larmore et al., 1977](#); [Ludwig et al., 1972](#); [Putnam et al., 1989](#)), as well as heart rate and respiration ([Bahnon and Smith, 1975](#)); differences in electromyography, ([Larmore et al., 1977](#)), electroencephalographic changes ([Cocores et al., 1984](#); [Coons et al., 1982](#); [Larmore et al., 1977](#); [Ludwig et al., 1972](#); [Thigpen and Cleckley, 1954](#)), evoked potentials ([Braun, 1983](#); [Larmore et al., 1977](#); [Ludwig et al., 1972](#); [Putnam, 1984](#)), and regional cerebral blood flow ( [de Vito et al., 1985](#); [Lefkof et al., 1984](#); [Mathew et al., 1985](#); [Saxe et al., 1992](#)); and differences in cognitive functioning ([Armstrong and Loewenstein, 1990](#); [Coons and Sterne, 1986](#); [Erickson and Rappaport, 1980](#); [Lovitt and Lefkof, 1985](#); [Ludwig et al., 1972](#); [Silberman et al., 1988](#); [Wagner et al., 1983](#)). Data from these kinds of studies, even when viewed with caution because of their small or single case sample size, do suggest that physiologic changes occur in different personality states, and some of these changes cannot be feigned by method actors or by subjects pretending to suffer from DID.

### CLINICAL PICTURE

It is harder to diagnose DID in children than in adults. The switches from one personality state to another may be fleeting and may go unnoticed. The characteristics of alternate personality states are often less fixed and their differences are less pronounced, so when changes from one identity state to another occur, they may be attributed simply to mood swings. Symptoms and behaviors characteristic of the disorder also mimic numerous other more commonly recognized psychiatric disorders. Many of the signs, symptoms, and behaviors of the illness (e.g., communicating with vivid imaginary companions, behaving like an animal, changing voice and demeanor, having peculiar beliefs or convictions) are easily dismissed as child's play. Further complicating recognition of the disorder is the finding that the abuse history is almost invariably concealed by both children and caregivers. However, the major reason for the failure to recognize DID is that many clinicians question its very existence, and one cannot see what one does not believe exists.

Assuming now a willingness to entertain the diagnosis, what will the clinician encounter? The most common sign in children suffering DID is a tendency for the child to fall into trancelike states and to become oblivious to the environment. Before witnessing these behaviors in the office, the clinician hears complaints from teachers or caretakers that the child "spaces out" and fails to respond to questions or instructions. This particular symptom is often so prominent that it leads clinicians to wonder whether the child suffers from a seizure disorder. At the Bellevue Dissociative Disorders Clinic, we evaluated a 10-year-old child whose lapses were so severe, beginning at age 7 years, that at another clinic she was diagnosed with narcolepsy and was treated with stimulants. Usually, however, lapses or trances are less obviously pathologic and are dismissed as manifestations of boredom or daydreaming.

Although these trancelike states may appear to others to be random, they seem to occur in response to stimuli that have special, idiosyncratic meanings to the child. A teacher raises her voice and momentarily sounds like an abuser; a phrase in a book awakens a painful memory, and the child suddenly dissociates. Often a word or a nudge on the playground acts as a sudden reminder of past horrors. In a blink, the child unconsciously switches into another personality state to cope with the potential threat. At such times, the ordinarily docile child may curse or may even assault the perceived enemy. Later on, the child is oblivious to what transpired. Adults witnessing these sudden behavioral changes often describe the child as "not himself" or even as "possessed."

Another hallmark of DID is amnesia for behaviors and events. These amnesias are often spotty. Children may recall certain happy events, such as visits to the park with a parent, but are amnesic for abusive experiences. Dissociative children sometimes recall abusive events, but they misidentify perpetrators. Unaware of their amnesias, they deny any loss of memory. Several of the children we evaluated at Bellevue complained spontaneously of not knowing what was real and what was a dream. Many suffered the nightmares, flashbacks, and episodes of apparent sleepwalking typical of patients with PTSD.

Trances, lapses, amnesias, and personality state switches can wreak havoc on academic performance. When children are "spaced out," in alternate states of consciousness, they are oblivious to what is being taught. Subsequently, perplexed by unfamiliar homework, these children accuse teachers of never having taught the material. These children may study for a test while in one state, take the test in a different state, and consequently draw a complete blank. Scores on intelligence tests and achievement tests are often erratic, causing perfectly intelligent, capable, but dissociative children to be labeled learning disabled or even retarded. Homework papers and other assignments may vary from messy and indecipherable to neat and flawless. Occasionally, a neat, bright, well-organized aspect of the child always performs impeccably at school while dissociative episodes occur primarily in other settings. Contrary to the folklore that insists that persons with DID are exceptionally bright, we have evaluated several dissociative children, adolescents, and adults who were of borderline intelligence or severely learning disabled.

The same lapses and switches that often compromise academic performance give rise to severe behavioral problems in school settings. Several children whom we have evaluated have described imaginary friends who entertain them and tell them jokes at times of stress. Reviews of the school records of these children reveal comments such as "laughs inappropriately in class." Sometimes these imaginary friends give unfortunate advice. For example, one 9-year-old girl who was forever in trouble for "having a fresh mouth," would hear a voice in her head whisper, "Say 'dumb' to the teacher."

Alternate personality states may appear briefly to take objects, break things, or shout insults or curses. They may disappear as quickly as they arrived, leaving the bewildered child to deal with the consequences of his or her acts. Sometimes children suffering from DID find objects in their rooms or in their pockets and have no idea how they got there. In one state, they may assault a peer and, in another state, deny it. When the evidence against them is strong and the denials are vociferous, such children are often called pathologic liars.

As is evident from the foregoing description, children suffering from DID are changeable. One moment they may be sweet and agreeable; the next they are having a tantrum or assaulting a playmate. They may start the day upbeat and end it withdrawn and depressed, even suicidal. If their behavioral and academic problems have not already earned for them a disruptive disorder diagnosis, then these fluctuations may cause them to receive the diagnosis of a mood disorder. As mentioned earlier, sometimes they do indeed suffer from such a disorder as well as from DID.

One of the most common symptoms of DID is auditory hallucinations. Dissociative children hear the voices of imaginary friends or alternate personality states speak to them and to each other. They also receive instructions from them. Often they talk aloud to these voices. Caretakers, listening in on such conversations, sometimes think the child is playing with a friend, so different are the voices overheard. Several children and adolescents whom we have evaluated have also experienced vivid, grotesque, visual hallucinations of blood and body parts, apparent flashbacks to overwhelming experiences. Sometimes children report a hierarchy of imaginary companions that has the quality of a fixed delusion. As children report their experiences, they often become confused, contradictory, and momentarily inarticulate. They stutter; they pause and look upward, as if listening to instructions, before resuming speech. The combination of command hallucinations, voices speaking to each other, delusional beliefs, illogical thought patterns, and ostensible thought blocking sometimes leads to a diagnosis of schizophrenia. However, this cluster of signs and symptoms is far more common in patients with DID than in schizophrenic patients ([Kluft, 1987b](#); [Ross et al., 1990b](#)).

Thus, children with DID have a plethora of signs, symptoms, and behaviors suggestive of many different kinds of medical and psychiatric disorders. If clinic and emergency room or hospital records can be obtained, they often document numerous doctor visits and a multiplicity of diagnostic procedures ranging from barium enemas to magnetic resonance imaging scans and electroencephalograms. Depending on the personality state of the child at the time of a psychiatric evaluation, he or she may be treated with stimulant medication, antidepressants, antipsychotics, antiepileptics, antacids, stool softeners, enemas, or all of these. When none of

these interventions has lasting benefit (although at first any one of them may seem to help), such children are dismissed either as having a disruptive disorder or as malingering.

**Nature of Alternate Personality States in Children and Adolescents**

The trances, the amnesias, and all the behaviors that follow from them are like the dust storm underneath which hides the child's alternate personality states. A principle to keep in mind is that each identity state has a function. Without it, the child on some level feels vulnerable. Therefore, all identity states are important, and the memories, thoughts, and feelings of each must be understood and respected.

The different personality states of children with DID are remarkably similar to those of adults, and they serve very similar functions. Together, their major function is to protect the child from experiencing physical and emotional trauma. By their "taking over" at the time abuse is occurring, memories of maltreatment are kept out of conscious awareness. Sometimes alternate personality states function as violent protectors, attacking both real and imagined abusers. Those alternate identity states that retain memories of past horror are typically the most aggressive and dangerous. In fact, it is common for an alternate personality state to take on the characteristics, even the name, of an abuser.

Closely related to the aggressive personality states are seductive, sexually precocious identity states. They serve several functions. In such states, children act as if they enjoy and even invite the sexual activity to which they are being subjected. Sometimes they perform explicit sexual acts that the child was forced to perform for the abuser or for the camera of the abuser. We have seen a 4½-year-old child who was used in pornographic films scuffle with a male anatomically correct doll, stomp on its genitals, fall on top of it, twist its arms while holding it between her legs and, in a voice strangely similar to the child's mother's voice, call it a bastard. Shortly thereafter, when the doll was placed out of reach, the child lay back, knees to her chest and panties exposed, and beckoned toward the doll, purring, "I need him!"

Not all identity states are aggressive or sexually inappropriate. There are almost invariably benign identities that are also protective. Sometimes they are the first to come into being, emerging at a time of loneliness and vulnerability. These are characters who comfort and amuse. Some are "friends," even "twins." Others are like fairy godmothers. Some are infants. We have treated several young children who had 1- or 2-year old personality states.

Is there a "host" personality? Therapists tend to consider the "host" the first personality state they meet, the one who first walks into the office. Therapists tend to assume the existence of a solid, core personality from which other personality states diverge. However, if maltreatment begins very early, during infancy, a core sense of self may never develop. The child's personality is undeveloped, fragmented, and changeable. There is no unified core personality structure.

Children who suffer from DID usually have no idea of the nature of their disorder. They know only that they have imaginary friends who reside in their heads, or in other parts of their bodies, or who come to them from afar, and who both help and torment them. [Figure 70.1](#) illustrates a self-portrait, by a 6-year-old boy, showing an alternate personality state who, as he described him, "lives in my heart."

**Figure 70.1.** Self-portrait of a 6-year-old boy with dissociative identity disorder/multiple personality disorder, depicting the place where his alternate personality lives—"in my heart."

[Figure 70.2A](#) shows the drawing an 8-year-old boy did of his alternate personality state, "Joe," who, he explained, lived in a scalloped area of his brain ( [Fig. 70.2B](#)). This boy drew other compartments in his brain; he volunteered that others lived there, but he did not know who they were.

**Figure 70.2.** A: Picture drawn by an 8-year-old boy with dissociative identity disorder/multiple personality disorder of his alternate personality, "Joe." B: Picture drawn by the same boy, depicting the place in his brain where "Joe" lives.

Individual experiences and cultural practices influence the nature of alternate personality states. Strong defenders are often identified as the latest superhero or television character. Angry, aggressive identity states are identified by some children as a devil; benign personalities sometimes receive names like Angel. Many dissociative children name their inner friends after cousins or schoolmates, thus making it hard for therapists to know whom the child is describing.

Animal personality states are especially characteristic of young children. [Figure 70.3](#) was drawn by a 10-year-old child with DID. Listed are her numerous alternate personality states. The most powerful is a bull, depicted here as occupying half her body.

**Figure 70.3.** Picture, drawn by a 10-year-old girl, depicting a powerful alternate personality, a bull, as taking over half of her body. Also listed are her numerous other alternate personalities.

In our experience, animal personality states have tended to be protectors. For example, one 4½-year-old severely abused boy, when threatened, became a tiger, growled, and bared his teeth. On one occasion, he actually bit his foster mother. Another 8-year-old boy, who was referred to our clinic with numerous dissociative symptoms, had a dog as an imaginary companion. We did not realize that the dog took control of the boy's behavior until we reviewed videotapes of a therapy session; the microphone picked up a menacing growl that was inaudible to the therapists during the interview.

### Imaginary Companions Versus Alternate Personality States

Many normal children have imaginary companions or special toys that seem real to them. By the time a psychologically healthy child reaches the age of 6 or 7 years, most imaginary companions are long gone. Thus, the existence of an imaginary companion much beyond 8 years of age could be cause for concern. However, even 4- and 5-year-olds can usually distinguish between what is real and what is a product of their imaginations.

In a study we conducted on the nature of imaginary friends in dissociative children and in normal school children ( [Trujillo et al., 1996](#) ), we found that although similar proportions of children reported having had imaginary friends, by 10 years of age the normal children had all dispensed with their fictional playmates; many of the dissociative children, conversely, reported that their imaginary friends were still active parts of their lives. The functions of the imaginary friends also differed between groups. All the imaginary friends of the normal children were benign, played games with them, and offered good advice. The imaginary friends of the dissociative children, however, were not always benevolent. Often they were menacing and provocative. How the imaginary companions of young dissociative children evolve into alternate identity states remains to be understood psychologically and neurophysiologically.

### Other Signs and Symptoms

Many of the indicators of DID in children are also characteristic of psychologically healthy children (e.g., imaginary companions, spacing out, or day dreaming) and others are seen various other diagnoses (e.g., conduct disorder, attention deficit hyperactivity disorder). Several authors have created lists of the most prevalent signs, symptoms, and behaviors of childhood DID ( [Fagan and McMahon, 1984](#); [Hornstein and Putnam, 1992](#); [Kluft, 1985](#); [Peterson, 1990](#); [Putnam, 1993](#) ). These include trancelike states, amnesias, fluctuations in mood, fluctuations in abilities, disavowed behaviors (e.g., lying or stealing and denying having done so), marked behavioral changes (e.g., from aggressive to overly good), rapid regressions in behavior, evidence of active imaginary companions, auditory hallucinations, flashbacks, apparent sleepwalking, amnesia for having been abused, hysterical symptoms, fluctuating physical complaints, and referring to the self in the third person. Refractoriness to various forms of psychotherapy and medication directed at treating other diagnoses is also frequently part of the history. We would add to this list difficulty in distinguishing fantasy from reality (e.g., believing certain experiences were dreamed), acting like an animal (e.g., making animal sounds; moving in animal-like ways), using different names at different times, and having different writing and drawing styles. The clinician must keep in mind that any one of the foregoing characteristics may be seen in normal children and in children with disorders other than DID. There is no fixed number of signs and symptoms that unequivocally indicates the existence of DID. However, unlike other diagnoses with coherent sets of symptoms (e.g., depression), the extraordinary number of diverse signs, symptoms, and behaviors (e.g., auditory hallucinations, amnesias, trance states, mood swings) should alert the clinician to the possibility of a dissociative disorder.

### Psychosomatic Symptoms and Phenomena

Children who suffer from DID tend to complain of the very same kinds of physical symptoms as do their adult counterparts.

#### HEADACHES

A history of frequent, sometimes severe *headaches* is common. At least some of these headaches occur in response to conflicts among different personality states. For example, a 9-year-old child with a history of sexual abuse experienced severe headaches when the characters in her head argued over whether or not to visit the former abuser.

#### SEIZURES AND NARCOLEPSY

*Seizurelike symptoms* or *pseudoseizures* also may be part of the picture in children suffering from DID. We have evaluated several children and adults with seizurelike symptoms who underwent extensive neurologic evaluations before referral. We have evaluated three children with DID whose symptoms led previous doctors to suspect (and in one case treat) narcolepsy. In all these cases, the children suddenly seemed to fall asleep for no apparent reason. These "attacks" occurred in response to perceived threats in the child's environment.

#### ANESTHESIAS AND SCARRING

Children and adolescents with DID often report being able to block out physical pain. Often, they are amnesic for events that resulted in severe *scarring*. Proof of abuse can often be found on the child's back, arms, legs, and even on genitalia. Dissociative children often also have scars from self-inflicted cuts or burns for which they are amnesic. Sometimes one dissociated aspect of the child whispers "Cut yourself" or "Jump in front of a car."

#### PARALYSES

Conversion symptoms, including apparent *paralyses*, have also been observed in children with DID. One 4½-year-old, severely traumatized boy claimed at times to be unable to walk. During therapy, it was learned that the boy had an infant personality who could not yet walk. Suggestions that the "baby" would mature and be able to walk cured the problem.

#### VISUAL, AUDITORY, AND SPEECH ALTERATIONS

The kinds of differences in *visual acuity and hearing* reported to exist among the so-called "alters" of adult patients may well exist in children but go unrecognized. At the Bellevue clinic, although we do not test the visual acuity of different personality states, we occasionally observe a slight strabismus in a child while in one state, but not in others. It is also common in children to have one or more personality states that cannot or will not speak. Sometimes a personality state is reported to be too young to speak. Some children, while in particular states, are selectively mute. However, many children, while in these states, write to the therapist. Selectively mute personality states are often very concrete. Abusers have threatened them if they tell what happened to them, but writing is somehow permitted. Penmanship differs markedly in different states. In one case, an adolescent boy had an alternate personality state that spoke with an Irish brogue.

#### HANDEDNESS AND WRITING

Adults with DID have been known to change *handedness* while they are in different identity states ( [Putnam, et al. 1986](#) ). We have treated several children who spontaneously changed writing hands after switching into different identity states. [Figure 70.4](#) illustrates the right- and left-handed writings of a 13-year-old girl with DID. Handwriting styles change not only with handedness but also according to the developmental stage of the alternate personality state.

**Figure 70.4.** A: Writing sample of a 13-year-old, right-handed female patient with dissociative identity disorder/multiple personality disorder. B: Writing of left-handed alternate personality of the same 13-year-old girl.

## GASTROINTESTINAL AND GENITOURINARY PROBLEMS

Boys and girls with DID often have histories of a variety of *gastrointestinal and genitourinary complaints*. Some of these complaints (e.g., painful defecation) are the direct result of sexual abuse. We have found a history of constipation and encopresis to be especially common among sexually traumatized, dissociative boys (Morrow et al., 1997). Unfortunately, during medical workups, the examinations, tests, and treatments (e.g., digital rectal examinations, barium enemas, suppositories) further traumatize these already abused children. Such children often have nausea and vague abdominal pains for which no medical cause can be found. For example, the female personality state of an adolescent boy in our clinic experienced episodic gagging when reliving fellatio by an older male relative. Another adolescent girl could not tolerate using toothpaste because it reminded her of the semen she had been forced to swallow.

## DIAGNOSTIC EVALUATION

As is true of most other psychiatric diagnoses, there are no specific physiologic tests for DID. Careful, comprehensive clinical interviews, not only with the child, but more importantly with knowledgeable adults in the child's life, are the only accurate means of diagnosing the disorder.

### Screening Instruments and Interview Protocols for Dissociative Disorders

Several screening instruments have been created to identify the signs, symptoms, and behaviors indicative of pathologic dissociation in children and adolescents (Fagan and McMahon, 1984; Kluff, 1985; Peterson, 1990; Putnam et al., 1993; Reagor et al., 1992). These instruments are completed by caregivers and other adults who know the child well. The Child Dissociative Checklist by Frank Putnam and colleagues (1993), a 20-item behavioral screening tool, is the most widely used checklist in circulation. The checklist reportedly has good test-retest reliability and satisfactory concurrent and discriminant validity (Putnam and Peterson, 1994; Wherry et al., 1994). Conversely, when we have asked two different family members to fill out the Child Dissociative Checklist for the same child, we have found striking differences between the two reports.

Two self-report screening instruments are also available. The Children's Perceptual Alteration Scale (Evers-Szostak and Sanders, 1992) is a 28-item measure completed by children between the ages of 8 and 12 years. The Adolescent Dissociative Experiences Scale (A-DES) (Armstrong et al., 1997) is a 30-item screening instrument designed especially for adolescents between the ages of 12 and 18 years. Initial psychometric data on the A-DES have demonstrated good validity and reliability (Armstrong et al., 1997; Smith and Carlson, 1996).

High scores alone on any of these instruments are not necessarily diagnostic of a dissociative disorder; a comprehensive diagnostic interview is the only accurate means of making the diagnosis. One such interview protocol, the Structured Clinical Interview for DSM-IV Dissociative Disorders—Revised (Steinberg, 1994), originally designed for adults, is reportedly useful for adolescents as young as 14 years of age (Steinberg, 1996; Steinberg and Steinberg, 1995). It assesses the presence and severity of five core dissociative symptoms (i.e., amnesia, depersonalization, derealization, identity confusion, identity alteration). However, because the protocol does not inquire about issues other than pathologic dissociation, it must be used in conjunction with a more comprehensive diagnostic interview protocol, such as the *Diagnostic Interview for Children—Revised* (Shaffer et al., 1993).

We at the Bellevue clinic created a semistructured diagnostic interview for both children and adolescents, the *Bellevue Dissociative Disorders Interview for Children* (Lewis, 1996). The protocol not only taps signs, symptoms, and behaviors indicative of pathologic dissociation, but it also inquires about medical and neurologic symptoms, mood dysregulation, auditory and visual hallucinations, aggression, posttraumatic stress symptoms, experiences of physical and sexual abuse, neglect, and intrafamily violence, and parental dissociative symptoms. Because the protocol was designed to permit an experienced interviewer to inquire about topics in a flexible order, it has been especially useful with very disturbed, anxious children and adolescents who are unable to cooperate with the demands of a highly structured protocol. To date, the protocol has been pilot tested on a group of severely abused children who were in residential treatment and on a sample of ordinary fifth grade school children. It distinguishes well between the groups and has good interrater reliability regarding the presence or absence of specific dissociative symptoms. Test-retest reliability has not yet been tested.

### Clinical Interview

The goals of the diagnostic interview are (a) to learn how the child experiences his or her inner world, (b) to identify the nature of personality states, (c) to learn when these states first appeared, (d) to understand their functions, (e) to explore their memories of past events, and, most important, (f) to determine whether the child is safe from further abuse. The child who continues to be abused will not improve with psychotherapy, no matter how talented the therapist, because the child must continue to dissociate to survive.

In addition to assessing for signs, symptoms, and behaviors indicative of pathologic dissociation (as described earlier), a thorough evaluation for DID should cover questions regarding history of caretaking, forms of parental and caretaker discipline, parental dissociative behaviors, sexual experiences including pornography and prostitution, various medical questions dealing with gastrointestinal, genitourinary, and neurologic symptoms, accidents, loss of consciousness, and the origin of scars. The *Bellevue Dissociative Disorders Interview for Children* (Lewis, 1990) addresses these important topics.

Dissociative children and adolescents often do not know they suffer from a psychiatric condition, or, if they are aware that something is wrong with their minds, they tenaciously guard their secret. We have found that asking about the child's imagination is an acceptable way of beginning the clinical interview; it is a nonthreatening topic for the child and can produce a wealth of important information for the clinician. Questions about favorite television shows and movies can elicit information about intense absorption in fantasy, as well as about trances and time loss. Questions about special toys and make-believe friends often reveal a complex inner world to which the child escapes to block out painful or frightening events. This line of questioning enables the child to talk about imaginary characters who seem real and who talk to the child and to each other. Questions about what "they" do for the child often bring forth descriptions of how they take over when the child is in a tight spot. Some children switch spontaneously into other identity states in response to the clinician's asking, "Would it be okay for me to talk with [a particular character]?"

A word of caution regarding the discovery of alternate personality states: until the time the child is evaluated, the very existence of these states has been a secret kept from the rest of the world. Alternate personality states in children as well as adults perceive this secrecy as vital for survival. The clinician's discovery of the existence of these personality states is often viewed by "them" as betrayal, and "they" may retaliate (e.g., tell the child to harm himself). After the child reveals his or her secret inner life, it is not unusual for self-mutilation or even a suicide attempt to occur. For this reason, after almost every session, and especially after the first session in which one learns of alternate identity states, it is prudent to end the session by expressing gratitude and admiration for all aspects of the child and by asking for a promise from all not to hurt themselves, each other, or anyone else.

It is vital that the child undergo a physical examination at some point during the evaluation process. The purpose of the of the physical examination is threefold: (a) to obtain a detailed medical history; (b) to assess the nature of specific physical symptoms such as seizurelike episodes, headaches, trancelike states, and stomach pains; and (c) to document evidence of physical or sexual abuse if it has occurred. Children with a suspected dissociative disorder should not be referred to a

pediatrician for simply a routine examination. The pediatrician must be informed of the clinician's suspicions that the child may have been abused, and care must be taken to avoid retraumatizing the child during the examination. An essential part of this physical examination is an examination of the skin for scars. Dissociative children usually carry the signs of physical abuse and self-mutilation all over their bodies, especially on their heads, arms, legs, and backs. The most severely abused children are often consciously unaware of particular scars and their origins. Sometimes just pointing out scars and inquiring about them causes the child to dissociate, so traumatic are the memories associated with them.

### Use of Drawings to Aid in Diagnosis

Asking the child or adolescent to draw can be a useful adjunct to the clinical interview. Such drawings can range from age-appropriate to infantile and primitive, again, depending on which personality state the child is in while performing the task. Children with DID may make self-portraits that are divided or split, or they may draw multiple heads or many appendages. In addition, patients with personality states of the opposite sex sometimes draw sexually ambiguous figures. The drawings in [Fig. 70.5](#) were done by Karen, a young adolescent girl. The first set of drawings ([Fig. 70.5A](#)) was done in her usual personality state in response to the requests: "Draw a Person. . . . Now draw the opposite sex." The second set ([Fig. 70.5B](#)) was done while she was in a younger personality state in response to the same requests. Note the immaturity of the drawing as well as the sexual confusion (i.e., the boy figure, on the left, is wearing a dress, and the girl figure, on the right, is wearing slacks).

**Figure 70.5.** Drawings of a girl and boy made by a 13-year-old girl with dissociative identity disorder/multiple personality disorder. *B*: Drawings made by an infantile alternate personality of this same adolescent girl.

We have also asked children to draw a picture of their brain. Children with DID often imagine their brains to be compartmentalized, housing different identity states. [Figure 70.6](#) shows a picture of her brain, drawn by a 9-year-old girl with DID. Note how she depicts different characters living in different sections of her brain. [Figure 70.7A](#) shows an 8-year-old boy's picture of his brain. [Figure 70.7B](#) shows a picture of his brain drawn by the same child approximately 30 minutes later in response to the very same request by a different clinician. At the time of the second drawing, this child was in an altered state and had no memory of having drawn the first picture.

**Figure 70.6.** A drawing by a 9-year-old girl depicting her brain. Sections are designated for several alternate identity states.

**Figure 70.7.** A: Picture, drawn by an 8-year-old boy with dissociative identity disorder/multiple personality disorder, depicting his brain. *B*: Picture, drawn minutes later by the alternate personality of the same 8-year-old boy, depicting his brain.

The simplest task of all is to ask the child to write his or her name while in different identity states. Not only does handwriting vary, but also the very ability to write at all may differ from state to state. Some characters may simply make an "X" or a special sign because they are illiterate; others may have an immature way of lettering, characteristic of a small child; and others may be too young to write at all. The way in which the child grasps the writing instrument also tells a lot about the age of that particular personality state.

### Use of Schoolwork and Journals to Aid in Diagnosis

A dissociative child's handwritten and drawn materials can provide excellent corroborative evidence of DID. In contrast, the writings produced in the course of an evaluation may be influenced by the examiner and may become the focus of suspicion by DID skeptics. Therefore, it is especially helpful diagnostically to find graphic evidence of DID from writings and drawings made before the evaluation. Homework and classroom exercises are invaluable sources of documentation. A careful examination of all available written work not only can confirm the diagnosis, but also can furnish information regarding the names, identities, and functions of alternate personality states. Sometimes the content of these extraordinary caches can even document the nature of the abuse endured by a child. The following figures come from homework papers, classroom exercises, and journals of children with DID.

[Figure 70.8](#) illustrates four different signatures found in the homework of a 12-year-old boy. They illustrate the different developmental levels of several of his personality states. [Figure 70.9](#) illustrates the age-appropriate signature found at the top of the worksheets of an 8-year-old boy with DID; below it is the signature of an immature personality state, and below that is the crossed-out name of a personality state (Mikey), followed by the child's given name. [Figure 70.10](#) illustrates the

markedly different handwritings found in the school journal of an 8-year-old boy with DID. This right-handed child had several alternate personality states, some of similar age, some several years younger, and one a left-handed baby. [Figure 70.11](#) and [Figure 70.12](#) were found in the schoolwork of two school-age boys with DID who had been sexually abused or used in pornography. These kinds of writings and drawings provide some of the most objective, untainted evidence of the phenomenon of DID in children.

**Figure 70.8.** Four different signatures found in the schoolwork of a 12-year-old boy with dissociative identity disorder/multiple personality disorder.

**Figure 70.9.** Three different signatures found in the schoolwork of an 8-year-old boy with dissociative identity disorder/multiple personality disorder: the first, his usual signature; the second, the signature of a younger personality; the third, the signature of a personality named Mikey, hastily scribbled out and replaced.

**Figure 70.10.** Different penmanship and spelling ability from the school journal of an 8-year-old boy with dissociative identity disorder/multiple personality disorder.

**Figure 70.11.** Drawing found in a notebook of a sexually abused boy with dissociative identity disorder/multiple personality disorder.

**Figure 70.12.** Drawing found among the papers of an 8-year-old boy who was used in pornography.

## DIFFERENTIAL DIAGNOSIS

The signs, symptoms, and behaviors of children and adolescents with DID mimic a multiplicity of other, more commonly made diagnoses. These include attention deficit hyperactivity disorder, complex partial seizures, mood disorders, schizophrenic disorders, borderline states, and conduct disorder. [Table 70.3A](#), [Table 70.3B](#),

[Table 70.3C](#), [Table 70.3D](#), [Table 70.3E](#) and [Table 70.3F](#) lists many of the signs, symptoms, and behaviors common to DID and to the disorders for which DID is most frequently mistaken.

- 
1. Hearing voices
  2. Command hallucinations
  3. Hearing voices talking to each other
  4. Feeling controlled from outside
  5. Having a hierarchy of "imaginary" companions
  6. Apparent illogical thought processes
- 

**Table 70.3.A. Signs and Symptoms of DID/MPD That Cause It to Be Confused with Schizophrenia**

- 
1. Dreamlike states
  2. Blackouts/loss of time
  3. Impaired memory for acts, violent and otherwise
  4. Appearing as though in a trance
  5. Out-of-body experiences
- 

**Table 70.3.B. Signs and Symptoms of DID/MPD That Cause It to Be Confused with Psychomotor Seizures**

- 
1. Restlessness and difficulty concentrating
  2. Fluctuating academic abilities (e.g. math, spelling, language skills)
  3. Tantrums
  4. Problems following instructions
  5. Impaired memory for learned material
  6. Changes in maturity of handwriting
- 

**Table 70.3.C. Signs and Symptoms of DID/MPD That Cause It to Be Confused with Hyperactivity or Attention Deficit Disorder**

- 
1. Fights with peers and authority figures
  2. Episodic violence
  3. Apparent lying
  4. Apparent stealing
  5. Inappropriate sexual behaviors
  6. Running away
  7. Use of aliases
  8. Apparent lack of feelings or guilt when describing violent acts
- 

**Table 70.3.D. Signs and Symptoms of DID/MPD That Cause It to Be Confused with Conduct Disorder or Antisocial Personality**

- 
1. Mood swings
  2. Episodic rages
  3. Suicidal behaviors
  4. Long periods without sleep
  5. Inappropriate sexual behaviors/hypersexuality
  6. Grandiosity
  7. Self-mutilation
- 

**Table 70.3.E. Signs and Symptoms of DID/MPD That Cause It to Be Confused with Manic-Depressive Disorder**

- 
1. Psychosomatic pain
  2. Mood swings
  3. Binge eating
  4. Suicidal behaviors/self-mutilating behaviors
  5. Episodic rages
  6. Unstable interpersonal relationships/poor social adaptation/impulsivity
  7. Episodic psychotic symptoms
- 

DID/MPD: dissociative identity disorder/multiple personality disorder.

**Table 70.3.F. Signs and Symptoms of DID/MPD That Cause It to Be Confused with Borderline Personality Disorder**

We found that among a group of severely abused, dissociative children in residential treatment, the most common diagnosis they had received before admission was attention deficit hyperactivity disorder. This diagnosis tended to be made because of their frantic, hyperactive behaviors and their apparent distractibility. Unlike most other children with attention deficit hyperactivity disorder, however, these children periodically experienced auditory hallucinations, retreated into trancelike states, and were amnesic for discrete periods of time. Their responses to stimulant medication were also equivocal.

The trancelike states and memory lapses of dissociative children often cause them to be diagnosed as having seizure disorders. These episodes tend to occur in the presence of others, at times of stress, and usually are not accompanied by the loss of urine or feces. Unlike epileptic attacks, during these spells, dissociative children can hear and respond to the therapist's suggestions (e.g., "I want everyone to calm down. Everyone is safe. Now, when I count to 3 you will wake up and feel fine.").

Children with DID exhibit rapidly changing moods as they switch from one personality state to the next. The changes are sometimes so striking that they appear to be evidence of a bipolar mood disorder. Certain personality states "keep the memories" and are always sad. Others are jokesters. However, in bipolar illness, moods are usually of longer duration, and switches from sad to happy are not instantaneous. Unlike children with mood disorders, children with DID have memory lapses, trancelike episodes, and other signs and symptoms of dissociation. That is not to say bipolar mood disorders cannot be concomitant with DID.

Almost all children who suffer from DID experience auditory hallucinations, and, when these are revealed, a misdiagnosis of schizophrenia is often made. Children with DID, like their adult counterparts ([Kluft, 1987b](#); [Ross et al., 1990b](#)), have numerous first-rank symptoms (e.g., command hallucinations, voices arguing in their heads, feeling controlled from outside). Periodically, as they switch from one personality state to another, their thought processes may become confused, vague, and illogical. Blocking also occurs when one personality state tries to silence another. However, unlike children diagnosed with schizophrenia, children with DID usually relate to others warmly and with a normal range of affect. Their episodic amnesias, trances, and changes in voice and demeanor also distinguish them from children with the kinds of psychoses traditionally designated as schizophrenic.

Children who suffer from DID often behave in dangerous, aggressive ways. They run away. They take things, and they deny behaviors that they cannot recall. Sometimes they are cruel to peers and animals, and they appear cold and unfeeling. These behaviors often result in a misdiagnosis of conduct disorder. Again, the amnesias, trances, and auditory hallucinations of DID distinguish it from conduct disorder.

A word should be said regarding the diagnosis of borderline personality disorder. Whether this diagnosis is appropriate for children may be debatable, but the diagnosis tends to be made. The psychosomatic pain, the mood swings, the impulsivity, the unstable interpersonal relationships, the self-mutilation, and the episodic psychotic symptoms characteristic of adult patients who are called "borderline" are also characteristic of persons with DID. We suggest that many children and adults called "borderline" actually suffer from severe dissociative disorders, including DID. Therefore, the very consideration of such a diagnosis in a youngster should alert the clinician to the strong likelihood that he or she is dealing with a severely dissociative child.

Because of the tendency of DID to mimic other conditions, there is no single, easy way of making the diagnosis of DID in children. The multiplicity of symptoms, the fluctuating moods and behaviors, and the invariable history of amnesic states or well-documented behaviors for which the subject denies responsibility, as well as a history of having received several different diagnoses in the past, alert the clinician to the possibility of DID. Another clue to the diagnosis is that children with DID have often received different medications (e.g., stimulants for attentional problems, antipsychotic medications for hallucinations, antiepileptic medication for trances). However, the attentional problems of DID do not respond to stimulants, the hallucinations are untouched by antipsychotics, and the trances continue in spite of antiepileptic medications. A history of abuse cannot be relied on to make the diagnosis because the child and caretaker are often amnesic for the abuse or protective of each other, and they are reluctant to tell what they know.

This confusing conglomeration of neuropsychiatric phenomena should in and of itself indicate to the clinician the need for the kind of diagnostic evaluation described.

## TREATMENT

Clinicians who have treated adults and children suffering from DID have reported that progress toward integration is easier and faster with children than with adults ([Hornstein and Tyson, 1991](#); [Kluft, 1996](#)). In children, alternate personality states tend to be less fixed and less invested in separateness. However, we have found that this greater flexibility or malleability in children is often counterbalanced by the problem that children are often still in the care of extremely disturbed families whose child-rearing practices engendered the disorder in the first place. In these cases, we have found that children are unable to make much, if any, progress until their parent's psychopathology is addressed. As [Hornstein and Tyson \(1991\)](#) suggest, when a child with DID fails to make progress or regresses to more seriously disturbed behaviors, it is likely that events in the home are reigniting feelings of endangerment. Often siblings and parent figures must be assessed and even engaged in treatment if the child is to feel secure at home. It is not unusual to discover that older siblings have continued to intimidate or abuse a child after parental abuse has subsided.

We have found improvement to be fastest in cases in which formerly severely abused children have been placed in excellent foster or adoptive homes or when the abuser has been removed from the home. When a child is in a secure home, we often include the parent or surrogate parent in therapy sessions. In so doing, we teach parents to recognize the phenomena characteristic of DID and to deal fairly and lovingly with the child in all of his or her personality states.

Once a diagnosis has been made and a therapeutic alliance is created, the tasks of learning about the memories and experiences of each personality state, working through trauma, and sharing knowledge among personality states are similar to those of working with adult patients. Care must be taken with children to show empathy and respect for each personality state while encouraging all aspects to work together. Usually the child's most problematic behaviors result from the actions of one or more aggressive protector personality states. We have found it useful to recognize the power of these angry entities, to interpret their original need to be strong to protect the child, and to suggest that their powers could better be used in new, helpful ways, such as in sports. One rather skinny 10-year-old boy with whom we used this strategy became his football team's most valuable player.

We have found that, over time, as children feel increasingly safe, and as the needs, fears, and functions of different personality states are addressed, their distinct characteristics begin to blur, and they become so similar to each other and to the child as to be almost indistinguishable. Unfortunately, we have also found that months of progress can be undone when a child who seems to have recovered is forced once again into the company of a former abuser.

### Role of Pharmacotherapy

Until recently, prevailing opinion was that dissociative disorders were not amenable to psychopharmacologic treatment. Indeed, such psychotic symptoms as auditory and visual hallucinations, delusions of being two or more separate individuals, and feelings of being controlled by outside forces that are typical of DID are not touched by neuroleptic medications. However, when DID is viewed as chronic, complex PTSD with episodic panic attacks, then medication can play a very important role in alleviating the kinds of posttraumatic intrusions (e.g., flashbacks), hyperarousal symptoms, and panic episodes that trigger switches into alternate personality states. The tricyclic drugs amitriptyline (Elavil) and imipramine (Tofranil) and the selective serotonin reuptake inhibitors fluoxetine (Prozac) and sertraline (Zoloft) have successfully controlled core PTSD symptoms in adults. Anticonvulsant agents such as carbamazepine (Tegretol) and divalproex (Depakote) also have shown promise

in reducing hyperarousal, flashbacks, and sleep disturbance in adults ( [Amaya-Jackson, 2000](#); [Brady et al., 2000](#); [Krystal et al., 1998](#)). Clinically, we have found that when panic attacks diminish, dissociative youngsters switch personalities less frequently, become calmer and less aggressive, think more clearly, and thus are able to make progress in psychotherapy. Of course, if the child is diagnosed with a comorbid psychiatric illness such as depression or bipolar mood disorder, it goes without saying that the child first must be stabilized pharmacologically before the problem of dissociation can be addressed.

In the coming years, as we gain a greater understanding of the neurobiology of dissociation, new pharmacologic approaches targeting specific neurotransmitter systems that mediate dissociative symptoms may be found. Already, [Chambers and colleagues \(1999\)](#) have proposed for further study drugs that limit glutamate release and enhance hyporesponsive g-aminobutyric acid-ergic and endogenous opiate systems.

## RESEARCH DIRECTIONS

The 1990s have seen a shift from the study of DID to the study of PTSD. Although PTSD research has done much to legitimize dissociation as a normal response to extreme physical and psychological stress, such research has been unable to shed much light on the development of DID. Clearly, DID in children continues to provide fertile ground for psychodynamic and psychophysiological exploration. The autonomic, electroencephalographic, and immunologic differences among alternate personality states make the disorder especially useful for the study of mind-body interactions. The finding that it is common for several members of the same family to suffer from the disorder makes it a promising research area for the study of the intergenerational transmission of symptoms and behaviors. The relationship of early, ongoing trauma to the development of DID makes the illness especially relevant to studies of child abuse and of normal and pathologic child development. The timing, nature, and duration of abusive experiences sufficient to engender the phenomenon remain to be understood. Above a certain age, are human beings invulnerable to the disorder? Will the disorder always respond to appropriate therapy, or, after a certain period, is integration impossible? Will the disorder ever resolve over time on its own if a traumatized, dissociative child is given proper nurturing? Longitudinal and cross-sectional studies of children and adolescents suffering from pathologic dissociation should begin to answer these kinds of questions.

From the point of view of child psychiatry and of the welfare of children, the most important questions must concern the early identification of the signs, symptoms, and behaviors associated with the development of DID. What are the features of an incipient dissociative disorder in infancy? What does the disorder look like in childhood? Adolescence? The answers to these kinds of questions will lead to a better understanding of the incidence, prevalence, and early manifestations of the disorder and, hence, will have implications for prevention as well as treatment.

From the day of a child's birth, his or her sleep patterns are a matter of primary concern to the parents, second only to feeding and excretion patterns. Because in the early weeks and months of life, feeding, excretion, and sleeping frequently alternate with periods of crying, often interrupting parental sleep cycles, it is only natural for parents to be concerned if their child's sleep is irregular or frequently interrupted or if the infant is slow to sleep throughout the night. Parental concern about sleeping habits is established very early in a child's life. Thus, it is logical that sleep disturbances and disorders will come to the attention of professionals working with children throughout the childhood years.

In the psychiatric assessment, diagnosis, and treatment of children and adolescents, a history of variations in the usual patterns of the sleep–wake cycle is often the key to a more complete understanding of the presenting disorder. Such alterations may be either transitory phenomena or manifestations of normal phases of development. However, they may also appear as signs or symptoms of specific sleep disorders or of certain other mental, emotional, and physical disorders of childhood. It is therefore essential to have a full understanding of sleep, sleep patterns, and all their various manifestations to diagnose and manage these disorders appropriately.

For our purposes, we define childhood as the period extending from birth to the completion of adolescence or approximately 18 years of age. Although sleep disturbances may be transitory and relatively benign, sleep disorders, in general, are characterized by greater severity, duration, and degree to which they significantly disrupt or interfere with the child's daily functioning. Thus, the disruptions of sleep that we cover are those of more than occasional duration and more than minimal severity. They include specific sleep disorders that often are related to emotional or physical alterations associated with specific phases of development.

## SLEEP–WAKE PATTERNS IN CHILDREN

### Development of Sleep–Wakefulness Cycle

The newborn infant alternates between sleep and wakefulness every 3 or 4 hours, with awakenings usually related to hunger. The periods of wakefulness during the day gradually lengthen, the number of naps dwindles, and nighttime sleep periods grow longer. A definite diurnal cycle is established at 5 weeks in the majority of infants ([Kleitman, 1963](#)). Sleeping through the night, or “settling,” is found in 70% of infants by 3 months of age ([Moore and Ucko, 1957](#)). However, it takes about 5 years from birth for a child to develop the single night–day cycle that is retained throughout the balance of childhood and adulthood.

Newborn children sleep about 16 hours a day, and, by the 16th week of life, an extended, uninterrupted period of nocturnal sleep may reach 8.5 hours ([Kleitman and Englemann, 1953](#); [Parmelee et al., 1964](#)). Sleep requirements diminish to 12 hours plus a 1-hour nap at 2 to 3 years of age; in studies of normal preschool children, duration of sleep at 2 years was about 10 hours ([Kohler et al., 1968](#)). Requirements for sleep further decrease to about 9 hours at 8 to 12 years of age ([Ross et al., 1968](#)), whereas it appears that adolescents probably need more sleep than prepubertally. Nocturnal sleep time stabilizes at about 8 hours in young adulthood and remains there through midlife ([Feinberg and Carlson, 1968](#)).

The development of the diurnal cycle is most likely related to maturation of the central nervous system (CNS) because the ability to sustain prolonged periods of sleep and wakefulness appears to depend on an increasingly higher level of organization of the CNS. Infants who have suffered some type of prenatal injury or trauma such as anoxia fail to develop until a later age than normal the ability to sustain sleep without interruption ([Preston, 1945](#)).

Learning and conditioning are also involved, in terms of the child's response to the family's patterns of sleep–wake behavior ([Anders and Weinstein, 1972](#); [Parmelee et al., 1964](#)). From a practical standpoint, the sleep of the infant gradually becomes similar to that of the parents and is therefore less disturbing to parents; as this occurs, the infant is able to sleep for more prolonged periods and predominantly at night ([Kleitman, 1963](#)).

### Sleep Stage Patterns

Early sleep laboratory studies by [Aserinsky and Kleitman \(1953\)](#) focused on the assessment of sleep in children, first with regard to slow eye movements and, later on, rapid eye movement (REM) sleep. Subsequently, [Rechtschaffen and Kales \(1968\)](#) published the first manual standardizing terminology, techniques, and scoring systems of adult stages of sleep. This was followed by a similar manual that standardized terminology, techniques, and criteria in newborn infants ([Anders et al., 1971](#)).

Three basic sleep states occur in infants: active-REM sleep and quiet–non-REM (NREM) sleep—which are considered precursors of REM and NREM sleep—and indeterminate sleep ([Anders et al., 1971](#)). At term, the approximate percentages of the sleep phases are as follows: active-REM sleep, 50%; quiet-NREM sleep, 35%; and indeterminate sleep, 15% ([Parmelee et al., 1967](#)). In the infant, frequent sucking movements are observed during REM sleep, as well as fine twitches, grimaces, tremors, and smiles. Indeterminate sleep, which is poorly organized, is derived from the concept of transitional sleep. It is considered an immature state that is characteristic of premature infants but is also present in full-term infants and infants with various abnormalities ([Anders et al., 1971](#)).

The proportion of the various sleep phases in the newborn also changes considerably within a short period. The percentage of REM sleep decreases progressively after birth to a level of 20% to 25% in childhood and continues a more gradual decline in the adult years ([Feinberg and Carlson, 1968](#); [Roffwarg et al., 1966](#)). Because premature and full-term infants spend approximately two-thirds of the day asleep, the total REM time for this group is considerably higher than the total REM time for any other age group, in whom the total sleep time is invariably less. By about 3 months of age, the electroencephalographic (EEG) patterns of quiet sleep can be divided into various stages of NREM sleep. Combined stages 3 and 4 sleep (slow-wave sleep) are longest in childhood, about 20% to 30% of total sleep time, decreasing to 10% to 20% in young adults ([Feinberg and Carlson, 1968](#); [Roffwarg et al., 1966](#)) ([Fig. 71.1](#)).

**Figure 71.1.** Changing sleep structure and duration with age. (Data from Roffwarg H, Muzio I, Dement W: Ontogenetic development of the human sleep-dream cycle. *Science* 152:604–619, 1966.)

This age-related shift in the proportion of NREM to REM sleep is thought to indicate maturation of the CNS. REM sleep, which is characterized by irregular respiration and heart rate, is considered an archisleep or primitive sleep. NREM sleep, a more highly controlled state, with more regular respiration and heart rate, is regulated by higher cerebral centers, including the cortex.

The temporal sequences of REM and NREM sleep within a sleep cycle also change with age. Newborn infants frequently initiate sleep with a period of REM sleep and have relatively equal amounts of REM sleep in the first and second halves of a sleep period (Roffwarg et al., 1966). In contrast, adults begin sleep with about 70 to 100 minutes of NREM sleep and have a much larger proportion of REM sleep in the last third of the night's sleep (Feinberg and Carlson, 1968).

## CLINICAL SLEEP EVALUATION

### History

Before any formal sleep laboratory evaluation is conducted, an adequate sleep–wakefulness history is essential for the accurate evaluation and proper management of any sleep disorder of infancy, childhood, or adolescence (A. Kales et al., 1980d). A description of the disorder and its frequency, severity, development, and associated circumstances should be obtained, with a complete, 24-hour profile of active and quiescent periods. The history should include a description of the chronologic development of sleep patterns and any reports of difficulties with sleep as well as difficulties with feeding and toilet training. The pattern and level of achievement of all developmental milestones should be noted. The history also should ascertain the presence or absence of prenatal infections or illnesses of the mother, prematurity, trauma in relation to the birth process, or history of fetal distress. In addition, the occurrence of infections or injuries during infancy and childhood must be determined.

Further, in assessment of infants for sleep problems, addressing maternal limit setting, anger, and parenting doubts is essential (Morrell, 1999). Temperamentally intense, negative emotions may be significantly associated with sleep disturbances (Owens–Stively et al., 1997). Maternal sleep patterns, distress, and depression both before and after pregnancy may also be factors (Armstrong et al., 1998).

The child's psychological adjustment should be thoroughly evaluated (A. Kales et al., 1980d), including assessment of the maturity, competency, and emotional health of the parents and other caretakers. Changes in residence or sleeping environment are noted; for example, sleep disturbance may appear among children who are moved frequently from one home to another.

### Differential Diagnosis

In young children, it is important to differentiate between sleep difficulty that is secondary to immaturity of the CNS or other organic factors and that caused by a disturbance in the parent–child relationship. If this distinction is not made, the parent may assume responsibility for the disturbance even when he or she is not at fault and, through guilt and anxiety, superimpose psychological difficulties on the original problem.

It is also important to determine whether the sleep problem has been present since birth or early infancy or whether it appeared after the normal development of sleep patterns and behavior. The infant or young child is more likely to present with a sleep disturbance that has existed since birth or early infancy. In these cases, the physician is primarily concerned with the possibility of physiologic immaturity or organic conditions, such as prematurity, birth trauma, infection, thyroid dysfunction, or other physical illness. After such developmental and organic factors have been ruled out, the mother–child relationship must be evaluated to determine whether it is the primary factor causing the disorder or whether it is contributing to another, underlying disorder. It is important to differentiate between sleep difficulty caused by separation anxiety and chronic resistance to going to sleep (Ferber, 1989; Spock, 1957). Sleep disturbances associated with separation anxiety usually occur in the second or third year and are associated with the symptom of fear, whereas marked resistance to going to sleep usually occurs in the first year.

In children more than 3 years of age, it is more likely that the sleep problem has been acquired. Here, the physician assesses psychological, environmental, or organic causes, as well as developmental milestones that can account for the temporal development of the sleep disturbance. In children of this age and older, psychiatric disorders that may have a sleep problem as a symptom must be considered.

In the 3- to 5-year-old child with sleep difficulties, the factors mentioned earlier are evaluated, as well as the child's relationship with peers and his or her adjustment to nursery school or other preschool activities. In the child who is more than 5 years old, general daytime behavior and adjustment are thoroughly assessed, including evaluations of the child's adjustment at school, relationship with peers, and general social adaptation.

In a community-based survey of school children and their parents (Blader et al., 1997), bedtime resistance predominated. This was associated with falling asleep away from bed and inconsistent bedtime. Insomnia, night waking, and anxiety were also noted. Decreased verbal creativity and abstract thinking occur after decreased sleep (Randazzo et al., 1998), as does daytime sleepiness (Ishihara, 1999). Too early school starting time (Epstein et al., 1998) and bedtime television watching (Owens et al., 1999) also affect daytime behavior. Treatment lies in child–parent training (Mindell, 1999).

Adolescents in our society are currently obtaining less sleep than at previous times in history, as well as less sleep than in other cultures. Carskadon and colleagues (1998) at Brown University in Providence, Rhode Island, performed extensive research documenting the degree of the problem, as well as its various causes. Increased need for sleep, circadian changes associated with a pattern of decreasing total sleep time and delaying the timing of sleep secondary to school schedules, extracurricular activities, part-time employment, and decreased parental involvement in setting bedtimes are the main underpinnings of adolescents' sleepiness. Thus, a detailed assessment of an adolescent sleep schedule and daytime routine and activities during the weekdays and weekends is of great importance.

Furthermore, when an adolescent presents with a sleep difficulty, a thorough assessment of the patient's adjustment in school, peer relationships, and relationships with parents or parental figures is indicated, especially in terms of issues of dependence and independence, response to authority, and need to rebel. The physician also determines whether there is a history of delinquency or other types of acting-out behavior. Psychiatric disorders, such as depression, must also be ruled out (Wolfson and Carskadon, 1998).

## SLEEP DISORDERS

Although the categories and criteria set forth in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) (American Psychiatric Association, 1994) are more appropriate for classifying sleep disorders in adults than in children, in this chapter we follow the DSM-IV nomenclature and nosology as follows. Sleep disorders may be divided into four major groups: the *dyssomnias*, which show disturbance in the duration, type, and pattern of sleep; the *parasomnias*, which consist of experiences a child may have during sleep that are directly related to the sleep process and sleep stages; sleep disturbances that frequently accompany the common major child *psychiatric disorders* seen in clinical practice; and sleep disorders resulting from *general medical conditions or substance abuse*

(Anders and Eiben, 1997).

## Dyssomnias

### PRIMARY INSOMNIA AND CIRCADIAN RHYTHM DISORDERS

Unlike adults or adolescents, younger children and, of course, infants are less likely than their parents to complain about their sleeplessness. *Insomnia* in children may best be defined as observable prolonged or abnormal sleeplessness. The DSM-IV characterizes insomnia as a problem in initiating sleep, maintaining it, or not feeling rested after an apparently normal nocturnal sleep period (nonrestorative sleep). Insomnia in children as well as adults may be related to other mental disorders, which we discuss later in this chapter.

In one epidemiologic study, 14% of 3-year-old children were found to have problems with persistent waking at night, and 12% had difficulty in falling asleep. In 8-year-old children, 12% had trouble falling asleep, and 3% were troubled by waking at night ( Richman et al., 1982).

Sleep difficulty in children tends to have causes that are different from those in adults ( Ferber, 1989; J. Kales et al., 1984). The problem, even in younger children who are less than 2 years of age, does not seem to be neurodevelopmental ( Anders and Keener, 1985; Anders et al., 1980). Rather, it seems to be related more to interactional patterns between parents and their children and to parental reaction to short-term transitory behavior problems that have become more chronic. In a study of 23 infants 6 months of age, Keener et al. (1988) found that differences in waking at night varied according to whether the infant cried for the parents on awakening or simply self-soothed and went back to sleep. Infants fed to sleep were more likely to cry on awakening and to seek parental attention. The more a parent becomes overinvolved in the child's sleep, the more likely it is that a sleep problem, including insomnia, will develop and persist ( Ferber, 1989). Anders et al. (1992), using all-night time-lapse video recordings of 21 infants at 3 weeks, 3 months, and 8 months of age, found that, by 3 months of age, infants who were awake when put in their cribs at bedtime were more likely to return to sleep on their own when they awoke later in the night than those who were put in their cribs asleep. At 8 months of age, "problem sleepers" were all boys who were put in their cribs when they were already asleep. No other sleep factors were predictors. In a similar study, Minde et al. (1993) found, in 12- to 36-month-old children, that good sleepers woke as frequently as poor sleepers, but the latter had more behavior problems, more difficult temperament, and adverse medical histories. Comparing the mothers of 20 sleep-disordered toddlers with 21 mothers of toddlers without sleep disorders, Benoit et al. (1992) found that 100% of the former mothers were insecure with respect to attachment, as compared with only 57% of the controls. Changing patterns of feeding also may frequently affect sleep patterns in infants ( Ferber, 1989). In contrast, preschool and school-age children have few sleep difficulties, except as they relate to lack of limit setting or bedtime struggles, in which the child wishes to remain awake and active in play or with parents. It is recommended that excessive napping or sleeping during the day be restricted in children, particularly those of school age, to prevent interference with the normal length or onset of nocturnal sleep ( Ferber, 1989).

Fears of nightmares may also occur, giving rise to insomnia problems (J. Kales et al., 1984). In a comprehensive review, King et al. (1992) addresses the issue of children's nighttime fears, their variation according to level of cognitive development, their causes, and successful treatment approaches without medication. Infants fear direct environmental stimuli; preschoolers, imaginary creatures; and school children, representations of real sources of anxiety in their environment, such as the possibility of health problems, physical injury, or school failure. With regard to treatment of night fears, *emotive imagery*, in which children are trained to imagine a superhero who helps them to be brave in the face of the fears, has been most successful. Parents have been successfully taught to help their own children with this method, strengthened by positive reinforcement. In a related study, Connell et al. (1987) reported on six children, three boys and three girls, between the ages of 10 and 12 years who developed severe phobic anxiety at bedtime subsequent to exposure to the death of a relative or close friend. Psychotherapy with them focused on their confused concepts of the relationship between sleep and death. Pollock (1994), in a 5-year prospective study, also reported that emotional distress, as well as chronic medical conditions, commonly caused night waking at age 5, but less frequently by age 10.

Because insomnia in children seems to be more of a psychosocial problem based on the relationship between parent and child, treatment is best addressed primarily through psychological or behavioral means. It appears that sleeping alone through the night without parental intervention is a learned process. In helping the parents to facilitate this process, a few principles are critical in a successful behavioral intervention: first is reducing the amount of parental involvement at sleep onset, second is consistency; and last is the need to deal effectively with child or parental anxiety ( Dahl, 1998). Richman et al. (1985) found that behavioral methods of treatment improved bedtime disturbances and night waking (childhood equivalents of adult insomnia) in 35 children aged 1 to 5 years, whereas treatment with medication (trimeprazine) of 22 children with severe waking problems showed no permanent effect on sleep patterns ( Richman, 1985).

Minde et al. (1994), reporting on a study of the effects on daytime mother-child interactions of a treatment program for severely sleep-disturbed children aged 12 to 36 months, found that relatively simple interventions, such as having the father put the child to bed instead of the mother, helped to improve the mother-child relationship, as well as alleviating the sleep problem.

Adolescents seem to have an increased need to sleep during the daytime. In one study, ( Price et al., 1978), 13% of adolescents were classified as having difficulty sleeping through the night on a regular basis. Similar findings have been reported for an adolescent psychiatric outpatient population ( Monroe and Marks, 1977). Morrison et al. (1992), reporting on 943 adolescents from the general population, found that 10% reported difficulty falling asleep. In addition, whether male or female, those who had sleep problems showed more DSM-III disorders, namely anxiety, depression, inattention, and conduct disorder. Carskadon (1990) reported accident proneness, daytime sleepiness, and behavior and mood problems in adolescents who had insufficient sleep. Based on a large survey of more than 1,000 metropolitan households (Bixler et al., 1979), only 11% of adults with chronic insomnia reported the onset of their disorder in adolescence (between the ages of 11 and 20 years), a finding suggesting that chronic insomnia is relatively uncommon in this age group. However, because insomnia in the adult population is frequently associated with depressive or dysthymic disorders, appropriate diagnosis and clinical treatment of those conditions in adolescents with antidepressant medication and psychotherapy may serve to relieve symptoms of insomnia (see later).

In adolescents, insomnia unrelated to other primary psychiatric disorders may also appear as *delayed sleep phase syndrome* (DSPS) (Carskadon et al., 1998; Ferber and Boyle, 1983; Thorpy et al., 1988). DSPS consists of a chronic involuntary delay in falling asleep at night when desired and an inability to awaken at an appropriately scheduled time in the morning. In the sleep disorders clinic population, it is often associated with major depression and is more resistant to treatment than other sleep disorders (Regestein and Monk, 1995). Multiple and varied treatments of DSPS in adolescents include behavioral approaches ( Cashman and McCann, 1988), sleep phase advance techniques ( Thorpy et al., 1988), light therapy, and antidepressants. Moreover, high doses of methylcobalamin (vitamin B<sub>12</sub>) (Ohta et al., 1991) or melatonin (Okawa et al., 1998b) have been reported to foster the establishment of an appropriate 24-hour sleep pattern, resulting in improved school performance, mood, and behavior.

More recently, in case reports or noncontrolled studies, investigators have suggested that the hormone melatonin may be useful for the treatment of sleep-wake cycle disorders in children and adolescents ( Ellis et al., 1996; Jan et al., 1999; Okawa et al., 1998a). Although the potential usefulness of melatonin in circadian rhythm sleep disorders warrants further investigation ( Okawa et al., 1998a), melatonin appears to be of no use in persistent insomnia ( Ellis et al., 1996). In addition, dosage levels are uncertain, and long-term side effects are unknown.

---

#### CASE ILLUSTRATION

A 14-year-old girl presented with the primary complaint of difficulty falling asleep at night; she remained awake 1 to 2 hours after going to bed, a finding suggesting delayed sleep phase syndrome. Psychotherapy revealed an obsessional preoccupation with the need for a full night's sleep. This disturbance eventually resolved in the course of psychotherapy without the use of medication, and she returned to her normal sleep pattern.

---

### PRIMARY HYPERSOMNIA (EXCESSIVE DAYTIME SLEEPINESS)

*Hypersomnia*, or excessive daytime sleepiness, affects about five in 100 people in the general population, with a slight male predominance ( Bixler et al., 1979). In children, it tends to appear more often as they approach or enter adolescence. Carskadon and Dement (1987), Carskadon (1990), Carskadon et al. (1998), and Wolfson and Carskadon (1998) describe the evolution of daytime sleepiness in adolescents. In several studies of children over a decade who maintained a stable 10-hour sleep time, these investigators assessed whether the need for sleep actually gradually decreased as youngsters entered adolescence. The study indicated that sleep needs did not change significantly during adolescence. Total sleep appeared to remain at a stable level when the opportunity existed to have a continuous 10 hours of sleep. There were some differences between boys and girls. The only changes noted during the adolescent years were that the combined duration of

slow-wave sleep stages relative to other stages tended to decline.

Although primary or CNS hypersomnia is thought to be a relatively rare disorder, the diagnosis should be considered in children and adolescents who complain of excessive daytime sleepiness. In a large series published by [Roth \(1980\)](#), about 50% of patients with idiopathic hypersomnia had the onset of their symptoms before the age of 20 years. This disorder is characterized by excessive daytime sleepiness, prolonged and deep sleep, and morning sleep drunkenness or grogginess. Usually, it is diagnosed several years after the onset of the symptoms.

---

#### CASE ILLUSTRATION

A 15-year-old male student was reported to be regularly falling asleep in class, including once when standing in line. His history was positive for major depressive disorder and chronic dysthymia, whereas in the sleep laboratory, he demonstrated a nighttime sleep latency of 25 minutes and rapid eye movement (REM) latency of 102 minutes. During the first of two naps, the patient demonstrated a sleep latency of 4 minutes and an REM latency of 53 minutes. During the second nap, the patient demonstrated a sleep latency of 0 minutes and an REM latency of 51 minutes. There was no evidence of sleep apnea. Treatment with modafinil, 100 mg every morning, resulted in remission of these symptoms attributed to primary (idiopathic) hypersomnia.

---

#### KLEINE-LEVIN SYNDROME

A rarer form of periodic hypersomnia, usually evidenced in adolescents, is the *Kleine-Levin syndrome* ([Billiard, 1989](#)). This disorder is a periodic condition characterized by episodes of continuous daytime hypersomnolence associated with hyperphagia, irritability, aggression, sexual disinhibition, and mental disturbances, with a slight male predominance. The initial onset of this disorder is often related to an ill-defined flulike condition. Diffuse paroxysmal slowing is found in the EEG. Treatment of this disorder has included amphetamines and lithium carbonate, but a definitive cure has not been achieved.

---

#### CASE ILLUSTRATION

A 16-year-old boy experienced the onset of hypersomnolence during holiday home visits from a residential school. These visits were characterized by excessive holiday food intake, followed by a 1- to 2-week period of hypersomnolence, and a drunkenlike condition in the daytime. Medical workup, which was negative for other abnormal findings, confirmed the diagnosis of Kleine-Levin syndrome. The onset had been related to a flulike illness approximately 1 year previously.

---

#### NARCOLEPSY

*Narcolepsy* is a disorder consisting of excessive somnolence in the nonsleep or daytime hours ([Guilleminault et al., 1976](#); [A. Kales et al., 1982](#); [Roth, 1980](#)). The general population prevalence among both adults and children is less than one in 1,000 ([Roth, 1980](#)). The age of onset of narcolepsy tends to be late adolescence or young adulthood, although rarely its onset may be traced during the first decade of life.

Children with narcolepsy have excessive daytime sleepiness, with irresistible sleep attacks usually occurring in conjunction with one or more of three auxiliary symptoms: cataplexy, sleep paralysis, and hypnagogic hallucinations ([Guilleminault and Pelayo, 1998b](#); [Guilleminault et al., 1974](#); [Guilleminault et al., 1976](#); [A. Kales et al., 1982](#); [Roth, 1980](#)). The sleep attacks may last from a few seconds to 30 minutes and may be precipitated by sedentary, monotonous activity, such as watching television, reading, or sitting in class. Narcolepsy in children with hypersomnia, particularly in early stages, is not always accompanied by cataplexy, sleep paralysis, or hypnagogic hallucinations, so it may be underdiagnosed ([Kotagal, 1996](#)).

*Cataplexy*, present in about 60% to 80% of patients with narcolepsy ([Hishikawa and Kaneko, 1965](#); [Roth, 1980](#)), is a brief (lasting a few seconds to about 2 minutes), sudden, complete or partial loss of muscle control that, in its severe form, may cause the person to collapse while remaining conscious. This loss of muscle tone, which may include facial and neck muscles and slurring of speech ([Anic-Labat et al., 1999](#)), frequently occurs in relation to strong emotional experiences such as laughter, surprise, or anger. In patients who have cataplexy, REM periods usually occur at or shortly after sleep onset ([Hishikawa and Kaneko, 1965](#); [A. Kales et al., 1982](#); [Roth, 1980](#)), rather than preceded by the 70 to 90 minutes of non-REM sleep seen in normal controls.

With *sleep paralysis*, patients have a temporary loss of muscle tone and a resulting inability to move, most often occurring on awakening. *Hypnagogic hallucinations* are vivid hallucinatory perceptions (usually visual or auditory) that occur even in normal children at sleep onset.

Sleep attacks and certain manifestations of the auxiliary symptoms of narcolepsy appear to be closely related to the neurophysiologic mechanisms of REM sleep ([Broughton, 1971](#); [Hishikawa and Kaneko, 1965](#); [Rechtschaffen and Dement, 1969](#)). Two lower brainstem centers discharge together during REM sleep. The nucleus reticularis pontis caudalis stimulates an ascending activating system and produces EEG patterns of arousal, REM bursts, autonomic irregularity, myoclonic twitches, and pontogeniculoccipital spikes. Conversely, the locus ceruleus triggers a descending inhibitory system and causes areflexia and loss of muscle tone ([Broughton, 1971](#)).

Sleep attacks may involve a dysfunction of the activating part of the reticular formation in addition to a dysfunction of REM mechanisms ([Broughton, 1971](#); [Roth, 1980](#)). The intense muscle atonia of cataplexy and sleep paralysis is probably more directly related to stimulation of the descending inhibitory pathway, whereas hypnagogic hallucinations can be viewed as dreamlike experiences accompanying REM sleep.

Hereditary factors are clearly involved in the development of narcolepsy; 10% to 50% of patients have a first-degree relative with either narcolepsy or idiopathic hypersomnia ([Broughton, 1971](#); [Hishikawa and Kaneko, 1965](#); [Guilleminault et al., 1974](#); [A. Kales et al., 1982](#); [Kessler et al., 1974](#); [Nevsimalova-Bruhova and Roth, 1972](#); [Rechtschaffen and Dement, 1969](#)). Genetic studies have revealed human leukocyte antigen markers in most narcoleptic patients and in almost 100% of patients with cataplexy ([Langdon et al., 1984](#); [Mignot, 1998](#)). The pattern must be multifactorial, however, because monozygotic twins have a high rate of discordance ([Honda and Matsuki, 1990](#)). In addition, both clinical and polygraphic characteristics of the disorder, such as disturbed nocturnal sleep and abnormal timing of REM sleep, suggest the presence of a chronobiological abnormality ([Leckman and Gershon, 1976](#)). More recent studies have shown that somnolence-inducing cytokines are elevated in narcolepsy ([Vgontzas et al., 1997](#)), and canine narcolepsy is caused by a mutation in the orexin receptor 2 gene ([Lin et al., 1999](#)). Narcolepsy is unrelated to epilepsy; their respective symptoms are easily distinguishable ([Guilleminault et al., 1976](#); [A. Kales et al., 1982](#); [Roth, 1980](#)).

Attention deficit disorder (ADD) in children may include symptoms of inattention, impairment of learning, and hyperactivity, all of which may be symptoms of childhood disorders of excessive daytime sleepiness, including narcolepsy. The presence of daytime sleepiness, sleep attacks, or even cataplexy would suggest the presence of narcolepsy.

Treatment of narcolepsy has consisted primarily of therapeutic naps and the use of stimulant substances, such as methylphenidate or pemoline ([A. Kales et al., 1987b](#)) or more recently modafinil ([Billiard et al., 1991](#); [Boivin et al., 1993](#)). Tricyclic medications and serotonin reuptake inhibitors may also be considered when cataplexy is a problem, although the former are used with caution in children because of their anticholinergic side effects and association with cardiac conduction defects.

---

#### CASE ILLUSTRATION

A 17-year-old boy evaluated in a sleep disorders clinic complained, "I've been sleepy and tired since seventh grade." He reported feeling sleepy and fatigued during the day, falling asleep in classes, and taking a 3- to 4-hour nap at home after school. After getting a driver's license, he could drive no longer than an hour before stopping because of irresistible sleepiness. During the past 12 months, he had also been experiencing sudden buckling of the knees, dropping of the jaw, slurred speech, and, on one occasion in the car with his father, sudden complete paralysis and inability to talk. In the sleep laboratory, he presented no evidence of sleep apnea but, on 3 successive nights, demonstrated decreased sleep latencies and sleep-onset REM. During his nap studies, sleep latency was 3 minutes and 5 minutes and REM latency 30 minutes and 8 minutes, respectively. He was diagnosed as having narcolepsy with cataplexy. The treatment recommended included methylphenidate a stimulant medication for sleepiness, imipramine for cataplexy, and appropriate driving precautions.

## BREATHING-RELATED SLEEP DISORDER (SLEEP APNEA)

*Sleep-disordered breathing* and *sleep apnea* based on polysomnographic studies have been reported in infants as well as children ( [Guilleminault and Pelayo, 1998a](#); [McNamara and Sullivan, 1996](#); [McNamara and Sullivan, 1998](#)). These disorders are serious and may produce symptoms ranging from failure to thrive, behavioral problems, and enuresis to disruptions in sleep (increased wake and stage 1 sleep and reduced REM sleep).

Breathing-related sleep disorder (sleep apnea) is a condition characterized by intermittent periods of cessation of breathing during sleep ( [Block, 1980](#); [Guilleminault, 1987](#); [Guilleminault and Dement, 1978](#); [A. Kales et al., 1985](#); [A. Kales et al., 1987b](#); [Lugaresi et al., 1978](#); [Sadoul and Lugaresi, 1972](#)). These periods last more than 10 seconds and are often followed by loud and prolonged snoring sounds. Two general types of sleep apnea are described, obstructive and central. The former is characterized by peripheral obstruction of the airway, whereas the latter is characterized by the absence of respiratory drive, most likely secondary to CNS dysfunction. Some cases of sudden infant death syndrome have been thought to be caused by central sleep apnea ( [Guilleminault, 1987](#); [Steinschneider, 1975](#)).

Significant sleep and breathing disorders (sleep apneas) have been reported in 0.7% of 4- to 5-year-old children ( [Ali et al., 1993](#)). Habitual snoring (12.1%) has been associated with daytime sleepiness, restless sleep, and hyperactivity. Obstructive sleep apnea–hypoventilation syndrome is described as negatively affecting school performance in young children ( [Gozal, 1998](#); [Owens et al., 1998](#); [Rosen, 1999](#)).

In young children, the signs and symptoms of breathing-related sleep disorders, which primarily consist of the obstructive sleep apnea syndrome, are more subtle than those in adults, and the diagnosis is more difficult to establish. In children younger than 5 years old, nighttime manifestations, such as observed apnea, labored breathing, or restless sleep, are more often the presenting symptoms. In older children, the presenting complaint is often the presence of daytime symptoms, such as sleepiness, attention and learning difficulties, and morning headaches. Other signs and symptoms associated with breathing-related sleep disorders in children include brief arousals, nocturnal enuresis, and daytime mouth breathing.

In children, obstructive apnea may frequently be seen secondary to enlarged tonsils ( [Guilleminault, 1987](#)). Other less frequent anatomic causes include mandibular malformation, micrognathia, acromegaly, and glottal web ( [A. Kales et al., 1987b](#)). A strong positive correlation exists between sleep apnea and obesity and between sleep apnea and certain endocrinopathies, such as hypothyroidism ( [Guilleminault, 1987](#)). In addition, children with Down's syndrome are at risk of obstructive sleep apnea, with a prevalence of 31% to 72% ( [Marcus and Loughlin, 1996](#)).

When sleep apnea syndrome is suspected, parents should be questioned about whether the child exhibits loud snoring, heavy breathing, or interrupted nocturnal breathing ( [Block, 1980](#); [Guilleminault, 1987](#); [Guilleminault and Dement, 1978](#); [A. Kales et al., 1987b](#); [Lugaresi et al., 1978](#); [Sadoul and Lugaresi, 1972](#)). A thorough physical examination must be undertaken, including the careful inspection of the upper airway, neck, and jaw. In children, polysomnography in association with direct observation and recording of the child's breathing pattern is useful in confirming the diagnosis. There are no established criteria for obstructive sleep apnea syndrome in children, but common sleep laboratory findings include partial obstructive hypopneas, snoring, and labored breathing, with its associated brief semiarousals or awakenings.

Severity, as determined by the sleep laboratory indices and level of daytime functioning, should be considered when deciding on the treatment for a child with sleep apnea ( [Block, 1980](#); [Guilleminault and Dement, 1978](#); [A. Kales et al., 1987b](#); [Lugaresi et al., 1978](#); [Sadoul and Lugaresi, 1972](#)). When the origin is secondary to tonsillar or adenoidal hypertrophy, tonsillectomy and adenoidectomy are often curative. In other cases, the treatment options are not always as convenient or successful. Weight reduction can be helpful in some patients in whom the condition is secondary to obesity ( [Lugaresi et al., 1978](#); [Sadoul and Lugaresi, 1972](#)). Weight control in children with obstructive sleep apnea and morbid obesity may provide a partial cure, but adenoidectomy and tonsillectomy may result in marked improvement in the presence of retained obesity ( [Kudoh and Sanai, 1996](#)). Continuous positive airway pressure is used in those children who do not exhibit any adenotonsillar hypertrophy or who do not respond to adenotonsillectomy ( [Marcus and Loughlin, 1996](#)). In the past, in some cases, tracheostomy was used to relieve the symptoms and possible long-term adverse effects of severe sleep apnea ( [Handford et al., 1984](#)).

---

### CASE ILLUSTRATION

An 8-year-old boy with classical hemophilia A (factor VIII deficiency <1%) was referred to a sleep research and treatment center after a period of stuporous hypersomnia. His history revealed daytime sleep attacks and dull and uncoordinated behavior on arising in the morning. He was also reported to be falling asleep frequently in the classroom and experiencing declining academic ability. Physical examination revealed hypertrophy of the tonsils and cardiac enlargement with evidence of left-sided heart failure. Because of the potential seriousness of the condition, sleep laboratory studies were conducted. These revealed the presence of severe obstructive sleep apnea, with more than 500 events recorded in an 8-hour period, each lasting 20 to 40 seconds. During apneic periods, minimum oxygen saturation was 50% or less. Because the patient did not show improvement after tonsillectomy, a permanent tracheostomy was undertaken, to place an open tracheostomy tube during sleeping ( [Handford et al., 1984](#)). Five-year follow-up revealed that significant improvement resulted from all initial measures. At age 18, however, death occurred secondary to pulmonary complications of human immunodeficiency virus (HIV) infection.

---

## Parasomnias

### SLEEPWALKING AND SLEEP TERROR DISORDERS

*Sleepwalking* (somnambulism) and *sleep terrors* (formerly called night terrors) are much more common in children than in adults ( [Jacobson et al., 1969](#); [A. Kales et al., 1980c](#); [A. Kales et al., 1987a](#); [J. Kales et al., 1980](#)). About 15% of children are estimated to have had at least one sleepwalking episode ( [Jacobson et al., 1969](#)), compared with 2.5% of the general adult population ( [Bixler et al., 1979](#)). Sleep terrors are reported as a problem for 1% to 3% of all children and are considered to be disorders of impaired arousal ( [Broughton, 1968](#)). These conditions usually begin in late childhood or early adolescence and generally cease by late adolescence ( [A. Kales et al., 1980b](#); [A. Kales et al., 1987a](#); [J. Kales et al., 1980](#)). In a sample of 50 sleepwalkers, only three began sleepwalking after age 18 ( [A. Kales et al., 1980a](#)).

A sleepwalking episode usually lasts less than 20 minutes. During this period, patients generally have blank expressions, behave as though they are indifferent to the environment, and show low levels of awareness and reactivity. After awakening, they usually do not remember the events that occurred during the episode ( [Broughton, 1968](#); [Jacobson et al., 1969](#)).

The sleep terror episode has the additional and often dramatic characteristics of extreme vocalization and motility, excessive autonomic discharge, and intense terror or panic ( [Broughton, 1968](#); [J. Kales et al., 1980](#)). These episodes generally occur within a more restricted range than do sleepwalking episodes; for example, fewer patients with sleep terrors report leaving their homes during the event ( [J. Kales et al., 1980](#)). Sleepwalking and sleep terrors are believed to share a common neurophysiologic substrate and thus share many clinical and physiologic similarities ( [A. Kales et al., 1987a](#)), as summarized in [Table 71.1](#).

---

Episodes early in night  
Confusion on waking and minimal recall of event  
High risk of injury  
Family history of sleepwalking or night terrors usually present  
Onset usually in childhood or early adolescence  
Most often outgrown by late adolescence  
Psychopathology suspected if onset is in adulthood

**Table 71.1. Differentiation of Night Terrors and Nightmares**

Genetic ( [A. Kales et al., 1980a](#)), developmental ( [A. Kales et al., 1980c](#)), organic ( [J. Kales et al., 1979](#)), and psychological factors ( [A. Kales et al., 1980b](#); [A. Kales et](#)

al., 1987a; J. Kales et al., 1980) have been identified as causes of both sleepwalking and sleep terrors. In a study of a large sample of patients, a family history of either or both conditions was present in 80% of probands with sleepwalking episodes and in 96% of those with sleep terrors ( J. Kales et al., 1979). The frequent onset of these disorders in childhood, with termination by late adolescence, strongly suggests the role of maturational factors ( A. Kales et al., 1980c; A. Kales et al., 1987a; J. Kales et al., 1980). In addition, in a group of children with somnambulism, an “immaturity factor” (sudden, rhythmic, high-voltage, slow activity) has been identified in the EEG pattern during sleep (Jacobson et al., 1969). In a few cases, febrile episodes have been noted to precede the onset of somnambulism (J. Kales et al., 1979).

Psychological factors are not usually prominent in children who develop these disorders early in childhood ( A. Kales et al., 1980c; A. Kales et al., 1987a; J. Kales et al., 1980). However, sleep terrors, as well as other sleep disturbances, such as inability to fall asleep and nightmares, have been described as symptoms of posttraumatic stress disorder in children (Benedek, 1985). Children who develop these disorders and continue to have them as adults are much more likely to show significant psychopathology when they are evaluated as adults. Sleep terrors need to be differentiated from temporal lobe epilepsy, which rarely occurs only at night (J. Kales et al., 1980). EEG studies confirm that sleepwalking and sleep terrors are rarely manifestations of seizure activity ( Soldatos et al., 1980; Tassinari et al., 1972).

The most important consideration in managing children and adolescents with sleepwalking or night terror episodes is protection from injury ( A. Kales et al., 1980c; A. Kales et al., 1987a; J. Kales et al., 1980). Attempts to interrupt sleepwalking and night terror episodes should be avoided because intervention often confuses and frightens the child even more. Specific safety precautions may include special latches for outside doors and bedroom windows and sleeping accommodations on the ground floor. An important aspect of management consists of counseling and reassuring the parents that children with these disorders will usually outgrow the conditions by late adolescence, if not sooner.

With regard to more specific treatment, Lask (1988) reported the successful elimination of sleep terrors and sleepwalking by behavioral alteration of the sleep pattern, that is, charting the approximate time of the episodes each night and then waking the child 10 to 15 minutes before (when autonomic arousal is observed). Relief of the disorders occurred within a week, both initially and when there was recurrence. Psychotropic drugs (e.g., diazepam, imipramine) for controlling sleepwalking and night terrors should be used cautiously in children and only if the disorders are frequent, intense, and very disruptive ( Lask, 1988).

#### CASE ILLUSTRATION

A 16-year-old boy reported, “They tell me I get up at night and walk around.” His parents reported that, since the age of 5 years, he would abruptly awaken during the first third of the night frightened, disoriented, somewhat unresponsive, and screaming. These episodes seemed to cluster around stressful events in his life and would occur every 3 to 4 months. In addition, in the past year he had a dramatic episode in which, while sleeping at a friend’s house, he arose while asleep, left the house, walked through several backyards to his own home, retrieved the house key from the garage, entered the house, and returned to his own bed for the rest of the night without awakening. No such activity was recorded during 3 nights in the sleep laboratory, but, based on history, the diagnoses of sleep terror disorder and sleepwalking disorder were made. Management with diazepam at bedtime and bedroom security measures were recommended.

#### NIGHTMARE DISORDER

The problem of chronic *nightmares* usually begins early in life; the onset of the condition for about half of adult patients with nightmares is before the age of 10 years (A. Kales et al., 1980b). In a sample of 900 schoolchildren aged 6 to 12 years, 22% reported having nightmares ( Vela-Bueno et al., 1985).

Nightmares are most often associated with fears of attack, falling, or death, and, in many patients, the nightly themes recur ( A. Kales et al., 1980b; A. Kales et al., 1987a). Nightmares occur during periods of REM sleep and thus are most likely to occur late in the night, when REM sleep periods increase in duration ( A. Kales et al., 1980b). The characteristics of nightmares easily differentiate them from the more dramatic sleep terrors ( Broughton, 1968; A. Kales et al., 1980b; A. Kales et al., 1987) (Table 71.2), which occur during slow-wave sleep early in the night and generally are not well remembered, if at all. An REM-sleep behavior disorder has been described that is associated with dream-enacting behavior, often resulting in violent acts or injuries. However, this disorder is more prevalent in advanced age and is often associated with neurologic disorders ( Schenck and Mahowald, 1996).

Characteristic	Night Terrors	Nightmares
Vocalization	Intense	Limited
Autonomic activity	Marked increase	Slight increase
Arousal	Difficult	Easy
Motility	Marked	Limited
Recall	Minimal	Vivid
Sleep stage	Non-rapid eye movement sleep	Rapid eye movement sleep

Adapted from Kales A, Soldatos CR, Kales JD: Sleep disorders: insomnia, sleepwalking, night terrors, nightmares, and enuresis. *Ann Intern Med* 106:582-592, 1987, with permission.

**Table 71.2. Differentiation of Night Terrors and Nightmares**

When nightmares occur in childhood, they are most often related to specific developmental phases ( A. Kales et al., 1980a; A. Kales et al., 1987a; Mack, 1965). They are especially frequent during the preschool and early school years because a child between the ages of 3 and 8 may at times be unable to distinguish among reality, fantasy, and dream content. Because the child has an active fantasy life during this developmental period, fears of imaginary figures and misperceptions of shadows and objects frequently trouble the child while he or she is preparing to go to sleep, thereby predisposing the child to fears during the night. Nightmares in children have also been associated with febrile illness ( Karacan et al., 1968). When they occur frequently in late childhood and adolescence, nightmares are more suggestive of psychopathologic causes (A. Kales et al., 1980b).

The family of a child who has nightmares needs to know and be reassured that children frequently experience nightmares as part of normal development ( A. Kales et al., 1980b; A. Kales et al., 1987a). Otherwise, they may treat the child as though he or she were psychologically disturbed. In addition, minimizing the child’s exposure to potentially traumatic experiences, such as terrifying movies and television programs or frightening bedtime stories, can be helpful ( A. Kales et al., 1987a). In general, pharmacotherapy is not indicated for this disorder.

#### CASE ILLUSTRATION

A 4-year-old girl complained of frequent nightmares of monsters. One especially vivid dream was that her two younger sisters were killed by a monster while she survived. This dream was particularly disturbing to her and resulted in her crying and going to her parents’ bedroom. Historically, there was a detailed history of sibling rivalry problems, as well as parental discord and a tendency on the part of the parents to favor the two younger siblings over this child. She was also having serious behavior problems. A brief focused course of therapy for the child and for the parents proved helpful for relief of the nightmare symptom.

#### ENURESIS

*Enuresis* is defined as bedwetting that occurs after bladder control should have been achieved, usually between the ages of 2 and 3 years ( A. Kales et al., 1987a). This condition is among the most distressing of childhood sleep disorders for both child and parents, and its impact frequently persists long after the disorder has ceased. Between the ages of 3 and 12 years, about 10% to 15% of children still wet the bed at night ( Essen and Peckham, 1976). The prevalence decreases with age, reaching about 3% at age 12 (A. Kales et al., 1987a).

This sleep disorder exists in two forms: primary (persistent) and secondary (acquired or regressed) enuresis ( A. Kales et al., 1987a). In *primary enuresis*, children

have never been able to stop bedwetting for more than a month. Often, they have a family history positive for the disorder and usually have a small functional bladder capacity (A. Kales et al., 1987a; Starfield, 1967). Patients with *secondary enuresis* may be dry for months or years before bedwetting begins once again. Primary enuresis is by far the most prevalent of the two types, and both forms of the disorder are more prevalent in boys (Rutter et al., 1973).

Sleep laboratory studies have shown that enuresis is related more to time of night than to sleep stages (A. Kales et al., 1977; Mikkelsen et al., 1980). A common misconception is that enuresis occurs primarily during REM sleep. Two-thirds of all enuretic episodes occur during the first third of the night, predominantly during non-REM sleep (A. Kales et al., 1977; Nevéus et al., 1999). If the child is not awakened and given a change of clothes after an episode of bedwetting, the sensation of wetness may later be incorporated into a dream about bedwetting during the next REM period (Pierce et al., 1961). Nevéus et al. (1999) comment that enuretic children with a high arousal threshold may sleep more deeply than other children.

Genetic and maturational factors underlie primary enuresis, with the major problem being a smaller than normal functional bladder capacity (Starfield, 1967). Anatomic abnormalities of the genitourinary system are causative in only a few patients with enuresis (Starfield, 1972). Although general population surveys have shown an association between psychiatric disorders and enuresis (Rutter et al., 1973), most children with primary enuresis are actually free from any problems (other than bedwetting) affecting their behavior. Thus, in children with primary enuresis, psychopathologic disorders, when they are present, are predominantly the effects rather than the causes of their enuresis. Yeung et al. (1999), reporting on children with persistent nocturnal enuresis studied with a combination of cystometry (bladder studies) and polysomnography, found combination patterns of sleep disturbances and bladder dysfunction in these children.

In secondary enuresis, psychological factors are usually the etiologic agents (A. Kales et al., 1987a), for example, a significant event that disrupts the child's life, such as the birth of a new sibling or the parent's separation or divorce. However, bedwetting may also be a symptom of diabetes mellitus, diabetes insipidus, nocturnal epilepsy, severe mental retardation, or neurologic disorders.

Determining whether a child has primary or secondary enuresis is critical to the effective management of the patient (A. Kales et al., 1987a). Therefore, evaluation of the patient with enuresis should include a thorough history, with specific attention to the development and clinical course of bedwetting, life events at the onset of bedwetting, and family history of this disorder (A. Kales et al., 1985d). General growth and development, as well as parental attitudes and expectations regarding toilet training, are evaluated.

Physical examination and urinalysis are also required for a complete assessment. Only 1% to 4% of children with enuresis are found to have genitourinary abnormalities (Starfield, 1972). To determine the baseline functional bladder capacity, the physician should have the child refrain from voiding as long as possible and then measure the volume of urine voided (Starfield, 1967).

The physiologic, psychological, and behavioral principles (Doleys, 1977) in the management of primary enuresis are listed in Table 71.3 (Chapter 56). Given the psychological difficulties that typically underlie secondary enuresis, psychotherapeutic management is usually indicated (A. Kales et al., 1987a). Such an approach may range from parental education to psychodynamic treatment for the child and family. In taking this approach, it is important to explore the specific life-stress events usually found to have precipitated the onset of the enuresis. In young adults with enuresis unrelated to organic factors, psychotherapy is indicated.

1. Physiologic	Decreased functional bladder capacity is often present. Bladder training exercises are indicated to increase capacity and sphincter control. Child drinks increased amounts of water and waterfalls diverting urination for gradually increasing time periods; child is trained to stop and start urination. Most children eventually outgrow disorder as bladder capacity increases.
2. Psychological	The case of a child with enuresis is frequently mishandled. Guilt, shame, and anxiety are often superimposed on the problem. Parental counseling and reassurance are critical. Psychotherapy may be indicated.
3. Behavioral conditioning	Bed and pad are placed in the bed at night. Bell or buzzer awakens the child after first drops of urine. Complications include anxiety and skin irritation. Initial success rate is 75%, but there is a high relapse rate.
4. Pharmacologic	Imipramine markedly decreases frequency of urination. Difficulty with urination may be a side effect. A high relapse rate occurs after withdrawal of drug therapy. Treatment recommended mainly for older children with persistent enuresis. Desmopressin (DDAVP) may be a more reliable replacement.

Adapted from Kiese A, Speltz M, Jones K, et al. Sleep disorders (nocturnal, sleepwalking, night terrors, nightmares, and enuresis). Am J Orthopsychiatry 1994;64:100-106, with permission.

**Table 71.3. Principles in the Management of Primary Enuresis**

In the pharmacologic management of enuresis, imipramine has long been the drug of choice (A. Kales et al., 1977; A. Kales et al., 1987a; Werry et al., 1975). However, its use should usually be limited to older children and adolescents. The dosage approved by the U.S. Food and Drug Administration (FDA) is 1 to 2.5 mg/kg of body weight, or 25 to 75 mg daily in an average child. Fritz et al. (1994) confirm that imipramine is efficacious in 73% of reported cases at a dosage level of 2.5 mg/kg; side effects are rare but include cardiac conduction changes. Responses improve with increased measured serum levels, but these levels vary at least 700% between subjects at equal dosage levels, a finding indicating limited usefulness overall in determining therapeutic serum levels. Because of the potential for cardiotoxicity, a baseline electrocardiogram should be obtained, and higher doses should be avoided.

The antidiuretic hormone desmopressin (DDAVP) has also been employed with success in enuretic children. It is described as being more expensive but clinically safer than imipramine and as having fewer side effects (Shaffer, 1994).

#### CASE ILLUSTRATION

A 9-year-old boy, who was placed at the age of 6 years in a residential school because his unmarried mother was unable to care for him, experienced nightly enuresis. Further evaluation revealed a history of grossly inadequate mothering before and continuing maternal rejection after placement. The boy responded to weekly play therapy and a course of 50 mg of imipramine at night with a marked decrease in enuretic episodes. However, there were periodic recurrences whenever his mother demonstrated unpredictability and open rejection with regard to holiday home visits.

### Sleep Disorders Related to Another Mental Disorder

Children with *psychiatric disorders* appear to suffer more frequently from sleep disorders. Reporting on the comparison of a university psychiatric outpatient clinic population of 150 children and adolescents with a nonclinical sample of 309 subjects, Simonds and Parraga (1984) found that a significantly higher prevalence of restless sleep, limb movements, nightmares, night terrors, reluctance to go to sleep, needing to sleep with others, bedtime rituals, fears of dying, and daytime overactivity distinguished the clinical from the nonclinical population. Certain characteristic sleep problems were also associated with specific psychiatric disorders and are described in this section.

#### PERVASIVE DEVELOPMENTAL DISORDER (AUTISTIC DISORDER)

Sleep disturbances are frequently observed in children with *pervasive developmental disorder (autistic disorder)* (Hosino et al., 1984; Richdale, 1999; Segawa, 1982). However, because of their frequent perseverant motor activity, these children are very difficult to assess in the sleep laboratory. In general, children with pervasive developmental disorder or autism tend to continue their restlessness or stereotyped activities into the usual hours of sleep; they often have difficulty in falling asleep and show nocturnal or early-morning awakening patterns.

Sleep patterns of 75 autistic children showed that 65% had sleep disturbance beginning very early in life (Hosino et al., 1984; Patzold et al., 1998). The form that the disturbance takes can be difficulty in both falling asleep and remaining asleep. This study suggests that the sleep disturbance of these children is closely related to the severity of their disorder and their overall prognosis. Rutter (1968) reported that 43% of nonverbal autistic children showed problems with sleep, as compared with 30% of verbal autistic children. Environmental factors are also found to contribute to sleep disturbance, which is decreased by means of psychotherapy or play

therapy ([Segawa, 1982](#)).

In contrast, [Hering et al. \(1999\)](#), comparing actigraphy with parental questionnaires in 22 autistic children, find sleep patterns of autistic children like those of psychologically normal children, with the exception of early morning arousal time. When sleep studies are restricted to questionnaires or sleep diaries ([Patzold et al., 1998](#); [Taira et al., 1998](#)), parents of autistic children report sleep difficulties more frequently.

[Richdale \(1999\)](#), in a comprehensive literature review, reports the success of behavioral interventions in the sleep problems of autistic children. The use of melatonin and chronotherapy is also reported as potentially useful in autistic children ([Jan and O'Donnell, 1996](#); [Jan et al., 1994](#)), although further studies are needed.

*Rett's syndrome*, an autisticlike neurologic disorder appearing primarily in girls, is also characterized by changes in normal sleep patterns ([Glaze et al., 1987](#)). REM sleep is decreased in percentage. Respiratory patterns are abnormal during waking hours, characterized by disorganized breathing and compensatory hyperpnea, but nocturnal respirations are usually normal.

#### ATTENTION DEFICIT HYPERACTIVITY DISORDER AND CONDUCT DISORDER

Clinical and parental reports on children with *attention deficit hyperactivity disorder* (ADHD) indicate that certain alterations in sleep patterns are associated with this common childhood psychiatric disorder ([Busby et al., 1981](#); [Day and Abmayr, 1998](#); [Kaplan et al., 1987](#); [Khan, 1982](#); [Stein 1999, 2000](#)). Difficulty in falling asleep and tiredness on awakening are the most common reported complaints ([Trommer, 1988](#)). However, objective studies fail to show consistently that children with ADHD have longer sleep latencies or decreased total sleep time ([Corkum et al., 1998](#)).

[Ramos-Platon et al. \(1990\)](#) report a large number of nocturnal awakenings and a high increase of slow-wave sleep percentage in ADD, and patients with ADD with hyperactivity and ADD without hyperactivity show distinct hypnographic correlates, findings indicating that they may be different clinical states. These findings support the hypothesis that ADHD is related to deficient control of the arousal level, either hypoarousal or hyperarousal, perhaps at the level of the reticular formation. Hyperarousal may occur in situations with new stimuli, and hypoarousal may occur in situations that require sustained attention ([Douglas, 1984](#)).

Studies of these children at home also suggest a significant increase in body movements during sleep ([Porrino et al., 1983](#)). Comparing children in psychiatric clinical settings with those in nonpsychiatric nonclinical settings, [Simonds and Parraga \(1984\)](#) found that children with ADHD have significantly more snoring, head banging, restless sleep, and nighttime awakening problems. [Palm et al. \(1992\)](#) found three children with ADHD in a series of 10 to have short daytime sleep latencies suggestive of daytime hypersomnolence. [Ring et al. \(1998\)](#) compared medicated children with ADHD with their siblings using a sleep questionnaire and found initial and middle insomnia reported in those with ADHD. [Corkum et al. \(1998, 1999\)](#), also using sleep questionnaires, described dyssomnias, parasomnias, and involuntary movements in children with ADHD. Only involuntary movements seemed directly related to ADHD, combined type. Looking at the reverse situation in one small study, [Picchetti et al. \(1998\)](#) found two-thirds of the children with ADHD studied to have periodic limb movement disorder. More recently, [Chervin and Archbold \(2001\)](#) reported a significant association between periodic leg movements and hyperactivity in 113 children evaluated for sleep-disordered breathing.

Based on their review of the literature on sleep problems in children with ADHD, various investigators ([Barkley et al., 1990](#); [Busby and Pivik, 1985](#); [Dahl and Puig-Antich, 1990](#); [Dahl et al., 1991](#); [Greenhill et al., 1983](#); [Hunt et al., 1985](#), and [Wilens et al., 1994](#)) concluded that difficulty in falling asleep and shorter sleep duration—often a stimulant-induced insomnia in these medicated children—constitutes a problem calling for additional treatment. Based on their clinical experience, these investigators advised the use of clonidine at bedtime in 4- to 7-year-old children with ADHD, at a dosage of 0.05 mg, titrated upward to as high as 0.4 mg, to improve sleep. Although not FDA approved for use in children, clonidine has been demonstrated to be effective as an alternative to stimulant medication in ADHD when insomnia is a problem ([Hunt et al., 1985](#); [Prince et al., 1996](#)).

In a comprehensive review of the literature, [Stein and Pao \(2000\)](#) conclude that children with ADHD who are not treated with medication do not commonly show disrupted sleep, and increased sleep latency with methylphenidate (Ritalin) is to be tolerated. These investigators also caution that sleep deprivation itself may replicate the symptoms of ADHD, a finding calling for further study.

*Conduct disorder*, which widely overlaps with ADHD because of the secondary behavioral effects of the chronic inability to focus attention and to control behaviors, has shown a similarity to ADHD in terms of increased slow-wave sleep EEG activity ([Coble et al., 1984](#)). This finding further substantiates the close relationship between the two disorders that is observed clinically.

#### DEVELOPMENTAL LEARNING DISORDER

In a controlled study of sleep patterns of 24 8- to 10-year-old boys with developmental reading disorder ([Mercier et al., 1993](#)), findings included significantly more stage 4 sleep, less REM sleep, a longer REM onset latency, and an extended initial non-REM (NREM) cycle. Such factors could conceivably impair information processing and could contribute to the cognitive deficits seen in these children. In children with severe *learning disabilities*, severe sleep problems, and strong daytime challenging behaviors, Wiggs and Stores found that a behavioral program led to mothers' reporting improvement in their own as well as their children's sleep patterns and an increased sleep duration in the children ([Wiggs and Stores, 1998](#); [Wiggs and Stores, 1999](#)).

#### DEPRESSIVE DISORDER

Because sleep disturbance is one of the primary vegetative symptoms reported in *major depression*, it could be expected that depressed children may have abnormal sleep patterns. [Hawkins et al. \(1985\)](#) report extended sleep in depressed patients aged 17 to 25 years. Compared with age-matched control subjects, these depressed patients have almost double the length of extended sleep when they are allowed to sleep as long as they want.

A group of depressed children 9 to 14 years of age showed decreased REM latencies ([Emslie et al., 1987](#)), a finding that is in agreement with some previous data by [Lahmeyer et al. \(1983\)](#). However, [Puig-Antich \(1987\)](#) found the opposite and conclude that depressed children seem to differ from depressed adults because of developmental factors. This suggests that REM sleep disturbance may not be a reliable criterion for the diagnosis of depressive disorder in prepubertal children. However, further work by [Emslie et al. \(1990\)](#), who compared 25 hospitalized, depressed prepubertal children with 20 age-matched healthy controls, and by [Kutcher et al. \(1992\)](#), who compared 23 teenagers with major depression with matched controls, again showed reduced REM sleep latencies in both age groups. The depressed children and adolescents also had an increase in sleep latency and an increase in REM sleep, but without stage 4 differences.

Like 30% to 70% of depressed adults, experimentally sleep-deprived, depressed adolescents show a significant decrease in depression severity, with a persistence of 1 day after recovery sleep. These findings suggest a common pathophysiology in depressed adolescents and adults and a relationship between depression and sleep regulation ([Naylor et al., 1993](#)). [Dahl et al. \(1992\)](#) show a blunting of sleep growth hormone beginning with sleep onset in suicidal adolescents with major depressive disorder. This finding is in contrast to adolescents with major depressive disorder who are nonsuicidal and to prepubertal subjects with major depressive disorder, who show an increase in sleep growth hormone. This finding, in addition to other sleep-onset changes, may be a combined result of depression and developmental changes in adolescence and is comparable to the blunting of growth hormone stimulated by sleep in recurrently depressed adults. The possible significance of this finding is that major depressive disorder occurring in adolescence may be related to sleep dysregulation and age-related hormonal changes, combined. [Kallepalli et al. \(1997\)](#) compared the relief of insomnia in 20 inpatient adolescents (aged 13 to 17 years) with depression by using the antidepressant medications trazodone and fluoxetine. Both drugs resolved insomnia by 11 days; the median resolution was twice as fast with trazodone (2.5 versus 5.1 days).

#### BIPOLAR DISORDER

Although the symptoms of young children who are not yet adolescents with *bipolar disorder* may be atypical compared with those of adolescents or adults, sleep disturbances are frequently associated with the disorder in children. As in adults or adolescents, decreased sleep duration or early wake-onset time may predict manic or hypomanic behavior the next day ([Leibenluft et al., 1996](#); [Reite, 1998](#)). Clinically, as with bipolar adults, once patients are taking a mood stabilizer, an atypical neuroleptic agent may be used to assist sleep onset in children with bipolar disorder.

#### GENERALIZED ANXIETY DISORDER AND POSTTRAUMATIC STRESS DISORDER

The sleep disturbances in *generalized anxiety disorder* (formerly overanxious disorder) and *posttraumatic stress disorder* may be fairly specific ([van der Kolk, 1987](#)). They are often characterized by nightmares relating to specific traumatic events or experiences, that is, traumatic, physically injuring episodes, such as falling off

one's bicycle or being in an automobile accident. Depending on their intensity, such traumatic events may result in recurrent nightmares depicting the episode. In addition, patients may have difficulty in getting to sleep as a result of these same psychological factors. Significant sleep disruption in children may also follow involvement in a major disaster ([Benedek, 1985](#); [Dollinger, 1986](#)).

Some evidence has been reported in the stress literature that corticosteroid receptors are increased in the hippocampal area of the brain subsequent to traumatic stress in experimental animals ([van der Kolk, 1987](#)). The hippocampal area has often been associated with dream activity. However, there are no sleep laboratory studies confirming such findings in children.

Treatment considerations suggest that a combination of psychotherapy, behavioral therapy, and anxiety-reducing medications, such as benzodiazepines, is useful in preventing or alleviating this condition. This approach appears more helpful if treatment is administered at the time of the traumatic event or shortly thereafter ([Dollinger, 1986](#)).

#### PSYCHOTIC DISORDER

Clinically, children and adolescents with *psychotic disorders* may complain of sleep disturbance secondary to nocturnal hallucinations. [Krishnamoorthy and King \(1998\)](#) report a small study including children with psychosis not otherwise specified and schizophrenia whose sleep was improved when they used the atypical neuroleptic agent olanzapine for their psychosis.

#### PERSONALITY DISORDER

Although not described as a specific symptom associated with *personality disorder*, sleep disturbances may be reported by these patients. [Dagan et al. \(1998\)](#) reported that 10 of 63 hospitalized adolescents with personality disorders suffered from delayed sleep phase syndrome (DSPS). These investigators hypothesize that the morning sleepiness associated with this disorder may contribute to the development of Axis II disorders.

#### NEUROLOGIC DISORDERS AND MENTAL RETARDATION

Pediatric neurologists commonly treat children with specific *neurologic disorders* who also have signs and symptoms of sleep disturbance ([Scher, 1998](#)). These disorders include epilepsy, benign neonatal myoclonus, infantile spasms, static encephalopathies, cerebral palsy, familial dysautonomia, muscular dystrophy, and structural lesions such as myelodysplasia.

Patients with Tourette's disorder have very disturbed sleep patterns ([Glaze et al., 1983](#); [Hashimoto et al., 1981](#); [Mendelson et al., 1980](#); [Scher, 1998](#)). One study found an increased percentage of stages 3 and 4 sleep, a decreased percentage of REM sleep, and an increased number of awakenings during a nocturnal session ([Glaze et al., 1983](#)). Sudden, intense arousal was also seen in stage 4 sleep, including combativeness. In addition, Tourette's disorder is frequently associated with other sleep disorders, including enuresis and sleepwalking. [Sverd and Montero \(1993\)](#) reported the presence of obstructive sleep apnea and sudden infant death syndrome in the pedigrees of families with Tourette's disorder. Dopaminergic mechanisms are cited in the pathogenesis of this illness ([Glaze et al., 1983](#)). Treatment with a dopamine-blocking agent, such as haloperidol or pimozide, results in some improvement in the sleep patterns of these patients.

Sleep disturbances are also commonly reported in *brain-injured and mentally retarded children* ([Lancioni et al., 1999](#)). *Circadian rhythm sleep disorder* (formerly sleep-wake schedule disorder), in which a person's circadian sleep-wake pattern varies significantly from the sleep-wake schedule of the person's environment, has been reported to follow a closed head injury, a finding suggesting that the insomnia that follows head injuries may represent such a disorder ([Patten and Lauderdale, 1992](#)). Irregular sleep-wake rhythms appear in patients with Down's syndrome ([Levanon et al., 1999](#)) and severe mental retardation, as well as in autistic behavior with retardation and Rett's syndrome ([Okawa and Sasaki, 1987](#); [Segawa, 1982](#)). *Prader-Willi syndrome*, characterized by hypotonia, mental retardation, obesity, hypogonadism, and hyperphagia, also includes excessive daytime somnolence and sleep-onset REM periods, disturbances that are mostly independent of obstructive sleep apnea or obesity ([Okawa and Sasaki, 1987](#); [Vela-Bueno et al., 1984](#); [Vgontzas et al., 1995](#); [Vgontzas et al., 1996a](#); [Vgontzas et al., 1996b](#)). Other disorders of retardation also show sleep changes, findings indicating that malfunctions in sleep patterns may be characteristic of brain dysfunction in general.

In a review article on sleep studies in mentally handicapped children, [Stores \(1992\)](#) reports sleep spindle abnormalities in stage 2 NREM sleep and increases in stage 4 NREM sleep. In children with tuberous sclerosis and mental handicap, more than 90% had sleep disturbances, even more so when seizures were present. Melatonin has been reported to improve sleep in this disorder ([O'Callaghan et al., 1999](#)).

In *epilepsy*, severe sleep problems are also seen ([Beran et al., 1999](#); [Quine, 1991](#)), with marked shifting of sleep stages, apart from nocturnal seizures or medication effects ([Quine, 1991](#)). In a study of 200 children with severe mental handicap, 33% who had sleep problems had epilepsy, whereas only 13% of those without these problems had epilepsy. Quine believes that this finding strongly suggests a neurologic component in sleep disorders and is indicative of the wide prevalence of sleep problems in epilepsy.

#### General Medical Disorders and Substance Abuse

Many *general medical disorders* may produce either temporary or more prolonged disruption of normal sleep patterns in children. An example of the latter is found in pediatric HIV infection ([Franck et al., 1999](#)), in which children studied had significantly more postsleep-onset wake time, more frequent awakenings, and daytime naps and tiredness. In chronic fatigue syndrome, adolescents also were found to have more frequent and longer than normal awakenings ([Stores, 1997](#); [Stores et al., 1998](#)).

Adolescents using alcohol, tobacco, and coffee showed a significant relationship between sleep habits, *substance use*, and perceived daytime tiredness ([Tynjala, 1997](#)). Illegal substance use affects sleep patterns, depending on the specific substance, from the insomnia of cocaine and amphetamine abuse to the hypersomnolence of the opiates.

#### GENERAL RESEARCH DIRECTIONS

Despite the tremendous expansion of our knowledge in adult sleep disorders, our understanding of sleep disorders in children is in its infancy. Current data are limited or inconsistent. Sleep research in children should include studies on the epidemiology, etiology, and treatment of primary sleep disorders in children and on sleep problems accompanying specific psychiatric disorders and mental retardation syndromes. Data-based comparisons of behavioral therapies such as bedtime fading and response extinction, chronotherapy, and psychopharmacologic treatment interventions are sorely needed. These data would permit generalizations about specific characteristics and effective treatments of sleep disorders of children. In addition, in these studies, the various stages of the metabolic development of children's brains should be accounted for because changes in brain function, relative to the maturation of neurotransmitter systems occurring during childhood, may influence the nature of sleep dysfunction associated with psychiatric disorders ([Puig-Antich, 1986](#)).

In the 1990s, there was a dramatic increase in the use of multiple psychopharmacologic agents in children ([Campbell and Cueva, 1995a](#) and [b](#)) which continues in the present. Controlled, primarily polysomnographic studies to measure their effects on child sleep patterns, and changes in daytime behavior, will improve our knowledge of the usefulness of medication in the treatment of sleep disorders in children.

Finally, technical improvements in sleep laboratory and home-based polysomnographic assessment of children, including telemetry and computerized methods, will also enhance the ability of clinical investigators to gather the data necessary to understand these disorders in children better. As a result of these changes, clinicians will be able to determine more accurately the diagnostic criteria most appropriate for children with sleep disorders and the most effective treatments for these disorders.

### HISTORICAL NOTE

Early definitions of “borderline” features were largely drawn from inferences based on psychoanalytic theory and psychodynamic descriptions ( [Bemporad et al., 1982](#); [Ekstein and Wallerstein, 1956](#); [Frijling–Schreuder, 1969](#); [Kernberg, 1975](#); [Pine, 1974, 1983](#); [Robson, 1983](#)). From the side of early theory and clinical observations at that time, some clinicians postulated a condition in which functioning impairment was less severe than that observed in childhood psychosis but more severe than in neurosis, as though there were a continuum from neurosis to psychosis with borderline somewhere in between ( [Mahler, 1971](#)). [Ekstein and Wallerstein \(1956\)](#), for example, suggested that in this borderline state constant fluctuation occurred between neurotic and psychotic modes of functioning.

In many respects, these early descriptions influenced the description of *borderline personality disorder* in adults ([Kernberg, 1975](#)). Among adults, the term *borderline* also has a similarly complicated history, with the observation of borderline functioning on projective testing, of intense transference–countertransference reactions, and a tendency for patients to regress markedly when faced with perceived abandonment. There was also a putative possible relationship with schizophrenia.

This earlier emphasis on theoretical speculation was not tested with empirical studies, and this continues to be limiting in this area. Meanwhile, the utility of a continuum concept of schizophrenia in children was subsequently questioned as the validity of well-defined conditions such as autism came to be established ([Volkmar, 1996](#)). Petti and Vela, in their 1990 review of the existing extensive child literature in this area, dryly note that “the amount of space required to present a topic area is inversely proportional to the degree of scientific certainty associated with it” and conclude more seriously that “there appear to be a number of borderline disorders with different etiologies, phenomenology, associated features, and required treatments” ( [Petti and Vela, 1990](#)).

Although the condition is firmly recognized in adults, many questions regarding the validity of borderline conditions in childhood remain to be addressed. Indeed, some investigators propose an alternative concept of multiple complex developmental disorder (MCDD) and eschew the term *borderline* altogether ( [Towbin et al., 1993](#)).

### DEFINITION

A *personality trait* may be defined as an enduring pattern of perceiving, relating to, and thinking about one's environment and oneself ( [Lewis and Volkmar, 1990](#)). This is a dimensional concept, which in its extreme form may be recognized as pathologic, although not necessarily fulfilling the criteria for a disorder. A personality trait becomes a *personality disorder* (i.e., a disease) when the trait not only is severe, but also becomes inflexible and maladaptive and causes either distress or impairment in social or occupational functions. Although it was once fashionable to question the validity and stability of personality traits over the course of development, several studies have suggested that some such continuities do exist; for example, uncontrolled 3-year-old children tend, as adults, to be more impulsive and antisocial, whereas inhibited ones tend to become depressed ( [Caspi, 2000](#)).

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) ([American Psychiatric Association 1994](#)) codes adult personality disorders on Axis II. Clinically, personality disorders in adults appear to be divided among three broad clusters ( [Table 72.1](#)).

Cluster A	Cluster B	Cluster C
Paranoid	Antisocial	Avoidant
Schizoid	Borderline	Dependent
Schizotypal	Histrionic	Obsessive-compulsive
	Narcissistic	Not otherwise specified

Adapted from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (DSM-IV) Washington, DC, American Psychiatric Association, 1994, with permission.

**Table 72.1. DSM-IV Clusters of Adult Personality Disorders**

There is no single or specific description of borderline disorders in children or adolescents. However, children and adolescents less than 18 years of age who seem persistently, and over a long time, to have the essential characteristic features, modified by developmental factors, of any of the personality disorders described for adults may be diagnosed in the same way as adults.

In contrast to the DSM-IV, the tenth edition of the *International Classification of Diseases* (ICD-10) ([World Health Organization, 1992](#)) classifies abnormalities of personality in adults into personality disorders, personality trait accentuation, and enduring personality change, and it also has a separate category for organic personality disorder, but it does not include schizotypal, borderline, or narcissistic personality disorder under personality disorders. Under the heading “Disorders of Adult Personality,” the ICD-10 does include a description of borderline personality disorder (F60.31) as a subcategory of emotionally unstable personality disorder ([World Health Organization, 1992](#)). Among the particular additional characteristics noted are the presence of a disturbance of self-image, aims, and internal preferences (including sexual) and chronic feelings of emptiness. “Intense and unstable relationships may cause repeated emotional crises and may be associated with excessive efforts to avoid abandonment and a series of suicidal threats or acts of self harm” ( [World Health Organization, 1992](#)).

### CHILD CLASSIFICATIONS

The diagnosis of personality disorders, including borderline personality disorder, in children has been in doubt in part because it appears to be based on the assumption that whereas personality disorders may be appropriately diagnosed in adulthood when the constellation of traits subsumed under the term “personality” are presumed to be relatively stable, similar stability has not been documented in children. However, as noted earlier, a body of work does suggest the stability of

some personality traits in children (Caspi, 2000), although empirical data supporting the stability of personality disorders are still lacking.

In one study, Guzder et al. (1999), in a chart review of 98 latency-age children in day treatment, find that those who had “borderline pathology” are significantly more likely to have histories of sexual abuse, severe neglect, and parental substance abuse or criminality. These investigators also note that these findings parallel findings of studies in adults with borderline personality disorder; that is, these adults similarly report high frequencies of childhood sexual abuse, physical abuse, and neglect (Paris, 1994). Guzder et al. also hypothesize a continuity between children with borderline pathology and adults with personality disorders, this time on the basis of similarities in risk factors that may indicate a common origin and may therefore give some support to the concept of continuity between children and adults. Similarly, in a study using a family study method, Johnson et al. (1995) find adolescents with a borderline personality disorder and further find that these adolescents have first-degree adult relatives with increased prevalence of borderline personality disorders.

Follow-back studies of adults with borderline personality disorder are complicated in that childhood precursors of the condition may include a range of difficulties, such as problems in modulation of affect, attention, or excessive shyness and insecurity. Again, the evidence regarding the existence of a similar borderline personality disorder in childhood is not a simple matter because children with such problems may exhibit many different outcomes, including depression and schizophrenia.

The DSM-IV definition of *borderline personality disorder* (Table 72.2) does presume to be applicable at least to adolescents, by citing as an example dropping out of school just before graduation (as an expression of undermining oneself) (American Psychiatric Association, 1994). One method by which the DSM-IV criteria for borderline personality, at least in adults and adolescents, may be measured is the *Personality Disorder Examination (PDE) Manual* (Loranger et al., 1988).

---

A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment. Note: Do not include suicidal or self-mutilating behavior covered in criterion 5.
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.
3. Identity disturbance: markedly and persistently unstable self-image or sense of self.
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating). Note: Do not include suicidal or self-mutilating behavior covered in criterion 5.
5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior.
6. Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days).
7. Chronic feelings of emptiness.
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights).
9. Transient, stress-related paranoid ideation or severe dissociative symptoms.

**Table 72.2. DSM-IV Diagnostic Criteria for Borderline Personality Disorder**

## PREVALENCE

Borderline personality disorder in adults is said to be diagnosed predominantly (about 75%) in women (American Psychiatric Association, 1994). Again, there is no specific mention of children. Given the uncertain validity of the concepts and the poorly established diagnostic criteria and outcomes, true prevalence figures are not available for children. Among adults, borderline personality disorders are estimated at 2% of the general population and constitute 30% to 60% of all personality disorders.

## CLINICAL FEATURES

Clinically, several features commonly seen in children (Table 72.3) have been suggested to constitute the diagnosis of borderline personality disorder. There may be rapid, unpredictable (so-called “predictably unpredictable”) regression in thinking, reality testing, and affective control. Extreme vulnerability to stress may lead to sudden suicidal or homicidal behavior or to psychotic manifestations, including hallucinations. Such children may reintegrate quickly once the stress stops, for example, when they are placed in a safe, structured, stress-free environment, such as a hospital. The child may be chronically regressed. Severe regression on separation from the parent (who often also has a borderline personality condition) and reintegration when reunited with the parent may occur, as though the child can function only within the symbiotic relationship with the parent. In theory, there seems to be a failure of individuation and of object constancy. A generalized restriction in the development in relationships, affective range, cognitive functions, and language may occur. Retreat into a preoccupation with fantasy and emotional withdrawal from relationships may occur, leading to a schizoidlike clinical picture. The child may be flooded and overwhelmed with rage and violent fantasies that threaten the child’s self-control and produce extreme anxiety. Symptoms such as rage, temper outbursts, violent fantasies, regression, and impulsivity may all occur, sometimes mimicking aspects of attention deficit hyperactivity disorder (ADHD) or anxiety disorders with depression (Table 72.4).

---

Rapid regression in thinking, reality testing, and affective control  
 Extreme vulnerability to stress, with psychotic decompensation  
 Chronically regressed state  
 Severe separation anxiety and regression  
 Generalized restricted development (e.g., in relationships, affect, cognition, and language)  
 Schizoid retreat into preoccupation with fantasy life and withdrawal from relationships  
 Overwhelming rage and violent fantasies with extreme anxiety and loss of control

**Table 72.4. Comorbid Disorders (Symptom Clusters) in Borderline Conditions in Childhood**

## COMORBIDITY

Such associated symptom clusters may be conceptualized as *comorbidity*, or the total clinical picture may be characteristic of borderline personality disorder in children, comparable perhaps to the way in which the term *conduct disorder* is sometimes used as an all-inclusive term that covers a wide range of behaviors that may otherwise be viewed as other associated conditions.

The issue of comorbidity is complex (Chapter 39), given the sometimes very different approaches used in the DSM-IV and ICD-10. As it happens, few conditions in child and adolescent psychiatry are mutually exclusive (in the way that, say, autism and Down's syndrome do not commonly coexist in the same child). On the contrary, children diagnosed with borderline personality disorder may well have such associated DSM-IV diagnoses as ADHD, anxiety disorder, major depressive disorder, and posttraumatic stress disorder. In any event, these other conditions present a need for a careful differential diagnosis.

Hypotheses to account for these coexistent diagnoses include the following:

1. The child with a borderline personality disorder may be particularly vulnerable to the other diagnoses listed earlier.
2. The borderline condition may itself be an atypical variant of one or more of these other disorders.
3. A more fundamental disorder may be the basic factor common to all the concomitant diagnoses.
4. True comorbidity, that is, the concomitance of one or more of the conditions by chance alone, may account for the multiple diagnoses.
5. The appearance of comorbidity or coexistence may be an artifact of our classification systems (DSM-IV and ICD-10), which are currently based largely on symptom lists and not on mechanisms, etiology, or natural history of the alleged disorder.
6. The reported apparent coexistence in some instances may result from flawed research design or other factors and may ultimately not be significant.

Whatever the explanation, clinicians report that they are not surprised to find that a child or adolescent with a borderline personality disorder has a history of having been labeled with several other diagnoses over the course of the illness.

In general, the behavior of a child or adolescent with a presumed borderline personality disorder is characterized by unpredictable moods and a pervasive, fluctuating, and unstable level of organization in multiple functions in such major areas as impulse control, affect modulation, attention, cognition, and relationships. Relationships are immature, often at a need-fulfilling stage, with a great deal of ambivalence and dependency and a minimal capacity for empathy. The child may have paranoid rages and may regress to the point of uncontrolled temper tantrums and loss of reality testing. A fluctuating thought disorder is often present, accompanied by a disorder of mood (especially depression), of behavior (which may be disorganized, aggressive, withdrawn, or bizarre), or of perception (with delusions and hallucinations). The anxiety level in these children is often quite high and is poorly defended against, resulting in an interference with relationships and thinking. Compensatory omnipotent fantasies are often quite prominent. Unfortunately, the striking lack of empathy in the child may lead to repetitious reinforcement of failure and rejection in almost every social interaction in which the child is involved and a consequent increase in the child's depression, despair, and anxiety.

## COURSE AND PROGNOSIS

Regrettably, most outcome studies use variable definitions and are poorly controlled. In essence, there are still no satisfactory systematic studies on the course of children diagnosed as having a borderline personality disorder (Petti and Vela, 1990). Several clinically interesting treatment and follow-up case studies have been reported (Kestenbaum, 1983; Petti and Unis, 1981).

## ETIOLOGY AND PATHOGENESIS

As has been true for borderline personality disorder in adults, various potential etiologic mechanisms have been identified. Given the early interest in psychodynamic theory and treatment of these conditions, many theories invoke various experiential factors. However, a growing body of work suggests the potential importance of biological vulnerability, which may, itself, shape the course of development and personality. For example, Weiss and colleagues (1996) report that children of mothers with borderline personality disorders are themselves at significantly increased risk of various forms of psychopathology. One could postulate that vulnerabilities in impulse control or processing experience may negatively affect social interactions, and this, in turn, may adversely influence the development of self-concept and affective development (Marohn, 1990). Another possibility is that not only does the child have multiple comorbidities (however defined), but also the comorbidities themselves may have multiple causes. Such causal pathways may include those shown in Table 72.5. Thus, a working model for understanding the pathogenesis of this disorder (or perhaps cluster of disorders) may be a complex interactive model involving polygenic, organic, cognitive, intrapsychic and interpersonal, and socioenvironmental factors.

---

Genetic loading (Andriuloni, 1990)
Organic factors (Bemporad et al., 1982)
Disturbances in the development of relationships (Pine, 1982)
Serious disturbances in family functions and systems (Combrink-Graham, 1988)
Major parental psychopathology and major external stresses, especially abuse (Pine, 1988)

---

**Table 72.5. Causal Pathways in Borderline Personality Disorder**

### Biological Factors

Personality styles (or temperament) in general are derived in part from genetic factors (Torgesen and Kringlen, 1978). In addition, several disorders embedded in or comorbid with borderline personality disorder have been shown to have some genetic components. Such disorders may include antisocial personality disorder (Schulsinger, 1972) and ADHD (Cantwell, 1976; Zametkin and Rapoport, 1987). The heritability of certain aspects of personality and of certain major psychopathologic disorders may be in the range of 30% (Plomin, 1990).

There is no established pathognomonic organic finding in children who have a borderline condition. However, several reports support the presence of some form of organicity (Aarkrog, 1981; Bemporad, 1982), and one report suggests a disturbance of the enzyme dopamine b-hydroxylase (Rogeness et al., 1984, 1986). More research is required to confirm these reports.

### Psychological Trauma and Environmental Factors

The psychoanalytic theories of Kernberg (1975) and Kohut (1971) regarding borderline disorder are essentially " sleeper " theories. They imply a delayed effect of early psychological trauma during the separation-individuation phase, because the effects are not readily apparent at the time of the trauma but appear later, as a result, it is hypothesized, of an induced or heightened vulnerability to subsequent stresses. In adults with borderline personality disorders, various studies, mostly relying on retrospection, suggest that difficulties in early parent-child relationships (e.g., as a result of psychological problems in the parents, separation from the parents, or loss of the parent) and sexual and physical abuse are strongly related to the disorder (Kernberg, 1975). Although data in children are quite limited, one study (Bradley, 1979) notes that children and adolescents with borderline personality are significantly more likely to have experienced early separation from the mother.

The generally retrospective nature of these data limit their validity. Such experiences undoubtedly are major risk factors for difficulties, and the specific issue of why one person goes on to develop a presumed borderline personality while another does not remains to be addressed, although, of course, it is possible that some

interaction of experiential and biological factors may occur at just this point.

## DIFFERENTIAL DIAGNOSIS

The hypothesis of multiple comorbidities mentioned earlier often translates clinically into a difficult differential diagnosis ( [Table 72.6](#)). Many of the children labeled borderline may also have symptoms of ADHD, major depressive disorder, conduct disorder, somatoform disorder, dissociative disorder, posttraumatic stress disorder, cyclothymic disorder, schizophrenia, anxiety disorders, and partial complex seizure-type disorders.

---

Attention deficit hyperactivity disorder  
Major depressive disorder  
Conduct disorder  
Somatization disorder  
Schizophrenia  
Partial complex seizures  
Posttraumatic stress disorder

---

**Table 72.6. Differential Diagnosis in Borderline Conditions in Children**

In some instances, a child who presents with the clinical picture labeled borderline personality disorder (an Axis II diagnosis) may be suffering from a peculiar form of dissociative disorder, specifically dissociative identity disorder (an Axis I diagnosis, not commonly diagnosed in children). Both disorders appear to have a similar origin, including severe sexual abuse during childhood. In addition, the symptoms of the two conditions are often similar, including some form of thought disorder, and the course is often chronic and difficult, with suicide attempts not infrequent.

The diagnostic distinction between borderline personality disorder and dissociative identity disorder is important because the treatments are different. In particular, in the treatment of children with dissociative phenomena, including dissociative identity disorder ( [Chapter 70](#)), an effort must be made to help the child to become conscious of dissociative defenses, such as splitting and regression, which appear to take place as a way of dealing with the terror of the sexual abuse, and the of consequent seemingly inexplicable episodes of rage and violence that sometimes occur and that the child does not appear to remember.

A history of trauma, often sexual abuse, is relatively common in patients with borderline personality disorder, particularly if the sexual abuse is recurrent. It is clear that severe stress can produce phenomena suggestive of psychosis, such as hallucinations, in some persons ( [Spivak et al., 1989](#)). In addition, hallucinatory phenomena can be part of the intrusive “flashback” experienced in posttraumatic stress disorder. Usually, such hallucinations capture some aspect of the traumatic event; they may be accompanied by feelings of depersonalization or anxiety ( [Mueser and Butler, 1987](#); [Waldfoegel and Mueser, 1988](#)).

The overinclusiveness of the diagnosis can be problematic. Thus, its use may carry two burdens. First, once the label is given, no further diagnostic studies may be done, and a basis for treatment planning may accordingly be lost. Second, the treatment may be half-hearted because the prognosis of such a personality disorder is generally thought to be guarded at best.

Because eventual adult outcomes are unclear ( [Rutter, 1988](#)), outcome for children with borderline personality disorder may similarly be unclear and may eventually turn out to represent an intermediate cluster of behaviors in the development of a child in whom multiple causes and possible multiple comorbidities are present. For this reason, one should not easily settle for the diagnosis of borderline personality disorder in children. Perhaps the concept of a “multiple complex developmental disorder” ( [Towbin et al., 1993](#)), together with a carefully documented dimensional account, may eventually have more appeal.

## TREATMENT

The recognition of symptom clusters of other treatable conditions, including bipolar illness, ADHD, or complex partial seizure disorder, is very important because specific targeted treatment, including psychopharmacotherapy, for these better-defined conditions may then be offered. Unfortunately, well-controlled treatment response studies for the basic borderline personality disorder are not available at present. In one study ( [Bentivegna et al., 1985](#)), only half the treated children improved, and in those who did improve, residential treatment was often requested, and the treatment was long term. In any event, the fluctuating range of etiologic factors and of clinical features, along with the paucity of well-designed natural history and treatment outcome studies, leads to the present need to use multimodal treatment approaches ( [Table 72.7](#)).

---

Individual therapy  
Parental therapy  
Family therapy  
Behavioral therapy  
Pharmacotherapy  
Residential treatment  
Day (partial) hospitalization  
Hospital treatment  
Milieu therapy

---

**Table 72.7. Multimodal Treatments of Borderline Personality Disorder**

Such treatments may include family therapy, individual therapy, parent therapy, pharmacotherapy, hospital and milieu therapy (residential treatment, day treatment, or both), and behavioral therapy. At present, data are insufficient to rely solely on any one of these approaches; all may be necessary when clinically indicated. Controlled follow-up studies are not currently available.

One major consideration in the intensive psychotherapy of children presumed to have a borderline personality disorder, especially those children who are in the context of residential treatment, is the development of *reality testing*. Reality testing helps the child to recognize and understand his or her reactions to various events within current life experiences, such as disappointments when parents fail to show up, provocations from peers, and imposition of controls by staff. Precipitating events, fantasies, and warded-off affects are defined for the child. In this way, the child’s regressive behavior is made more understandable not only to the child, but also to the therapist, the staff, and the parents.

Reality testing often requires the close day-to-day contact of residential treatment to understand the meaning of the child’s behavior. Reality testing clarifies not only what is real and what is fantasy, but also which thoughts, fantasies, and ideas belong to the child and which belong to the therapist, parent, or child care staff member. Further, when the child demonstrates an essentially correct perception of his or her parents, this should be confirmed for the child.

Because of the instability of object representation, especially when the other person is not present, psychodynamic interpretation of preconscious or unconscious

affects, fears, or wishes is often limited in its effectiveness, at least during the early phases of treatment. In some instances, it seems as though the child can barely hold onto the concepts being conveyed in the verbal interpretation and only for the time it takes to say them; once the verbal interpretation is completed, the child seems to lose touch with the words and is at the mercy of other demands, usually primitive inner demands. Because interpretation is sometimes limited in its effectiveness in this way, "working through" is also difficult in these children (see [Chapter 79](#)).

The phenomenon of *delayed object constancy* may provide a key to an important therapeutic agent, perhaps even a key agent: the need for the reliable presence of a stable person in the child's life. Thus, the single most important component of the treatment of these children may be the availability of a consistent, stable relationship. This finding reflects in part a metapsychological view of the development of these children, in which early instinctual needs are still experienced, unstable early defenses (such as projection and identification) and impaired reality testing prevail, and primary process is clinically evident. The child manages to make the therapist feel a regressive pull toward similar chaotic and archaic levels of functioning. Whether the child does this intentionally as part of the child's desire to project his or her own feelings of impotence onto the therapist, thus leaving the child to feel temporarily more omnipotent and the therapist to feel acute discomfort, or whether the effect on the therapist is simply a product of being in the presence of such a child, is not always clear. However, the therapist can use the reaction evoked to gain some understanding of what the child may be experiencing.

Essentially, the therapist conveys to the child, mostly through the *metaphor of play*, his or her understanding of what the child appears to be experiencing, consciously or preconsciously, in the here and now. Boundaries are defined: What is fantasy? What is actuality? The therapist then offers an explanation to the child that is simple and convincing, again, most often through the metaphor of play. The purpose of using the metaphor of play is to enable the child to maintain the buffer of distance and not be overwhelmed by anxiety.

At the same time, the therapist also begins to suggest other, more effective and realistic ways of obtaining gratification and dealing with staff or parents. This, too, is frequently done through play, but eventually it can be done in a straightforward, almost didactic way.

The therapist as well as the staff must maintain controls during the treatment, to limit regressive, sexualized, and aggressive behavior to manageable levels and to avoid the excessive guilt and anxiety that is so quickly mobilized in the child who feels that controls are slipping. Similarly, when the child begins to act out aggressive impulses toward the therapist, this, too, must first be controlled before it is explored and interpreted. The acting out may begin as "accidentally" throwing some of the therapist's desk belongings on the floor, then kicking them. This may escalate to breaking the various objects or throwing them out the window. It is essential to prevent this kind of escalation by imposing controls early. Because children who are regressed or regressing feel acutely uncomfortable, limits must be set and regression halted to prevent any further increase in anxiety. Separations, for example, may precipitate intense feelings of abandonment, accompanied by characteristic regressive behaviors, which, in turn, need supportive but firm controls.

The high level of anxiety is not the only complication in the treatment of these children. Depression is often present, too. The sense of despair, hopelessness, and helplessness and, at times, the frightening anger need to be acknowledged, clarified, and understood. Usually, this comes at a later stage in the treatment, when the child feels more secure in his or her relationship with the therapist, has a better defined sense of self, and is not in dread of being overwhelmed by inner feelings. Often a child who is ready to look at his or her depression is also ready to hear and comprehend a reconstruction that will help the child to make some sense and give some order and meaning to his or her state of feelings and turmoil.

In any case, it is almost always useful, whether or not in the context of exploring depression, to provide the child with a meaningful history of his or her life, a history that will help the child to understand why he or she had, or has, to feel and behave in certain ways. In some cases, it may be helpful to depict this pictorially, in a concrete way, with pictures and drawings, with the child participating in the drawing and labeling process.

Concomitant work with the parents is essential. Sometimes the parent is idealized by the child, even the parent who repeatedly fails the child. Sometimes the parent has an ambivalent, or unrealistic, expectation of the child. In some instances, the parent must be helped to enable the child to live in another setting when that is in the best interests of the child.

The child may present to the staff a distorted picture of the parent as part of the child's unconscious attempts to ward off anxiety through splitting and projection. Sometimes the child will use the therapist and other staff members as convenient scapegoats in expressing rage at a parent.

The regressive pull and the reactions evoked in the therapist who treats a borderline child are almost pathognomonic. Anxiety and defensiveness in the presence of a child who is almost incomprehensible or who is threatening to lose control constitute a common experience. Rescue fantasies, unrealistic goals, and despair may also occur. The therapist often needs emotional support during this work with the child.

The loose use of the term *borderline* attached to a child is misleading because it is used as an adjective or label, and not a diagnosis, for what are after all a varied collection of symptoms that together may suggest the existence of serious and multiple, pervasive, and unstable affective, behavioral, and cognitive regulatory dysfunctions, none of which may have been fully validated. Further, this clinical picture may be further qualified by specific dimensional descriptions of the prominent clinical features in a given child, features that may be used as a basis for formulating and monitoring a multimodal treatment plan for that child. Finally, adolescents who have unstable relationships, identity disturbances, chronic feelings of emptiness, inability to relate appropriately, and especially such behavioral elements as impulsivity, inappropriate anger, and almost frantic efforts to avoid abandonment, may need hospitalization ([Sarrislow et al., 2000](#)).

## DIRECTIONS FOR RESEARCH

The problem of the lack of definitive scientifically valid research must be addressed. Even the question of whether or not a personality disorder is a mental disorder is still unsettled ([Kendell, 2002](#)). In some ways, attempts at closure on the diagnosis of borderline personality disorder in children are premature. Before closure, careful longitudinal studies of the developmental pathways ("chain of operations") and individual symptoms or clusters of symptoms, family studies, and both short-term and long-term treatment outcome studies are needed. There are indications that current studies are moving in these directions. For example, [Ad-Dab'bagh and Greenfield \(2001\)](#) have performed an extensive review of several electronic databases in relation to the term "borderline" and subsequently proposed a process for arriving at a new nomenclature to be called "multiple complex developmental disorder" (MCDD) for children who have the symptoms currently being subsumed under the label "borderline." Perhaps such a change may occur in time for DSM-V.

---

### CASE ILLUSTRATION

Timmy, a 9-year-old child in residential treatment, generally did fairly well in the on-grounds school. One week, he became obsessed with fantasies about airplane crashes, boats being torpedoed, and people getting burned or drowned. At the same time, he began to smash toy cars and trucks and developed a sleep disorder. The treatment team finally discovered that a few days earlier he had overheard his parents discussing a vacation they were going to take, and he was very resentful that they were not taking him. He was almost panicked at the thought that his hostility toward them for that, and for other things, may somehow endanger them. The "unpacking" of these fantasies and the terror that they evoked were made possible by a process of interdisciplinary interstaff collaboration, whereby little bits of information were gathered from the school, child care staff, and therapists and pieced together at a combined staff conference.

Alcohol and drug abuse are of epidemic proportion in our adolescent population and is a major public health problem. Although most adolescents (85%) at least experiment with alcohol and drugs without serious consequences, substance abuse may have devastating effects on children and adolescents. Accidents, suicides, and homicides account for more than 80% of the deaths in the teenage years, and alcohol and drugs are involved in at least half of these tragedies ( [Soderstrom et al., 1993](#)). Substance abuse is a major or complicating factor in at least 40% of teenagers treated in day and residential state programs ( [Gruenbaum et al., 1991](#)) and in two-thirds of teenagers detained in juvenile delinquent facilities. Although the number of teens abusing illicit drugs and alcohol has declined slightly from 11.4% in 1997 to 9% in 1999, data from the Substance Abuse and Mental Health Services Administration (2000) indicate that those who are abusing substances are experiencing more drug-related problems. These data indicate that all mental health clinicians involved with teenagers need to be knowledgeable of the assessment and treatment of adolescent substance abuse.

Adolescent substance abuse qualitatively differs from adult substance abuse in certain important aspects. These include the following:

1. *Developmental level:* The biopsychosocial level of development must be considered. The early adolescents' diminished ability to delay gratification and to plan for the future and pubertal physical and drive intensity changes make normal early adolescents very different from late teens or young adults. Evaluation and treatment planning need to recognize these different physical, emotional, and cognitive immaturities.
2. *Use of multiple drugs:* Adolescents who progress to substance abuse or dependency disorder, as defined by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* ( [American Psychiatric Association, 1994](#)), tend to use multiple drugs. Drug-abusing adolescents move from cigarettes and beer or wine to other forms of alcohol and then to marijuana. If the abuse progresses, this stage is followed in sequence by problem drinking, use of downers or uppers, crystal methamphetamine, cocaine, and heroin. Adolescents frequently continue to use the drugs they previously used in the sequence. Adolescents usually have a drug of choice but also intermittently abuse those drugs used earlier.
3. *Use of inhalants:* Inhalant abuse, which includes inhalation of gasoline, glue, freon, and butane, has a peak incidence in preadolescence and early adolescence and is almost nonexistent in adult populations.
4. *Use of "club" drugs:* The club drugs became increasingly popular in the 1990s and are primarily used by older adolescents and young adults. These drugs include ecstasy (methylenedioxymethamphetamine or MDMA), g-hydroxybutyrate (GHB), and ketamine ("special K"). These drugs are rarely used by older adults.
5. *Presence of comorbid disorders:* Comorbid disorders, such as attention deficit hyperactivity disorder (ADHD), conduct disorder, affective disorders, and anxiety disorders, exist in 40% to 90% of adolescents with a substance abuse or dependency disorder ( [Jaffe, 1996](#)). Some studies show that comorbidity is more common in adolescents than in adults ( [Kandel et al., 1999](#)). Comorbid depressive disorders in adolescents with substance use disorder (SUD) tend not to resolve after a few weeks of abstinence, whereas in adults, the comorbid depressive disorders usually resolve ( [Bukstein et al., 1992](#); [DiMileo, 1989](#)).

In the following sections of this chapter, the epidemiology, risk factors, clinical issues of drugs of abuse, assessment, treatment, comorbid conditions, and prevention of child and adolescent alcohol and drug abuse are addressed.

## EPIDEMIOLOGY

From 1996 to 2001, illicit drug use reached levels not seen since the previous usage peaks in the late 1970s and early 1980s. Recent drug use has not yet climbed to the heights of the 1970s and 1980s, when marijuana was used by one of two high school seniors in 1979 as compared with one in four in 1996. Still illicit drug use "within the last month" among 12- to 17-year-olds doubled from 1992 to 0.9% in 1995.

Inhalants were the fourth most commonly used drug among students of high school age. Inhalant use was almost twice as high among eighth graders (6% cited use during the last month) than among 10th or 12th graders (3% cited use in the last month). Twenty-one percent of eighth graders had tried inhalants at least once, likely because of the availability of these drugs ( [National Institute on Drug Abuse, 1996](#)). The highest annual use rate of inhalants was reached in 1993 at 7%, among high school seniors. This represents the highest rate seen since 1975, when usage rates climbed to 7.2%.

Usage of lysergic acid diethylamide (LSD) and phencyclidine (PCP) approached its late 1970s and early 1980s peak in 1996. LSD use among high school seniors

increased from a low of 8.3% in 1989 to 12.6%, and hallucinogen use rose to 14% for lifetime prevalence. Use of marijuana, the most common illicit drug used among youth, has continued to expand since 1992. Lifetime annual and current use of marijuana has doubled in eighth graders since 1992, with 11% reporting use in the last month and 5% reporting daily use. Although marijuana use has fallen among older teens (10.7% of high school seniors admitted using the drug in 1978 compared with 2.0% in 1991), it is troubling that younger teens are now experimenting with the drug. The statistics are particularly worrisome because research has shown that earlier use indicates a greater risk for later development of substance abuse and dependency.

In 1996, 66% of high school seniors reported lifetime use of any illicit drug, and more than 85% of all adolescents had tried alcohol and drugs by the time they finished high school (Johnston, 1996). Eighty-five percent of high school seniors surveyed that same year had some experience with alcohol, and 31% had drunk five or more drinks on at least one occasion during the past month. Two percent of high school seniors reported trying heroin. By 1996, heroin use had doubled its 1991 levels. Any reports of heroin use are significant because the potency of heroin on the streets in the 1990s is much greater than that available in the late 1970s and early 1980s.

Through 1999, use of some illicit substances decreased. A significant drop occurred in the use of crack cocaine among eighth and 10th graders. The use of crystal methamphetamine or "ice" declined to its lowest level in 5 years in 1999. A continuing decline in cigarette smoking among younger teens was also documented. Club drugs such as flunitrazepam (Rohypnol) began to be included in surveys in 1996. A small, significant decline occurred in 1999 among eighth graders to an annual prevalence rate of 0.5%. However, use of another popular club drug, MDMA (ecstasy), began to rise in older teens. In 1999, 4.4% of 10th graders reported use of MDMA during the prior 12 months, (up from 3.3% in 1998) and 5.6% of the 12th graders (up from 3.6% in 1998). No data have been collected on another club drug, GHB. Accidental deaths have been attributed to use of this drug.

Among younger teens, eighth and ninth graders, anabolic steroid use rose in 1999. Use by eighth graders rose from 1.6% in 1998 to 2.5% in 1999; for 10th graders, it rose from 1.9% to 2.8% during the same period (Johnston, 1996; Johnston, 1999; National Institute on Drug Abuse, 1996).

## RISK AND PROTECTIVE FACTORS

Clearly, many risk or protective factors lead to substance abuse or dependence. Field professionals have begun to recognize that these factors can be classified into three types: markers (known as surface indicators), modifiers (which either augment or modify), and mediators (or causal mechanisms) (Pandina, 1996).

Cicchetti and Rogosch (1999) divide markers further into two types: fixed (e.g., sex or premature birth) and variable (e.g., exposure to peer use). However, it is possible for some variable factors to become causal factors. For instance, if a variable factor is intervened on and the intervention changes what would have otherwise been a negative outcome, the variable factor will also become a causal risk factor (Cicchetti and Rogosch, 1999).

No one risk factor leads to substance abuse. In fact, the more risk factors someone has, the greater the risk is of developing the disorder. If changing a variable factor such as a parent's favorable attitude toward drinking, for example, did not prevent the child from using alcohol, then other risk factors may have influenced this outcome (e.g., the child has a conduct disorder). Different combinations of risk factors can lead to different potentials for negative outcomes, based on the strength and nature of the individual risk factors. Some protective factors, however, may cushion the effect of the risk factor and may modify the severity of or prevent a negative outcome. Investigators have begun to identify an interaction between risk and protective factors (Johnson et al., 1992; Newcomb, 1995).

The age at which a risk factor has its greatest influence is also important to consider. Newcomb's work has begun to enlighten some of us in the field about how specific risk factors have a greater influence at certain developmental stages than others. He divides risk factors into four domains: cultural and societal, interpersonal, psychobehavioral, and biogenetic (Table 73.1). According to Newcomb, cultural and societal elements seem to influence risk factors throughout all developmental stages.

**Table 73.1. Domains of Factors Associated with Drug Use**

Interpersonal risk factors clearly delineate those factors with the most influence during childhood and adolescence. Research examples of interpersonal risk factors expected to demonstrate the most influence during childhood include the following: the effects of parental modeling (Johnson and Leff, 1999; Kandel et al., 1978); parents' belief in the harmlessness of substances (Kandel et al., 1978); parental monitoring (Chilcoat and Anthony, 1996; Duncan et al., 1998; Molina et al., 1994); family abuse (Bennett and Kempfer, 1994); family disruption, negative communication patterns, and lack of anger control in families of substance abusers (Baumrind, 1983; Reilly, 1979); and lack of closeness and involvement with children's activities, maternal passivity, and low academic aspirations (Brook et al., 1980).

The impact of parental monitoring in initiating alcohol, tobacco, or other drug use has been found to have the greatest risk for children younger than 11 years old. A higher risk of initiating marijuana, cocaine, and inhalant drug use occurs in children who are seldom monitored during middle childhood (Chilcoat and Anthony, 1996). Not only may many of these risk factors increase the probability of initiating illicit substance use, but also combining multiple factors may influence continued use. For instance, modeling by smoking parents influences children in initiating smoking, but, when coupled with poor school adjustment, low levels of parental monitoring, easy access to cigarettes, and other risk factors, early initiators are more likely to continue smoking (Jackson et al., 1998). The effect of family abuse increases the risk of substance use not only in families with that history, but also in families without substance abuse (Bennett and Kempfer, 1994).

In considering interpersonal risk factors that are more powerful during adolescence, peer influence plays an important role. Peer attitudes about use of substances predict initiation of alcohol and other substance use (Bauman and Ennett, 1994; Kandel et al., 1978). In fact, strong peer attachment rather than parental attachment has been shown to be more influential during adolescence in predicting susceptibility to substance abuse (Brook, 1980; Kandel et al., 1978). Peer influence also plays a strong role in predicting relapse. Ninety percent of teens who have a relapse do so because of peer pressure (Brown, 1993).

The third category of risk factors established by Newcomb—psychobehavioral—can influence drug use during childhood and adolescence, as well as after adolescence and throughout life. Age is a risk factor likely to influence the onset of substance use during childhood and adolescence. Youngsters who begin drinking at an early age, at 11 to 12 years, have a higher percentage of probability of meeting the criteria, set forth by the third revised edition of the DSM (DSM-III-R), for substance abuse (13.5%) and substance dependence (15.9%), compared with those who begin drinking at age 13 or 14 years (13.7% and 9.0%, respectively). Those who drink at age 19 or 20 years of age have rates of 2% and 1%. Importantly, rapid progression of alcohol and drug disorders often occurs in persons with an earlier age of onset and frequency, not duration, of use (DeWitt et al., 2000; Kandel et al., 1992). Those persons with an earlier onset have a shorter time span from first exposure to dependence than do groups with adult-onset disorders (Clark et al., 1998). The age of onset of heavy drinking also predicts alcohol-related problems (Lee and DeClemente, 1985). An early age of onset also is associated with higher risks of the use of other substances. Adults with adolescent-onset substance abuse have higher lifetime rates of cannabis and hallucinogen use disorders, shorter times between the development of their first and second dependence diagnosis, and higher rates of disruptive behaviors and major depression (Clark et al., 1998).

Academic failure and low commitment to school are other psychobehavioral influences on drug use during childhood and adolescence. Beyond early onset of use, poor academic achievement, poor social skills and competence, learning problems and poor self-esteem are found to be related to drug abuse (Scheier et al., 1999; Stacy et al., 1993). Although many early-onset adolescent substance abusers may meet criteria to diagnose dependence—and the effect of this abuse can have

devastating results on their development—many do not continue to meet these criteria during young adulthood ( [Hasin et al., 1990](#)). Much research is needed to determine which psychobehavioral factors are more likely to lead to continued abuse and dependence in adulthood. Newcomb's work does show that young adults who continue to be problem drinkers are likely to have been rebellious, nonconforming, and deviant during high school ( [Newcomb, 1997](#)). For those who do not continue to abuse alcohol, it has been suggested that they display an increasing responsibility and maturation after the age of 24 years ( [Donovan and Jessor, 1983](#)).

As noted, persons with continued symptoms of rebelliousness and antisocial behavior are more likely to abuse substances in adulthood. However, other factors such as temperament are important. Both [Cloninger \(1987\)](#) and [Babor \(1992\)](#) identified personality traits consistent with those who have poorer prognoses. Persons with Cloninger's type 2 and Babor's type B alcoholism share common characteristics such as early onset of spontaneous alcohol-seeking behavior, diagnosis during adolescence, and rapid course of onset; they are thought to have genetic precursors that put them at risk to develop substance abuse, and they have severe symptoms of deviant behavior including fighting and arrests when drinking, as well as greater psychological vulnerability. Persons with these types of temperaments also share other characteristics found under Newcomb's psychobehavioral factors that lead to continued substance use in adulthood: high novelty seeking, low harm avoidance, and low reward dependence. Patients with Cloninger's type 1 and Babor's type A alcoholism share opposite characteristics of those cited earlier and are unlikely to continue substance abuse into adulthood.

Psychiatric disorders are also classified under Newcomb's psychobehavioral risk factors that continue to influence substance abuse throughout life. Lewinsohn identifies risk factors common to SUD and the specific comorbid diagnosis of major depression disorder. Risk factors specific to SUD are tobacco use, academic difficulties, and a past episode of SUD. Risk factors specific to major depression disorder are stress, emotional reliance, physical symptoms and disease, a history of a suicide attempt, and a history of depression or anxiety. Risk factors common to both disorders are current symptoms of depression, internalizing and externalizing behavior problems, poor coping skills, interpersonal conflict with parents, and dissatisfaction with grades ( [Lewinsohn et al., 1995](#)). Research pertaining to psychiatric disorders found under Newcomb's psychobehavioral risk factors are discussed in the section of this chapter on comorbidity. Postpsychobehavioral factors are not explored because they are more pertinent to young adulthood than to childhood or adolescence.

The final domain set forth by Newcomb that contributes to risk factors related to drug use is biogenetic. Inherited susceptibility often plays a role once a person begins to use substances, usually during adolescence. Psychophysiological vulnerability to drug use usually occurs after a person is persistently exposed to substances and would typically have an effect much later in adulthood. An example could be cirrhosis of the liver resulting from chronic alcoholism. Inherited susceptibility can be explained by the neurobiological research done by Nestler ( [1994, 1995](#)). Those who have a greater genetic predisposition to develop substance abuse may be more susceptible to the influence by alcohol on gene expression. Consistent exposure of the ventral tegmentum and nucleus accumbens to alcohol and other drugs may form permanent changes in the second messenger system inside the cell. This may influence the turning on of genes, which may, in turn, influence the drive mechanism to use substance.

The dopamine D2 receptor found on chromosome 11 ( [Blum et al., 1990](#)) and allele A1 was thought to be associated with alcoholism. However, A1 is also associated with Tourette's syndrome, ADHD, and autism. Persons with variants of three different genes for dopamine seem to have a higher number of symptoms associated with ADHD. Persons with two variants have fewer symptoms and those with one variant have even fewer symptoms of ADHD. These findings may help to support a reward deficiency syndrome thought to be associated with addictive, impulsive, and compulsive behavior and personality disorders ( [Blum et al., 1996](#)).

Repeated self-administration of cocaine appears to be associated with the D1 receptor. Three dopamine receptors—D1, D2, and D3—are involved in cocaine-seeking behaviors. Activating the D1 receptor can suppress cocaine seeking in drug-experienced animals, whereas activating D2 can trigger cocaine seeking ( [Self et al., 1996](#)). Adoption studies have shown an increased risk of alcoholism of adopted-away children of persons with alcoholism ( [Goodwin et al., 1974](#)) and an increased risk for substance abuse other than alcohol in studies of adopted-away children ( [Cadoret et al., 1986](#)). However, alcohol use by adoptive parents did not increase risk of alcohol abuse in adoptive children ( [Cloninger et al., 1985](#)).

In the cases mentioned here, greater genetic susceptibility seems to be a stronger predictor of risk of substance abuse rather than exposure to adoptive parents who use substances. However, both genetic and environmental influences may be correlated to substance use initiation, whereas progression to substance abuse and dependence may be more strongly related to genetic factors alone. In adoption studies conducted by Kendler and Prescott ( [1998a,b](#)), 485 monozygotic and 335 dizygotic female twins demonstrated that cannabis use was influenced by genetic and familial environmental factors, whereas cannabis abuse and dependence were solely related to genetic factors. This was also true for cocaine use versus abuse and dependence. [Schukit \(1999\)](#) showed greater tolerance in children of parents with alcoholism. In his study, children of parents with alcoholism had to use greater proportions of alcohol before the reflex response to a stimulus was delayed to the same degree as the degree found in responses of children of parents who did not have alcoholism. In children of nonalcoholic parents, the reflex response to a stimulus was delayed to the same degree on lower proportions of alcohol. This diminished response to alcohol was also measured by subjective feelings, levels of body sway, electrophysiologic functioning, and change in three hormones ( [Schukit, 1999](#)).

Biological susceptibility may also influence the early onset of substance abuse. [Buydens-Branchey et al. \(1989b\)](#) report that persons with early-onset substance abuse have a low ratio of plasma tryptophan, a finding that suggests a decline in serotonin. The teens in this study were incarcerated for violent crimes and had a severe course. Nicotine self-administration may be explained by the nicotine receptor. Mice lacking the  $\beta_2$  subunit of the nicotine receptor (one of the 10 proteins making up the nicotine receptor) fail to self-administer nicotine ( [Picciotto et al., 1998](#)).

It seems that protective factors tend to have an extreme influence on the prevention of SUDs. In a study of resilience in the sons of fathers with alcoholism, more good life events and an internal locus of control seemed to cushion the development of SUD ( [Springer and Gastfriend, 1995](#)). Because protective factors tend to cushion risk factors, finding interventions that would turn risk factors into protective factors would be useful in treating adolescents and in reducing continued use and progression of SUDs. This conversion of risk factors into protective factors is even more important when one considers that an accumulation of risk factors appears to have a more powerful effect than an accumulation of protective factors. Examples of protective factors include a stable environment, a high degree of motivation, a strong parent-child bond, consistent parental supervision and discipline, bonding to prosocial institutions, association with peers who hold conventional attitudes and consistent, and community-wide messages against drug use ( [Glantz and Sloboda, 1998](#)).

## DRUGS OF ABUSE: CLINICAL ISSUES

### Alcohol

Alcohol continues to be the most commonly used psychoactive substance. About one-third of high school seniors have had a binge (five or more drinks) episode in the past month. The blood alcohol level (BAL) is calculated by the milligram of alcohol per 100 mL of blood. In many states, the BAL of illegal driving while intoxicated is at or above 0.10%, whereas other states use 0.08%. The psychological and behavioral effects are related to the BAL. In nontolerant adolescents, impaired judgment occurs at a BAL of 0.06%, impaired muscle coordination at 0.08%, impaired reaction time at 0.10%, impaired balance at 0.15% and confusion or unconsciousness at 0.30% ( [Dimeff et al., 1999](#)). Adolescents need to learn that excessive intake can cause death, which may occur at 0.40% to 0.50%.

Drinking alcohol causes a biphasic response; an initial rising BAL is associated with arousal, excitement, and increased confidence. This is always followed by falling BALs, which are associated with fatigue and dysphoria. Tolerance to alcohol decreases the initial stimulating effects and increases the secondary depressant effects ( [Dimeff et al., 1999](#)). Pathologic intoxication occurs when, after drinking alcohol, the adolescent suddenly becomes violent and aggressive, in contrast to his or her usual temperament. Sedation with benzodiazepines may be needed for behavior control.

Adolescents may develop nausea, vomiting, peptic ulcer disease, and gastrointestinal hemorrhaging. Alcohol withdrawal may yield the following symptoms: nausea and vomiting, tremors, increased heart rate, elevated blood pressure, sweating, anxiety, irritability, and seizures. Adolescents who drink heavily may develop a life-threatening withdrawal syndrome with fever and convulsions, although delirium tremors are not seen. Detoxification is indicated with a stabilizing dose of benzodiazepine followed by tapering doses. Adult studies have shown that symptom-triggered dosing using a withdrawal rating scale such as the Clinical Institute Withdrawal Assessment reduces the total dose, shortens the length of stay, and maintains patient comfort and safety ( [Gastfriend et al., 1998](#)).

### Marijuana

Marijuana is the most commonly abused illegal drug. The principal psychoactive agent is D-9-tetrahydrocannabinol, which is lipid soluble. The mean elimination half-life is 4 days. Acute physiologic effects include increased heart rate, conjunctival injection, photophobia, dry mouth, tremor, and bronchodilation. Acute psychological effects include euphoria or apathy, sensation of slowed time and intensified perception, and often increased appetite. For adolescents, the most dangerous effects are in the areas of cognition and psychomotor performance. [Schwartz et al. \(1989\)](#) describe the short-term memory loss in marijuana abusers that

persists for 6 weeks after last use of the drug. This loss, combined with decreased attention, may markedly impair the adolescent's ability to learn and to do schoolwork. A double-blind study of experienced pilots ([Leirer et al., 1991](#)) using a flying simulator demonstrated that a single marijuana cigarette impaired complex visual-motor functioning up to 24 hours after smoking. Of significant concern is the issue that six of the seven pilots were not aware that they were impaired. This finding may explain why so many adolescents believe they are better at driving cars when they are high on marijuana. There is extensive evidence linking fatal accidents to cannabis use ([Nahas and Latour, 1992](#)). Long-term daily marijuana users often fulfill DSM-IV criteria for substance dependency disorder. Abrupt cessation after long-term heavy use has been reported to result in a withdrawal syndrome characterized by insomnia, irritability, restlessness, drug craving, depression, body aches, and general malaise ([Duffy and Milin, 1996](#)). Marijuana use may precipitate anxiety, panic, and, rarely, psychosis. Development of toxic delirium suggests that the marijuana is adulterated with PCP.

### **Hallucinogens**

LSD showed a resurgence of use by adolescents during the 1990s. Whereas the sugar cube dosage of the 1960s contained 150 to 250 µg of LSD, the 1-inch square "hit" blotter paper dosage of the 1990s contained 50 to 80 µg. Adolescents often take two or more hits at a time. Physical effects of a "trip" include dilated pupils, increased body temperature, increased heart rate and blood pressure, decreased appetite, sleeplessness, dry mouth, and tremors. Psychological effects vary greatly and may include altered states of perceptions of reality, distorted feelings and experiences of time and space, and impaired perceptual motor performance. Visual hallucinations may occur. "Bad trips" involve experiences of anxiety, panic, and paranoia. Flashbacks in which the adolescent reexperiences an LSD trip, although he or she has not recently ingested any LSD, are quite frequent, especially in heavy, chronic users. Psychotic disorders and affective and anxiety disorders have developed after LSD experiences.

Milder hallucinogens used by adolescents include mescaline, from the peyote cactus, and psilocybin, which comes from mushrooms. Jimson weed, whose seeds when chewed may produce a hallucinatory experience, contains atropine and scopolamine and may produce an anticholinergic syndrome.

### **Dissociative Anesthetics**

PCP was developed as an anesthetic but was discontinued because patients became agitated and delusional. PCP is illegally manufactured and is sold for a low price. It can be ingested, snorted, smoked, or injected intravenously. As a powder, it can be dusted on tobacco or marijuana, and adolescents may smoke it without knowing that it is present. Physical and psychological effects are extremely variable. Feelings of detachment and derealization are common. PCP may produce euphoria, dysphoria, paranoia, perceptual distortion, psychosis, aggressive and violent behavior, depression, seizures, coma, and even death. Neurologic signs include horizontal and vertical nystagmus, ataxia, dysarthria, seizures, and, at high doses, open-eyed coma. Hypertension, flushing, and sweating may also occur. Effects and presence in the urine may last for several days. Confusion with disorientation, bizarre behavior with delusions, and agitation with violence are possible ([Brown and Coupey, 1993](#)).

Ketamine is an animal anesthetic that may be snorted, smoked, or injected intramuscularly. Large doses may produce dissociation and derealization, but high doses may also produce delusions, amnesia, poor motor functions, and increased blood pressure. Death from respiratory failure may also occur. Use of ketamine is mainly by older adolescents and by young adults as a club or "rave" drug.

The other club or rave drugs include stimulants and depressants. MDMA or ecstasy is the most common club drug because of its combined stimulant and hallucinogenic effects. Decreases in heart rate, blood pressure, and body temperature may occur. An increased sense of alertness may contribute to dancing for hours, and this has led to dehydration, heart and kidney failure, and even death. Acute effects include anxiety, jaw clenching, and the positive experience of feeling a special connection to others. Higher doses may produce panic and paranoia. MDMA is the most recent example of a drug that was at first publicized as having very positive effects on enhancing psychotherapy and promoting love, but then continued experiences yielded evidence of brain damage, memory loss, and death.

GHB as a club drug is used for its intoxicating sedative effects, which can last up to 4 hours. The euphoria and sedation may be accompanied by nausea, vomiting, dizziness, and decreased respiration. GHB has been associated with overdoses, date rape, coma, and death.

Flunitrazepam, a sedative benzodiazepine that is odorless and tasteless, produces anterograde amnesia. These properties have resulted in the use of this drug for date rape and sexual assault. In addition to slurred speech and a staggering gait, flunitrazepam may cause decreased blood pressure, visual disturbances, confusion, gastrointestinal disturbances, and urinary retention.

### **Depressants**

These drugs include barbiturates, benzodiazepines, and specific sleeping pills such as methaqualone. These drugs are abused for their sedative and anxiety-relieving effects. Although rare in adolescents, physical dependence can occur, resulting in life-threatening withdrawal symptoms. Restlessness, postural hypotension, seizures, and death may ensue if detoxification is not done. Because of the long half-life of some benzodiazepines, such as diazepam (Valium), withdrawal symptoms including seizures may not occur for 7 to 10 days after use. Management of physical dependence involves gradual tapering of the dose or substitution of a same-class long-acting agent and slow tapering of the substitute ([Gastfriend et al., 1998](#)).

### **Stimulants**

Ephedrine and pseudoephedrine are mild stimulants that adolescents often obtain from convenience stores. These legal over-the-counter preparations are mixed with guaifenesin and have labels such as Mini-Thins or Magnum 357s. These names are related to their appetite suppression and exhilarating effects.

Amphetamines, which include dextroamphetamine (Dexedrine), biphphetamine, are often intermittently used by adolescents to lose weight, stay awake, or feel excited. Amphetamines may be taken orally or injected intravenously. The "rush" of intravenous use is often followed by the "crash" of dysphoria and irritability. Increasing doses of amphetamines may result in teeth grinding, repetitive picking of the skin of the face and extremities, and perseverative speech and behavior. Suspiciousness and paranoia also often develop. Withdrawal symptoms in long-term users of high doses results in dysphoria, fatigue, apathy, and somnolence lasting for several days.

Methamphetamine is a synthetic stimulant closely related to amphetamines, but its stimulating effects are stronger and last longer. Methamphetamine may be smoked, snorted, injected, or ingested by mouth. Low doses can produce agitation, decreased appetite, increased respiration, hyperthermia, and euphoria. Higher repeated doses may produce insomnia, confusion, tremors, aggressiveness, and paranoia. Cardiovascular collapse, strokes, and convulsions may result and may cause death.

Cocaine is usually snorted and is quite expensive, whereas the freebase form, a small rock called crack, is smoked and costs significantly less. It takes 8 seconds after smoking crack for the euphoria to develop, which lasts for 5 to 10 minutes. Dysphoria and paranoia may rapidly follow the brief euphoric state. Intranasal cocaine use produces intense euphoria with increased energy, dilated pupils, decreased appetite, tachycardia, and hypertension. Tolerance rapidly develops. Cocaine users tend to take repeated doses over periods of hours or days, which are commonly referred to as "runs." Depression and exhaustion follow the "runs." Heavy use of cocaine frequently causes paranoia and psychosis. Often, repeated use never achieves the initial euphoria of the first high. Cocaine produces the most intense cravings between binges, and chronic abusers describe an irresistible compulsion to use the drug again regardless of negative consequences. Certain medications used to treat cocaine withdrawal or postwithdrawal anhedonia have been studied (e.g., dopamine agonists such as bromocriptine or amantadine, antidepressants, antipsychotics and anticonvulsants), but results of controlled adult trials have not been positive ([Gastfriend et al., 1998](#)). Acute intoxication can produce delirium, confusion, paranoia, hypertension, tachycardia, seizures, cardiac arrhythmia, and death. Sudden death may occur with the first use. This apparently happened to Len Bias on June 19, 1986, when he died of a cocaine overdose after he signed a multimillion dollar professional basketball contract ([DuPont, 1997](#)). Ulcerated nasal mucous membranes and nasal septum collapse may occur with prolonged cocaine snorting.

### **Opiates: Heroin (Diacetylmorphine Hydrochloride)**

Opiates include opium, opium derivatives, and other synthetic substitutes. These substitutes include codeine, fentanyl, morphine, meperidine (Demerol), and oxycodone. Medical uses are for pain relief, cough suppression, and relief of diarrhea. Opiates may be swallowed, snorted, smoked, or injected. Heroin is the usual drug of choice for opiate addicts because it has a very short duration of action, which gives it a quick peak effect with intense euphoria. Onset of the euphoria is usually within 30 minutes after snorting, 15 minutes after subcutaneous injection, and 16 seconds after intravenous injection. Heroin use by American high school students was higher in 1997 than in any year between 1990 and 1996. The reason for this increase appears to be that middle-class white adolescents were initiating

heroin use by the intranasal route ([Schwartz, 1998](#)). An increase in emergency room visits and heroin overdose-related deaths in adolescents occurred.

Acute physiologic effects include drowsiness, pinpoint pupils (miosis), reduced cough reflex, and constipation. Higher doses may produce nausea, vomiting, and respiratory depression. Acute opiate intoxication or overdose produces miosis and respiratory and central nervous system depression. Associated hypothermia, hypotension, and bradycardia may also occur. Overdoses can occur when the use of opiates is combined with alcohol or sedatives. Overdoses also occur when potent heroin is used unexpectedly. In the emergency room, a diagnostic trial of low-dose naloxone (Narcan) at 0.1 to 0.2 mg is given intravenously to suspected addicts for heroin overdose ([Schwartz, 1998](#)). The target symptom for the naloxone administration is reversal of the respiratory depression produced by the heroin overdose.

Heroin produces rapid tolerance, so increased doses are needed to give the same euphoric effect. Physical dependence evolves, and a characteristic withdrawal syndrome develops when heroin use is terminated. Acute withdrawal symptoms begin within 8 hours, peak at 48 to 72 hours, and decrease over the next 4 to 7 days. Withdrawal symptoms include agitation, piloerection, tachycardia, mild hypertension, and pupillary mydriasis. Sweating, vomiting, diarrhea, and urinary frequency also occur. At 8 to 12 hours after termination of heroin use, anxiety is high, and tremors, shakes, muscle cramps, and joint pain develop. Although there is much discomfort, the withdrawal state is not life threatening. These symptoms are usually treated with clonidine or methadone ([Brown and Coupey, 1993](#)).

We had a teenage patient who developed an opiate withdrawal syndrome from the opium he had sprinkled on his daily marijuana joints and blunts. Clonidine was used to alleviate the withdrawal symptoms. Adolescents who use drugs intravenously (opiates or amphetamines) are at increased risk of human immunodeficiency virus infection and hepatitis B and C. These infections may result from shared needles or unprotected sexual intercourse.

## Inhalants

Inhalants are breathable chemical vapors that produce mind-altering effects. The abuse of inhalants is highest in the early adolescent years. Inhalants include industrial solvents (gasoline, paint thinner), office supply solvents (correction fluid), household aerosol propellant, household or commercial product gases (butane, freon), and medical anesthetic gases (nitrous oxide). Inhalants may produce excitation followed by depression, confusion, and disorientation. Inhalant use may produce severe irreversible consequences, which include hearing loss, peripheral neuropathy, central nervous system brain damage, and liver, kidney, and bone marrow deterioration. Sudden sniffing death syndrome occurs when the adolescent "huffing" an inhalant is suddenly surprised by another person and dies of cardiovascular collapse. It is hypothesized that the inhalant sensitizes the heart muscle to ventricular fibrillation.

## ASSESSMENT

Evaluation of the child and adolescent presenting with a possible substance abuse problem involves a full biopsychosocial psychiatric evaluation (described in other chapters), as well as specific evaluation of the substance abuse and possible consequences. In addition, any adolescent being evaluated for emotional, cognitive, or behavioral problems needs to also be evaluated for possible abuse of alcohol and drugs. In this section, the focus is on the specific evaluations of the substance abuse. The adolescent should be interviewed alone and with his or her family.

### Interview

In evaluating the teenager, the clinician should be knowledgeable about the drugs teenagers use and the types of effects that may occur. The clinician may quickly obtain an education about the drugs and the latest "druggie language" by simply asking teenagers what their peers use and abuse and what names are used. The clinician's personal experience with alcohol and drugs should not be revealed except in exceptional circumstances. An attitude of concern, interest, and seriousness, mixed with a little humor, is often best.

Substance-abusing youth often distort, minimize, and deny the existence or extent of their drug abuse and other problems. Therefore, information from parents, school personnel, and legal authorities is essential. Other family members, especially siblings, as well as concerned peers, are important sources of information. The degree of difficulty in interviewing the possibly substance-abusing adolescent will vary with the motivation and openness of the adolescent. The drug-abusing adolescent who knows that he or she has a problem and who comes willingly for help, although rare, does exist. It is much more common for the adolescent to appear because someone else (e.g., parent, judge, principal) requests the evaluation and the adolescent begrudgingly submits to the interview. This situation calls for the clinician's highest level of skill and patience. Beginning with a nonconfrontational approach is usually most helpful to engage the adolescent in the interview process. The first issue is to clarify the adolescent's understanding of why he or she is at the interview. The television character Colombo portrays how one may slowly investigate the presenting problem by asking clarifying questions with the clinician taking a position of confused ignorance. Current life circumstances, including home, family, and school relationships and level of functioning, are then explored. Peer relationships, leisure activities, employment, and self-perception are carefully reviewed. It is important to evaluate accomplishments and strengths as well as weaknesses and problems.

Finally, one explores the adolescent's use of drugs and alcohol. One helpful approach described by [Anglin \(1987\)](#) uses an ordered discussion of the substances the teenager ingests. The clinician asks questions first about dietary patterns (e.g., snack food, whether breakfast is skipped) and then questions about prescribed medications and compliance with these. Next are over-the-counter medications (including antihistamines to sedate and caffeine or ephedrine pills to stimulate) and finally substance abuse. Here questions move from tobacco to alcohol to marijuana, sedatives and stimulants, hallucinogens, cocaine, and opiates. Use of inhalants, which peaks in early adolescence, is also explored. [Bukstein \(1995\)](#) describes that evaluation of substance use behavior involves inquiring into (a) patterns of use (onset, how often, agent and route), (b) negative consequences, (c) context of use (time, place, peers), and (d) control (attempts to decrease, use more than planned). It is extremely important to explore high-risk behavior engaged in by the adolescent under the influence of alcohol and drugs. This includes driving under the influence of alcohol, marijuana, or LSD or being in a car in which the driver is high or intoxicated. Other high-risk behaviors, such as unprotected sex or becoming intoxicated on substances (e.g., alcohol or ecstasy) in a social setting in which the adolescent could be beaten or raped, are extremely important to identify because of their life-threatening nature.

Evaluating negative consequences involves exploration with the adolescent and family members about how the adolescent functions at school, at work, within the family and peer group, and at recreational activities. Other family members may be abusing substances, and it is essential to identify those members. School failure is one of the most common signs of substance use or abuse. Marijuana use impairs concentration and short-term memory and leads to schoolwork decline. Direct objective information from the school is helpful. A change in peer group or a loss of interest in previous activities, such as music or athletics, often results from drug involvement. Legal issues such as arrests and involvement with the juvenile justice system must also be ascertained.

[Halikas \(1990\)](#), in a study of adolescents and delinquency, developed specific key questions to examine patterns of use and abuse in teenagers. Questions related to alcohol are the following:

1. Do you drink on school grounds?
2. When you are truant, do you ever go drinking?
3. Do you miss school because of drinking or being hung over?

Halikas found that a positive answer to one of these questions correlated highly with severe alcohol problems. Three key questions related to drug use are as follows:

1. Do you mix alcohol and drugs?
2. Is your family concerned about your drug use?
3. When you are truant, do you get high on drugs?

A positive answer to one of these questions correlated highly with severe drug problems. [Bergmann et al. \(1995\)](#) developed specific key questions that also correlate significantly with alcohol and drug problems. These questions are as follows:

1. Do you prefer to go to places where drugs and alcohol are available?
2. Do you ever drink or use drugs more than you planned?
3. Does it take more alcohol or drugs to get you high than it used to?

## Confidentiality

Confidentiality holds with regard to what is discussed with the teenager, except it must be broken if there are concerns of safety. This means not just issues of suicide and homicide, but also if the teenager is engaging in sufficiently high-risk behavior. If the teenager is driving while intoxicated or tripping on LSD, confidentiality must be broken and the parents informed. This issue calls for the considered judgment of the physician.

A useful intervention technique to handle the issue of confidentiality during an initial assessment is the following: After interviewing the teenager, the clinician asks the parents to join the interview and asks the teenager to talk about some of his or her high-risk behavior in the presence of the parents. In this situation, the teenager reveals the life-threatening, high-risk behavior directly to the parents, so the clinician does not have to break confidentiality. In many situations, if the clinician informs the parents about the teenager's alcohol and drug abuse, the parents, because of their own denial, may be confrontational. Asking the teenager to reveal directly to the parents what has been discussed allows the clinician to maintain an alliance with the parents, so the clinician and the parents can respond to the high-risk drug-related behavior the teenager has revealed.

## Standardized Assessments

While the CAGE screening questions have not been demonstrated to be useful for adolescents, some screening and evaluation instruments have been specifically developed to identify adolescent substance abuse. The CRAFFT questions developed by [Knight et al. \(1999\)](#) have been studied in medical office screening. Two or more "yes" answers suggest a serious problem with alcohol or drugs, and referral for further evaluation is indicated. The CRAFFT questions are as follows: C: Have you ever ridden in a car driven by someone (including yourself) who was "high" or had been using alcohol or drugs? R: Do you ever use alcohol or drugs to relax, feel better about yourself, or fit in? A: Do you ever use alcohol or drugs while you are alone? F: Do you ever forget things you did while using alcohol or drugs? F: Do your family or friends ever tell you that you should cut down on your drinking or drug use? T: Have you ever gotten into trouble while you were using alcohol or drugs?

Two self-administered initial screening instruments yield scores indicating possible problems in 10 domains. This approach is important because substance abusing adolescents have problems in many areas of their life. The Problem Oriented Screening Instrument for Teenagers (POSIT) developed by Elizabeth Rahdert, Ph.D., at the National Institute on Drug Abuse (NIDA), includes 139 true-or-false questions that can be self-administered in 20 to 30 minutes. The ten domains are substance use or abuse, physical health status, vocational status, mental health status, family relationships, peer relationships, educational status, social skills, leisure and recreation, and aggressive behavior or delinquency. As a screening instrument, domains identified as possible problem areas are to be further, rigorously evaluated. The POSIT is available at no charge from the NIDA.

The Drug Use Screening Inventory ([Tarter, 1990](#)) consists of 149 self-report yes-or-no questions that take 20 to 30 minutes to answer. As with other screening instruments, the clinician must decide whether the answers are honest and valid. The 10 domains are substance abuse, behavior patterns, health status, psychiatric disorder, social competence, family system, school performance or adjustment, work adjustment, peer relationships, and recreation. Converting the scores into absolute and relative problem densities yields bar graphs showing which problem areas need more comprehensive evaluations and specific targeted treatment interventions.

Winters ([Center for Substance Abuse Treatment, 1999](#)) has developed three adolescent instruments. The Personal Experience Screening Questionnaire is a 38-item self-report questionnaire that is administered in 10 minutes. Problem severity and drug use history, along with validity scales for lying, are measured by this initial screening instrument. The Personal Experience Inventory is a more extensive 300-item self-report inventory that usually takes 45 minutes to complete. The Problem Severity Scales measure the onset, nature, degree, and duration of chemical involvement. The Psychological Scales identify the personal risk factors that may precipitate or sustain substance abuse. Validity scales estimate honesty of report. Five Problem Screens address eating disorders, sexual abuse, physical abuse, family chemical dependency, and suicide potential. The third instrument is the Adolescent Diagnostic Interview, a structured interview that evaluates the following: the presence of DSM-III-R diagnosis of psychoactive SUD (PSUD), school and interpersonal functioning, psychosocial stressors, and a rating of orientation and memory. The Personal Experience Inventory and the Adolescent Diagnostic Interview may be computer scored.

Another important assessment instrument in development is the Teen Addiction Severity Index ([Kaminer et al., 1991](#)). This is a modification of the Adult Addiction Severity Index. The Teen Addiction Severity Index is a semistructured interview given by a trained technician in 30 to 45 minutes. Using a five-point scale, the patient rates the severity of his or her problems in the domains of chemical use, school status, employment-support status, family relationships, and psychiatric status. The interviewer also rates severity and need for treatment. This instrument is being developed to be used repeatedly as a measure of change before and after treatment for follow-up studies.

## Urine Drug Screens

Urine drug tests are commonly used to detect recent use of illegal drugs. Mental health professionals and parents need to be aware of the uses and limitations of the urine drug screen ([Wolf and Sherman, 1995](#)). The urine must be obtained under observed conditions to make sure that it is the test subject's sample, that a foreign substance such as apple juice has not been substituted, and that it has not been adulterated. Most teenagers are well versed in ways to beat the urine drug screen. A small amount of bleach or blood or the taking of a diuretic with huge amounts of fluid often makes urine drug screen results negative. Drinking large amounts of water will yield a very dilute urine sample and may make the sample negative. The urine drug test is limited to the length of time the specific drug stays in the body and will therefore be present in the urine ([Schwartz, 1993](#)). Stimulants may be detected for up to 48 hours after last use, cocaine and its metabolite benzoylecgonine may be detected for up to 3 days, and opiates (morphine, codeine) may appear for up to 2 days. Short-acting barbiturates are detected for 1 day, diazepam for up to 4 days, and methaqualone for up to 2 weeks. Marijuana, which is stored in fatty tissue, may be detected in the urine for up to 4 days in recreational users and for up to a month in chronic daily users ([Schwartz, 1993](#)).

To determine whether an adolescent has smoked marijuana after an initial positive urine test, the cannabinoid:creatinine ratio can be followed in successive urine tests. Passive inhalation of marijuana smoke in an average-size, ventilated room does not produce a positive urine test, but passive inhalation in a closed car or nonventilated small room may produce a positive urine test. Urine drug screens should not be done on a routine basis. They should be done only when there is suspicion of drug use. Adolescents' resistance to giving a urine sample, although they may claim it is based on issues of freedom, independence, and privacy, is usually related to their use and abuse of drugs. Teenagers who ask, "Don't you trust me?" should be answered with, "No, show me you are not using."

## STAGES OF DRUG USE AND CORRESPONDING TREATMENT

As a result of the evaluation, the clinician should make a determination of the stage of substance abuse involvement. The American Society of Addiction of Medicine has developed treatment levels of care ([Hoffman et al., 1993](#)), which include the dimensions of treatment resistance, relapse potential, and recovery environment. These levels are presently currently revised. The following framework describes each stage of substance abuse involvement and the corresponding treatment approaches, to provide an initial strategy for relating treatment to the degree of substance involvement. The American Society of Addiction of Medicine dimensions, as well as issues of comorbidity and availability should also be considered.

### Experimental, Recreational, or Social Use

This is the beginning stage of substance use, with curiosity and doing what peers may be doing being the important factors. Teenagers often learn that drugs are fun and seek the thrill of doing something they are not supposed to be doing. They often find that substance use helps them gain acceptance by specific peers.

STAGE	TREATMENT STRATEGIES
Experimental use	1. Education
Recreational use	2. Counseling: individual and family

### TREATMENT STRATEGIES

For adolescents at this stage (experimental, recreational, or social use), education and counseling are appropriate. Teenagers use drugs in direct proportion to availability and perceived safety. Learning about the realistic dangers of drugs and alcohol is helpful. For example, although adolescents tend to view marijuana as a benign drug, the reality is that marijuana poses a serious threat to brain functioning. It decreases attention span, impairs short-term memory, and impairs complex

behavior such as driving. Interestingly, impairment in complex visuomotor behavior is not often recognized by teenagers. Counseling is also needed for adjustment issues, and parents may need help in how to set appropriate limits with rewards and consequences.

### Substance Misuse

In this stage, teenagers are actively seeking the pleasurable experiences of using alcohol and drugs. Often they have already learned that misuse helps them to escape from feelings of frustration, anger, depression, and inadequacy. At this stage, teenagers tend to use substances primarily on weekends, and there will be some deterioration in grades and adherence to rules.

STAGE	TREATMENT STRATEGIES
Substance misuse	<ol style="list-style-type: none"><li>1. Education</li><li>2. Counseling: individual and family</li><li>3. Individual and group therapy</li><li>4. Family treatments</li><li>5. Abstinence or "honest look" contract</li><li>6. Motivational interviewing</li></ol>

At the substance misuse stage, in addition to education and counseling, individual and group therapies, family treatments, and an abstinence contract may be needed. At this stage, family therapies such as strategic, structural, systemic, and behavioral approaches are important interventions. Behavioral family therapy involves parent management training as well as contingency contracting. Here, specific clear rules are established between parents and adolescents such that there are negative consequences to any drug use. Positive reinforcement is given for going to school, doing homework, avoidance of drug-using peers, and developing other recreational activities that are incompatible with drug use.

The abstinence or "honest look" contract is often very helpful ([Bailey, 1996](#)). In this situation, the teenager expresses a willingness to stop using drugs and alcohol and to stop "druggie" types of behavior. Specific rewards and punishments related to this goal are established. Unannounced urine drug screens are included. Specific consequences are dictated if adolescents are unable to abide by this abstinence contract and include attending treatment at a more intense level of care.

Brief interventions using a combination of motivational interviewing and education and coping skills development have been developed as a harm-reduction approach for the prevention and treatment of heavy alcohol drinking at college ([Dimeff et al., 1999](#)).

### TREATMENT OF SUBSTANCE ABUSE DISORDER AND SUBSTANCE DEPENDENCY DISORDER

Substance abuse disorder (SUD) and substance dependency disorder are DSM-IV diagnostic categories indicating that alcohol and drugs are taking over the adolescent's life and are causing significant problems. Drugs and alcohol are used during the week, and the peer group is primarily a drug- and alcohol-using group. Usually the adolescent has become very secretive, deceptive, and dishonest. DSM-IV abuse disorder criteria involve direct, negative consequences. These involve the following: failure of major role obligations at work, school, or home; recurrent use in physically hazardous situations; recurrent substance-related legal problems; and continued use despite recurrent social or interpersonal problems.

DSM-IV dependency disorder criteria involve serious negative consequences in addition to evidence of physical dependency (tolerance and withdrawal symptoms) and preoccupation with substance using or compulsive use. At this stage of addiction, alcohol and drugs cannot be used in moderation. These adolescents may be able to have some periods of not using alcohol or drugs, but when they return to using these substances, the use rapidly goes out of control, with the return of severe negative consequences. Induced neurobiological changes in brain functioning, especially in the reward circuitry ([Roberts and Koob, 1997](#)), underlie this disorder. Although research has not established the validity of these two disorders or the criteria differences between them for adolescents, the DSM-IV does define clinically useful syndromes that require specific intense treatment programs.

In 1991, Catalano et al. extensively reviewed the literature on adolescent drug abuse treatment and found that, in residential programs, time in treatment was related to reduced alcohol or drug use. Family participation was associated with better outcome. No treatment modality was significantly better than any other, and these investigators could only conclude that some treatment was better than no treatment.

In the 1990s, significant progress was made. NIDA specifically increased support and direction for controlled studies on adolescent drug abuse treatment and for the development of clinical researchers. The American Academy of Child and Adolescent Psychiatry published both a 10-year research review ([Weinberg et al., 1998](#)) and the "Practice Parameters for the Assessment and Treatment of Substance Abuse in Children and Adolescents" ([American Academy of Child and Adolescent Psychiatry, 1997](#)). In addition to the specific treatments for SUD, the frequently occurring comorbid ADHD, affective anxiety, and conduct disorders should be evaluated and treated in an integrated, concurrent manner ([Riggs and Whitmore, 1999](#)).

### Family Treatments

Family therapy treatment studies have demonstrated the strongest empirical support for their efficacy. [Stanton and Stadish \(1997\)](#) conducted a metaanalysis of controlled studies for the treatment of drug abuse. They conclude that family therapy or couples therapy results in significantly greater improvement across drug use outcome measures for both adult and adolescent drug abusers than does individual therapy, peer group therapy, or family psychoeducation. [Liddle \(1995\)](#) carefully reviewed and critically evaluated studies of family therapy and family-based intervention for adolescent drug abuse from 1979 to 1995. These are random-assignment clinical trials with specific family therapy models. These studies demonstrate that family therapy can retain families in treatment and can reduce adolescent drug abuse. Methodologic limitations such as varying retention rates and outcome measures, incomplete reporting of procedures, unclear diagnostic criteria, lack of attention to therapist factors, and treatment integrity make efficacy "promising but not definitive." A representative study is that of [Joanning et al. \(1992\)](#), whose Family System Therapy yielded an abstinence rate of 54% compared with 28% for Adolescent Group Therapy and 16% for Family Drug Education.

Classic family therapy is based on the hypothesis that a connection exists between family relationships and the development or maintenance of drug abuse. Family therapy targets these specific interpersonal family processes. With structural-strategic family therapy, emphasis is on establishing a coherent family hierarchy with appropriate rules and authority. [Lewis et al. \(1990\)](#) combined various different family therapy models to develop a 12-session treatment called the Purdue Model. The goals were to decrease family resistance to treatment, to redefine substance use as a family problem, to reestablish parental influence, to interrupt dysfunctional sequences of family behavior, to assess the interpersonal function of the drug abuse, to implement strategies to change family interpersonal functioning, and to provide assertion training for the adolescent. Families receiving this treatment model significantly decreased adolescent drug abuse compared with families receiving parent skill training.

Two important extensions of family therapy have significant controlled research support. [Azrin et al. \(1994\)](#) integrates family therapy with behavior therapy techniques, whereas Henggeler's Multisystem therapy ([Pickrel, 1996](#)) integrates family therapy with direct interventions in the multiple interacting systems involving the individual, school, peer group, and community.

#### FAMILY BEHAVIOR THERAPY

In this controlled treatment study, the specific active treatment procedures involved stimulus control, urge control and family-social contracting. Stimulus control included defining safe situations versus risk situations and learning to increase the safe activities and decrease the risk activities. Urge control involved describing a drug-using activity to stimulate drug-using urges, which were then interrupted and replaced with a drug-incompatible activity. The most important treatment component was the social-family contracting in which parents reinforced drug-incompatible activities, supervised home urge-control assignments, and employed written specifications of desired behavior with contingent reinforcers. The control group received only supportive counseling. Significant results were demonstrated, with abstinence rates after 6 months of treatment of 73% for the treatment group and only 9% for the supportive counseling group. Treated youth also had improved schoolwork and family relationships ([Azrin et al., 1994](#)).

### Multisystem Therapy

Multisystem therapy views the adolescent as being affected by multiple interconnected systems involving the individual, family, and extrafamily (peers, school, and

community) environment. Adolescent problem behavior, such as delinquency and substance abuse, are proposed to be maintained by dysfunctional reciprocal interactions of any of these systems. This therapeutic intervention involves assessing the strengths and weaknesses of the various systems and intervening to change current behavior and relationships. Responsible behavior among all family members is promoted as well as developing capacities to manage their own problems. Therapists work intensely with each adolescent patient and family member and see them within their home, school, and even neighborhood peer group.

[Henggeler et al. \(1993\)](#), in randomized studies of multisystem therapy compared with individual counseling or probation for chronic juvenile offenders, demonstrated reduced criminal activity continuing through a 4-year follow-up. Preliminary data on a current study on multisystem therapy for substance abusing delinquents demonstrate excellent retention rates and favorable outcomes ([Pickrel and Henggeler, 1996](#)).

Three other specific substance abuse treatment modalities have been studied in adult patients with alcoholism who were randomly assigned and whose counseling sessions were based on treatment manuals. In this research study, called Project Match, 12-step facilitation therapy was compared to cognitive-behavioral therapy (CBT) and motivational enhancement therapy. All three were effective in decreasing alcohol consumption, with 12-step facilitation therapy the most effective in promoting abstinence ([Humphreys, 1999](#)) and motivational enhancement therapy best for those with high baseline anger ([DiClemente et al., 1999](#)). These modalities need to be modified to be appropriate for the adolescents. There is some empirical support for the efficacy of CBT in adolescents, and studies of motivational enhancement therapy and 12-step facilitation therapy are being done.

### **Cognitive-Behavioral Therapy**

This therapeutic modality uses the learning principles of classic and operant conditioning along with approaches to correct cognitive distortions and underlying negative belief systems. This treatment includes learning specific techniques to deal with drugs and alcohol. Skills to refuse alcohol and drugs are taught and are practiced by role-playing exercises. For example, adolescents are taught to say “no” immediately in a firm manner and to make direct eye contact with the person offering them alcohol or drugs. They are then to suggest an alternative activity, or if that is not successful, simply to tell the person to stop asking. Cognitive-behavioral coping skills to deal with urges, to manage substance-using thoughts, and to handle emergencies and lapses are taught and practiced. Because deficits in coping skills for negative feelings and life stresses contribute to continued substance abuse, more general coping skills such as communication skills, problem solving strategies, anger, and mood management, as well as relaxation training, are taught and are practiced. A functional analysis for adolescent substance use examines internal and external triggers, short-term positive consequences, and long term negative consequences of using alcohol and drugs, as well as nonusing behavior. This information is then used to develop positive sobriety reinforcements and cognitive-behavioral relapse prevention strategies. CBT is being studied in randomized clinical trials. [Kaminer and Burlison \(1999\)](#) compared CBT group therapy with interactional group therapy in adolescents with dual disorders. Patients undergoing CBT demonstrated a decrease in severity of substance use, but CBT was not superior to interactional group therapy at the 15-month follow-up.

### **Motivational Treatment**

[Prochaska and DiClemente \(1982\)](#) state that a person in stopping an addictive behavior goes through a series of stages of change. These stages are the following: precontemplation, in which the person is not even thinking about stopping and does not recognize any problem with alcohol or drug use; contemplation, which is the stage of ambivalence when the person goes back and forth between reasons to change and reasons not to change; preparation, in which the person increases the commitment to change; action, in which the person stops using alcohol and drugs; and maintenance, in which the person develops a lifestyle to avoid relapse. People have different levels of motivation, depending on their stage of change. Therapeutic intervention involves helping the patient in an empathetic, nonconfrontational manner to move along the stages.

Motivational treatment approaches include brief motivational interventions, motivational interviewing, and motivational enhancement therapy. Brief motivational interventions consist of one to four sessions in which, after an assessment, direct feedback and advice are given in a nonconfrontational manner respecting the person's personal responsibility for making a decision. At the November 1999 American Society of Addiction Medicine meeting, Dr. Peter Monti presented a study on a single 45-minute emergency room brief motivational interview for adolescents with alcohol use-related injuries. Six- and 12-month follow-up self-reports revealed fewer alcohol-related problems, but not fewer number of drinks per occasion for those who received the intervention.

Motivational interviewing is the individual counseling approach developed by [Miller and Rollnick \(1991\)](#) in which specific interviewing techniques are used to help the patient work through ambivalence to move out of the contemplative stage. An empathetic nonconfrontational relationship is formed in which reflection and reframing help the patient to explore the pros and cons of substance-using behavior. Self-efficacy is enhanced as the patient is helped to realize his or her capacities and options while recognizing that it is the patient's decision whether to change. Motivational interviewing is being used for one to two sessions with adolescents before a CBT program.

Motivational enhancement therapy is the four-session therapy based on motivational interviewing that was specifically developed for Project Match. After extensive assessment by standard instruments, personalized feedback is given. The patient's ambivalence is clarified, motivation for change is enhanced, a change plan is developed and commitment to change is strengthened. In Project Match, motivational enhancement therapy was best for adults with alcoholism who had a high base level of anger. There is a need for motivational enhancement therapy to be studied in substance-using adolescents.

### **Twelve-Step Approaches**

Twelve-step-based treatment is one of three common types of adolescent substance abuse treatment that is described in the [Center for Substance Treatment's protocol series \(1999b\)](#). Although this has been the most common treatment model for adolescents, there has been little research on its efficacy. Because of the many misconceptions about 12-step programs, their historical beginnings and applications for adolescents are presented in some detail.

Twelve-step programs involve the recovery group process for treatment of chemical dependency that began with the development of Alcoholics Anonymous (AA). This was the strongest group movement of the 1980s and 1990s. AA began in 1935. Bill Wilson had become involved in the Oxford Group in an attempt to stop drinking and to live a better life. The Oxford Group was a self-help program in which members surrendered their will to that of God, took a personal moral inventory, confessed transgressions, made amends to others they had harmed, and helped others without thought of financial reward. While attending Oxford Group meetings, Wilson found that trying to help other persons with alcoholism often saved him from taking another drink. In the spring of 1935, while on an unsuccessful business trip in Akron, Ohio, and being close to a drink, Bill Wilson met with Dr. Robert Smith, a physician who was also struggling with trying to stop drinking by means of Oxford Group meetings. From this famous meeting, in which they helped each other, these two men visited the local hospital, where they helped a third patient with alcoholism, and AA began. There are almost 2 million members in 63,000 groups, with memberships doubling every 10 years ([Roberston, 1988](#)).

In the development of AA, Bill Wilson set up clear guidelines that enable AA to avoid problematic issues of money, politics, and powerful leaders. AA owns no property, does no fundraising, accepts no outside contributions, and is open and free to anyone who wants to stop drinking. The 12 steps were written by Bill Wilson and other early members. The 12 steps were published in *Alcoholics Anonymous* in 1939 ([Alcoholics Anonymous, 1976](#)). The 12 steps are the guide for the changes in actions, thoughts, feelings, and belief that an individual addict slowly undergoes to establish a state of recovery and to abstain from drinking. Because an addict cannot use alcohol or drugs in moderation, abstinence is the necessary goal. Working the 12 steps is an extremely concrete process that does not require abstract thinking.

The following descriptions present the first five steps and how they can be modified to make them meaningful for adolescents. [Jaffe \(1990\)](#) uses a workbook format in which the adolescent writes answers to specific questions, which are reviewed by counselors and may be presented at a group.

#### **STEP 1**

“We admitted we were powerless over alcohol—that our lives had become unmanageable.” For adolescents, the workbook has the adolescent examine in detail the negative consequences of alcohol or drug use. Putting their own and others' lives in danger and the effects on family, school, work, mood, and self-esteem in relation to alcohol or drug use are explored. The major issue is whether drugs and alcohol are destroying their lives such that they need to stop using drugs or alcohol to make their lives better. Because adolescents desire to become more powerful, the workbook emphasizes that by abstaining from alcohol and drugs, the adolescent will become powerful to have a life. While many adult programs emphasize the concept of “surrendering” and admitting that one is an addict, these approaches are not useful for adolescents. Rather, enhancing power by doing what one needs to do (i.e., stop using alcohol and drugs) instead of doing what one wants to do (i.e., use alcohol and drugs) is emphasized.

## STEP 2

"We came to believe that a power greater than ourselves could restore us to sanity." The adolescent workbook approaches this step by recognizing that a child's first Higher Power is the person that raises them. For many drug abusing or addicted adolescents, parental figures have been neglectful or abusive. Mourning the pain and sadness from the disappointments of their childhood Higher Powers enables them to begin to develop a sense of something positive in the universe that they can turn to for help. The Higher Power concept is not a religious belief, but a spiritual feeling that one can trust something positive (e.g., the group, another person, nature) to take care of those aspects of one's life that one cannot control. One needs to have trust in the stability of the world and to realize that one controls one's own behavior but not what others say or do. For many adolescents, the concrete positive feelings of their relationships with other members becomes their first Higher Power.

## STEP 3

"We made a decision to turn our will and our lives over to the care of God as we understand Him." The adolescent workbook interprets this step to involve having the adolescents make a decision to commit themselves to working the steps and to having a positive spiritual power. The teenagers are helped to recognize that they turned over their lives to alcohol and drugs. Now they are being asked to turn their lives over to a positive program.

## STEP 4

"We made a searching and fearless moral inventory of ourselves." The workbook has the adolescents answer numerous detailed questions covering all aspects of their childhood and present life.

## STEP 5

"We admitted to God, to ourselves, and to another human being the exact nature of our wrongs." Now the adolescent verbalizes his or her inventory to a counselor or his or her sponsor.

## PROVISIONS AND RESULTS

Twelve-step programs also provide the opportunity to attend free AA or Narcotics Anonymous meetings, which are conducted several times a day in almost every city and town in the United States and most other countries. It is well recognized that adolescents will return to using alcohol and drugs if they return to contact with their alcohol-using or drug-using friends. Twelve-step programs provide a recovering peer group, which is essential for continued sobriety ( [Jaffe, 1992](#)). Twelve-step programs also provide big brother or big sister relationships in the form of sponsors. Here an older member with at least a year of sobriety provides a relationship and guidance on how to work the program toward sobriety. Twelve-step programs accept that addiction is a chronic progressive disease whereby the addict is unable to control and moderate drinking or drug using, so the only viable alternative is complete abstinence ( [Humphreys, 1999](#)). For many adolescents, it is sometimes helpful for them to view themselves as being "on the way to becoming an addict" if they do not see themselves as already being one.

Although research on 12-step adolescent programs has been sparse, the CATOR [Harrison and Hoffman, 1989](#)) residential treatment follow-up indicates that those teenagers who attended two or more meetings per week were almost six times more likely to report abstinence at 1 year than those who never attended meetings. A more recent follow-up study by Winters, as described in the [Center for Substance Abuse Treatment Protocol no. 32 \(1999b\)](#), uses improved methods with a high follow-up contact rate and meaningful comparison groups. At 12-month follow-up, those completing 12-step-based treatment had an abstinence rate or minor relapse rate of 53% compared with 27% of those who needed but did not receive treatment.

Both motivational interviewing and 12-step facilitation therapy develop motivation in the adolescent to stop using alcohol or drugs through the adolescent's personal recognition of the negative consequences of substance using. Jaffe's *Adolescent Substance Abuse Intervention Workbook* has the adolescent use this framework to answer concrete, simple questions that explore 12 areas of the adolescent's life that may have been negatively affected by alcohol or drugs ( [Jaffe, 2001](#)). These include, among others, putting another's life in danger, making depression worse, messing up the body and brain, impairing school and work, breaking the law, and inability to moderate use. [DiClemente \(1991\)](#) describes four types of adolescent drug-abuse precontemplators: the reluctant, who does not know that a problem exists; the rebellious, who oppositionally will not acknowledge a problem; the resigned, who feels too hopeless to face the problem; and the rationalizing, who has excuses not to do anything about the alcohol or drug problem. Jaffe adds the following: the restricted-thinking adolescent, who has marijuana in his or her brain for 1 to 3 weeks after use that impairs short-term memory and meaningful thinking; and the faking contemplation precontemplator, who tells therapists that he or she wants to stop using drugs and realizes the problem, but in the back of his or her mind is thinking he or she is going to tell everyone what they want to hear, to be able to resume using alcohol and drugs. The *Intervention Workbook* deals with this issue by presenting the using druggie thinking (e.g., "drugs are fun") along with healthy recovering thinking (e.g., "but my life is a mess"). This workbook is completed individually and also may be presented to a group. It is extremely useful as an initial diagnostic and treatment tool to help the adolescent to develop motivation to stop using drugs or alcohol and is appropriate for use in outpatient, inpatient, and juvenile justice programs.

### Community-Reinforcement Approach

The community-reinforcement approach is an adult alcohol treatment approach with strong empirical research support in which the person's life is rearranged so abstinence is more rewarding than drinking. Treatment strategies include increasing a person's motivation to stop drinking by clarifying negative consequences and positive reinforcers, initiating sobriety with a trial period of sobriety sampling (e.g., 1 month), doing a functional analysis of drinking patterns, establishing involvement with sober peers and alcohol-free activities, rehearsing new coping skills, and coaching significant others not to reinforce drinking patterns (e.g., stop enabling). The therapist using this approach is positive, energetic, optimistic, and sympathetic ( [Miller et al., 1999](#)).

The community-reinforcement approach closely resembles the "enthusiastic sobriety" adolescent program developed by Bob [Meehan \(2000\)](#). This 12-step based program uses young, energetic, enthusiastic, recovering, well-trained counselors. They are role models demonstrating that one can have fun without drugs or alcohol. The adolescent is asked to try 30 days without alcohol or drugs. The adolescent participates in daily groups, meetings, and social functions with recovering peers who make sobriety more fun and rewarding than using drugs and alcohol.

### Using Multiple Treatments for Adolescent Substance Abuse

No one particular treatment modality has been demonstrated to be clearly superior to the others. Multiple approaches are often needed to achieve progress. The Center for Substance Abuse Treatment has developed five different protocols to study various outpatient treatments for adolescent marijuana abuse. Motivational enhancement therapy is combined with CBT therapy in two of the protocols. A third protocol combines motivational enhancement therapy with CBT and at-home family therapy. Preliminary positive results are being obtained, with more intensive treatments most beneficial for more severe abusers.

### Treatment Setting

Adolescents rarely need medical detoxification. Reasons seem to relate to the finding that adolescents tend to use multiple drugs in an episodic time course. Moreover, adolescents are usually in better general physical health than adults. In spite of this, physical addiction to alcohol, sedatives, or minor tranquilizers may occur, with life-threatening withdrawal symptoms, that necessitates detoxification in an inpatient setting. Other indications for inpatient hospitalization include danger to self or others, psychotic symptoms, and high-risk behavior that could be of a life-threatening nature. Adolescents with SUD or substance dependency often need a short period of inpatient hospitalization to be fully evaluated and stabilized. Then they may be stepped down to a day-patient or intensive outpatient program. Within these programs, family therapy, 12-step facilitation therapy, CBT, and motivational interviewing may be used. Full biopsychosocial evaluation is needed because comorbid disorders are present in 40% to 90% of these patients. These comorbid affective, behavioral, and anxiety disorders should be defined and considered for concurrent treatment. The major issue for adolescents with abuse or dependency disorders to be treated in day or intensive outpatient programs is whether they can resist returning to contact with their substance-using peers.

## COMORBIDITY

There is a higher rate of comorbidity in adolescents with SUD. Specifically, rates of mood and disruptive disorders have been found to be higher in adolescents with SUD than in adolescents without SUD. When compared with adult samples, rates of current comorbidity of SUD in adolescents with psychiatric disorders are the same as in adults, except for disruptive or antisocial personality disorders. Adults have higher rates of the latter. This finding continues to reemphasize the importance of early intervention to prevent the development of pervasive disorders ( [Kandel et al., 1999](#)).

When relapse rates are focused on in adolescents, those adolescents with comorbid psychiatric disorders and other problems, such as high stress, low social skills, a lack of involvement in productive activities or active leisure, and no follow-up interventions, are found to have a higher risk of relapse ( [Kaminer, 1999](#)).

Costello et al. looked at the onset of several disorders to determine whether they are likely to precede the development of SUD or whether they are more likely to follow the onset of substance abuse. All disorders, including ADHD, conduct disorder, oppositional defiant disorder, and anxiety disorder, occurred well before the onset of any substance use. However, depressive symptoms occurred 1 year after the onset of alcohol abuse but 2 years before the onset of smoking. Disruptive disorder and depression had higher rates and earlier onset of substance use and abuse in both sexes ( [Costello et al., 1999](#)).

[Angold et al. \(1999\)](#) point out many reasons why clinical research on comorbidity may be flawed. First, clinical studies are not representative of the general population and may be biased. However, samples on which we base prevalence of substance abuse and dependence in adolescents are done annually in the national survey results of drug use from the NIDA-sponsored Monitoring the Future Study. However, this study is based on students in high school and middle school. Many severely substance-abusing adolescents have already dropped out of high school and are not included in this survey. Many populations may not be representative of the clinical population, as well, when surveys are done.

Second, clinical sample correlates of disorders may be correlates of the referral population. The solution is to use longitudinal studies of the general population and referred, but these studies are expensive and are often underfunded. Third, several diagnostic categories have overlapping symptoms. This would provide an explanation of how ADHD and obsessive-compulsive disorder overlap but not conduct disorder and depression. Fourth, clinical research may not distinguish between heterotypical and homotypical disorders. Heterotypical depression is an ongoing process that manifests different forms over time. Heterotypical depression would produce subtypes found under a diagnostic category. Homotypical depression, like dysthymia and depression, would be a phenomenon that changes over time.

Although these are problems that have occurred in comorbidity research, [Angold et al. \(1999\)](#) believe that it would be foolish to ignore the research and that the solution is to find research designs that overcome these problems in the future. The following comorbidity research has been divided into categories by diagnosis, to allow a more organized discussion.

### Mood Disorders

Depression in women is related to substance abuse. Among referred adolescents, conduct disorder, major depression, and ADHD may be important concomitants of substance dependence. In female patients, however, depression may be the primary variable related to substance dependence ( [Whitmore et al., 1997](#)). Another study demonstrated that posttraumatic stress disorder and depression were strongly associated with alcohol dependence in female patients ( [Clark et al., 1997](#)). Predictors of comorbid alcohol and substance abuse in depressed adolescents girls were longer depressive episodes, more conduct problems and psychosocial impairment, and school or work problems ( [King et al., 1996](#)).

In a study of female patients with conduct disorder and substance abuse, major depression was related to a more severe level of substance abuse ( [Riggs et al., 1995](#)). Another study that compared depressed adolescents girls without previous SUD to controls found the risk of SUD high in both groups (34.6% in the depressed group and 24.2% in the control group). However, depressed girls with SUD had more significant psychosocial impairment than depressed girls without SUD, and girls with depression had earlier onset of SUD than girls without depression. The girls with depression and SUD had more anxiety traits and elevated cortisol levels near sleep onset, when the hypothalamic–pituitary system is expected to be less active, than did depressed girls without SUD ( [Rao et al., 1999](#)).

In a study of 99 delinquent boys with comorbid substance abuse and conduct disorder, depression played a significant role. Depressed boys were more likely to have ADHD, posttraumatic stress disorder, and anxiety disorders as compared with nondepressed boys. Depressed boys tended to develop conduct disorder earlier than nondepressed boys ( [Riggs et al., 1995](#)). Although conduct disorder and depression seem to increase the risk of earlier onset of SUD, this may not be true for bipolar disorder. One study looked at the risk to develop SUD independent of the diagnosis of conduct disorder. In a study by Wilens, youth with adolescent onset bipolar disorder were at significant risk relative to those who developed child onset bipolar disorder. Adolescents with bipolar disorder had an 8.8 times greater risk for the development of SUD than those with child-onset bipolar disorder, and conduct disorder or other comorbidity did not account for the risk ( [Wilens, 1999](#)).

The question whether dysthymia or major depression precedes or follows the onset of PSUD has been examined in adolescents in a few small studies. Among hospitalized adolescent substance abusers with dysthymia and PSUD, 53% had dysthymia before the development of the PSUD ( [Hovens et al., 1994](#)), and in a study of adolescents with dysthymia and behavioral symptoms that were indicative of poor behavior skill, moderate to heavy alcohol consumption followed this history ( [King et al., 1993](#)).

In a study of 156 inpatient adolescent substance abusers with major depression, 60.4% had secondary depression and 16.7% had the primary form ( [Bukstein et al., 1992](#)). In a study examining comorbid conduct disorder, substance abuse, and depression in delinquent boys, the depression did not seem to be secondary to the substance abuse because the depressive symptoms were not alleviated after 4 weeks of abstinence ( [Riggs et al., 1995](#)). Research is needed to delineate better whether dysthymia or major depression with or without conduct disorder is more likely to occur before or after the development of SUD.

### Anxiety Disorders

Results of the International Consortium in Psychiatric Epidemiology demonstrate that the onset of anxiety disorders is more likely to precede that of substance disorders in all countries ( [Merikangas et al., 1998](#)). In considering anxiety disorders, different types may play different roles in the risk of development of SUD. In a treatment population with early-onset alcoholism, 50% had at least one lifetime anxiety disorder, and the most common anxiety disorder (25%) was posttraumatic stress disorder ( [Clark et al., 1995](#)).

Social phobia may play a major role in the development of SUD when anxiety disorders are considered. For instance, social phobia was highly comorbid with depressive disorder, somatoform disorder, and SUDs in a study of 1,035 adolescents, ages 13 to 17 years ( [Essau et al., 1999](#)). In one study (from epidemiologic surveys, field studies, and family studies), social phobia and agoraphobia preceded the onset of alcoholism, whereas generalized anxiety disorder and panic disorder did not ( [Kushner et al., 1990](#)). This finding may provide clinicians with unique opportunities for intervention when they evaluate children with this history who would not present in schools as likely candidates for intervention. Their compliant behavior in the classroom does not bring their needs to the attention of a teacher.

Teachers would recognize only shy children with aggression as those who need intervention. This combination is extremely important when one considers that boys with shyness and aggression have a higher risk of the development of SUD boys with than aggressiveness alone. In fact, 26 years after following-up boys with aggressiveness and aggressiveness and shyness, both traits and combinations were valid predictors of current levels of cocaine use in adults ( [Swan, 1995](#)). In another study, the most common psychiatric disorders associated with inhalant use were social phobia, major depression, and antisocial personality disorder (Compton et al., 1994).

### Attention Deficit Hyperactivity Disorder

Patients with ADHD and conduct disorder are at a higher risk of developing substance abuse than those with ADHD alone ( [Wilens et al., 1996](#)). In fact, in a prospective study following-up two groups of children for 8 years (one with ADHD and conduct disorder and one with ADHD alone), the ADHD–conduct disorder group used two to five times more alcohol and cigarettes than the ADHD group alone ( [Barkley et al., 1990](#)). Genetic research for the increased risk for substance abuse in adolescents with ADHD and conduct disorder has been confirmed in a twin study. In this study with 626 pairs of 17-year-old twins, ADHD did not increase the risk of substance abuse unless it was associated with concomitant conduct disorder ( [Disney et al., 1997](#)).

The drug of choice for adolescents with ADHD may be marijuana. In a 10-year follow-up study of children with ADHD, the most commonly used drug was marijuana

([Mannuzza et al., 1993](#)). Although a great risk for the development of substance abuse in adolescents with ADHD is not readily apparent, adults with persistent ADHD had an increased risk of developing substance abuse (52%) when compared with controls (27%). In fact, adults with ADHD without antisocial personality disorder had a twofold elevation of PSUD as compared with controls ([Biederman et al., 1995](#)).

### Conduct Disorder

Adolescents with conduct disorder that occurs before the development of SUD have a poorer prognosis than those who develop conduct disorder during the SUD ([Myers et al., 1998](#)). Differences between female and male patients with conduct disorder and SUD have been examined. Girls with comorbid conduct disorder and SUD are more likely to have experimented with nonprescription diet pills and caffeine, have a diagnosis of nicotine dependence, start drinking at a later age, have an interval between alcohol use and depression that is shorter than in boys, and have more running-away behavior ([Mezzich et al., 1994](#)).

Boys in the differences study were more likely to have had more aggressive symptoms of conduct disorder including stealing (with and without confrontation), destruction of property, weapon fights, breaking and entering, and torturing of animals. Conduct severity (aggression), ADHD, and major depression predict an earlier age of onset of conduct disorder and severe dependence in boys. As noted earlier, only major depression relates to more severe substance dependence in girls ([Riggs et al., 1995](#)).

As noted earlier, patients with early-onset ADHD and conduct disorder have a high risk of substance abuse, but late-onset conduct disorder not associated with ADHD has also been shown to be a risk for substance abuse ([Grillo et al., 1996](#)). In this study, Grillo et al. suggest that late-onset conduct disorder (which they believe is a form of personality dysfunction) is more likely to be associated with substance abuse than is early-onset ADHD and conduct disorder (which they believe is associated with a neurologic problem secondary to ADHD). More research is needed to determine whether the foregoing hypothesis is true.

[Randall et al. \(1999\)](#) studied what is known about the effects of externalizing and internalizing juvenile offenders. In this study, juveniles with externalizing disorders versus those with internalizing disorders were examined. Comorbidity for externalizing disorders was associated with higher rates of antisocial behavior and predicted a worse 16-month outcome than did substance abuse alone or substance abuse with comorbid internalizing disorders. The presence of internalizing disorders buffered the deleterious effects of externalizing disorders on substance-abusing and substance-dependent juvenile offenders ([Randall et al., 1999](#)).

### Sexual Abuse

In a study of 174 children, two groups were matched for age, race, sex, gender, socioeconomic status, and psychiatric diagnosis. The results revealed that on every measure of substance abuse, the abused group had scores indicative of more serious abuse involvement. It also revealed that the abused group used marijuana and stimulants more frequently, got drunk more often, and initiated drug use at a younger age. The abused group also was more likely to use drugs or alcohol to deal with problems or to avoid feelings of inadequacies ([Hussey and Singer, 1993](#); [Singer et al., 1989](#)).

### Suicide Risk

Substance use can increase the risk of suicide. Psychological postmortem studies of adolescents who committed suicide found that 70% were drug and alcohol users ([Shofii, 1988](#)). Among 10 to 19 year olds, those who committed suicide were found to be 4.9 more likely to have been drinking ([Brent et al., 1987](#)). In fact, white boys who were intoxicated were more likely to commit suicide using a firearm. In that study, depression, conduct disorder, and personality disorder accompanied by a precipitating event were frequently present ([Kaminer, 1992](#)).

Other risks factors found in suicide victims are active substance abuse, comorbid major depression or affective illness, suicidal ideation within the past week, family history of depression and substance abuse, legal problems, and the presence of a hand gun in the home ([Brent et al., 1993](#); [Bukstein et al., 1993](#)). With regard to suicidal thoughts, when these thoughts coincide with morbid ideation for an extended duration, the probability of suicide increases ([Deykin et al., 1994](#)). Persistently high levels of problem drinking and depressive symptoms have also been associated with higher levels of suicidal thoughts and attempts. In this study, suicide ideation could be distinguished from suicide attempts. Higher levels of depressive symptoms and greater cigarette use was found in the youth who attempted suicide (Windle and [Windle, 1997](#)).

Cultural affiliation can put youth at higher risk of suicide. A study of 3,094 high school students surveyed revealed that native Hawaiian cultural affiliation rather than ethnicity was predictive of suicide attempts. Rates of suicide attempts in native Hawaiians were greater than non-Hawaiians. Depression, substance abuse, grade level, cultural affiliation, and mean wage earner's education predicted suicide attempts in native Hawaiians, whereas depression, substance abuse, and aggression predicted suicide attempts in non-Hawaiians ([Yuen et al., 2000](#)).

### Eating Disorders

Binge eating in anorexia nervosa predicts later onset of substance abuse ([Strober et al., 1997](#)). However, patients with bulimia have been found to have a higher incidence of substance abuse than those with restrictive anorexia ([Bulik et al., 1992](#)). We have also shown that bulimic women with substance abuse have higher novelty seeking than bulimic women without substance abuse ([Bulik et al., 1994](#)). It would be interesting to study whether these high novelty-seeking bulimic women would more likely to have personality disorders, as suggested in Cloninger's type 2 high novelty-seeking individuals.

## PSYCHOPHARMACOLOGY

The number of studies on psychopharmacology in adolescents with comorbid substance abuse is minimal. The most commonly asked question is whether to treat an adolescent with a substance abuse problem and ADHD with psychostimulants. Two articles have described the effectiveness of bupropion (Wellbutrin) and the less addictive stimulant pemoline (Cylert). Both studies found these medications effective in relieving the symptoms of ADHD in a juvenile justice population ([Riggs et al., 1996](#); [Riggs et al., 1998](#)). Caution should be used in using pemoline because of the increased risk of liver failure, and monitoring of liver functions is necessary.

Clearly, if an adolescent has a history of substance abuse and ADHD, a trial of bupropion would first be warranted. If the attentional symptoms are relieved but problems with hyperactivity continue, a trial of guanfacine (Tenex) or clonidine may prove helpful. Adolescents with ADHD, a tic disorder, and a substance abuse history may be effectively treated with nortriptyline. In all cases, weekly random urine drug screens should be done to avoid any complications that may result from using psychotropic medications with illicit drugs. If other medications are not successful, stimulants such as methylphenidate may be used ([Riggs, 1998](#)). However, the medication must be allocated by a responsible parent or guardian who does not have an active SUD. Obviously, the patient should be enrolled in some type of substance abuse treatment, and periodic urine drug screens should be monitored. One article finds that if an adolescent does have a diagnosis of ADHD and is treated, the risk of developing a substance abuse problem is reduced by 85% ([Biederman et al., 1999](#)).

A few articles have addressed the psychopharmacologic treatment of mood disorders in adolescents with substance abuse. Fluoxetine proved to be effective in the treatment of depression in drug-dependent delinquents ([Riggs et al., 1997](#)). Geller et al. reported one of the most interesting findings in adolescents with comorbid bipolar disorder and substance abuse. In a double-blind and placebo-controlled study of lithium for adolescent bipolar disorders with secondary substance dependence, the lithium not only relieved the symptoms of bipolar but also decreased the use of alcohol ([Geller et al., 1998](#)).

Naltrexone (ReVia), which has been used to decrease alcohol cravings in adult patients with alcoholism, was helpful in a case report of a 17-year-old alcohol-dependent boy ([Wold, 1997](#)). Disulfiram (Antabuse) has been used as aversion therapy in adult patients with alcoholism, but it probably has limited use in adolescents because of issues of noncompliance ([Solhkhah and Wilens, 1998](#)).

## PREVENTION

As pointed out by Hansen, some of the decline of drug use in the early 1990s may be attributed to the Omnibus Anti Drug Act. This act provided funds to schools and communities to decrease drug use. However, because drug use began another upward trend in the mid-1990s, it is clear that the effects of these programs were not long term. Most prevention programs now focus on research to find effective programs with long-term results ([Hansen, 1996b](#)).

According to Hansen, evidence now exists that certain aspects of program development are essential to provide effective interventions. They are: program focus,

delivery technique, evaluation and training, and support ( [Dusenbery and Falco, 1995](#); [Hansen, 1991](#); [Tobler and Stratton, 1997](#)).

Program focus describes what the expected outcome is and what it is supposed to change. According to Hansen, the three periods of program development are institution driven, theory driven, and data driven. Earlier efforts formulated by institution-driven programs allowed researchers to test the programs and to learn from their mistakes. One such well-intentioned effort was the DARE program. Results demonstrated that drug use in control schools and those using the DARE program was almost equal. No substantial short-term or long-term effects were documented ( [Ennett et al., 1994](#)).

Some programs ( [Hansen, 1996b](#) ) grew out of research and hence were called theory-driven programs. The problem with these programs is that resources needed to evaluate these programs were minimal. Hansen reviewed the effectiveness of programming outcome components such as information, affective education, social influence, and multiple components. Overall, programs that had an informational or affective component had very little effect, whereas those that used social influence approaches, or life skills approaches with social influence approaches, were the most effective. Examples of these types of programs include Project SMART ( [Hansen et al., 1988](#) ), Life Skills Training ( [Botvin et al., 1990](#) ), and Project STAR ( [Pentz et al., 1989](#) ).

The third type of program to develop was based on data-driven prevention. Hansen pointed out that data-driven prevention programs used only variables that had strong statistical relations to drug use, whereas theory-driven programs used all variables. Hansen, in 1993, performed a metaanalysis on 242 studies and found 11 major variables in etiologic studies. The variables that had a strong statistical relationship including drug use by peers, previous drug use, bonding, commitment to school, and deviance. Variables with average statistical relationships were beliefs about psychological and social consequences of drug use and attitudes about drug use, pressure to use substances, and perceived attitudes about drug use among others. Belief about health consequences was not as strongly correlated. Weakest were home factors, psychological traits of parents, parental marital status, parental education, family composition, and socioeconomic status. Parental attentiveness, parenting style, and parental drug use had higher correlation ( [Hansen et al., 1993](#) ). Just as Newcomb's work has helped to indicate at what developmental stage risk factors for substance abuse occur and when these targets should be intervened on, Hansen's work can help to prioritize which of these risk factors should be intervened on initially because of a stronger statistical relation to the development of substance abuse.

Three targets of prevention programs have been found to have strong correlations to predicting future drug use, and therefore targeting those factors in prevention programs may have the most success: normative beliefs, lifestyle-behavior incongruence, and commitment. The only program developed to target these variables specifically has been the All Stars program ( [Hansen, 1996a](#) ). Clearly important to analyze in the effectiveness of any program is delivery technique. It has been determined that interactive programs are far more effective than noninteractive ones ( [Tobler and Stratton, 1997](#) ). All programs require training and support. A strong initial dose with booster interventions for at least 2 years is also essential ( [Botvin et al., 1995](#) ).

In the sixth triennial report to Congress, Alan Leshner, Ph.D., included some other important prevention programs, as discussed later ( [Leshner, 1999](#) ). One type of multicomponent program, the Seattle Social Development Project, has been developed to enhance protective factors. It is designed for elementary school-age children in first through sixth grades. It involves parent and teacher training. Teachers are trained to use active classroom management, interactive teaching strategies, and cooperative learning ( [Hawkins et al., 1992](#) ).

A specific prevention program aimed at high school athletes, to avoid steroid use, is called Adolescents Training and Learning to Avoid Steroids (ATLAS). Not only has this program proved effective in reducing anabolic steroid use, it also has increased belief in athletic ability and strength training and has improved nutrition and exercise behaviors ( [Goldberg et al., 1996](#) ).

A program that targets youth with poor academic achievement and potential for dropping out of school is called the Reconnecting Youth Program. The program uses skill to build resilience and also targets youth with substance use, depression, and suicidal ideation. Research also shows this program to be effective in reducing the three-targeted behaviors stated earlier ( [Eggert et al., 1995](#) ). Of course, for clinicians who are evaluating children and their families, recognizing potential risk factors and addressing them during the treatment process are important to prevent development of substance abuse.

A population that is only beginning to receive attention is that comprising adolescents in the juvenile justice system. One study looked at grouping of delinquent boys over a 2-year period. It compares pairing of boys as follows: one delinquent and one nondelinquent, two delinquents, and two nondelinquents. In the mixed pair and the pair with a nondelinquent and a delinquent member, interaction centered on normative talk and laughter. The delinquent pair interaction was typical of interaction that increased self-reported delinquent behavior. Therefore, interventions that pool together high-risk youth into homogenous groups should be avoided ( [Dishion et al., 1996](#) ).

Two family interventions have been evaluated and found to be effective on parents' child management practices and on child-parent affective quality. The programs are Preparing for the Drug-Free Years and the Iowa Strengthening Families Program. Preparing for the Drug-Free Years involves five sessions for parents and one for the children. The Iowa Strengthening Families Program involves seven sessions attended by both the parents and their children. A 1-year follow-up of the Iowa Strengthening Families Program showed increased youth resistance to peer pressure to use drugs, reduced interaction with other antisocial peers, and decreased levels of problem behaviors ( [Kosterman et al., 1997](#); [Spath et al., 1998](#) ). Project Family evaluated these programs.

One family program has been developed that has been culturally sensitive to African-American, Asian-Pacific Islander, and Hispanic families. It is targeted at substance-using families and their 6- to 10-year-old children and has three components: a parent-training program, a children's skills training program, and a family skills training program. The positive outcomes of this 14-weekly session program include the following: reductions in family conflict; improvement in family communication and organization; and reductions in youth conduct disorders, aggressiveness, and substance abuse ( [Kumpfer et al., 1995](#) ).

Another program that targets minority students is called the Jump Start Program. It targets high sensation-seeking African-American students. The most important results of this program are that high and low sensation-seeking behaviors are neutralized ( [Harrington and Donohew, 1997](#) ). A family program that is aimed at parents using methadone treatment and their children is called the Focus on Family Program. This program has shown parent drug use significantly lowered and their parenting skills improved. It consists of a 5-hour family retreat, 32 parent sessions, and 12 sessions with children, in which they practice appropriate skills to interact with their parents ( [Catalano et al., 1996](#) ).

## CONCLUSION

In summary, all mental health professionals who treat adolescents need to be knowledgeable about the role and treatment of substance abuse in this population. Since the early 1990s, escalating progress has been made as effective treatments are being developed and clinical research has been expanded.

## DEFINITION

The definition of trauma varies with context. In the broadest sense, it includes both physical and psychological injury or wound ( [The American Heritage Dictionary, 1992](#)). Posttraumatic stress disorder (PTSD) and acute stress disorder (ASD), as diagnoses, refer to a characteristic set of psychological and physiologic symptoms following exposure to a stressor or traumatic incident.

## HISTORICAL NOTE

Psychological reactions to severe stress have been recorded for thousands of years. Early depictions date to the Old Testament and Roman Empire, with more scientific descriptions emerging by the 17th century ( [O'Brien, 1998](#)). Commonly applied to combat situations, a number of terms have been used to describe these reactions—battle fatigue, shell shock, combat neurosis, and war neurosis, to name a few. The descriptions include similar symptoms such as anxiety, reenactment, sleep disturbance and nightmares, amnesia, dissociation, unresponsiveness, numbness, detachment, social isolation, hypervigilance, irritability, concentration difficulty, and impulsiveness ( [Herman, 1992](#); [Kentsmith, 1986](#); [O'Brien, 1998](#); [van der Kolk et al., 1994](#)) and are consistent with the diagnostic criteria for PTSD in the Diagnostic and Statistical Manual series ( [American Psychiatric Association, 1980, 1987, 1994](#)). The Vietnam War and its aftermath brought widespread social and professional attention to the psychological sequelae of trauma, creating an intense debate about the existence of a unique disorder associated with trauma exposure. Interest in the condition has resulted in extensive research on the subject with subsequent modification in psychiatry nosology. As with many disorders, recognition of the condition in children came later.

The psychiatric nomenclature that guides diagnosis is codified in a series of manuals published by the American Psychiatric Association ( [1952, 1968, 1980, 1987, 1994](#)). The first *Diagnostic and Statistical Manual of Mental Disorders* (DSM) ( [American Psychiatric Association, 1952](#)), published in 1952, included a category of transient situational personality disorders for acute symptom responses to overwhelming situational stress in which no “apparent underlying personality disturbance” was present (p. 40). In this category were several diagnoses, including gross stress reaction in which the individual responded to “overwhelming fear” associated with severe or unusual stress (p. 40). These reactions were reversible but could progress to other diagnoses. Responses that persisted were considered an indication of more severe underlying problems and were classified elsewhere. Other diagnoses in this category included adult situational reaction and adjustment reaction of infancy and childhood.

In the DSM-II ( [American Psychiatric Association, 1968](#)), the transient situational disorders category was renamed transient situational disturbances. It was reserved for “transient disorders of any severity (including those of psychotic proportions)” in individuals with no “apparent underlying mental disorders” (p. 48). The diagnosis was to specify the cause and manifestations of the disturbance if they were known. Symptoms were thought to diminish as the stress decreased in those with good adaptive functioning. Persistence of symptoms after the stress disappeared warranted another diagnosis. The disorder was classified according to the patient's age as, for example, adjustment reaction of adult life or adjustment reaction of childhood.

Posttraumatic stress disorder first appeared by that name in the DSM-III ( [American Psychiatric Association, 1980](#)). DSM-III required a “recognizable” stressor (p. 238) “generally outside the range of usual human experience” (p. 236) that “would evoke significant symptoms of distress in almost everyone” (Criterion A) (p. 238). Symptoms in each of three clusters were required: reexperiencing, numbing, and arousal. Reexperiencing could occur through recurrent and intrusive recollections, dreams, and/or “sudden acting or feeling as if the traumatic event were reoccurring” (Cluster B) (p. 238). Numbing or decreased “involvement with the external world” not present before the trauma could be evidenced through decreased interest in “significant activities,” feeling detached or estranged from others, and/or constricted affect (Cluster C) (p. 238). Arousal symptoms not present before the trauma included increased alertness or startle response, sleep disturbance, survivor guilt, concentration or memory problems, avoidance of traumatic reminders, and/or increased symptoms when exposed to situations that symbolize or resemble the stressor (Cluster D). The Cluster C symptoms did not include avoidance; rather, avoidance was associated with arousal and classified in Cluster D. The diagnosis required at least one reexperiencing, one numbing, and two arousal symptoms.

Like DSM-III, DSM-III-R ( [American Psychiatric Association, 1987](#)) required characteristic symptoms following a psychologically distressing event “outside the range of usual human experience” that “would be markedly distressing to almost anyone” (p. 250) and that would usually be “experienced with intense fear, terror, and helplessness” (p. 247). DSM-III-R included characteristic symptoms of reexperiencing, avoidance and numbing, and increased arousal. Physiologic reactivity was categorized as a Cluster D arousal symptom and avoidance was categorized with numbing as a Cluster C symptom. At least one reexperiencing, three avoidance/numbing, and two arousal symptoms were required for diagnosis. Avoidance/numbing and arousal symptoms were required to have onset after exposure to

the stressor. New to DSM-III-R was the requirement that symptoms endure at least 1 month.

DSM-III-R also added age-specific features to describe symptoms presenting in children. These included reexperiencing in action such as repetitive play, "loss of recently acquired developmental skills" (p. 250), mutism or refusal to discuss the trauma, generalized nightmares, and physical symptoms.

The current edition of the DSM-IV ([American Psychiatric Association, 1994](#)) requires exposure to "an extreme traumatic stressor involving direct personal experience of an event," witnessing an event, or "learning about" an event (p. 424) and that the individual responds with "intense fear, helplessness, or horror" (p. 428). In children, the response may involve "disorganized or agitated behavior" (p. 428). At least one reexperiencing, three avoidance/numbing, and two arousal symptoms must be present with a temporal relationship between the event and the avoidance/numbing and arousal symptoms. The symptoms must be persistent and endure for more than 1 month. DSM-IV criteria modified DSM-III-R by moving physiologic reactivity from the arousal cluster (Cluster D) to the reexperiencing cluster (Cluster B) and added a requirement that the disturbance cause "clinically significant distress" or functional impairment (p. 429). Child-specific symptoms include repetitive play, generalized nightmares, and "trauma-specific reenactment" (p. 428).

Acute stress disorder (ASD) was added as a new diagnostic category in DSM-IV. Diagnosis requires at least three dissociative symptoms either during or after the event, at least one persistent reexperiencing symptom, marked avoidance, and marked anxiety or hyperarousal. There must be "clinically significant distress" or functional impairment (p. 432). Acute stress disorder must occur within 4 weeks of exposure and last 2 days to 4 weeks. It cannot be caused by the use of a substance, a general medical condition, a brief psychotic disorder, or an exacerbation of a preexisting mental disorder.

The changes in diagnostic nomenclature over successive editions of the DSM attest to the increase in understanding of and research about the condition over the last two decades. Of note, changes have occurred in the definition of the stressor, the clusters to which specific symptoms are assigned, the required number of symptoms from each cluster, onset and duration, and the requirement of clinical distress or functional impairment.

The application of the diagnosis to children did not occur in earnest until Terr ([1979](#), [1981b](#), [1983](#)) studied the child victims of a school bus kidnapping. Terr's detailed descriptions of the children she studied present a compelling picture of the mental suffering traumatized children may experience.

## PREVALENCE AND EPIDEMIOLOGY

Exposure to traumatic events and situations is increasingly common, especially in some environments. The estimated lifetime prevalence of PTSD in the general population ranges from 1% to 14% ([American Psychiatric Association, 1994](#); [Helzer et al., 1987](#); [Kessler et al., 1995](#)). [Giaconia and colleagues \(1995\)](#) found that by the age of 18 years, more than two-fifths of youths in a community sample of predominantly working class or lower-middle-class households met criteria for at least one DSM-III-R trauma and over 6% met criteria for a lifetime diagnosis of PTSD. Owing to the nature of disasters, most studies investigate children exposed to specific stressors and yield higher rates depending on the sample used, characteristics of the event and exposure, assessment tools, and time elapsed since the event ([Cohen et al., 1998](#)).

## CLINICAL DESCRIPTION AND DIAGNOSIS

DSM-IV ([American Psychiatric Association, 1994](#)) identifies six criteria to establish the diagnosis of PTSD. The essential feature of the disorder is the development of characteristic symptoms after exposure to a traumatic event that arouses "intense fear, helplessness, horror;" children may present with "disorganized or agitated behavior" (Criterion A) (p. 428). Exposure can occur through direct experience, with witnessing, or through learning about a traumatic event that caused "actual or threatened death," "serious injury," or "threat to the physical integrity" of oneself or others (p. 427). Symptoms are categorized into three clusters: persistent reexperiencing of the stressor (Criterion B), persistent avoidance of reminders of the event and numbing of general responsiveness (Criterion C), and persistent symptoms of increased arousal (Criterion D). DSM-IV stipulates that there be at least one reexperiencing, three avoidance/numbing, and two arousal symptoms. The symptoms must endure for more than 1 month (Criterion E) and must cause "clinically significant distress" or impaired functioning (Criterion F) ([American Psychiatric Association, 1994](#), p. 429).

### Exposure and Response (Criterion A)

Exposure and response to the stressor constitute the first criterion for PTSD, the stressor criterion. By DSM-IV criteria, the stressor need not be outside the range of normal human experience as required by DSM-III-R ([American Psychiatric Association, 1987](#)), but it must cause "intense fear, helplessness, or horror" ([American Psychiatric Association, 1994](#), p. 428). A host of stressors, both natural and man-made, have the potential to evoke symptoms. Naturally occurring stressors include, for example, tornadoes, earthquakes, and medical illnesses. Man-made events include accidents, domestic and community violence, murder, terrorism, and war. Some of these are singular events; others involve chronic or repeated exposure.

It may be difficult to identify the precise nature and aspects of the event, exposure, or initial response that create the trauma. Perceived threat, emotional states and physiologic arousal during the event, and associated experiences, including losses and disruption, sometimes are included as part of exposure ([Schwarz and Kowalski, 1991](#); [Vernberg et al., 1996](#)). This is consistent with the placement of response to the stressor as part of the stressor criterion.

### Reexperiencing Cluster (Criterion B)

DSM-IV identifies five ways in which reexperiencing may present: recurrent and intrusive distressing recollections, recurrent distressing trauma-related dreams, "acting or feeling" as if the event were reoccurring, "intense psychological distress" with exposure to trauma cues, and physiologic reactivity to traumatic cues ([American Psychiatric Association, 1994](#), p. 428). In children, reexperiencing may be evident in repetitive play with trauma themes, generalized nightmares, and trauma-specific reenactment. Criterion B requires at least one reexperiencing symptom.

### Avoidance/Numbing Cluster (Criterion C)

The avoidance/numbing cluster includes both purposeful actions and unconscious mechanisms. Specific symptoms identified in Criterion C are efforts to avoid trauma-related thoughts, feelings, or conversations; efforts to avoid activities, places, or people reminiscent of the trauma; inability to recall important aspects of the trauma; greatly decreased "interest or participation in significant activities"; feeling detached or estranged; "restricted range of affect"; and a "sense of a foreshortened future" ([American Psychiatric Association, 1994](#), p. 428). Criterion C requires at least three avoidance/numbing symptoms, and they must be temporally related to the stressor. Children may not experience numbing ([Terr, 1983](#)), be unaware of it ([American Psychiatric Association, 1994](#)), or have difficulty understanding the concept ([Earls et al., 1988](#)). Evaluations of them, therefore, should include reports by parents, teachers, and others.

### Arousal Cluster (Criterion D)

Increased arousal includes sleep disturbance, irritability or outbursts of anger, difficulty concentrating, hypervigilance, and exaggerated startle response. Criterion D requires at least two of these symptoms, and as with the avoidance/numbing cluster, arousal symptoms must have a temporal relationship to the event. The heightened arousal required by Criterion D is generalized arousal; arousal in response to reminders of the stressor is a Criterion B symptom. Over time, a repeatedly traumatized child may develop symptoms of chronic stress and arousal with other signs and symptoms such as tachycardia, anxiety, hyperactivity, and impulsive behavior ([Perry et al., 1995](#)).

### Duration (Criterion E) and Onset

Many studies fail to report duration of symptoms essential to the diagnosis of PTSD and in determining impairment. Symptoms must be present for more than 1 month and may persist for months to years. If symptom duration is less than 3 months, the disorder is acute PTSD; chronic PTSD endures 3 months or longer. Symptoms usually begin within 3 months after exposure but may be delayed for months or even years. If onset occurs 6 months or more after the stressor, PTSD is considered delayed ([American Psychiatric Association, 1994](#)). Very delayed onset appears uncommon. It may occur, however, without apparent trigger and may persist ([Yule et al., 2000](#)).

## Distress and Impaired Functioning (Criterion F)

The importance of clinical distress and functional impairment in the diagnosis of PTSD has been recognized by their inclusion in DSM-IV criteria. Few studies of children address this criterion ([de Vries et al., 1999](#); [Giaconia et al., 1995](#); [Kinzie et al., 1986, 1989](#); [Mollica et al., 1997](#); [Sack et al., 1986, 1993, 1995b, 1999](#); [Weine et al., 1995](#)), perhaps because it was not specifically required by DSM-III-R, which was in use when much of the currently available research was conducted. The use of diagnoses in clinical settings, although not necessarily in research, generally reflects the presence of distress and/or impairment.

One important measure of functioning in children is school performance, although impaired functioning also may be evident in other settings and interpersonal relationships. Although some have minimized the impact of trauma on academic functioning ([La Greca et al., 1998](#); [Terr, 1983](#); [Weine et al., 1995](#)), several studies have found diminished scholastic performance in children positive for PTSD or PTSD symptomatology ([Giaconia et al., 1995](#); [Lipschitz et al., 2000](#); [Saigh et al., 1997](#); [Shannon et al., 1994](#)). Discrepancies across studies may reflect diversity of samples, stressors, and methodology.

Perhaps the most exhaustive work on this topic is that of Sack and colleagues, who examined functioning in two series of studies of adolescent refugees—a small school-based convenience sample ([Kinzie et al., 1986, 1989](#); [Sack et al., 1986, 1993, 1999](#)) and a large community-based random sample ([Sack et al., 1994, 1995a, b, 1996, 1997](#)). Their results with respect to functioning are complicated and difficult to interpret. In the school-based sample, the diagnosis of PTSD (using DSM-III criteria) was associated with impaired functioning ([Kinzie et al., 1986](#)). Most of the youths had experienced severe disruption in their education; many were in the protective environment of special educational placement; and less than one-fourth could pass the high school graduation test ([Sack et al., 1986](#)). Their culturally derived commitment to education and respect for authority undoubtedly influenced their teachers' views of them as well as their attitudes and classroom behavior ([Sack et al., 1986](#)). At follow-up 3 years later, those who received psychiatric diagnoses were more likely to have poorer social adjustment ([Kinzie et al., 1989](#)). At 6-year follow-up, functioning was described as "impressive," with almost two-thirds in college and about one-third married ([Sack et al., 1993](#), p. 436). The 12-year follow-up revealed persistent high rates of PTSD (using DSM-III-R criteria) without major functional impairment, although the investigators acknowledged limitations in their measure of functioning ([Sack et al., 1999](#)).

In their second series of studies, Sack and colleagues ([Sack et al., 1994, 1995a, b, 1996, 1997](#)) examined a larger random sample of approximately 200 adolescents and young adults and their parents or guardians. There were few significant differences in functioning between those with and without PTSD. Many were in, or had graduated from, college and many were employed. Almost 20% of those with PTSD and/or depression had sought mental health treatment, however, suggesting that their symptoms created distress, if not functional impairment ([Sack et al., 1995a](#)).

## Symptoms and Symptom Patterns

Endorsement of some PTSD symptoms is normal following trauma exposure and alone does not imply pathology. Indeed, certain PTSD symptoms can be adaptive, especially when danger persists. Intrusive phenomena may stimulate action or planning. Arousal is associated with the fight or flight response, a process promoting survival in the face of threat. Avoidance may constitute an important psychological defense. Partial symptomatology may also be disabling ([Giaconia et al., 1995](#)), and the full symptom complex may develop over time ([American Psychiatric Association, 1994](#)). This is particularly important in children because PTSD often has a chronic course that may disrupt normal development ([Gaensbauer, 1994](#); [Perry, 1994](#)). Because of developmental influences, symptoms in young children may not correspond exactly to those in adults ([American Psychiatric Association, 1994](#); [Scheeringa et al., 1995](#)).

Reexperiencing symptoms are common in traumatized children ([La Greca et al., 1996](#); [Najarian et al., 1996](#); [Silva et al., 2000](#); [Vernberg et al., 1996](#)), although avoidance/numbing and arousal may be more frequent in some situations ([Garrison et al., 1993](#)). The avoidance/numbing cluster ([Garrison et al., 1995](#); [Lonigan et al., 1998](#); [Sack et al., 1997](#); [Silva et al., 2000](#)) and arousal ([Sack et al., 1997](#); [Silva et al., 2000](#)) may be more pathognomonic.

Identification of avoidance/numbing symptoms can be problematic with respect to children if they have difficulty understanding the concept of numbing ([Earls et al., 1988](#)). Effective avoidance and numbing may mask reexperiencing symptoms, giving the impression that the child is unaffected by the trauma ([Cohen et al., 1998](#); [Stuber et al., 1991](#)). Children, and adults observing them, may also be less aware of avoidance/numbing symptoms ([Almqvist and Brandell-Forsberg, 1997](#); [Green et al., 1991](#); [Vernberg et al., 1996](#)).

## Comorbidity

Comorbid conditions are common with PTSD. They include anxiety, affective, and substance use disorders ([Asarnow et al., 1999](#); [Bolton et al., 2000](#); [Giaconia et al., 1995](#); [Goenjian et al., 1995](#); [Helzer et al., 1987](#); [Hubbard et al., 1995](#); [Kessler et al., 1995](#); [Kinzie et al., 1986, 1989](#); [Lipschitz et al., 2000](#); [March et al., 1997](#); [Sack et al., 1986, 1993, 1994, 1996](#)). In one study of over 300 youths, a lifetime diagnosis of PTSD by the age of 18 years significantly increased the risk of other lifetime diagnoses such as depression, anxiety, and alcohol and drug dependence ([Giaconia et al., 1995](#)). It may be that factors predisposing to other conditions, such as anxiety ([Silva et al., 2000](#)) and depression ([Brent et al., 1995](#)), also predispose to PTSD. In addition, some comorbid conditions—[anxiety and depression, for example—share symptoms with PTSD \(Brent et al., 1995\). Indeed, if the diagnostic criteria for PTSD were limited to symptoms more specific to the disorder, comorbidity might decrease \(Davidson and Foa, 1991\). On the other hand, one study found severity of depression associated with a number of PTSD symptoms that did not overlap with depressive symptoms \(Goenjian et al., 1995\).](#)

Comorbid conditions may precede, follow, or develop at the same time as PTSD ([Bolton et al., 2000](#); [Deykin and Buka, 1997](#); [Giaconia et al., 1995](#); [Green et al., 1994](#)); and the course of the illnesses may vary ([Sack et al., 1993, 1994](#)). [Asarnow and colleagues \(1999\) emphasize the importance of distinguishing depressive disorders that preexist and those that occur after trauma exposure. Although PTSD stems from the primary traumatic event, depression may result secondarily from persistent severe PTSD symptoms, intervening stressors, or unresolved grief \(Goenjian et al., 1995\), and it may be less enduring than PTSD \(Sack et al., 1993, 1996\). In a long-term follow-up of children in a shipping disaster, Bolton and colleagues \(2000\) found that most of those who developed PTSD also suffered from another disorder. Most cases of comorbid major depression had onset coincident with or after PTSD, occurring after recovery from PTSD in approximately one-third of these cases. Specific phobia and separation anxiety had onset close to the disaster, and specific phobia—which may reflect persistent fear and avoidance of situations reminiscent of the initial trauma—tended to persist for many years, whereas other comorbid conditions were of shorter duration. Generalized anxiety disorder, obsessive-compulsive disorder, and substance misuse among children in the study did not differ significantly from controls.](#)

## ETIOLOGY AND PATHOGENESIS

Alarm, fear, and stress all have physiologic components that prepare the body for action. These are evident in the fight or flight response, a complex interplay among several systems of the body, which leads to increased blood pressure, pulse, and respiratory rate; increased blood supply to the muscles; focused attention; and vigilance ([Guyton and Hall, 1997](#); [Perry and Pate, 1994](#); [Perry and Pollard, 1998](#)). This response dissipates with time except in cases of severe, prolonged, or chronic stress, in which it may persist and have potentially detrimental consequences, especially for the developing child ([Perry and Pate, 1994](#); [Perry and Pollard, 1998](#)). [Perry \(1994\) submits that large increases in neurotransmitter activity associated with severe and prolonged stress in children may alter the physical development of the brain, placing traumatized children at risk for developmental disorders.](#)

[Perry and colleagues \(1995; Perry and Pollard, 1998\) maintain that the fight or flight response is not adaptive in very young children exposed to chronic or repeated trauma. The child's initial reaction to trauma, such as crying, is initiated to summon the child's caretaker who may then either fight the trauma or flee with the child. If no caretaker responds, as may be the case with abused children whose caretakers are the perpetrators of the abuse, the child will abandon the crying in favor of a surrender response leading to dissociative behaviors \(Perry and Pollard, 1998; Perry et al., 1995\). The first response is to freeze—the child becomes immobile and compliant. Freezing is adaptive because it allows more intense scrutiny of the environment and it may conceal the child's presence, decreasing the likelihood of attention from a potential perpetrator. Dissociative responses allow the child to ignore external stimuli in favor of an internal focus through mechanisms like daydreaming, fantasy, and dissociative states that result, for example, in numbing, compliance, avoidance, and restricted affect \(Perry et al., 1995\).](#)

## FACTORS AFFECTING RESPONSE

By definition, posttraumatic stress conditions emerge following exposure to a stressor or traumatic event. A number of factors contribute to outcome following trauma including aspects of the event and exposure; characteristics of the victim; and family and sociocultural factors ([La Greca et al., 1996](#); [Vernberg et al., 1996](#); [Warheit et al., 1996](#)). Because each child's exposure to a traumatic event is unique, the characteristics of that individual exposure should be evaluated.

## The Traumatic Event

Characteristics of the stressor can be important in the child's response. For example, man-made events are thought to be more traumatic than natural ones ([American Psychiatric Association, 1994](#)). Community-wide disasters may prompt an outpouring of support not found when events affect only a few residents or when victims are dispersed over wide geographic areas. On the other hand, community-wide disasters may deplete available resources and thereby deter response and recovery ([Berren et al., 1989](#)).

## Exposure

Exposure takes many forms including physical presence, direct victimization, and witnessing or learning of an event experienced by a family member or close associate ([American Psychiatric Association, 1994](#)). A number of studies demonstrate the role of physical proximity in trauma response and a dose–response relationship between exposure and symptomatology ([Breton et al., 1993](#); [Goenjian et al., 1995](#); [March et al., 1997](#); [Nader et al., 1990](#); [Pynoos et al., 1987](#)). Widespread interpersonal exposure and extensive media coverage may obscure the dose effect ([Tyano et al., 1996](#)).

Physical injury as an aspect of exposure has not been well examined in children, although it is likely to relate to PTSD symptomatology ([Green et al., 1994](#)). Investigators have explored posttraumatic stress in samples of physically injured or ill children in whom the injury, illness, and/or aspects of treatment represent the traumatic stressor ([Aaron et al., 1999](#); [Butler et al., 1996](#); [Daviss et al., 2000a,b](#); [de Vries et al., 1999](#); [Stoddard et al., 1989](#); [Stuber et al., 1991](#)). For example, in a sample of severely burned children, [Stoddard and colleagues \(1989\)](#) found a positive relationship between the extent of injury and post-burn diagnosis of PTSD.

The role of interpersonal exposure through relationship to direct victims also has been established ([American Psychiatric Association, 1994](#); [Bloch et al., 1956](#); [McCloskey and Walker, 2000](#); [Milgram et al., 1988](#); [Pfefferbaum et al., 1999a,c,d](#); [Stoppelbein and Greening, 2000](#)). The closeness of the relationship between the child and victim may influence response ([Pfefferbaum et al., 1999c,d](#)), and indirect interpersonal exposure—relationship to one who knows a direct victim—also has been documented in samples of indirect or distant victims ([Pfefferbaum et al., 2000](#)).

### INDIRECT AND DISTANT TRAUMA

DSM-IV identifies both direct and indirect exposure in the diagnosis of PTSD. Television viewing as a form of indirect exposure may be associated with symptom development ([Breton et al., 1993](#); [Nader et al., 1993](#); [Pfefferbaum et al., 1999a,c](#)). [Nader and colleagues \(1993\)](#) found that television exposure contributed to PTSD symptomatology even after controlling for the effects of other forms of exposure in Kuwait children following the Gulf War. Disaster warnings have also raised concern as potential trauma-inducing events ([Handford et al., 1986](#); [Kiser et al., 1993](#)).

[Terr and colleagues \(1999\)](#) have proposed a “Spectrum PTSD” classification for indirect trauma. They examined children's responses to the 1986 Challenger space shuttle explosion resulting from three forms of perceptual exposure—observing the launch directly from the viewing stands, watching it live on television, and hearing about it later—and from three levels of interpersonal involvement—personal relationship with the teacher on the flight, residence in the same geographic region but not students of the teacher, and residence on the West Coast with no relationship to the teacher. The spectrum classification includes distant trauma (reaction to a real event observed at the time but from a distant safe site), close call (near miss), indirect trauma (reaction to an event not directly observable), vicarious trauma (reaction to a highly threatening event that was not directly observable but was nationally threatening), mass threat (reaction to a pending or possible national or worldwide event), mass hysteria (reaction to a nonspecific threat with acquisition of symptoms through social means), and copycatting (imitation of symptoms transmitted through social means).

### MULTIPLE FORMS OF TRAUMA EXPOSURE

Traumatized children are commonly exposed to a stressor in multiple ways, yet few studies have examined the relative impact or interactions among various forms of exposure ([Macksoud and Aber, 1996](#); [March et al., 1997](#); [McCloskey and Walker, 2000](#); [Milgram et al., 1988](#); [Nader et al., 1993](#); [Saigh, 1991](#); [Silva et al., 2000](#)). [Nader and colleagues \(1993\)](#) found PTSD symptomatology correlated positively with direct exposure through witnessing and with indirect exposure through television coverage but not with indirect exposure through interpersonal relationships. Nonetheless, multiple forms of exposure, such as physical and interpersonal, may increase risk for symptom development. [March and colleagues \(1997\)](#) found greatest risk for PTSD symptomatology emanating from combined physical and interpersonal exposure.

### SECONDARY ADVERSITIES AND TRAUMATIC REMINDERS

Process trauma refers to the various secondary adversities associated with a traumatic event ([Shaw et al., 1995](#)) such as displacement and relocation, property and economic loss, family and social problems, loss of interpersonal support networks, and conflict between victims and responders. Secondary adversities constitute important aspects of exposure ([Laor et al., 1996](#); [Najarian et al., 1996](#); [Pfefferbaum, 1998](#); [Sack et al., 1996](#); [Shaw et al., 1995](#)). Several studies have examined symptomatology in evacuated, displaced, or resettled children ([Breton et al., 1993](#); [Kinzie et al., 1986, 1989](#); [Laor et al., 1996, 1997](#); [Mollica et al., 1997](#); [Najarian et al., 1996](#); [Sack et al., 1986, 1993, 1994, 1995a,b, 1996, 1997, 1999](#); [Weine et al., 1995](#)) but have not isolated the specific impact of the dislocation itself. Traumatic reminders—stimulus cues that activate symptoms—may also interfere with recovery ([Pynoos, 1994](#); [Pynoos et al., 1996](#); [Shaw et al., 1995, 1996](#)). The potential effects of secondary adversities and traumatic reminders illustrate that the traumatic event does not occur in isolation of other sources of trauma, which may intensify symptoms.

## Initial Reaction

In some studies, response during the event or initial reaction is an important predictor of posttraumatic stress symptomatology ([Aaron et al., 1999](#); [Asarnow et al., 1999](#); [Garrison et al., 1995](#); [Lonigan et al., 1994](#); [Pfefferbaum et al., 1999d](#); [Schwarz and Kowalski, 1991](#)). In fact, one's subjective appraisal of danger and life threat at the time of exposure may be a better predictor of PTSD symptomatology than more objective measures of exposure ([Asarnow et al., 1999](#); [Green et al., 1991](#); [Schwarzwald et al., 1993](#)). Emotions, such as sadness, worry, fear, and loneliness during a traumatic event may also predict later symptomatology ([Lonigan et al., 1994](#)). [Schwarz and Kowalski \(1991\)](#) recommend, therefore, that they be considered an aspect of exposure. DSM-IV criteria for acute stress disorder emphasize the importance of peritraumatic dissociation, which has received relatively little attention in children ([Carrión and Steiner, 2000](#); [Daviss et al., 2000b](#); [Perry et al., 1995](#); [Terr, 1990, 1991](#)). Current methodologic difficulties in obtaining reliable and valid measures of such initial subjective reactions must be addressed to further explore this factor.

## Personal Characteristics

### DEMOGRAPHIC FACTORS

Research findings regarding the influence of demographic factors in childhood PTSD are inconsistent because the types of trauma and populations examined are highly varied. Of the demographic factors thought to be important—sex, age, intelligence, and ethnic status—only sex has been well studied and the results are contradictory ([Foy et al., 1996](#); [Green et al., 1991](#); [Korol et al., 1999](#); [La Greca et al., 1996](#); [Lonigan et al., 1991](#); [March et al., 1997](#); [Shannon et al., 1994](#); [Shaw et al., 1996](#); [Vernberg et al., 1996](#); [Yule et al., 2000](#)). Studies with large samples commonly find girls more symptomatic than boys ([Garrison et al., 1993, 1995](#); [Giaconia et al., 1995](#); [Green et al., 1991](#); [Lonigan et al., 1991](#); [Pfefferbaum et al., 1999c](#); [Shannon et al., 1994](#)), but some studies find boys more symptomatic or find qualitative differences in symptoms and recovery related to sex ([Blom, 1986](#); [Shaw et al., 1995, 1996](#)).

The influence of age on trauma is complex ([Foy et al., 1996](#); [Garrison et al., 1995](#); [Green et al., 1991](#); [Newman, 1976](#); [Sack et al., 1994](#); [Schwarzwald et al., 1993, 1994](#); [Vernberg et al., 1996](#)). It may be difficult to ascertain or interpret symptoms in very young children who, because of less mature verbal ability, may be unable to communicate certain aspects of their distress. On the other hand, several studies have documented stress responses in very young children ([Gaensbauer, 1994](#); [Terr, 1988](#)) and even infants ([Scheeringa et al., 1995](#)). The increased cognitive capacity of older children means that they are likely to have a clearer understanding of the stressor and the danger associated with it, but children should also have better developed coping skills as they mature ([Green et al., 1991](#); [Terr et al., 1999](#)). Higher intelligence also may be protective ([Silva et al., 2000](#)), whereas a history of academic problems may place children at risk ([La Greca et al., 1998](#)).

Few studies have demonstrated ethnic or cross-cultural differences in trauma response ([Foy et al., 1996](#); [Garrison et al., 1995](#); [La Greca et al., 1996](#); [March et al.,](#)

1997; Shannon et al., 1994), but some suggest that ethnic minorities may be at risk for maladaptation (March et al., 1997; Shannon et al., 1994). It is unclear, however, to what extent poorer outcome might represent exposure to other traumatic events, family influences, or differences in socioeconomic status rather than ethnicity.

In the final analysis, demographic characteristics may prove less important than exposure and other variables in predicting trauma response (La Greca et al., 1996; March et al., 1997; Sack et al., 1994; Shannon et al., 1994; Vernberg et al., 1996). These other variables include preexisting psychopathology and prior trauma (Aron et al., 1999; Asarnow et al., 1999; Boney-McCoy and Finkelhor, 1996; Daviss, 2000a,b; Earls et al., 1988; Garrison et al., 1995; La Greca et al., 1998), parental exposure (Almqvist and Brandell-Forsberg, 1997), and other family and social variables (Laor et al., 1996, 1997; McFarlane, 1987c).

#### PREEXISTING CONDITIONS AND PRIOR TRAUMA

Preexisting emotional and behavioral problems (Asarnow et al., 1999; Daviss et al., 2000a; Earls et al., 1988; Garrison et al., 1993, 1995; La Greca et al., 1998) and prior trauma (Daviss et al., 2000a; Garrison et al., 1995) adversely impact trauma response in children. This may be especially true for preexisting internalizing symptoms such as anxiety and depression (Aron et al., 1999; Asarnow et al., 1999; Boney-McCoy and Finkelhor, 1996; Daviss et al., 2000b; Lonigan et al., 1994). Asarnow and colleagues (1999) suggest that children with anxiety disorders may appraise threat as more severe and thus may experience greater physiologic reactivity associated with trauma than those without these disorders.

Prior trauma is widely believed to increase the vulnerability of children at times of stress, but few studies have actually investigated the issue and their results are not conclusive (Boney-McCoy and Finkelhor, 1996; Daviss et al., 2000a; Garrison et al., 1993, 1995; McCloskey and Walker, 2000). It is also possible that prior trauma is desensitizing. Terr and colleagues (1999) found children with prior trauma resistant to some trauma symptoms after media exposure to the Challenger explosion. Although these children developed less fear and fewer behavioral reenactments than those without prior trauma, they experienced diminished expectations about the future, which was attributed to their earlier trauma (Terr et al., 1999).

#### Family and Social Variables

Family and social mediators of posttraumatic stress include relationships within the family and social environment, the reactions of family members, family organization, and the family's long-term adaptation (Boney-McCoy and Finkelhor, 1996; Gaensbauer, 1994; McFarlane, 1987a,b; Prinstein et al., 1996; Solomon, 1989). Social factors, such as community disruption, competition for resources, and community response also may influence adjustment (Berren et al., 1989; Pfefferbaum, 1998; Quarantelli and Dynes, 1985; Solomon, 1989).

#### FAMILY RESPONSE AND PARENTAL SYMPTOMS AND FUNCTIONING

A number of studies document an association between child and parent symptomatology following trauma (Breton et al., 1993; Daviss et al., 2000a,b; de Vries et al., 1999; Earls et al., 1988; Foy et al., 1996; Green et al., 1991; Laor et al., 1996; McFarlane, 1987b,c; Sack et al., 1995b), which in some cases may reflect similar exposure. Children's reactions, however, do not always parallel their parents. In a study of families evacuated from Chernobyl, maternal somatization and maternal perception of child somatization were not reflected in the children's self-reported symptomatology (Bromet et al., 2000). The children were only secondarily exposed through parental exposure, which along with open parent-child communication, may have accounted for their general well being.

Sack and colleagues (1995b) found that the relationship between parental and child PTSD diagnosis was not mediated by amount of trauma, family separation and loss, socioeconomic status, or treatment. Parents had higher rates of PTSD and depression than their children, and mothers had higher rates than fathers (Sack et al., 1994). Onset of PTSD was generally earlier in parents than youths (Sack et al., 1995b), raising the possibility of secondary victimization of children, which has been described in clinical reports (Rosenheck and Nathan, 1985; Terr, 1981a) but not studied systematically.

Parental symptoms and poor parental functioning constitute important risk factors for symptom development in traumatized children (Green et al., 1991; Laor et al., 1997; McFarlane, 1987b,c). Specifically, problems in children appear to be associated with irritable, depressed, and overprotective families (Green et al., 1991; McFarlane, 1987a,b), especially when these characteristics occur collectively (McFarlane, 1987a). Consistency in reaction and mood between parents may also affect the intensity of the child's reaction (Handford et al., 1986), as may the quality of the parent-child relationship (Boney-McCoy and Finkelhor, 1996).

#### FAMILY RELATIONSHIPS AND ADAPTABILITY

Boney-McCoy and Finkelhor (1996) found that the parent-child relationship is important in trauma response. Positive family relationships are generally considered protective for traumatized children (Kinzie et al., 1986; Laor et al., 1997; Pynoos and Nader, 1989; Schwarzwald et al., 1994). In fact, family contact may mitigate adverse response to severe trauma (Kinzie et al., 1986), although this protection may dissipate as other life events ensue (Kinzie et al., 1989).

Family adaptability—the capacity to change the power structure, roles, and norms within the family—is likely to affect trauma response. Family cohesion—the flexibility of affective bonds—may be even more important. Both extremes of cohesion, too distant and too close, create risk for maladaptive outcome (Laor et al., 1996), although more research is needed to help clarify these family factors.

#### VICARIOUS TRAUMA

A contagious quality of trauma has been described (Perry et al., 1995; Pfefferbaum and Pfefferbaum, 1998; Rosenheck and Nathan, 1985; Terr, 1981a, 1983, 1985). Rosenheck and Nathan (1985) reported the development of PTSD symptoms in the young son of a war veteran. Perry and colleagues (1995) suggest a possible mechanism for this process, attributing "vicarious traumatization" to persistent unchecked hyperarousal in which the parent's response becomes a source of trauma to the child (p. 285). In such situations, of course, the parent is also less able to provide needed support to the child, compounding the problem. Terr (1981a) described a similar process in siblings. She found posttraumatic play in the younger sibling of a trauma victim that was then passed on to yet another sibling and speculated that the anxiety associated with the traumatic play attracted the nontraumatized child into the play.

#### INTERPERSONAL AWARENESS

Although not a consistent finding (Breton et al., 1993), a number of studies report that parents underestimate the deleterious effects of trauma on their children (Almqvist and Brandell-Forsberg, 1997; Burke et al., 1982; Daviss et al., 2000b; Earls et al., 1988; Handford et al., 1986; Korol et al., 1999; Sack et al., 1986, 1994; Yule and Williams, 1990). When it occurs, parent-child discrepancy may represent denial on the part of parents (Almqvist and Brandell-Forsberg, 1997), but children also may be especially compliant in the aftermath of trauma and may not fully display their distress (McFarlane et al., 1987; Shaw et al., 1995), perhaps to avoid burdening their parents (Mollica et al., 1997). Adults may collude in this avoidance to escape the discomfort of the posttraumatic experience—their own, their child's, or both.

#### LABORATORY STUDIES

The most commonly described response to threat is the fight or flight response involving the sympathetic nervous system. Physiologic changes in response to trauma include elevated pulse and blood pressure that may decrease in children if they begin to dissociate (Perry et al., 1995). Glod and Teicher (1996) found differences in circadian rhythm and activity level in abused children with and without PTSD. Loss of the normal inhibitory modulation of the startle response was demonstrated in a small sample of children with PTSD (Ornitz and Pynoos, 1989). De Bellis and colleagues (1994) found severe sexual abuse associated with biochemical changes in catecholamine synthesis, and Goenjian and colleagues (1996) found intrusion symptoms related to baseline cortisol levels and cortisol suppression by dexamethasone in adolescents 5 years after an earthquake.

Although physical changes associated with heightened arousal occur as part of the posttrauma response, there are no specific laboratory tests to diagnose the condition. Measures of autonomic functioning such as pulse, electromyography, and sweat gland activity (American Psychiatric Association, 1994) may demonstrate changes, but the diagnosis is made through careful history and clinical observation.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of PTSD includes a number of conditions, most notably acute stress disorder and adjustment disorder. Acute stress disorder, like PTSD, occurs after exposure to a traumatic event in which the individual responds with “intense fear, helplessness, or horror” ( [American Psychiatric Association, 1994](#), p. 431). It is distinguished from PTSD by its onset and duration and the prominence of dissociative symptoms. In contrast to PTSD, symptoms must occur within 4 weeks of the stressor and endure for only 2 days to 4 weeks. The diagnosis of PTSD requires the endurance of symptoms beyond 4 weeks; therefore, it cannot be made within the first 4 weeks following exposure to the stressor. The diagnosis of ASD places greater emphasis on dissociative symptoms but requires reexperiencing, avoidance, and anxiety or arousal as well.

An adjustment disorder is diagnosed when emotional or behavioral symptoms emerge following exposure to a stressor or stressors if the disturbance does not meet criteria for another disorder and does not represent bereavement ( [American Psychiatric Association, 1994](#)). Symptoms must occur within 3 months of exposure and may not persist beyond 6 months after the stressor terminates. Adjustment disorders are specified according to the predominance of affective, anxiety, or conduct symptoms. An adjustment disorder may differ from PTSD because the stressor may not meet the severity and response requirements of Criterion A of the PTSD diagnosis. The diagnosis of adjustment disorder may also be appropriate if Criterion A is met but the full symptom complex necessary to diagnose either ASD or PTSD does not emerge. Diagnostic criteria for an adjustment disorder also require that symptoms be clinically significant causing “marked distress . . . in excess of what would be expected from exposure to the stressor” and significant impairment (p. 626).

Posttraumatic stress disorder shares symptoms in common with other conditions as well. For example, other anxiety and affective disorders may include sleep disturbance with nightmares, social isolation and interpersonal estrangement, decreased interest or participation in significant activities, restricted range of affect, and increased arousal evidenced in outbursts of anger and difficulty concentrating. Obsessive-compulsive disorder includes recurrent intrusive thoughts, impulses or images, and repetitive behaviors or mental acts, but these are not related to a traumatic event and are experienced as inappropriate ( [American Psychiatric Association, 1994](#)). Flashbacks associated with PTSD must be distinguished from hallucinations and other perceptual abnormalities associated with psychotic conditions.

## ASSESSMENT AND TREATMENT

### Assessment

Assessment of trauma involves the traditional methods of psychiatric evaluation emphasizing the history of exposure and prior trauma, observation, the use of projective techniques such as play and artwork, and formal psychological testing. Children may not spontaneously report their symptoms and adults may underestimate trauma in children; therefore, it is essential to ask children themselves about exposure and their responses. In some situations, such as natural disasters or reported criminal victimization, exposure to trauma is obvious, and the clinician quite naturally inquires about the signs and symptoms of PTSD. In other situations, however, exposure is obscure and the need for evaluation may be less obvious. The prevalence of violence and other stressors in modern society is sufficiently great that clinicians should routinely assess exposure and symptoms in the children they see.

### Screening

[Stallard and colleagues \(1999\)](#) recommend routine screening of children after disasters, contending that most children with PTSD go unrecognized and relatively few receive treatment. Screening is especially important when groups of people are affected by incidents such as school or community disasters.

Rating scales can be used to identify those at greatest risk and to facilitate triage. These scales typically measure physical, interpersonal, and media exposure; personal consequences; initial emotional and physiologic response; PTSD symptoms; other related symptoms such as fear, anxiety, and depression; grief; and functioning. Although rating scales are inexpensive, take little time to complete, and require minimal clinician supervision, they may trigger emotional distress, introduce participant and rater bias, and create concern that the child's symptoms are less important than data collection ( [Pfefferbaum et al., 1999b](#)).

Group interviews, conducted in the classroom or other small clusters, also may be used to assess the need for more comprehensive individual evaluation and to begin the process of healing in traumatic situations that involve multiple victims. [Allen and colleagues \(1999\)](#) used this method following the 1995 Oklahoma City bombing to elicit cognitive and emotional responses, assess current adaptation, and explore coping strategies while validating feelings and encouraging support.

### The Initial Interview and Projective Assessments

In the immediate aftermath of trauma, it is often helpful for victims to discuss their experiences, clarify and validate what has occurred, describe their emotional responses, and recognize that others have survived similar experiences. Professional contact should focus on the traumatic event and encourage normalcy ( [Vernberg and Vogel, 1993](#)).

Individual work begins with a sensitive clinical interview. Nonverbal children may express their experiences through simple projective techniques, such as play, drawing, or storytelling, often revealing their distress in repetitive reenactment and graphic depictions. [Pynoos and Eth \(1986\)](#) describe an interview appropriate for assessment and to initiate treatment. The interview consists of three stages, beginning with drawing and storytelling, which invariably contain a reference to the traumatic event. This is followed by a discussion of the event, the child's perception of the threat, the consequences, and the child's feelings of fear, self-blame, and revenge. The interview concludes with a review of the session and the anticipated course of the child's response.

### Therapeutic Considerations

Treatment involves transforming the child's self-concept from victim to survivor because the trauma is resolved in a safe setting in which painful and overwhelming experiences can be explored ( [Amaya-Jackson and March, 1995](#); [Gillis, 1993](#)). A number of therapeutic considerations guide the treatment of PTSD.

The traumatic experience must be understood in the context of previous trauma, which may be rekindled and complicate recovery. The therapy process itself can evoke reexperiencing symptoms and heightened arousal. The therapist, therefore, must consider the pace at which the child can integrate the trauma and monitor the child's responses and progress.

Avoidance is a core symptom of PTSD and may prevent the initiation of treatment and impede progress once begun. Avoidance can be protective and it can decrease stress at least temporarily, but it also may be interrupted by intrusions and increased arousal that occur spontaneously or with reminders. The therapist must not only respond to what is presented, but also must be alert for important omitted information and associated feelings ( [Gillis, 1993](#); [Pfefferbaum, 1997](#)). A discussion of avoidance should be included as part of the therapy so that children and their parents are aware that it may occur and may prevent them from obtaining help or dealing with issues.

Regardless of the approach, the child and family must be educated about common posttraumatic symptoms and the usual course of recovery. Older children and adolescents may be comfortable with a direct approach ( [Gillis, 1993](#)); for younger children, projective activities such as play, art, and storytelling provide opportunities for exploring the trauma. Treatment of prominent comorbid symptoms such as anxiety and depression must be considered.

Reenactment play may represent unresolved feelings about the traumatic experience and offers the opportunity for intervention, but the therapeutic effectiveness of reenactment play has been the subject of some controversy ( [Gaensbauer, 1994](#); [Gillis, 1993](#); [Terr, 1989b](#)). Repeated reenactment alone may reinforce pathologic patterns of response, but it also allows access to the trauma-associated affect that must be interpreted for the child ( [Gaensbauer, 1994](#)). Although she does not discourage direct interpretation within the context of the play, [Terr \(1989b\)](#) maintains that play therapy may have benefit even without interpretation and that overinterpretation may confuse the child.

Cognitive distortions associated with trauma are common ( [Gillis, 1993](#)). Inaccurate attributions, such as self-blame and omen formation, should be explored and challenged. This often involves a step-by-step analysis of the child's appraisals and attributions, which can be time consuming and emotionally difficult ( [Cohen et al.,](#)

1998).

## Treatment Modalities and Efficacy

A variety of modalities are used to treat PTSD, including individual psychodynamic and play therapy, cognitive-behavioral approaches, family therapy, group work, school-based interventions, and psychopharmacology.

Unfortunately, relatively little research documents the effectiveness of treatment ( [Cohen and Mannarino, 1996](#); [Deblinger et al., 1990, 1996](#); [Field et al., 1996](#); [Galante and Foa, 1986](#); [Goenjian et al., 1997](#); [Harmon and Riggs, 1996](#); [March et al., 1998](#); [Saigh, 1987a,b](#)) or the comparative advantages of therapeutic modalities ( [Cohen and Mannarino, 1996](#); [Deblinger et al., 1996](#); [Field et al., 1996](#)). Psychotherapy ( [Goenjian et al., 1997](#)), group work ( [Blom, 1986](#); [Galante and Foa, 1986](#); [La Greca et al., 1996](#); [Rigamer, 1986](#); [Stallard and Law, 1993](#)), and cognitive-behavioral approaches ( [Cohen and Mannarino, 1996](#); [Deblinger et al., 1990, 1996](#); [March et al., 1998](#); [Saigh, 1987a,b](#)) have been used. Novel approaches also may be beneficial. [Field and colleagues \(1996\)](#), for example, found massage therapy effective in treating children following a hurricane. In the final analysis, the specific treatment modality used may be less important than the focus on the trauma and the child's reaction to it ( [Cohen et al., 1998](#); [Friedrich, 1996](#)).

### CRISIS INTERVENTION, DEBRIEFING, AND GROUP TREATMENT

Crisis intervention, debriefing, and group therapy may be used when large numbers of children are exposed to a common event. Sessions may be held in schools, hospitals, or other settings. Groups vary with respect to structure. Some include play, artwork, storytelling, and/or role-playing ( [Galante and Foa, 1986](#); [Gillis, 1993](#)). Certain topics—such as usual responses to trauma, reactions to traumatic reminders and anniversaries, and coping mechanisms—should be addressed even if not directly introduced by participants. Parallel parent groups provide a means to address parental reactions and concerns and discuss effective management.

Group work is ideal for educating children and adults about symptoms and for providing age-appropriate explanations of the posttraumatic course. Sharing with others who have experienced the same or similar trauma can be reassuring for children who are hesitant to disclose their concerns or who believe that their experience was unique ( [Yule and Williams, 1990](#)). The group format provides opportunities to explore loss and reminisce, observe a variety of coping strategies and view others at various stages in the resolution of trauma, and gain satisfaction from helping others. Group work also provides an expedient means of identifying children in need of more intensive individual assistance ( [Gillis, 1993](#); [Terr, 1989b](#)). Group debriefing sessions may be especially helpful with respect to intrusion symptoms, perhaps by providing opportunity for ventilation, validating the child's experience, and reinterpreting attributions ( [Stallard and Law, 1993](#)).

There are also disadvantages to group work. Some children are uncomfortable sharing in a group and some need individual treatment. Group discussions may retraumatize children through reexposure to their own experiences or exposure to the experiences of others, and children may adopt the coping strategies of others before fully examining their own responses. It is important to set limits on the expression of anger and aggression, which may create anxiety in peers and signal the need for individual work ( [Gillis, 1993](#); [Pfefferbaum, 1997](#)).

### COGNITIVE-BEHAVIORAL TECHNIQUES

The literature suggests that desensitization, relaxation, and other cognitive-behavioral techniques are beneficial in treating children with PTSD ( [Cohen and Mannarino, 1996](#); [Deblinger et al., 1990, 1996](#); [March et al., 1998](#); [Saigh, 1987a,b](#); [Terr, 1985, 1989b](#)), but little research has addressed the issue. Cognitive-behavioral therapy and educational information may lend structure and support when anxiety and avoidance discourage exploration. [Saigh \(1987a,b\)](#) described the beneficial use of flooding in case studies of children with PTSD. Several studies have demonstrated benefit from structured cognitive-behavioral interventions for sexually abused children and their parents ( [Cohen and Mannarino, 1996](#); [Deblinger et al., 1990, 1996](#)), and [March and colleagues \(1998\)](#) found a group-administered cognitive-behavioral approach effective in children with PTSD related to single-incident stressors.

### FAMILY THERAPY

The family has a major role in the child's adjustment to trauma and parents should be included in treatment ( [Cohen and Mannarino, 1996](#); [Deblinger et al., 1990](#); [Gillis, 1993](#); [Pfefferbaum, 1997](#); [Rigamer, 1986](#); [Terr, 1985, 1989a](#)). Often, more than one family member is traumatized, although individual level of exposure and course of recovery may differ. The parent's own trauma may be so great that the needs of a young, perhaps less vocal child may be overlooked. [Terr \(1989b\)](#) recommends using projective techniques in family work because these engage children in sharing. Helping parents resolve their own emotional distress can increase their perceptiveness and responsiveness to their child ( [Gillis, 1993](#); [Pynoos and Nader, 1993](#); [Rizzone et al., 1994](#)). Parents also may benefit from psychoeducation about their child's symptoms and how to manage them effectively ( [Deblinger et al., 1990](#); [Rigamer, 1986](#); [Rizzone et al., 1994](#)).

The focus of family work includes validating the child's experiences and emotional reactions, helping the child regain a sense of security, anticipating situations in which additional support will be needed, and exploring ways to decrease traumatic reminders and secondary stresses. The child and parents should be educated about PTSD, its symptoms, and course ( [Pfefferbaum, 1997](#); [Pynoos and Nader, 1993](#)).

### PHARMACOTHERAPY

Few studies have examined the use of pharmacologic agents in children with PTSD, and there is little empirical support for the use of any particular medication ( [Cohen et al., 1998](#); [Pfefferbaum, 1997](#)). Pharmacotherapy, when used, is an adjunctive therapy that may be needed if symptoms are disabling ( [Marmar et al., 1994](#)). Clinicians must use their clinical judgment in determining what agents to use. Specific symptoms and the stage of the illness determine whether to use a drug, what drug to use, and the duration of use. Positive symptoms of reexperiencing and arousal may be more responsive to medication than negative symptoms of avoidance ( [Marmar et al., 1994](#); [Najarian et al., 1996](#); [Silva et al., 2000](#)). Comorbid conditions should be considered in selecting an agent ( [Marmar et al., 1994](#); [Pfefferbaum, 1997](#)).

A variety of drugs have potential efficacy in adults and appear to be appropriate if used cautiously in children. Selective serotonin reuptake inhibitors, which have a favorable risk/benefit profile, may be effective in treating childhood PTSD and comorbid anxiety and depression ( [Cohen et al., 1998](#)). Clonidine has been used with benefit in children with PTSD symptoms ( [Perry, 1994](#); [Pynoos and Nader, 1993](#)) and in severely abused and/or neglected preschool children with PTSD symptoms who did not respond to multimodal treatment in a day hospital setting ( [Harmon and Riggs, 1996](#)). [Famularo and colleagues \(1988\)](#) reported benefit from propranolol for PTSD in young children, although placebo effect was not ruled out. Carbamazepine also has been used in the successful treatment of sexually abused children with PTSD ( [Looff et al., 1995](#)).

### SCHOOL-BASED EFFORTS

School-based interventions are effective for traumatized children or children at risk for trauma. They provide access to children in developmentally appropriate settings that encourage normalcy and minimize stigma. School is also an environment in which PTSD and associated symptoms are likely to emerge. For example, intrusive thoughts and difficulty concentrating may interfere with academic performance and social adaptation; therefore, school consultation about the consequences of trauma and the recovery process may be both necessary and useful ( [Pfefferbaum, 1997](#)).

Following disasters, schools and classrooms provide formal and informal opportunities for assessing psychological response, correcting misperceptions and fears, and encouraging normalization and recovery. Such opportunities include group screening and assessment; curricular interventions addressing traumatizing events and stress responses; opportunities for disclosure and discussion; small group activities; and projective techniques such as play, artwork, and storytelling. The goals of school-based interventions must be appropriate for the setting, and it is imperative that school-based programs not supplant efforts to identify and refer children in need of more intensive individual work ( [Pfefferbaum, 1997](#); [Pynoos and Nader, 1993](#)).

### LONG-TERM TREATMENT AND PULSED INTERVENTIONS

Long-term treatment may be necessary for children with intense or enduring exposure and symptoms, preexisting or comorbid conditions, prior or subsequent trauma, or family problems. Treatment during the acute phase of trauma may be followed by planned interventions at strategic points. These may be especially important in mass casualty disasters where many have been exposed and can be reached for follow-up as groups. Patients and their parents should be advised that new issues related to trauma commonly emerge as the child matures and that these may require treatment. These pulsed interventions should anticipate and address the course

of recovery and reflect the child's developmental capabilities ( [Pynoos and Nader, 1993](#); [Terr, 1989b](#)). Intermittent treatment and pulsed interventions are especially useful during developmental transitions, anniversaries, or marker events ( [Amaya-Jackson and March, 1995](#)).

## NATURAL HISTORY, OUTCOME, AND COPING

Few studies have examined the longitudinal course of trauma ( [Bolton et al., 2000](#); [Boney-McCoy and Finkelhor, 1996](#); [Famularo et al., 1996](#); [Green et al., 1994](#); [Kinzie et al., 1989](#); [La Greca et al., 1996](#); [Laor et al., 1997](#); [McFarlane et al., 1987](#); [Nader et al., 1990](#); [Sack et al., 1993, 1999](#); [Shaw et al., 1996](#); [Terr, 1983](#); [Yule et al., 2000](#)). Specific symptoms and their intensity or severity may vary over time. For many, symptoms decrease ( [Green et al., 1994](#); [Milgram et al., 1988](#); [Sack et al., 1993, 1999](#)), but for others, they endure or even increase ( [Goenjian et al., 1995](#); [McFarlane et al., 1987](#)). In fact, trauma-related conditions may persist for years in highly traumatized youths ( [Green et al., 1994](#); [Kinzie et al., 1986, 1989](#); [Sack et al., 1993, 1994, 1999](#); [Terr, 1983](#); [Yule et al., 2000](#)). [Sack and colleagues \(1999\)](#) found new cases of PTSD emerging as late as 5 to 8 years after the end of the trauma. Very delayed onset may occur without apparent trigger and may persist but is uncommon ( [Yule et al., 2000](#)).

[Bolton and colleagues \(2000\)](#) conducted a controlled study of long-term survivors of a shipping disaster. Rates of psychopathology were higher in survivors than in the control group that was comprised of sex-, age-, and school-matched friends or acquaintances nominated by participants ( [Yule et al., 2000](#)). The development of other disorders was strongly associated with the development of PTSD, and most of those who developed PTSD also suffered from another disorder. Those with PTSD were more likely than controls to have a variety of comorbid anxiety and depressive conditions at follow-up 5 to 8 years after the disaster but not increased substance misuse, obsessive-compulsive disorder, or generalized anxiety disorder.

### Coping

The role of coping in childhood trauma victims has only recently been researched and its effects on the course of recovery remain unclear ( [Aaron et al., 1999](#); [Asarnow et al., 1999](#); [Compas et al., 1991](#); [Compas and Epping, 1993](#); [La Greca et al., 1996](#); [Prinstein et al., 1996](#); [Vernberg et al., 1996](#)). A number of conceptual models have been used to examine coping and a variety of terms have been applied to the strategies identified. No single strategy is effective in all situations for all people, and multiple strategies may be used at once ( [Compas, 1987](#)). Two conceptual models of coping are presented as examples of recent research in the area.

One conceptual model of coping identifies two basic approaches—problem-focused and emotion-focused efforts ( [Compas et al., 1991](#)). Problem-focused coping appears earlier than emotion-focused coping, which increases with age. Problem-focused coping involves attempts to change or master some aspect of the stressful situation, whereas emotion-focused coping represents efforts to regulate the emotions associated with it ( [Compas et al., 1991](#)). In a study of children confined to sealed rooms because of SCUD missile attacks during the Persian Gulf War, emotion-focused strategies involving avoidance and distraction were associated with less stress after the war ( [Weisenberg et al., 1993](#)). Indeed, avoidance, passive acceptance, and distraction may be effective in disasters where the child has no control over environmental conditions ( [Joseph and Williams, 1997](#); [Kinzie et al., 1986](#); [Weisenberg et al., 1993](#)). On the other hand, avoidant coping also may be associated with increased posttraumatic stress symptomatology ( [Aaron et al., 1999](#); [Asarnow et al., 1999](#)), and it may represent an aspect of PTSD itself.

The second model categorizes coping as avoidant, active behavioral, and active cognitive ( [Asarnow et al., 1999](#)). Avoidant coping strategies include cognitive and behavioral strategies to avoid thinking about the event or dealing with it directly. Active behavioral strategies include specific actions or behaviors to deal with the stressor. Active cognitive approaches include active thoughts about the event. Using this model, [Asarnow and colleagues \(1999\)](#) found active cognitive coping associated with PTSD symptoms and avoidant coping marginally associated with PTSD symptoms in children exposed to an earthquake. Active behavioral coping was not associated with PTSD symptoms.

Certainly in clinical work, coping is a major concern and attention to it represents a positive approach to treatment. [Allen and colleagues \(1999\)](#), for example, conducted group interviews of children in Oklahoma City schools in the year following the 1995 bombing encouraging children to identify and share the coping strategies they found helpful in dealing with the event. The children identified a host of approaches including communication, distraction, projective activities, and participation in memorial exercises; they also reported relying on parents, teachers, and classmates for support.

## PREVENTION

Prevention of PTSD involves preventing the traumatic stressor or event or recognizing symptoms soon enough to avert full manifestation of the disorder. A number of factors make this difficult: Traumatic stressors are ubiquitous and they may be unpredictable, PTSD has no single etiology, and exposure and the effects of exposure are not always obvious. Prevention at the community or institutional level entails the development of a disaster plan, which should include an organized mental health response as well as mechanisms to assure physical readiness. Prevention also involves efforts to minimize exposure and secondary adversities and educate victims and potential victims about symptoms that warrant intervention and about safeguards against emotional sequelae ( [Pfefferbaum, 1998](#); [Pfefferbaum et al., 1999b](#)).

It is important to identify high-risk situations and establish mechanisms for early detection and intervention. These measures are often educational in nature and they focus on the child, parent, school, and/or community. Facilitating disclosure of a traumatic event or stressor is important when denial, avoidance, or shame prevent the child from revealing what has occurred ( [Pfefferbaum et al., 1999b](#)).

Parents, primary care physicians, and those who work closely with children such as teachers, counselors, and other school personnel should be taught to recognize and address symptoms of trauma and should be informed about the contagious features of the condition. It is important to identify children with stress responses quickly and to refer them to an experienced mental health professional as soon as possible because the child's initial response may predict longer-term effects ( [Lonigan et al., 1994](#); [Pfefferbaum et al., 1999d](#); [Tyano et al., 1996](#); [Yule and Udwin, 1991](#)).

Health care professionals should develop relationships with local media and encourage responsible reporting to decrease transmission of posttraumatic symptoms. It is also possible to enlist the aid of the media in providing information about symptoms, factors that influence symptom development, and how and where to obtain professional help, although this must be done carefully to prevent misinformation and misinterpretation by the media ( [Pfefferbaum et al., 1999b](#); [Pfefferbaum and Pfefferbaum, 1998](#); [Terr, 1989b](#)).

The overwhelming and unpredictable nature of many traumatic events leaves some victims highly impressionable and susceptible. Those working in situations involving large numbers of individuals at once, such as in natural disasters, war, or war-like conditions, must avoid describing scenarios of response to prevent influencing symptom development in vulnerable individuals. The clinician must be sensitive to the need to explore the trauma but must avoid retraumatizing the child.

## RESEARCH ISSUES AND DIRECTIONS

As research methodology in the study of childhood trauma matures, a host of associated issues warrant investigation. These include the diagnosis of PTSD, symptom clusters, and individual symptoms; aspects of exposure, especially indirect exposure; biological parameters; the longitudinal course of the illness, comorbid conditions, and development; and treatment and coping.

### Diagnosis, Symptom Clusters, and Symptoms

Changes in diagnostic criteria over successive editions of the DSM ( [American Psychiatric Association, 1980, 1987, 1994](#)) suggest limitations in the diagnostic construct itself. For example, the DSM-IV ( [American Psychiatric Association, 1994](#)) Criterion C combines effortful avoidance and numbing into one cluster, but they may well represent distinct dimensions. Several studies using factor analysis identify three or four factors, with avoidance and numbing inconsistently placed ( [Anthony et al., 1999](#); [Dyregrov et al., 1996](#); [March et al., 1997](#); [Pynoos et al., 1987](#); [Sack et al., 1997](#); [Yule et al., 1994](#)).

The criterion requiring clinical distress and impaired functioning also awaits research attention. Given that some PTSD symptoms may represent a normal response to trauma, definitions of distress and functioning are especially important. Although both subjective and objective measures would be ideal, DSM-IV provides virtually no guidance on how to assess them. Failure to address the criterion in prior studies clouds findings that purport to establish diagnosis. A review of previously collected data and a new generation of studies may be needed to determine the degree to which PTSD symptoms and clusters result in distress or functional impairment in children and to identify qualitative as well as quantitative differences between the normal response to trauma and the PTSD diagnosis. This issue has important

implications for treatment.

Other issues related to the diagnostic construct are also of interest. For example, although DSM-IV requires that reexperiencing, avoidance/numbing, and increased arousal symptoms be “persistent,” it does not define the term and does not specify required severity or frequency of symptoms except as they, in the aggregate, cause clinically significant distress or functional impairment ( [American Psychiatric Association, 1994](#), p. 428). Clinically relevant definitions may be developed through further refinement in research-oriented operational definitions.

## Exposure

Although many studies examine the role of exposure in symptom response, a number of specific aspects of exposure have not been well explored. Of great interest are indirect forms of exposure and the PTSD spectrum along with the impact of these on functioning. Assessment of the specific aspects of initial response and their role in the development of symptoms is usually limited by retrospective assessment, yet initial response is important to our understanding of the posttrauma process and course of recovery, the relationship between the biology and psychology of the disease, the relative importance of specific symptoms and the symptom clusters, and treatment planning.

## Biological and Environmental Correlates

Neurohormonal and neurophysiologic correlates of PTSD in children are being identified. Their etiologic significance, relationship to specific symptoms or symptom complexes, and influence on long-term adjustment warrant exploration. Availability and choice of informants, inadequate measures, and complex analytic problems currently limit the study of family factors, which are vital to our understanding of the transmission of the disease, the interaction of biological and environmental influences, mediating factors, and treatment considerations. Social influences are even more difficult to assess.

## Longitudinal Course, Comorbidity, and Development

General population studies assessing response to a variety of stressors are rare but would offer the opportunity to explore effects of trauma on demographically diverse groups of children exposed to a range of events. These studies should investigate the impact of symptoms on functioning and the various factors that influence risk and resilience. Prominent among these factors are the effects of prior trauma, temperament and premorbid conditions, and family factors. Longitudinal assessment of cohorts of children would provide much needed information about the natural course of the illness and could examine comorbidity and coping. Posttraumatic stress disorder shares many symptoms in common with other disorders, requiring careful exploration of comorbid conditions and their temporal relationships to PTSD. Like many conditions, the recognition of PTSD in children lagged behind its recognition in adults, and studies in children tend to mirror those in adults. Therefore, research on the role of development in response to trauma and on the impact of trauma on development is needed.

## Treatment and Coping

Treatment approaches have developed despite a dearth of research about their effectiveness. Controlled studies assessing the impact of treatment on specific symptoms and clusters, the role of medication, the relative benefit of various modalities, and the merits of parental involvement are needed.

Coping is a complicated process ripe for investigation. Disaster coping studies suffer from methodologic problems and inconsistencies that make it difficult to interpret the results. Coping is a process that is difficult to define and operationalize. Investigators attempt to capture useful information by asking children to identify the worst aspect of their experience and the strategies they used to cope or by asking them to think of their coping in general. Studies tend to document the frequency of use of various strategies without reporting the benefit conferred ( [Asarnow et al., 1999](#); [Berman et al., 1996](#); [La Greca et al., 1996](#); [Vernberg et al., 1996](#)). Analyses also vary across studies. For example, data from the Kidcope questionnaire ( [Spirito et al., 1988](#)) used in some disaster studies can be analyzed in several ways—by categorizing strategies according to some schema such as positive/approach or negative/avoidance ( [Berman et al., 1996](#); [Spirito, 1996](#)) or by factor analysis ( [Spirito, 1996](#); [Vernberg et al., 1996](#)).

## Methodologic Issues

Methodologic concerns in PTSD and disaster research have potentially important implications for clinical work. The first involves sample selection. Most studies have examined exposed samples; instead of using control or comparison groups, samples are commonly stratified for within sample comparisons on variables such as exposure. Assessment, for both clinical and research purposes, at best uses multiple informants and measures, yet most trauma studies use survey design and query single informants. Self-report is important in child trauma research, in part, because adults underestimate the reactions of children. Children tend to be better informants of internalizing symptoms, whereas parents provide more accurate information about externalizing behavior ( [McClellan and Werry, 2000](#)).

Trauma research typically employs self-report questionnaires—ideal for screening large groups such as school children—and structured diagnostic interviews. Clinically, PTSD, like other disorders, involves a degree of symptomatology on a continuum rather than the mere presence or absence of symptoms. Therefore, measuring the frequency and severity of symptoms, as well as establishing the diagnosis, is important in understanding the development and progression of PTSD. Self-report measures are more efficient in cost and administration, but the quality and quantity of information obtained is limited. The two most widely used self-report measures in child work are the Impact of Event Scale ( [Horowitz et al., 1979](#); [McNally, 1991](#)) and the PTSD Reaction Index ( [McNally, 1991](#); [Pynoos et al., 1987, 1993](#)). Although they may be coupled with other measures, these tools alone do not measure functioning.

Structured diagnostic interviews have the advantage of establishing diagnosis, important because it represents a generally agreed on constellation of signs and symptoms warranting medical attention. The interview format allows participants to clarify questions and describe their experiences more fully. A number of structured diagnostic interviews are available, including the Child and Adolescent Psychiatric Assessment ( [Angold and Costello, 2000](#)), Diagnostic Interview for Children and Adolescents ( [McNally, 1991](#); [Reich, 2000](#); [Welner et al., 1987](#)), and National Institute of Mental Health Diagnostic Interview Schedule for Children ( [Shaffer et al., 2000](#)). The relative usefulness of structured diagnostic interviews for specific diagnoses or for specific clinical issues has not been studied, and their accuracy is limited by the unknown validity of the disorders they assess ( [McClellan and Werry, 2000](#)).

---

### CASE ILLUSTRATION

Valerie was 15 years old when she entered outpatient treatment following a brief psychiatric hospitalization for depression, suicidal ideation, and conduct problems. Valerie had run away from home after an altercation with her father who disapproved of her argumentative attitude and her choice of friends. Valerie had been placed on a selective serotonin reuptake inhibitor (SSRI) during hospitalization, which was continued as an outpatient. Valerie complained of depressed mood, extreme fatigue, and excessive somnolence. She routinely went to bed immediately on arriving home after school, joined the family for dinner with reluctance, and returned to bed to sleep until awakened each morning for school. Always a poor student, Valerie's grades dropped and she disengaged from extracurricular activities including girl's basketball, which she had previously enjoyed. Valerie came from an intact family with parents who were genuinely concerned about her.

Valerie provided little information that might be useful in her treatment, including history of trauma, current relationships or activities, or feelings. She had great difficulty confiding in her therapist, and her mother often accompanied her to sessions disclosing information about Valerie's progress at home and school. Valerie remained on the SSRI with gradual benefit in mood and sleep disturbance.

Within approximately 1 year of initiating treatment, Valerie started dating a boy from her school. She was devoted to him and felt pride at his interest in her. Her mood improved and her sleep pattern returned to normal. Eventually she began having sexual relations. This introduced conflict at home, although her mother was agreeable to Valerie's use of contraceptives. Over the next several months, internal conflict also emerged, and Valerie finally confided in her mother that at the age of 11 years, she had been seduced by an older boy and then raped by him and two of his friends. Her embarrassment had prevented her from disclosing the incident earlier, but the sexual nature of her relationship with her current boyfriend created enough conflict that she felt the need to discuss what had occurred. Because the perpetrators remained in the community, the incident was reported to authorities over Valerie's objections.

Valerie became more open in therapy, no longer requiring her mother's presence in sessions. She gradually described the traumatic sexual incident, providing increased detail over time, and she reported long-standing intrusive thoughts, dreams, and guilt. She acknowledged that she had purposefully disengaged from peers and assumed no other boy would want her. Sleep, Valerie now realized, had become her escape. She continued to have an uneasy visceral feeling when she thought about the incident, but conflict with her boyfriend and at home diminished. Valerie matured and blossomed socially. Her schoolwork improved, although she was never able to achieve more than marginal success academically. She was weaned off of medication without problem approximately 18 months after entering treatment. She was seen periodically over the next 2 years at developmental transitions but, for the most part, continued to do well, eventually learning to drive, graduating from high school, and entering a junior college in her home town.

### Chapter References

Mass disasters, whether natural, technical, or human-made, take an enormous toll in human life and exert untold physical, psychological, and economic hardships on survivors. They affect individuals, families, and whole communities. Recent years have witnessed a significant growth in mortality associated with nearly all types of disasters, apparently as a result of the increase in population density, urbanization, and climatic changes ( [Ursano et al., 1994](#)). Natural disasters killed nearly 3 million people in the 1970s and 1980s and affected the lives of at least 800 million more (WHO, 1991). Less developed countries account for a considerable proportion (about 40%) of the worst natural disasters, and an even higher proportion of disaster-related deaths. For example, three earthquakes during the last 12 years (Armenia, Turkey, and India) claimed about 30,000 lives each, mostly because of poor housing construction. In China, the costs incurred by natural disasters exceed \$12 billion annually ( [Wang et al., 2000](#)).

Modern technology and mass communication have increased the worldwide awareness of the devastating effects of earthquakes, tornadoes, floods, fires, epidemics, nuclear accidents, and wars. In December 1987, the United Nations General Assembly designated the 1990s the Decade of Natural Disaster Reduction. As part of this effort, research has been conducted on the short- and long-term physical and psychological effects of disaster on individuals at high risk, such as the very old and the very young. The present chapter focuses on the psychological impact of disasters on children. Unlike physical damage, which is usually easy to identify, internal suffering of children can remain hidden even from sensitive observers. Therefore, clinicians and researchers are attempting to elucidate the type, extent, and risks of maladaptive responses of children to mass disaster.

Earlier statements that children show only a mild response to traumatic conditions ( [Garmezy and Rutter, 1985](#)) have been shown erroneous by the application of modern empiric methodologies and direct observations. Indeed, the adverse psychological effects can be severe and long lasting, also in preschoolers ( [Pfefferbaum, 1997](#); [Pynoos et al., 1993](#); [Udwin, 1993](#); [Vogel and Vernberg, 1993](#); [Yule et al., 1999](#)), and they may persist even in the face of apparently normal social functioning ( [Laor et al., 1997](#)). Nevertheless, according to the Task Force Report of the American Psychological Association, "Few psychologists have had specific training for working with children after disasters, and discussions of children's responses to disasters have been rare in texts on psychopathology or issues in normal development" ( [Vogel and Vernberg, 1993](#)).

The aims of this chapter are fourfold:

1. To present a theoretical perspective of disaster as a systemic social phenomenon
2. To clarify the role of child mental health professionals in large-scale preparedness and community reactivation under conditions of disaster
3. To review the major findings on children's responses to disaster from the developmental aspect
4. To propose models of assessment and intervention for children, families, and communities exposed to mass disaster

## DEFINITIONS

The literature distinguishes between "trauma" and "disaster." Traumas are experiences that threaten individual health and well-being, render one helpless in the face of intolerable internal or external danger, overwhelm coping mechanisms, violate basic assumptions about survival, and stress the uncontrollability and unpredictability in the world ( [Eisen and Goodman, 1998](#)). A trauma may be caused by an isolated, unanticipated event or result from repeated exposure to several extreme external events ( [Terr, 1991](#)).

Disasters are relatively sudden, more or less time-limited, public events that extensively damage properties and lives, engendering a systemic continuously disruptive impact on the social network and basic daily routines of children and families ( [Laor and Wolmer, 1999](#); [Vogel and Vernberg, 1993](#)). The community as a whole is compromised in its capacity to negotiate the recovery of its individual members (e.g., massive displacement and relocation). Matters are often made worse when resources are overwhelmed ( [Ursano et al., 1994](#)) and the community's infrastructure is affected. This can result in unemployment, lack of housing and food, poor health and mental health services, school closures, school and job absenteeism, family dysfunction, and displacement of large populations.

Disasters differ in scope and schedule. Some result mainly in loss and disruption (loss of possessions and housing), whereas others involve also a threat to life. Some last a few seconds (e.g., earthquake), whereas others continue for years (e.g., war). Unlike traumas, disasters are characterized by the immediate, long lasting and repeated exposure of victims to reminders of the disastrous event (e.g., destroyed buildings after an earthquake). Usually, three types of experience are combined: terror owing to a danger to one's life or exposure to grotesque sights; grief following loss (e.g., human lives, basic trust, self-esteem); and the disruption of normal living ( [Austin and Godleski, 1999](#)). On the social level, there are shock, depression and mourning, confusion and social disarray, rage and blaming, norm breaking and delinquent behavior, emergence of mythic ideologies, collapse of formal leadership, ascension of informal popular leadership, and social disintegration into primary affiliations. Children feel the disruption in their family, neighborhood, and school ( [Laor and Wolmer, 1999](#)).

Theoretical, research, and intervention studies should follow both a systemic and a long-term design because the pathologic and recovery processes continue long after the disastrous event itself is over, even if it was restricted to a single point in time.

## SYSTEMIC THEORY OF DISASTER

## Disasters and the Mental Health System

Mass disaster poses a multifaceted challenge to the mental health system ([Laor, 2001](#)):

1. *Environmental*. There is an emergence of massive needs, routinely defined as pathologic.
2. *Systemic*. A multidisciplinary orientation and a multisystemic societal collaboration are needed to counter the adverse impact.
3. *Practical*. There are problems of resource allocation, extended deployment, organization, and dissemination of information and communications.
4. *Theoretical*. Similar to other relevant fields (e.g., medicine), the mental health system lacks a comprehensive and integrative “mass disaster theory,” mainly because of the lack of a general social perspective in addition to the public health perspective ([Pynoos et al., 1998](#)).
5. *Professional*. Most mental health teaching programs are not committed to disaster intervention training.

Hence, professionals have insufficient knowledge of diagnosis (of risk factors, clinical picture, and assessment) and therapeutic technology (protocol-driven, short-term, group- and community-based, and disaster-related), and little endurance owing to continuous stress (changing needs and priorities, traumatization, and burnout).

Mental health professionals operate within multiple social systems: psychiatric, medical, welfare, urban, and national. Each may be characterized by degree of adaptability and flexibility under stress. *Static* systems are rigid, indifferent to the environment, and show no adaptive change in structure or function over time. Under extreme stress, static systems may prove brittle and disintegrate. *Chaotic* systems show an anarchic response to the environment (disintegrated, disorganized, and dysfunctional). *Learning* systems respond in a flexible-reactive manner, show sensitivity to the environment and openness to some change in structure or function; however, their range of change is restricted to routine operations, based on past experience. *Meta-adaptive* systems are the most advanced, being both flexible and proactive. They are learning systems that contain units specializing in forecasting and preparing alternative scenarios for coping with change.

### Stages of Disasters

Different models have been proposed to describe the disaster response, most from the event perspective (e.g., warning, threat, impact, inventory, rescue, and recovery) ([Raphael, 1986](#)). The systemic model allows a formulation of disaster that integrates the event, the individual, and the sociocultural reaction, including the mental health response. From this perspective, disaster consists of three stages ([Laor, 2001](#)), but it may loom long before the expected event actually takes place (e.g., the months of expectation and rising anxiety preceding the outbreak of the Gulf War) ([Laor et al., 1996](#)). This *pre-disaster stage* includes warning, alert and alarm signs, and a sense of massive threat to community and personal security.

The *first stage* of a disaster consists of the damaging event itself, the primary disaster, and the attempts to alleviate its effects, that is, rescuing as many victims as possible and providing basic needs (food, water, and shelter) to the affected population. The *second stage* consists of massive changes in societal structure and function (e.g., establishment of evacuation centers and tent cities, movement of refugees), which may lead to loss of norms, structures, and functions. This loss, reflected in societal regression, may be viewed as the secondary disaster and may appear early, even as part of the first stage. Usually, the early optimism of survivors—encouraged by waves of incoming resources and VIP visits—diminishes after a few weeks and turns into disillusionment, and fears of abandonment and lack of justice and bureaucracy. For children, this stage may represent the loss of all social coordinates, causing confusion and disruption of meaning. Brittle social systems may collapse and turn chaotic, aggravating the damage. Here is where the advantage of metaadaptive systems is most conspicuous.

Life usually stabilizes in due course, generally after 18 to 36 months. At this point, there may be a *third stage* of disaster wherein the sociocultural losses, the tertiary disaster, threaten the existing collective ideology and identity (e.g., religious identity of generations of Holocaust survivors). Often, even when the first and second stages are well managed, the third stage is neglected, with effects surfacing even years later. [Note the reports on transgenerational transmission of the culture and the trauma of disaster ([Danieli, 1998](#); [Laor, 1998](#)). A recent report ([Kellerman, 2001](#)) concluded that nonclinical samples of children of Holocaust survivors and control individuals do not show different levels of psychopathology.]

Sometimes, the transition between stages and/or the increase in damage severity evolve gradually and over an extended period of time (e.g., AIDS epidemic in Africa, the recent armed conflict in the Balkans, and the Israeli–Palestinian conflict). Primary, secondary, and tertiary types of disaster coexist. The gradual pattern allows for preparation and short-term adaptation to minor increments of destruction. However, it may also engender habituation ([Solomon, 1995](#)), both within the affected and the international community, damaging the capacity for long-term forecasting and for proper coping.

## CHILDREN'S REACTIONS TO DISASTER: THE DISASTER SYNDROME

The child's protective matrix consists of various dimensions in the child's reality that could be disrupted and rehabilitated differentially: the political, cultural, social, physical, familial, maternal, and personal ([Laor, 1996](#)). Because disasters affect all these components, the disaster syndrome, unlike posttraumatic syndrome, involves all aspects of the child's developing cognitive structures and capacities and poses a more intricate pathologic threat. Children must cope with many different kinds of losses: of people, support systems, normal routines, and basic assumptions of safety and regularity. To help them, the mental health professional must recognize and help to restore the various dimensions of the destroyed reality. Children may become withdrawn and alienated from the reality they perceive as having betrayed them: nature, parents, society, and its technology. The withdrawal may take the form of psychic shock that may lead to a serious catastrophic reaction or it may partially resolve by the mobilization of coping mechanisms ([Krystal, 1968](#); [Valent, 2000](#)).

Specifically, disasters may affect children's ability to regulate the intensity of impulses and unconscious fantasies, thereby jeopardizing their sense of self-efficacy, security and autonomy, normal maturation of defensive functioning, object relations, reality testing, and attachment with caretakers. Structural developments, such as superego consolidation and its behavioral consequences (e.g., empathy, prosocial behavior); ego ideal structure, with its relevance to affiliation and ideology formation; and ego functions, with significance in areas of cognition and attention, may also be hampered during the primary, secondary, and tertiary disasters. Traumatization has a potentially damaging effect on the development of a lasting sense of identity that integrates thoughts, images, feelings, and sensations. The sense of historical continuity of the self (past, present, and future) therefore may be disrupted ([Pynoos et al., 1995](#)).

The clinical picture observed in children immediately after disaster is characteristic of acute stress and/or acute grief reaction, depending on the type of trauma and loss they have suffered. The severity of the response depends on many factors, such as level of exposure, developmental level, culture, parental support, and pre-disaster personality. Children may be in a state of shock and numbness hours or days immediately after a disaster. Dissociative symptoms, such as depersonalization and derealization—a sense of unreality of the world or oneself—may be the first line of defense against the overwhelming experience, before the prolonged process of reconstructing the internal world and external environment begins.

Preschoolers may show behavioral changes and regressive behaviors, mostly within the normal range. These may include irritability, sleep difficulties, separation problems, fears, nervousness, posttraumatic play, demanding or dependent behavior, and whining or temper tantrums ([Bingham and Harmon, 1996](#); [Laor et al., 1996](#); [Sullivan et al., 1991](#)). Older children may report disturbances in conscience functioning, although their moral functioning may seem advanced ([Goenjian et al., 1999](#)).

Studies suggest that parents and teachers tend to report fewer posttraumatic symptoms in children than the children themselves ([Korol et al., 1999](#); [Vernberg et al., 1996](#); [Yule and Williams, 1990](#)). Adults may be preoccupied with their own stress and not be attuned to their child's inner emotional states. Children also may be more reliable reporters of internalizing or dissociative symptoms. Thus, clinicians must be careful to assess children's functioning directly and not rely exclusively on external reports. They must bear in mind that although the initial response tends to predict later adjustment, initial symptomatic ratings may not correlate with later assessments ([Green et al., 1994](#)), and posttraumatic responses may show a delayed onset ([Sack et al., 1999](#)). If the disaster is limited and well controlled, most of the pathologic reactions in children will abate within the first year. In a 17-year follow-up of children exposed to a dam collapse, [Green and colleagues \(1994\)](#) found that survivors recovered from the initial symptomatic reaction and functioned similarly to nonexposed children; however, if community functioning is substantially disrupted, symptoms may persist for years ([Laor et al., 1997](#); [McFarlane, 1987a](#); [Pynoos et al., 1993](#); [Sack et al., 1999](#)). These data underscore the need for effective persistent disaster management on all levels: primary, secondary, and tertiary.

### Types of Postdisaster Symptoms

Children may show a combination of some or many of the following in reaction to disasters: specific posttraumatic stress symptoms, fears, depression and grief, and

dissociation ([Gordon and Wraith, 1993](#)).

### SPECIFIC POSTTRAUMATIC STRESS SYMPTOMS

The symptoms of posttraumatic stress disorder (PTSD) are grouped under three major domains: intrusion, avoidance/numbing, and arousal. Empiric studies have recognized certain symptoms that are specific to children, such as persistent posttraumatic play, omens, and somatic complaints ([Terr, 1983](#)). [Scheeringa and associates \(1995\)](#) proposed diagnostic criteria for the disorder in young children.

*Intrusive reexperiencing of the event* may be observed in thoughts (about the traumatic experience), feelings (as if the event were happening again), or sensations (being acutely distressed by stimuli related to the trauma). Children may tell their experiences over and over, report nightmares, and show repetitive trauma-related play. They also may describe vivid traumatic images: visual (e.g., mutilated bodies), auditory (e.g., the sound of the earthquake or screams for help), olfactory (e.g., odors of burned or decaying bodies), or kinesthetic (e.g., feeling as if they were buried under the rubble).

*Avoidance of reminders* is evidenced in the evasion of places, people, thoughts, or activities associated with the disaster. This can be both a symptom and a defensive maneuver to reduce internal stress; however, persistent avoidance coping is associated with negative mental health outcomes ([Asarnow et al., 1999](#)). The avoidance may be active (e.g., purposeful engagement in trauma-unrelated thoughts to avoid traumatic reminders) or passive (e.g., not engaging in social interactions) ([Anthony et al., 1999](#)).

*General psychic numbing* may be considered a mild dissociation response, and it is more difficult to detect in children than adults ([Yule and Williams, 1990](#)). Children exposed to disasters may lose interest in activities that were significant in the past, feel estrangement from others, show constricted affect, lose recently acquired developmental skills (e.g., toilet training or talking), and express a sense of foreshortened future.

*Increased arousal* symptoms are the most easily recognized by external observers, and include irritability, angry outbursts, exaggerated startle response, hypervigilance, difficulty in concentrating, and sleep disturbances (expectable in young children) such as difficulty getting to sleep or sleeping alone ([La Greca, 2000](#)).

In a study of Armenian children exposed to the 1988 earthquake, about 90% of those living adjacent to the epicenter met the diagnosis of PTSD 18 months later, compared to only 30% of children from the periphery of the earthquake zone ([Pynoos et al., 1993](#)). [Anthony and colleagues \(1999\)](#) found that anhedonia and attention and learning problems are the most common symptoms after disasters; however, they reflect the normal disruptive consequences of disasters rather than being markers of a pathologic reaction.

### FEARS AND DEPENDENT BEHAVIOR

Mass disasters typically induce specific fears and dependent behavior in children ([Goenjian, 1993](#); [Sullivan et al., 1991](#)). Old fears may be reactivated, current ones may intensify, and new fears may emerge with a more or less clear relationship to the event. Particularly in young children, fears may lead to dependent and clingy behavior, difficulty separating from caretakers, or refusal to attend school, thereby interrupting the separation-individuation process. [Vogel and Vernberg \(1993\)](#) explained the separation anxiety of children after disasters in terms of the child–parent attachment relationship. They claimed that disasters challenge the basic assumption that the world is a secure place, leaving the child helplessly vulnerable. The recent finding that young children's symptoms correlated with their mother's reaction 5 years after a disaster provided empirical support for this hypothesis ([Wolmer et al., 2000](#)).

### DEPRESSION AND GRIEF

Children exposed to disasters may show symptoms of depression and grief, but these are usually of lesser severity than the specific PTSD symptoms ([Vogel and Vernberg, 1993](#)). Because grief and posttraumatic stress symptoms may appear independently of one another, [Pynoos and coworkers \(1987b\)](#) stressed the need for separate diagnostic interviews for each domain. The mood symptoms, which have been suggested to be at least partially secondary to the posttraumatic reactions ([Goenjian et al., 1995](#)), are the result of different types of loss (e.g., of home, family members, personal belongings, and basic assumptions). The traumatic grief reaction, recently defined for adults, may include persistent preoccupation with thoughts of or searching for the deceased, feelings of disbelief about the death, or anger and detachment from others ([Noaghiul and Prigerson, 2000](#)). This construct still awaits validation in children.

After the 1999 earthquakes in Turkey, [Wolmer and colleagues \(2001b\)](#) found that children who had seen severely injured or dead people experienced hunger or lack of sleep after the event, or had had more traumatic experiences in the past reported more depressive and grief symptoms. [Goenjian and associates \(1995\)](#) reported high levels of depressive symptoms in the most affected Armenian children 18 months after the 1988 earthquake, apparently because of the extent of family losses and the persistence of posttraumatic symptoms.

### DISSOCIATION

Disasters may be perceived as an overwhelming interruption of human experience, thereby distorting the individual's basic assumptions, both cognitive (e.g., "What is real and what is imaginary?") as well as existential (e.g., "Is it happening to me?"). To reestablish well-being, some people define a different "spacial" arrangement of their position relative to the world: "*I am not affected by the circumstances because I am focused on my own task*" or "*I am not affected, because I am elsewhere.*" This type of distancing is adaptive. Pathologic dissociation goes one step further, with manipulation of adverse stimuli through the reconstruction of perception and the redivision of consciousness: "*What is happening to me is not real*" or "*I, the experiencing one, am not real*" ([Laor, 1996](#)). Under conditions of mass disaster, this maladaptive response may encompass extensive spheres of experience (moral, familial, social, cultural, and political) and affect a wide range of self-systems.

Dissociative reactions may be manifested by symptoms that reflect a discontinuation of personal experience (e.g., affective detachment, perceptual distortions or body- and self-distortions). Children may have out-of-body experiences, perceive life like a dream or movie, and "hear voices" of or "see" people who have died. Amnesia is apparently less frequent in children than adolescents. Under certain conditions, dissociative mechanisms provide temporary relief from the overwhelming trauma. If persistent, however, they may engender a long-term alteration in normally integrative functions of identity, memory, and/or consciousness ([Putnam, 1995](#)).

## FACTORS AFFECTING CHILDREN'S RESPONSES TO DISASTERS

Several factors influence the extent of the children's symptomatic response to disaster. Some relate to the disaster itself, others to individual, familial, and social characteristics.

### Factors Related to the Disaster

Children whose traumatic exposure is more severe tend to react in a more extreme way ([Solomon, 1995](#)). This "dose of exposure" effect is apparent, for example in proximity to the epicenter of an earthquake ([Pynoos et al., 1993](#)), the impact zone of a hurricane ([Shaw et al., 1995](#)), or the site of missile attacks ([Laor et al., 1996](#)). More severe responses have been noted in children who were exposed to the cruelest experiences, such as witnessing severely injured people and mutilated bodies, faced a direct threat to their own life, or suffered human loss, especially of family members ([Husain et al., 1998](#); [Pfefferbaum et al., 1999](#); [Yazgan et al., 2001](#)), and in children who sustained personal injuries ([Goenjian et al., 1995](#); [Green et al., 1991](#); [Laor et al., 2001](#); [Udwin et al., 2000](#)). Continuous displacement is also predictive of a worse psychological response ([Laor et al., 1997](#); [Lonigan et al., 1994](#)). Children exposed to several traumatic experiences are more likely to exhibit more posttraumatic symptoms ([Laor et al., 2001](#); [Macksoud and Aber, 1996](#); [Thabet and Vostanis, 1999](#)).

When the disaster is severe, children need to cope with a massive range of problems: lack of food, water, and shelter; property damage; inadequate housing; violence; lack of medical care; traumatic reminders; bereavement; relocation; separation from parents; and economic crisis. Their posttraumatic reactions may intensify and interfere with symptomatic recovery, at least during the first year, as well as with long-term development ([Freedly et al., 1993](#); [Husain et al., 1998](#); [McFarlane, 1987a](#); [Pynoos et al., 1993, 1995](#)).

### Factors Related to the Child

## AGE

The variations in both children's age and symptom domains examined among the various studies make generalizations difficult, although young children are considered more vulnerable ([Garbarino and Kostelny, 1996](#); [Solomon, 1995](#)). Nevertheless, behavioral problems, specific fears, regressive symptoms, and separation problems appear to be more characteristic of young children, whereas depression and anxiety are more characteristic of older children and adolescents ([Gleser et al., 1981](#)). Three months after Hurricane Hugo, preadolescent children reported more posttraumatic symptoms than early and late adolescents, who had similar responses ([Shannon et al., 1994](#)). [Green and associates \(1991\)](#) reported a similar level of some specific posttraumatic symptoms (intrusion and arousal) in preschoolers and school-age children and adolescents, although the latter reported more avoidant symptoms. This pattern may reflect different ways of expressing the same basic symptomatic domain in groups with different levels of cognitive and affective maturity, resulting in dissimilar coping styles and levels of appraisal.

## GENDER

Results are conflicting regarding gender differences. Some studies report no gender differences ([Laor et al., 1996, 1997](#); [Shaw et al., 1995](#)). Others found that girls tend to report more internalizing symptoms (anxiety, depression, fears) and boys more externalizing behavior (acting out, aggression). [Pynoos and coworkers \(1993\)](#) found that after the Armenian earthquake, girls reported more posttraumatic symptoms ([Shannon et al., 1994](#); [Udwin et al., 2000](#)); and [Gleser and colleagues \(1981\)](#) reported that after the Buffalo Creek flood, boys showed more belligerence. Girls tend to be described as more resilient than boys in childhood, but more vulnerable in adolescence ([Masten et al., 1990](#)). Girls' greater readiness to share their concerns may explain some of these gender differences.

## VULNERABILITIES AND RESILIENCY

Children with prior pathology, particularly anxiety symptoms ([Asarnow et al., 1999](#); [Lonigan et al., 1994](#); [Udwin et al., 2000](#)) and learning difficulties ([Udwin et al., 2000](#)), and children who have suffered more traumatic events in the past (e.g., divorce, surgery, car accidents, losses) ([Earls et al., 1988](#); [Laor et al., 2001](#)), are more prone to severe symptoms months after a disaster. By contrast, resilient children are those with caring adults during and after major stressors, who are also good learners, good problem-solvers, and engaging to other people. In addition, they have areas of competence and a high perceived efficacy by self or society ([Cohler et al., 1995](#); [Masten et al., 1990](#)). In a study of children exposed to the Northridge earthquake, a mild to moderate stressor, [Asarnow and associates \(1999\)](#) found that the role of heritable biology in the children's reaction was minor compared to the role of the children's subjective appraisals of stress and past psychopathology.

## COPING SKILLS

The child's coping skills also may mediate between the severity of the exposure and the response. More negative coping strategies (or a more immature defensive style) to deal with stress (e.g., blaming others, anger) are associated with greater symptomatic persistence over time ([La Greca, 2000](#); [Wolmer et al., 2001a](#)).

## Factors Related to the Family

### REACTION OF THE PARENTS

The presence of adults caring for the child during and after a major stressor is considered the most important and consistent protective factor ([Earls et al., 1988](#); [Masten et al., 1990](#)). Indeed, the reaction of the parents, especially the mother, to the disaster is generally correlated with severity of the child's responses ([Winje and Ulvik, 1998](#)). Researchers in Israel found that the reaction of preschool children to the missile attacks during the Gulf War was highly correlated with the reaction of their mothers ([Laor et al., 1996, 1997](#); [Wolmer et al., 2000](#)). This was true for 3- and 4-year old children, but not for 5-year-old children, probably owing to the latter's increasing autonomy and control of the psychological buffering systems for development ([Masten et al., 1990](#)). Five years after the war, the mothers' poor psychological functioning (increased symptoms, immature object relations and defense style) was associated with increased symptoms in their children ([Laor et al., 2001](#)).

[McFarlane \(1987a\)](#) stressed that the ability of parents to contain the anxiety generated by the extreme threats of disasters was the most important factor influencing their children's responses ([Sullivan et al., 1991](#)). Consistent love and encouragement to grieve and to discuss emotions openly within the family seem to have protected even unborn children and infants of parents evacuated after the 1986 Chernobyl disaster ([Bromet et al., 2000](#)). Parents are critical mediators of stress mainly owing to their roles in social referencing (pooling information and processing of meaning), responding emotionally, and caring for and supporting the child ([Masten et al., 1990](#)).

### FUNCTIONING OF THE FAMILY SYSTEM

The family is an important mediatory factor, particularly in young children ([Laor et al., 1996, 1997](#); [McFarlane, 1987b](#)). Families with extreme levels of cohesion—boundaries that are either too loose or too rigid—may not provide the appropriate support or allow the child to withdraw at times in order to process the traumatic experiences and reach a constructive resolution of concerns. Caring support, open communication patterns, and sensitivity to the child's needs enable parents and children to regulate dyadic processes and discuss disaster-related issues when necessary. Alternatively, parental stress may lead to a pattern of preoccupation with their own suffering and overprotection of the child, which interferes with the healthy process of resolution ([McFarlane, 1987a](#)).

## Factors Related to the Society and Culture

### FRIENDSHIPS

Friendships are valuable sources of reciprocal affection and attachment, mutual assistance, emotional security and self-esteem, and nonfamilial contexts for intimacy, thereby contributing to the child's ability to cope with stress ([Parker et al., 1995](#)). The natural sources of friendships, the family (the sibship), neighborhood, and school, may be shattered in times of disaster. Friendships may also include supportive relationships with teachers or other adults ([Udwin et al., 2000](#); [Vernberg et al., 1996](#)). Even the presence of a single concerned and caring adult may do much to offset the impact of misfortune in the lives of children ([Cohler et al., 1995](#)).

### COMMUNITY

Communities mobilize under disaster relying on their inner strength and external backup support. The inner strength of a community under disaster is a result of the operation of various factors and processes: (a) effective leadership; (b) social cohesiveness; (c) institutional empowerment; (d) available emergency services; (e) appropriate infrastructure; (f) disaster preparedness plans; (g) communal hardiness that depends on cultural factors (e.g., education, ideology).

### CULTURE

Cultural factors may also affect the clinical picture after a disaster. Cultures define the terms under which symptoms are expressed and set the parameters for the expression of personal distress. Some cultures encourage children to express their distressing feelings (anger, sadness, or longing), and others do not. For example, in some cultures, adults may admonish children who were victims of disaster to be prim and proper ([Goenjian, 1993](#)) or refrain from crying ([Laor et al., 2001](#)). Thus, cultural background, including strengths and weaknesses, needs to be taken into account by clinicians when planning treatment interventions. In addition, culture also mediates ideology and identity. As the purveyor of the meaning ascribed to disastrous events and consequences, the culture regulates the capacity of the individual to maintain an active and resilient stance. At the same time, it can lead some children to take risks that transcend their age (e.g., child soldiers, sexual exploitation).

## ASSESSMENT OF CHILDREN UNDER CONDITIONS OF DISASTER

It is extremely important that children at risk of psychopathology after exposure to disaster be identified and treated as early as possible. This is a difficult challenge for clinicians. Child mental health professionals need to be well informed about the valid assessment tools available. In the first and second stages of the disaster, they must remain sensitive to the setting in which they operate: an evacuation center, or destroyed neighborhood beset by fighting, flooding, or an infectious epidemic, or an existing natural setting, such as a school. Under both, the clinical evaluation must remain subordinate to the social one. That is, efforts must be directed not only to the treatment of the children themselves, but also to the reactivation of the society's child care systems via its existing child care workers. In a

natural setting, the assessment may be integrated into the normal institutional activity (see “School-Based Interventions” in the following). Furthermore, to identify the children's strengths and needs, professionals should also evaluate the group to which children belong (e.g., perceived support or hardiness of families, schools, and displaced communities). This mandates close collaboration among an interdisciplinary team of teachers, school counselors, social workers, psychologists, and community leaders.

The preferred clinical screening tools are those that directly assess the child rather than rely on external reporters. They should also be simple and quick to administer, accurate, repeatable, sensitive, and specific ( [Cochrane and Holland, 1969](#); [Stallard et al., 1999](#)). The criteria for identifying pathologic cases should be tempered by consideration of the psychological and economic costs of possible false-positives and false-negatives. Furthermore, the use of cutoff scores may facilitate the decision-making process, but they can obscure minor but “real” differences between children with scores slightly above or below threshold. [Green \(1982\)](#) suggested that clinicians think in terms of degree of impairment in a given sample rather than case identification. Also, the assessment of a single domain rather than the complex of posttraumatic, dissociative, and grief symptoms may decrease the sensitivity of the battery ( [Stallard et al., 1999](#)).

Brief validated assessment tools for children's posttraumatic symptoms include the Child-PTSD-Reaction Index ( [Pynoos et al., 1987a](#)) and the Diagnostic Interview for Children and Adolescents ( [Reich and Welner, 1990](#)). An abbreviated version (eight items) of the Impact of Events Scale ( [Horowitz et al., 1976](#)) has proven successful for use in children. Studies using these scales have suggested cutoff scores for case or symptom severity ( [Stallard et al., 1999](#); [Vogel and Vernberg, 1993](#)).

Symptoms of anxiety may be screened with self-report techniques such as the Revised Children's Manifest Anxiety Scale ( [Reynolds and Richmond, 1985](#)) or the State-Trait Anxiety Inventory for Children ( [Spielberger, 1973](#)). The Birelson Depression Inventory ( [Birelson, 1981](#)) and the Children's Depression Inventory ( [Kovacs, 1985](#)) are valid screens for depressive symptomatology, whereas the Grief Reaction Inventory ( [Pynoos et al., 1987b](#)) focuses on parameters of the grief process following loss.

The assessment of risk factors deserves special attention. Information should be gathered concerning the child's past functioning (traumatic experiences, mental and general health problems) as well as disaster-related events (personal injury, loss of family members or friends, witnessing severely injured or dead people, separation from parents, or experiencing hunger or lack of sleep).

## PRINCIPLES OF CHILD MENTAL HEALTH INTERVENTION

### Systemic Perspective

Mass disasters impact not only on the exposed children, but also on their families, school system, and whole sociocultural milieu. Derivative effects also appear in peripheral communities ( [Goenjian, 1993](#); [Shaw et al., 1995](#)). To cope with this complex challenge, interventions must be formulated from an integrative perspective and focus on maximizing well-being and self-efficacy and minimizing stress and disorganization; they must help victims find meaning and institute a sense of control.

In their approach to public mental health, [Pynoos and colleagues \(1998\)](#) provided guidelines for the effective utilization of government and social institutions, school communities, and interventional teams. They emphasized the need, among others, to resolve institutional conflicts over authority and resource allocation, address the teachers' own disaster experiences, and properly select and train intervention teams to work with severely traumatized victims. Population screening is useful to pinpoint areas that require specific resources and government support. Treatment interventions should be directed at the following factors: traumatic experiences and reminders, interplay of trauma and grief, and postdisaster adversities and their developmental impact.

The effect of mass disasters is so devastating because of the concomitant loss of sociocultural regulators, leading to the destruction of basic schemes, values, roles, and structures (family and individual), and leaving the community open to pain, grief, trauma, and anger. In this process, individual regression and dissociation reflect, complement and reinforce the collective ones. Working in such a milieu, professionals may find themselves embroiled in confusion and red tape among the various social/government systems (e.g., medicine, education, welfare, NGOs) and intervention teams that are trying to help. Therefore, a systemic perspective is needed to clarify the picture and help the psychiatrist: (a) formulate the newly established needs of child-oriented institutions; (b) transfer knowledge and empower professionals in related fields to resume their role; and (c) define their own role and carry out specific interventions collaboratively. This multifaceted systemic perspective was formulated and implemented after the 1999 earthquake in Turkey in the Tel Aviv-Istanbul Disaster Intervention Project ( [Laor, 2001](#)).

Mental health interventions for children and families exposed to mass disaster should follow the five AREST principles, as follows:

**Anticipate.** First, they must provide an integrated vision, foresee different scenarios, and include contingency plans. Professionals and paraprofessionals need to be trained, human and economic resources appropriately allocated, and relevant treatment protocols created. To accomplish these goals, efficient local, national, and international networks need to be developed, with collaboration among agencies (education, police, health), and sponsorship and legitimacy established ( [Vernberg and Vogel, 1993](#)).

**Redifferentiate.** The child psychiatrist must identify the extent of social loss in terms of institutional and role dysfunction and plan the process of context-related redevelopment of professional roles within and between systems (health, welfare, education) with the help of multidisciplinary teams. Attention should be addressed particularly to reconstitute the roles of parents and teachers.

**Empower.** The child psychiatrist needs to debrief (if necessary), educate, and empower social agents (e.g., teachers) who are in direct contact with children to serve as mental health mediators. They must help these agents adapt and restore their original roles, and delegate some therapeutic responsibilities to them. To this end, the child psychiatrist must take a leadership position and supply the team with a professional vision and positive expectations.

**Supervise and Assess.** The psychiatrist must define boundaries; provide knowledge, expertise, and support to therapeutic agents; assess program development; and identify needs by feedback mechanisms. As a leader, the professional needs to encourage creative initiatives in team members and provide them with individualized consideration.

**Treat and Follow-up.** Treatment focuses on the rehabilitation of individuals and families. Delayed responses should also be considered.

### Systems and Stages of Disaster

The application of the AREST principles as defined above is far from straightforward. Routine and disaster operations differ not only in intensity, speed, and expediency, but also—and primarily—in the planned systemic change. The response of the mental health professionals is determined, at each stage of the disaster, by the type of the reacting system. Preparedness and flexibility are key factors ensuring response effectiveness.

During the first stage of disaster—coping with the event itself—rigid systems tend to remain encapsulated in their normal routine, whereas learning systems may undergo structural modifications and create information centers and outreach programs. Meta-adaptive systems, owing to their forecasting capacity, may already be in state of partial readiness and will be able to initiate professional interdisciplinary teaming-up with social agencies early in the process of redifferentiation and empowerment.

In the second stage of societal regression, rigid systems treat acute referrals in existing clinics; learning systems establish field stations and initiate self-training toward the formation of larger trauma centers. Meta-adaptive systems concentrate on the rehabilitation of roles and institutions and draw on resources prepared by national and international collaborations.

In the third stage, rigid systems revert to their original constricted outlook and ignore the larger scope of the tertiary disaster—the loss of ideology and identity. They deal with suffering individuals as they are referred to their clinics, this time as chronic victims. Learning systems maintain operative trauma centers, although their perspective is narrow. They may, however, internalize some of the lessons learned from coping with the first two stages into the institutional response pattern. The main focus of metaadaptive systems is the establishment of community-based disaster intervention centers. These address the tertiary disaster by operating on both the sociocultural and communal clinical levels to enhance regeneration and growth, resilience, and hardiness. Such centers may be planned in advance and developed out of the existing community mental health system, in conjunction with the general public agencies responsible for disaster intervention.

## Professional Role Containment and Enhancement in Conditions of Disaster

First priority is given to basic survival at times of disaster. Safety, shelter, and food are the most immediate and conspicuous, and these are usually within the domain of professional relief teams. However, the members of these teams themselves may suffer from role-related problems because of the disaster-induced collapse of the sociocultural matrix of which they were a part. Therefore, to initiate an effective intervention, mental health professionals in positions of authority must respond to these needs, in their own team and teams in which they act as mediators (e.g., teachers, school counselors). They must make team members feel cared for and help them to develop a sense of belonging and purpose. Professionals may take a leadership position by formulating a vision (e.g., “developing the best intervention program,” “revitalizing our school and preventing suffering”), providing individualized consideration (being sensitive to individual needs of professionals), fostering an atmosphere of creative intellectual coping (supporting initiatives, delegating authority), and transmitting positive expectations (concerning the professionals' capacities and end results) ([Bass and Avolio, 1994](#)).

## Program Implementation

Studies of mental health interventions after disasters clearly support their effectiveness ([Galante and Foa, 1986](#); [Goenjian et al., 1997](#); [Wolmer et al., 2001](#)). However, their ongoing operation requires the continuous commitment of professionals, leaders, and local agencies. By endorsing a systemic perspective, mental health professionals may overcome the repeated adversities and challenges, inadequate professional training, limited resources, and organizational conflicts that tend to characterize the process.

Parents and teachers are known to underestimate the extent of children's suffering ([Yule and Williams, 1990](#)), perhaps because of their capacity to maintain routine functioning in the face of internal strife. Given that disaster survivors are also often reluctant to seek professional help ([Schwarz and Kowalski, 1992](#)), outreach efforts should be made to systematically screen victims at risk, optimally 1 to 3 months after the disaster ([Lindy et al., 1981](#)). Thereafter, clinical triage protocols could be utilized to match risk groups with intervention programs ([Austin and Godleski, 1999](#); [Lindy et al., 1981](#); [Pfefferbaum et al., 1999](#)).

Studies have demonstrated the applicability of Western therapeutic programs also in non-Western cultures ([Goenjian et al., 1997](#); [Wolmer et al., 2001](#)). The first step in implementing these programs is to train members of the affected community. The local staff may need continuous support and supervision. If handled correctly, this process may help traumatized survivors reduce their ambivalent resistance to what might be perceived as a foreign “intrusion” that threatens the “trauma membrane” protecting from an overload of psychic tension ([Austin and Godleski, 1999](#); [Lindy et al., 1981](#)).

## INTERVENTION MODELS

Effective treatments for traumatized children should include the psychoeducation of children and parents about the nature of the disorder, some form of exposure work, and dysfunctional cognitive restructuring ([Perrin et al., 2000](#)). Furthermore, the commonly accepted treatments specific to posttraumatic conditions need to be implemented within the broader social reality of the disaster (e.g., whole community, neighborhood, peer group) in order to alleviate the sequelae of the secondary and tertiary disasters. To this effect, the child psychiatry system must collaborate with three additional systems that provide the psychiatrist with the authority to intervene on all institutional levels: the community leadership, school, and medical clinics.

Commonly used structured treatment and rehabilitation community programs (e.g., psychotherapy, programs for the disadvantaged, adolescents, and women, as well as school empowerment and class activation), stressing participant's enhancement of initiative, activity, empowerment, hardiness, and responsibility may be adapted for disaster conditions. The adaptation rests on the formulation of disaster as destructive to both external (concrete) reality and internal functional representations—of stability (i.e., predictability and controllability) as well as of effective engagement with the environment (i.e., the physical and the communal world). Therefore, child intervention programs should aim to reconstitute the damage to both communal institutions and norms, and communal functioning (i.e., recovering communal roles: parent, teacher, worker, leader). Drawing on our understanding of the disaster syndrome, engendering massive grief, dissociation and trauma, intervention programs will be enriched by emphasizing the following transitions: from a freeze on past experience to a creative future orientation; from a fixation on death and loss to an involvement with life and revitalization; from being passively locked into grief, shame, and anger to owning up to one's potency; from withdrawal and alienation into reconciliatory involvement with nature, family, and society and its technology; and from recourse to mythologic world view into critical transformation of sociocultural identity ([Laor, 2001](#)).

In circumscribed mass disasters, effective programs may take 12 to 18 months. The first phase is dedicated to the assessment and reactivation of the community and its institutions, as well as to the introduction of clinical intervention programs. This phase may take up to a year and lead toward the first commemoration ceremony of the disaster. The community and individual taking responsibility for their future characterize the second phase: development of physical and social infrastructure and job opportunities.

## Immediate Interventions

During the acute stage, the role of the mental health professional needs to be modified because of the unique conditions, namely, the limited number of professionals and masses of individuals, often dispersed over a large area, that require help. Large populations need to be screened to identify children at risk. Other important tasks include initiating telephone crisis hotlines, supplying psychological first-aid for children and families in evacuation centers and hospitals, consulting authorities to assess immediate needs, and planning large-scale public health education programs. To prioritize needs and promote efficacy, professionals need to use medical criteria for classifying and assessing both levels of psychological damage and available individual (coping) and familial (support) resources.

At this stage, professionals become aware of the need to quickly acquire new disaster-related skills (e.g., debriefing). They may come on technically formulated protocol-based interventions, but soon discover that mastering new therapeutic techniques and implementing them under disaster conditions requires thorough training and ongoing supervision, which can be secured before proceeding with the intervention program.

The *mass media* (e.g., television, newspapers) can be helpful for confused parents. They can learn about typical reactions to stress and ways of coping with them and restoring the parental role. They should be advised to tolerate regression, encourage children to ask questions and express feelings, assure children that there are no bad thoughts or feelings, assign children appropriate activities, reestablish stability and family rituals, and convey positive expectations for the future ([Flynn and Nelson, 1998](#)). Television programs directly addressing children should cover the same issues.

Delegating age-appropriate functions to children, allowing them to take responsibility and provide active help (e.g., fill sandbags, take care of younger children), serves as an important mechanism for preventing the sense of helplessness and the passivity that leads to more severe responses.

The appropriate preparedness of a city/country can lessen significantly the consequences of a disaster. For example, as part of its general Disaster Preparedness Program, the Tel Aviv Municipality has developed an Emergency Treatment System (ETS) ([Spirman et al., 2001a](#)) that focuses on social and psychological welfare in times of emergency. The ETS is composed of eight multidisciplinary units dealing with: (a) on-site crisis (triage and evacuation); (b) family notification (of losses); (c) hospital liaison; (d) population behavior (information center); (e) brief psychological support over the phone; (f) emergency shelters (for evacuees); (g) community resources (volunteers and donations); and (h) delivery of basic needs. The ETS headquarters coordinates the units and their cooperation with relevant institutions (e.g., police, army) as well as with the clinical trauma and disaster community center, out of which the child mental health professionals operate ([Laor, 2001](#)).

## Interventions during the Second and Third Stages

### DEBRIEFING

The disaster syndrome may be viewed as a normal reaction akin to the fear response to danger or the mourning process following loss. In the long run, most affected individuals recover their functioning. It is assumed that the recovery of traumatized survivors may be facilitated by a process that allows them to review their experience (debriefing). In mass disasters debriefing is carried out in groups.

The aims of group debriefing are to allow the expression of traumatic experiences and flooding reactions; facilitate relaxation; promote cognitive organization and self-control; identify and mobilize internal and external resources; set realistic expectations; restore self-worth and hope; and prepare participants for future

experiences ([Stallard and Law, 1993](#)). The implementation of this structured technique with children may last one or more meetings and must be done by an educated professional. The technique may include play activities, such as individual or group drawing, writing, or imagery games. Participants are given time for expression and questions. The tasks of the leader are to protect limits, set rules, provide information, facilitate verbal and physical peer support, and manage containment. The leader also may identify symptomatic children and refer them for further help when the meeting ends, and distribute psychoeducational handouts on symptoms or positive coping strategies for follow-up.

Participants are encouraged to focus on thoughts, emotions, images, and sensations related to the event after reporting their trauma-related experiences. Special attention should be given to feelings of guilt and anger, because clinical experience shows that these may interfere with the process of working-through the trauma. Thereafter, participants explore personal and communal coping resources and use creative imagery to return to the "here and now," fantasize about a positive future and construct plans of action. Parallel sessions may be held with the parents.

Debriefing may be an efficient tool to help children and adults ([Chemtob et al., 1997](#); [Stallard and Law, 1993](#)); however, one should be aware that very early exposure to the memory of the traumatic event may interfere in some individuals with the normal affective-cognitive processes that lead to recovery, resulting in neutral effects or even an exacerbation of symptoms ([Mayou et al., 2000](#); [Wessely et al., 1998](#)). The specific therapeutic factors of the debriefing intervention, and who may benefit from it, remain open questions.

### *THE SCHOOL SETTING*

To assist as many children as possible, professionals may need to work with groups rather than individuals. Because teachers have trustful relations with children and parents, and most are ready to be educated and serve a therapeutic role, intact school environments are appropriate sites for societal recovery centers for early interventions ([Klingman, 1993](#); [Pynoos and Nader, 1988](#); [Vernberg and Vogel, 1993](#)).

Several researchers have found that support from classmates and teachers is a significant predictor of fewer posttraumatic symptoms after a major disaster and prevents withdrawal and isolation ([Pynoos and Nader, 1988](#); [Vernberg et al., 1996](#)). Furthermore, the class setting provides a predictable routine, clear expectations, consistent rules, and immediate feedback. It is recognized as the place to apply learning skills for exploring causes and consequences of disasters, and emphasizes that survivors may experience "normal reactions to abnormal events."

Teachers should allocate time to deal with traumatic experiences, model the children's responses, reinforce emerging coping skills, provide factual information and correct rumors, facilitate mutual support, identify suffering children, and prepare the class for future experiences. They also may encourage students to become active contributors to their family, school, and community.

For the program to be effective, mental health professionals should ensure that the teachers: (a) are not traumatized themselves; (b) are capable of mastering disaster-related educational techniques; and (c) have adapted their view of their role as teachers/educators to the new and harsh reality. To help regenerate the normal school setting after a disaster, the child psychiatrist needs to meet with the teachers, debrief them about their own experiences of the disaster, and clearly lay out the educational task at hand.

Based on these principles, [Wolmer and associates \(2001\)](#) implemented a three-stage supervision of one school's principal and teachers after the 1999 earthquake in Turkey. First, a group debriefing session was conducted to normalize responses and enable the expression of trauma-related affects (anger, guilt, helplessness, hopelessness). Thereafter, an experiential activity was introduced to help the teachers redefine their role with regard to the students as "educators" and "leaders." The authors stressed that in times of disaster, rather than merely covering the regular curricula, teachers were expected to maintain and enhance their role by providing individualized consideration, transmitting values, and conveying positive expectations. As part of this role, they were taught to implement a disaster-related classroom activation program (see the following). Finally, a continuous supervision process was begun, led by local professionals, wherein teachers not only were educated but also provided support for each other ([Goenjian et al., 1997](#)).

School-based interventions include single-session debriefings, small-group programs, and class activation programs.

### *SMALL-GROUP PROGRAMS*

Targeted small group programs within the school setting may benefit high-risk children or children who are more agitated and need closer attention than can be provided in the classroom ([Gillis, 1993](#); [Klingman, 1993](#)). [Smith and colleagues \(1999\)](#) formulated a three-session program to teach recovery techniques to small groups of children affected by disaster. The techniques used are psychoeducation, imagery and cognitive techniques, and exposure practice. Each session is dedicated to one domain of the posttraumatic syndrome: intrusion, avoidance, and arousal. The professional may also offer a fourth session for bereaved children and a session with parents, to provide them with information and suggest ways for them to help their children.

### *CLASS ACTIVATION PROGRAMS*

Programs implemented in the classroom itself may vary in focus, scope, and depth, but all are intended to minimize stigma, encourage normalcy, and reinforce the expectation that the children will soon resume their roles as students ([Klingman, 1993](#); [Pfefferbaum, 1997](#); [Vernberg and Vogel, 1993](#)). It is important to stress, however, that the teachers themselves may be struggling with severe posttraumatic symptoms and personal losses, and consequently, feel unable to help their students. Some teachers may try to avoid dealing with reminders of the event by stressing that children have no need to talk about their traumatic experiences ([Pynoos et al., 1998](#)).

[Galante and Foa \(1986\)](#) provided children who survived an earthquake in Italy seven monthly sessions for discussing and dealing with related feelings, and noted a significant reduction in symptoms. Other models also utilize expert mental health professionals in school settings with or without the presence of the teacher ([Eth, 1992](#); [Klingman, 1993](#)). Direct teacher involvement, however, is encouraged for disasters of large proportions, when expert resources prove insufficient. The class activation of [Wolmer and associates \(2001\)](#) was led by the teachers, and it consisted of an introductory meeting with the parents to provide information about the program and the children's expected reactions to the disaster, and to engage them in the process. The remaining eight 2-hour meetings of the whole class focused on various aspects of the recovery process (e.g., debriefing, establishing a safe place, learning about the earthquake, loss and death, dealing with anger and lessons of life, planning the future). The program combined psychoeducational modules, cognitive-behavioral techniques, play activities, and an ongoing documentation in personal diaries.

## **Clinical Interventions**

### *INDIVIDUAL INTERVENTIONS*

Although efficient and cost effective, group interventions may not be enough for the most affected children. Controlled and uncontrolled studies have confirmed the effectiveness of brief cognitive behavioral treatment in traumatized children ([Perrin et al., 2000](#)). Other modes of individual psychotherapy have been employed, such as play therapy, psychodynamic psychotherapy, or eye movement desensitization and reprocessing (EMDR) ([Lovett, 1999](#)). Particular attention should be directed to prior and current comorbid pathology as well as a thorough differential diagnosis (e.g., mania, ADHD).

After the 1988 earthquake in Armenia, [Goenjian and colleagues \(1997\)](#) implemented a brief treatment program combining classroom group psychotherapy and individual sessions focusing on trauma and grief. The sessions, led by therapists, allowed for open discussion of the traumatic experiences and associated feelings, assisted the children in solving intrapersonal and interpersonal problems, and offered effective cognitive-behavioral techniques to manage thought distortions, disturbing images, and stress-related sensations.

### *GROUP INTERVENTIONS*

#### *Parent-Child Groups*

Families have the potential to either protect children and mitigate their postdisaster suffering or jeopardize their adjustment to and processing of the event, thereby

exacerbating their symptoms. After disasters, children and parents tend to avoid discussing their distress, probably to avoid further disturbing each other ( [Udwin, 1993](#)). However, studies consistently show a significant association between the symptomatic response of parents (particularly of mothers) and their children ( [Laor et al., 1996, 1997](#); [Winje and Ulvik, 1998](#)), which may have a traumatic impact on the whole parent-child dyad ( [Wolmer et al., 2000](#)).

Based on the previous successful application of parent-child group psychotherapy in the treatment of child anxiety disorders ( [Toren et al., 2000](#)), and as a second stage of school-based intervention, [Laor and associates \(2001\)](#) formulated an eight-session therapeutic protocol for mothers and children (four to five dyads) with chronic posttraumatic symptoms. Led by two therapists, the group addressed dynamic, cognitive, and behavioral aspects of the disaster syndrome, and offered techniques to manage anxiety; relieve, control, and transform distressing affects; correct thought distortions; and plan for the future. Special attention was paid to identifying and correcting maladaptive family dynamics and helping mothers and children recover their attachment and roles. Preliminary clinical and empirical results showed significant symptomatic alleviation as well as a dramatic improvement in familial communication and mutual support.

### Mothers' Groups

Group interventions with mothers allow for the indirect focus on preschool children, a population that may not be reached in formal settings yet may show maladaptive behavioral reactions. These reactions are known to correlate highly with the mothers' psychological response ( [Wolmer et al., 2000](#)). Providing structured therapeutic interventions, psychoeducation and practical suggestions in regard to the children as well as strengthening the participants' confidence in their maternal role are important objectives for these groups ( [Spirman et al., 2001b](#)).

### Community-Based Interventions

Disasters affect whole communities, threatening social structures and functions. To be effective, interventions require collaborative efforts among nongovernmental organizations and formal and informal agencies. The development of a local leadership of committed individuals and its empowerment to actively meet the short- and long-term needs of the community provides a valuable source of support ( [Rappaport, 1987](#)).

In this regard, child psychiatry relief programs need to respond to disasters on three levels: (a) *The family*. Families may suffer from injured, lost, or dead members; relocation and unemployment; loss of boundaries, routines, and values (sometimes internalizing the societal anarchy); and loss of esteem and hope. (b) *The neighborhood*. During disasters, neighborhoods are subject to physical and economic destruction; loss of routines, boundaries, and safety; disintegration of informal networks, and restriction of leisure time activities; these apply also to temporary neighborhoods established by relocated families. (c) *The community*. Communities suffer from an insufficiency of proper leadership and resources, frozen initiative, dependence on external resources, destruction of social and cultural institutions (schools, community centers, religious centers) and as a result, a foreshortened sense of communal future.

Drawing on auxiliary social functions and structures introduced from the outside, as well as on professional clinical and social teams, it is possible to help temporary communities of displaced population gradually to develop coping and functioning. In a nutshell, the goal of the community-based intervention is to transform evacuated fragments of families and singles (first stage) into self-governing communities with autonomous individuals and families (third stage) ( [Laor, 2001](#)) ( [Table 75.1](#)). Professionals also may help facilitate the creation of new job resources in the community because children cannot be fully rehabilitated until their parents resume work and regain income.

Stage	Phase	Intervention	Notes
Social structures in the affected community	1	Empowerment groups	Community center
	2	Empowerment groups	Religious center
Auxiliary social structures and functions introduced from the outside	1	Self-help groups	Self-help groups
	2	Self-help groups	Self-help groups
Professional clinical health interventions	1	Individual therapy	Individual therapy
	2	Group therapy	Group therapy
Social structures	1	Self-help groups	Self-help groups
	2	Self-help groups	Self-help groups
Interventions	1	Self-help groups	Self-help groups
	2	Self-help groups	Self-help groups

**Table 75.1. The Recovery Process from a Mass Disaster in Evacuated Communities**

Using the intervention principles described in the preceding, child mental health together with child community workers and the local leadership can help set up community center programs for young mothers, children, and adolescents. Empowering- and hardiness-enhancing programs may include arts, sports, gardening and decorating, continuous education, job clubs, and volunteer recruitment and training in different areas ( [Kobasa, 1979](#)). By *empowerment* we mean a process of involvement by which individuals and communities replace their helpless stance by recovering their dignity and self-esteem, enhancing their critical self-awareness, control over resources and objectives, sense of personal and collective responsibility, and self-efficacy ( [Rappaport, 1987](#)). Individuals are able to identify specific needs and discover hidden leadership qualities, whereas communities gain a greater sense of interdependence, cohesion, and cooperation. In the case of dislocated population, communal empowerment is the process by which communities are formed and achieve greater control over their environment.

Interventions at the level of the whole community facilitate the integration of community members with the natural and social environments. For example, as part of the Community Reactivation Program after the 1999 earthquake in Turkey, [Spirman and coworkers \(2001b\)](#) developed a 2-week summer program for a whole village of displaced individuals to transform the community and its habitat as culturally internalizing death and alienation (e.g., withdrawn fathers, unemployment, uncultivated neighborhood). The method rested on five principles:

1. Team-up and train international and local youth leaders to serve as instructors on-site.
2. Identify a natural habitat adjacent to the village, representing "life" for the community, where the program's activities (e.g., arts, sports) take place.
3. Enlist the revitalization and initiative achieved, to construct recreation areas and cultivated gardens, within the original village habitat. As a result, the artificial prefab neighborhood representing "death and displacement" turns into a lively community.
4. Designate an area within the village to serve for the erection of an artistic commemoration monument, for which individuals are invited to contribute dear personal remains. The event culminates in an anniversary ceremony. This process of collective mourning allows for an honorable and lively representation of dear loss and the dynamic reconnection with historical identity.
5. Involve social and political leaders, local and international, to facilitate the social integration of the community.

These interventions allow child mental health professionals entry into the sphere of the long-term effects of the tertiary disaster, the sociocultural losses that threaten the collective ideology and identity. Professionals may take part in the modification of the school curricula to address group mourning and hardiness, collective memorials as well as celebrations of rebirth. The juxtaposition of commemoration and rebirth ceremonies help individuals to gain a new meaning of life in the face of deep mourning and lead to integration on both the personal and communal levels, which offers children an uninterrupted supportive matrix. For example, in Israel, the Independence Day celebrations follow on the heels of the Memorial Day ceremonies, and in Turkey, communities celebrated group circumcision of children about 1 month before the 1999 earthquake memorial ceremony.

### Pharmacologic Interventions

It is widely accepted that psychotherapy, rather than medication, is the first-choice modality for posttraumatic states ( [Foa et al., 1999](#); [Shiloh et al., 1999](#)). Most proposals for pharmacotherapy with children are based on studies with adult PTSD. These studies, too, invite improved controlled design ( [Marshall et al., 1998](#)). The systematic assessment of pharmacologic treatments for traumatized children has been limited so far ( [Perrin et al., 2000](#); [Vernberg and Vogel, 1993](#)). Benzodiazepines may be used in cases of acute PTSD, but only for the short-term and only intermittently ( [Foa et al., 1999](#)). They should be used with caution, particularly because, in adults, they have been implicated in worse long-term outcome ( [Gelpin et al., 1996](#)). Professionals should beware that well-intentioned donations of medications by drug companies and the urge to reach as many individuals as fast as possible may lead to anarchic management and nonprofessional

medication of children. A detailed description of pharmacologic interventions is presented in the relevant chapters.

Nevertheless, medications may be effective in alleviating anxiety or depressive symptoms ( [Terr, 1989](#)), and as part of the general principles of management in situations of disaster, they can be given even in the early stages of intervention in certain cases: to children with a known history of psychopathology prior to the disaster; individuals who do not respond to debriefing and short-term specific interventions; and members of at-risk families who are flooded by severe symptoms. These medications must be directed at specific symptoms, such as intrusion, hyperarousal, and impulsivity (e.g., carbamazepine, lithium, clonidine), anxiety (e.g., buspirone, alprazolam), depression (e.g., tricyclic medication or SSRIs), psychotic symptoms or severe aggression (e.g., antipsychotic drugs) ( [Shiloh et al., 1999](#)).

### **Taking Care of the Caretaker**

Professionals engaged in disaster intervention programs (psychologists, teachers, social workers, and nurses) are more analogous to marathon runners than to short-distance sprinters. Project coordinators need to be aware of each worker's strengths and weaknesses, personal losses, and vulnerabilities in order to regulate their exposure and prevent burnout. Program leaders need to help relief workers enhance their own coping mechanisms, tolerate the shock inherent in their work, and maintain high levels of commitment and motivation ( [Austin and Godleski, 1999](#); [Cohen, 1987](#)). Therefore, leaders should facilitate adequate training and peer supervision, encourage mutual support, lead debriefing sessions, teach stress management skills, and introduce appropriate work breaks (limiting shift durations or breaks in schedules).

## **DISASTER RESEARCH**

Disaster research is of utmost importance yet extremely hard to perform. Most disasters occur unexpectedly, and even those that are predictable have such an overwhelming impact, they exhaust all professional and economic resources. Furthermore, even when professional curiosity is maintained, assessment measures are enlisted, and questions are defined, both the victims and the clinicians resist the implementation of the research. They tend to perceive research under these conditions as hostile, foreign, exploitative, and abusive, intended to satisfy an alien agenda that is irrelevant to their priorities. There is a kernel of truth to this: The hands that give out questionnaires could have offered bread. Furthermore, from the standpoint of the clinician, many of the responses of disaster victims reflect a normal and time-limited reaction to stress and should not be structured as pathology.

The perspective offered in this chapter enables the mental health professional to deal seriously with these issues and not simply explain them away. Research initiatives need to be integrated within the systemic interventional program and rely on the direct assessment of the affected population at every stage. That way, real risks and needs can serve a basis for rational planning (e.g., resource allocation, assignment to different therapies) as well as for improvement of existing programs. It is the responsibility of the professional to educate community leaders to take practical advantage of assessment data.

The disaster scene, a large-scale natural experiment, offers access to communities that constitute different types of research groups and controls. Furthermore, in each community, one may encounter a large number of whole families whose members were simultaneously exposed and affected in different manners (direct or indirect) and degrees and for different lengths of time, as well as individuals suffering from losses of varying severity. An important issue in studies of children is the phenomenology and biological susceptibility to the disaster syndrome; that is, the interplay of traumatic grief, posttraumatic symptoms, and dissociation with psychoneuroendocrinologic and psychophysiological parameters. This particular setting provides a unique opportunity for genetic studies. Special attention also ought to be given to partial and delayed onset types of disorder as well as concurrent psychiatric and medical morbidity.

Another area of interest is the control study and comparative effectiveness of the various interventions (social interventions versus pharmacotherapies and psychotherapies), and the assessment of parameters of community hardiness and vulnerability. Other important avenues of research are the long-term sequelae of disaster in terms of developmental psychopathology of high-risk populations, the transgenerational transmission of trauma and grief, and the development of sociopolitical attitudes and preferences.

We would like to stress here that the search for answers to these intellectual questions, pressing though they may be, cannot at any time violate the privacy of the children being studied, and clinicians must be careful to comply with the accepted ethical guidelines. Institutional Review Boards can facilitate the process by offering a fast track for disaster-related research proposals.

## **CONCLUSION**

Disasters irrevocably destroy the space within which children and families thrive, thereby disrupting normal development. The overwhelming quality of the event combined with the massive extent of the loss gives rise to a complex clinical and social picture that may be termed the disaster syndrome. Children, families, neighborhoods, and whole communities are affected. Immediate damages can be only partially remedied; therefore, the physical, psychological, and social effects are long lasting.

For effective intervention, the child mental health professional needs a comprehensive systemic, social, and mental health perspective in order to develop the proper program, team-up with the proper authorities, accurately assess needs, and implement treatment. Best results are effected when the community is prepared. Some interventions are clinical and specific; educated professionals who work with children in schools and community centers can mediate others. No single community can cope on its own. This requires networking in advance on the local, national and the international levels. The challenge of disasters, thus, is offered to our vision of the brotherhood of humanity. A global community committed to the cause of children must respond to the challenge.

## OVERVIEW

In this first of two chapters on pediatric psychopharmacology, general principles of drug handling (*pharmacokinetics*) and drug mechanism of action (*pharmacodynamics*) are reviewed. The chapter highlights those aspects in which developmental factors play an important role, and serves as a complement to the following and related chapter, in which specific drug classes and individual agents are discussed in detail.

*Pharmacokinetic* principles relate to the handling and disposition of drugs within the body: to those biological processes occurring prior to engagement of drugs that lead to changes over time in drug concentration in body tissues and fluids. Drug concentration in target organs is responsible for determining how long a drug's therapeutic and adverse effects will last. Changes during development in drug absorption, distribution, metabolism, and excretion may all have an impact on the delivery of drug to target tissues. By contrast, *pharmacodynamic* principles are concerned with the biochemical and physiologic effects of drugs at their active sites, with their specific mechanisms of action. The effects of a medication may similarly change during development, as brain regions or neurotransmitter systems develop and mature at different rates. Stated succinctly, "pharmacokinetics describes what the body does to a drug; pharmacodynamics what a drug does to the body" ([Janicak et al., 1993](#)).

## PHARMACOKINETIC PRINCIPLES

In the first part of this chapter, pharmacokinetic factors that influence drug disposition during development are addressed. First, basic pharmacokinetic principles that are shared by children, adolescents, and adults are reviewed. Next, the broad pharmacokinetic differences that distinguish the pediatric population from adults are examined. This is followed by a review of specific factors affecting drug disposition, with an emphasis on developmental influences. One of the more clinically relevant applications of pharmacokinetic principles is in helping to understand (and at times predict) important drug interactions. Because of this, additional emphasis has been placed on mechanisms (e.g., the cytochrome P450 system) that are relevant to a large number of such interactions.

### Basic Principles

An understanding of pharmacokinetic principles is important for safe and effective patient care. Pharmacokinetic factors are often critical in a variety of clinical decisions, such as choosing between agents within a same drug class, switching between different medication preparations, adjusting dosages, preventing drug interactions, or correctly utilizing and interpreting therapeutic drug levels ([Preskorn, 1993b](#)).

Pharmacokinetics can be conceptualized as having four functionally distinct phases: absorption, distribution, metabolism, and excretion. Absorption and distribution are primarily responsible for determining the speed of onset of drug effect, whereas the processes of metabolism and excretion terminate the action of the pharmacologic agent by removing the active form of the drug from the body. Taken together, these four phases determine the duration of drug activity ([Paxton and Dragunow, 1993](#)).

Once a drug gains entry to the bloodstream, it is diluted in the plasma and bound at varying degrees to plasma proteins. The drug, usually protein-bound, is then either excreted by the kidneys or carried to the liver and transformed to a more water-soluble (and usually inactive) metabolite, which can then be excreted in urine, bile, or feces. This complicated and interdependent series of events is designed to reduce the effect of the foreign molecule, with the ultimate goal of eliminating the drug from the body. If the dose of a drug is sufficiently large to withstand this "pharmacokinetic assault," then a fraction of the drug molecules will endure to produce its pharmacodynamic effect ([Paxton and Dragunow, 1993](#)).

A basic working knowledge on key pharmacokinetics principles is relevant to the clinical practice of pediatric psychopharmacology so as to understand the fate of administered drugs. Practically all psychotropic medications follow *first-order* (or *linear*) kinetics, in which the amount of drug eliminated is proportional to its amount circulating in the bloodstream. First-order kinetics provide close to a 1:1 relationship between changes in dosage and plasma concentration. Such a linear association allows for clinically relevant predictions of the impact of a dose change on circulating drug levels. By contrast, *zero-order* (or *nonlinear*) kinetics prevail when metabolizing or eliminating mechanisms become saturated. This results in a fixed amount of drug being eliminated per unit of time, regardless of the plasma level. Certain drugs, such as fluoxetine, nefazodone, or alcohol, demonstrate zero-order kinetics at all clinically relevant doses, rather than just at saturation, making the relationship between dose changes and subsequent plasma levels much less predictable ([Janicak et al., 1993](#)).

For drugs that follow first-order kinetics, the concepts of biologic half-life and steady-state concentration are germane to the practicing clinician. Biologic *half-life* ( $t_{1/2}$ ) is the time required for the concentration of drug to decrease by one-half. In clinical practice, this parameter is usually assessed by measuring the decay of plasma or serum drug concentration and is referred to as the plasma (or serum) half-life. Plasma half-life values can be useful when determining dosing intervals. At consistent dosing intervals, it is the plasma half-life that determines the plasma *steady-state concentration* ( $C_{SS}$ ). This is defined as equilibrium between the amount of drug ingested and the amount of drug eliminated, resulting in no net change in plasma concentration over time.  $C_{SS}$  is reached in a time equal to approximately five half-lives. Conversely, if drug intake is abruptly stopped, then it takes a time equal to five half-lives for almost complete elimination.

### Pharmacokinetics in Children and Adolescents

There are many pharmacokinetic similarities between adults and children and adolescents. Indeed, age-independent genetic influences on protein binding, metabolism, and elimination can be more salient than those influences attributable to age and developmental change.

Nonetheless, children and adolescents do display unique pharmacokinetic properties. Unfortunately, data on children are scarce and fall considerably behind that available in adults. The result of this informational dearth is that dosage recommendations and therapeutic ranges utilized clinically in children and adolescents are, at least initially, extrapolated from adult studies, often arbitrarily ([Gilman and Gal, 1992](#)). The appropriate dose of a psychotropic medication in the pediatric age group should be empirically determined; a proportionately reduced adult dose based on body weight is frequently subtherapeutic or toxic. In addition, infants, children, and adolescents are not a homogenous group in terms of drug distribution patterns ([Jatlow, 1987](#)). These differences can be especially dramatic around the time of

puberty, when the release of gonadal hormones can strongly influence plasma drug concentrations ( [Morselli and Pippenger, 1982](#)).

Although pharmacokinetic data in children and adolescents are limited, one basic observation is suggested clinically: *Children and adolescents require larger, weight-adjusted doses of most medications than do adults to achieve comparable blood levels and therapeutic effects* ( [Jatlow, 1987](#)). This appears to be mostly a function of shorter half-life owing to an increased rate of metabolism and elimination.

## Factors Affecting Drug Disposition

### Absorption

Drugs gain entry into the body through a variety of portals. The bioavailability of a medication in the systemic circulation—its amount available to exert a biological effect on target tissues—is determined by its absorption and, for orally administered medications, by the *first-pass* effect of liver metabolism. Drugs given orally are absorbed in aqueous solutions through either the stomach or, as is the case of most psychotropic medications, the small intestine. The major factors influencing gastrointestinal absorption are pH-dependent diffusion and gastric emptying time. Absorption depends heavily on the route of entry, with intravenous administration being the equivalent of 100% absorption. Oral administration is by far the most common portal of entry but also the most unpredictable in terms of final bioavailability. An orally administered drug is absorbed from the gastrointestinal tract and must first enter the portal circulation, where it passes through the liver before reaching the systemic circulation. A considerable portion of the drug is hepatically metabolized during this first pass. Thus, only a fraction of the drug that was absorbed from the gastrointestinal tract enters the systemic circulation.

Little information is available regarding the effect of age on the absorption of psychotropic medications, although there are several theoretical considerations regarding the influence of this process in children and adolescents. For instance, stomach contents tend to be less acidic in children than in adults, causing weakly acidic drugs to be more highly ionized. Weakly acidic drugs may be absorbed more slowly in children because it is the unionized fraction that is absorbed from the stomach. Theoretically this process could affect anticonvulsants, amphetamines, and antidepressants ( [Taylor, 1994](#)). Another theoretical concern is that children generally have fewer and less diverse intestinal microflora. The fact that drugs such as phenothiazines can be absorbed or metabolized in the gut wall may help to explain why some children either are unusually resistant to phenothiazines or require a surprisingly large oral doses ( [Taylor, 1994](#)). Another factor that could reduce overall absorption is that intestinal transit time appears to be shorter in young children, which could result in incomplete uptake of slow-release preparations ( [Gilman and Gal, 1992](#)).

It is important to remember that despite the theoretical considerations outlined in the preceding, there are no data indicating a generally reduced absorption of orally administered drugs in children ( [Jatlow, 1987](#)). Anecdotal information and clinical experience suggest that absorption of certain psychotropic medications may be even more rapid in children than adults. Rapid absorption, however, may not be desirable because it results in greater peak-to-valley fluctuations in blood levels. This does not affect the final average steady-state level, but may be important because drug toxicity can be a function of peak plasma concentration, as in the case of lithium-induced tremor.

### Distribution

Drugs are distributed into intravascular and various extravascular spaces following absorption. Numerous physical factors can influence the distribution of a drug throughout the body: the size of body water compartments and adipose tissue depots, cardiac output, regional blood flow, organ perfusion pressure, permeability of cell membranes, acid–base balance, and binding to plasma and tissue proteins ( [Morselli and Pippenger, 1982](#)). Each of these factors may change during development, resulting in changes in the distribution of a drug and, subsequently, in its pharmacologic effect.

The two most important factors affecting distribution that change substantially during development are fat stores and the relative proportion of total body water to extracellular water. The relationship between the amount of drug absorbed (D), plasma concentration (Cp), and volume of distribution (Vd) can be summarized by the simple equation:  $C_p = D/V_d$ . Note that the larger the Vd, the smaller the Cp.

The proportion of body fat substantially affects the volume of distribution of highly lipophilic drugs, including most neuroleptics and antidepressants. The proportion of body fat is highest in the first year of life, followed by a steady decrease until an increase occurs prepubertally ( [Jatlow, 1987](#)). Children and adolescents at different ages have varying degrees of fat stores, and in general tend to have a proportion of body fat less than that found in adults. Hence, in children one would expect to find a larger plasma concentration with lipophilic drugs when compared with adults after being given the same weight-adjusted dose. It has been demonstrated, however, that children actually exhibit a lower plasma concentration than do adults under these conditions. Therefore, other mechanisms (e.g., increased metabolism) must explain the lower plasma concentration of lipophilic drugs in children ( [Jatlow, 1987](#)).

The relative volume of extracellular water is high in children and tends to decrease with development. For example, total body water decreases gradually from about 85% of body weight in a small premature infant to about 70% in the full-term newborn to about 60% in the 1-year-old infant, a level that is generally maintained throughout adulthood. Similarly, extracellular water decreases gradually from about 40% to 50% of body weight in the newborn to about 15% to 20% by age 10 to 15 years ( [Fetner and Geller, 1992](#)). Thus, drugs that are primarily distributed in body water (e.g., lithium) can be expected to have a lower plasma concentration in the pediatric population compared with that in adults because the volume of distribution is higher in children.

Following absorption and first pass through the liver, drugs are transported in the general circulation in two forms that are in dynamic equilibrium with each other: bound to plasma protein and unbound (free). Only the unbound drug is usually available to pass across membranes and have pharmacologic effects. Although drug protein binding may be reduced in young children, it does not appear to be an important developmental factor in older children and adolescents. A final theoretical consideration in children and adolescents is the relative permeability of the blood–brain barrier when compared with that in adults. This increased permeability could result in increased bioavailability of drugs within the central nervous system (CNS). This relative “porousness,” however, would concomitantly permit greater amounts of protein to enter the cerebrospinal fluid. Any drug that crosses the blood–brain barrier but also substantially binds to proteins, such as most psychotropics and anticonvulsants, in effect would then have its bioavailability reduced ( [Taylor, 1994](#)). Naturally, this special dispensation does not apply to unbound drugs such as lithium.

### Metabolism

Most drugs are lipid soluble, which is usually a necessary requirement for absorption, distribution, and availability at receptor sites. *Lipophilic* drugs need to be metabolized into more polar or *hydrophilic* forms (i.e., having a greater affinity for water) in order to be effectively excreted, however. Enzymes that catalyze these metabolic reactions are found in greatest abundance in the liver, the main organ of drug metabolism, but also in the wall of the small intestine, skeletal muscles, kidneys, and lungs.

Although some drugs are excreted unmetabolized (e.g., lithium, gabapentin), most undergo extensive biotransformation in the liver ( [Janicak et al., 1993](#)). *Phase I metabolic reactions*, including *hydroxylation*, *reduction*, and *hydrolysis*, convert drugs to forms more suitable for elimination. Hepatic microsomal enzymes (the cytochrome P450 system) are responsible for phase I reactions. In that role, they are of sufficient clinical relevance to warrant their being addressed separately (see following section). The products of phase I reactions, collectively referred to as *metabolites*, are usually less active and toxic than their parent compounds. A notable exception of clinical significance is desipramine, the demethylated active metabolite of imipramine.

In *phase II reactions*, *conjugation* of metabolites generated in phase I takes place with glucuronic acid, sulfate, or others. Conjugated compounds are then readily excreted in urine or other body fluids. It is clinically important to note that some drugs are never metabolized in a phase I reaction and instead simply undergo conjugation by glucuronic acid. This conjugative reaction may occur in almost any organ and therefore is not solely dependent on hepatic function. Hence, drugs such as the 3-hydroxybenzodiazepines (e.g., lorazepam, oxazepam) are rapidly cleared at equal rates regardless of age as long as renal function is normal ( [Janicak et al., 1993](#)), and are thus preferred in instances of liver insufficiency.

The relatively higher dosage requirement of most psychotropic drugs in children is most commonly explained by increased hepatic metabolic capacity. Cytochromes (CYPs), for example, come “on-line” at different developmental epochs of fetal life or infancy and reach 40% of adult capacity by the first year of life ( [Oesterheld, 1998](#)). During latency, CYPs are more efficient than in adulthood, and their activity declines to adult levels after puberty. Thus, higher doses are required on a mg/kg basis to achieve comparable steady-state plasma levels in latency children as compared to adults or adolescents, particularly for CYP-metabolized drugs.

## Excretion

The kidney is the most important organ for drug excretion. Three mechanisms are involved in the renal excretion of drugs: *glomerular filtration*, *tubular secretion* by active transport mechanisms, and *reabsorption*.

In contrast to hepatic function, renal functioning in infants approximates that of adults. Beyond early infancy, developmental changes in renal function apparently do not contribute substantially to age-related differences in psychotropic drug disposition, with the probable exception of lithium ( [Jatlow, 1987](#)).

## Drug Interactions: Focus on the Cytochrome P450 System

Given the increasing recourse to medication combinations and polypharmacy as an accepted and thoughtful ( [Wilens et al., 1995](#)) or as a controversial and potentially problematic ( [Woolston, 1999](#)) practice in child psychiatry, astute clinicians need to be aware and clinically suspicious of potential drug interactions. For children concurrently treated with nonpsychiatric drugs (including even “benign,” over-the-counter agents) the degree of oversight needs to be particularly heightened. Cytochrome-based interactions are especially common and relevant to psychotropic drugs; therefore, they are reviewed here in detail.

Cytochromes are heme-containing enzymes, located principally in the liver, which metabolize two types of substrates: endogenous (e.g., the body's own steroids, lipids, and fatty acids) and exogenous (e.g., toxins, drugs). The sequencing of CYP amino acids has led to a classification system based on similarity: Arabic numbers 1 through 4 designate family members, letters A through E label subfamily members, and Arabic numbers note specific enzyme (isoform, gene). CYP3A4, for example, is a member of family 3, subfamily A, and enzyme 4. CYP3A is the major CYP involved in human hepatic drug metabolism, constituting 30% of total CYP hepatic content that serves as a high-capacity reservoir. The other clinically relevant CYPs include 1A2, 2C9, 2C19, 2D6, and 2E1.

Most psychotropic drugs undergo both phase I and phase II reactions. A few drugs are metabolized by only one CYP (e.g., desipramine via CYP 2D6, triazolam via CYP3A). Some others undergo phase II conjugation only (e.g., lorazepam, oxazepam, and lamotrigine are glucuronidated only); however, most drugs require multiple CYPs to be completely metabolized. As examples, sertraline is *N*-demethylated via six different pathways ( [Greenblatt, 1999](#)), and clomipramine (CMI) demethylated by CYP1A2, CYP2C19, and CYP 3A to desmethylclomipramine (DCMI), an active metabolite that is then hydroxylated by CYP 2D6. In addition, CMI is directly hydroxylated by CYP 2D6.

Cytochrome-based metabolism of drugs is influenced by genetic factors. For example, 7% to 10% of whites have a genetic deficiency of CYP 2D6 and are less efficient in metabolizing 2D6 substrates, including many psychotropic agents ( [Table 76.1](#)). For these individuals, blood levels of drugs metabolized by 2D6 may increase considerably as unmetabolized drug enters the blood. Some Asian individuals have a 2D6 variant that causes them to be “somewhat slow” metabolizers; they require lower dosing of relevant drugs to achieve therapeutic blood levels. CYP 2C9 and CYP 2C19 also are genetically polymorphic. One to three percent of whites are slow metabolizers of CYP 2C9, and 18% to 23% of Japanese and 2% to 3% of whites and African Americans are slow metabolizers of CYP 2C19 ( [Bertilsson, 1995](#)). Fewer than five whites in a thousand are slow metabolizers of both CYP 2D6 and CYP 2C19, putting them at particular risk for high levels of substrates that are metabolized by *both* pathways (e.g., some tricyclics, propranolol, and citalopram) ( [Table 76.1](#)).

**Table 76.1. Cytochrome-Based Metabolism of Drugs**

## Cytochrome P450 Inhibitors and Inducers

Drugs that interact with CYPs can inhibit, induce, or have no effect on CYP activity. If a CYP is inhibited (or blocked), then more unmetabolized drug will enter the circulation, leading to increased levels of the drug (similar to a phenotypic slow metabolizer). Conversely, if a CYP is induced, additional enzyme will be available for metabolism, leading to lower drug levels. Inhibition occurs rapidly because inhibition requires blocking existing pathways. Induction takes some time to start (3 to 10 days) or stop (5 to 12 days), because protein synthesis must first occur and then cease. [Table 76.1](#) contains the five most relevant CYPs and selected common psychotropic and other pediatric drugs metabolized by them. Common potent inhibitors and inducers of CYPs are grouped alphabetically by CYP.

The table can be used to anticipate CYP-based drug interactions. If both drugs are listed on the same vertical axis, then a drug interaction is likely (especially for drugs that have only one metabolic pathway). Blood levels could be affected, depending on whether the medications are inhibitors, inducers, or substrates. Many of the most serious drug interactions occur when a potent CYP is added to a drug that is a substrate of that CYP and has a narrow therapeutic index. For example, fluoxetine or paroxetine (potent inhibitors of CYP 2D6) can increase the plasma concentration of desipramine (a substrate of CYP 2D6) about 400%. Sertraline, a less potent inhibitor of CYP2D6, increases desipramine levels only 25%. In contrast, fluvoxamine (a potent CYP3A inhibitor) can double levels of phenytoin within hours. Many of the drug interactions that result in inactivation of drugs occur when a potent CYP inducer is added to a same CYP substrate (e.g., ovulation and pregnancy can result when levels of an oral contraceptive, a CYP3A substrate, are reduced by carbamazepine, an inducer).

Although there are more limited data, glucuronidation (phase II) enzymes are also susceptible to inhibition and induction. As an example, lamotrigine is handled by glucuronidation alone, and the addition of valproate (a glucuronidation inhibitor) can significantly elevate lamotrigine levels, thereby increasing the likelihood of developing life-threatening Stevens-Johnson syndrome ( [Anderson, 1996](#)).

## PHARMACODYNAMIC PRINCIPLES

### Mechanisms of Action of Psychotropic Drugs

The second section of this chapter provides basic principles on three aspects of human brain function critical to an understanding of psychotropic drug mechanisms of action: neuronal circuitry, synaptic neurotransmission, and intracellular information processing. This information can be clinically relevant in helping to rationally guide therapeutic decision-making in pediatric psychopharmacology.

Modulation of neuronal activity via neurotransmitters is a fundamental mechanism of brain function. The premier therapeutic avenue of psychiatry, arguably, is the facilitation or inhibition of neurotransmitter systems in the brain, either through the administration of drugs or psychotherapy.

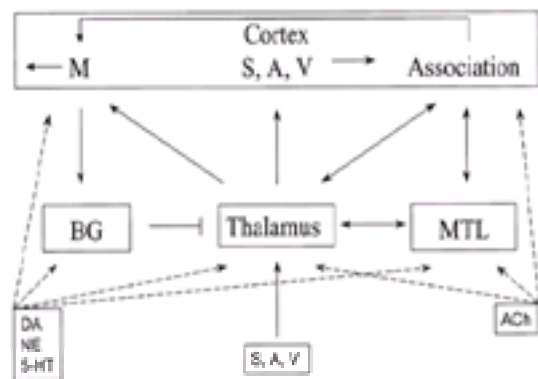

The release of neurotransmitters, their mechanisms of action, and their effect on target neurons are complex and still poorly understood; however, despite the diversity of neurotransmitters and receptors in the human brain, all forms of neural communication have the common goal of modulating neuronal activity. This is achieved by changing either the electrical or biochemical properties of the cell. The balance of intracellular and extracellular ions characterizes the electrical properties of the neuron. At rest, there are more negatively charged ions inside than outside the cell, thereby creating a negative resting membrane potential. Decreasing the resting potential leads to excitation, increasing it, to inhibition. The biochemical properties of the neuron are characterized by the expression of specific genes, the production of proteins, and the creation of a distinct metabolism. Regulation of gene expression and protein function determines the biochemical

status quo of the cell.

## Neuronal Circuitry

The adult cerebral cortex has about 1,011 neurons and each neuron establishes about 103 to 104 connections to other neurons. Neurons are arranged in distributed networks of brain regions to govern human behavior (Mesulam, 2000). This involves the collection of sensory information through perceptual modules, the creation of a representation, and the production of a response.

Here we focus on four major anatomic systems that are crucial for these three steps of information processing: the cortex, thalamus, basal ganglia, and medial temporal lobe (Fig. 76.1). The function of these four systems is modulated by several groups of neurons that are characterized by their use of a specific neurotransmitter.

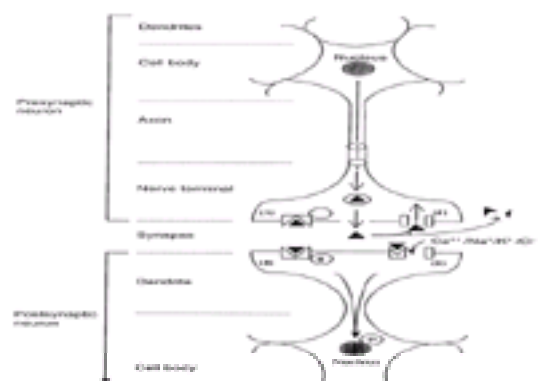

**Figure 76.1.** Neuronal circuitry: basic scheme of information processing in the human brain. Straight arrows indicate glutamatergic pathways. The BG–thalamus projection is GABAergic. The broken arrows indicate the widespread, neurotransmitter-specific projections arising from the basal forebrain (ACh) and brain stem (DA, NE, 5-HT). A1, primary auditory cortex; ACh, acetylcholine; BG, basal ganglia; DA, dopamine; 5-HT, serotonin; M, motor cortex; MTL, medial temporal lobe; NE, norepinephrine; S1, primary sensory cortex; V1, primary visual cortex. See text for further details.

1. The thalamus is the gateway to cortical processing of all incoming sensory information, here represented by the three major systems: somatosensory, auditory, and visual (S, A, V) (Fig. 76.1). Primary sensory cortices (S1, A1, V1) receive information from the appropriate input modules (sensory organ + thalamus).
2. The association cortex integrates information from primary cortices, subcortical structures, and brain areas affiliated with memory to create an internal representation of the sensory information.
3. The medial temporal lobe (i.e., hippocampus, amygdala) serves two major functions in the brain: to integrate multimodal sensory information for storage into and retrieval from memory, and to attach limbic valence to sensory information (e.g., pleasant or unpleasant, fight or flight).
4. The basal ganglia are primarily involved in the integration of input from cortical areas. The basal ganglia modulate cortical activity via a cortico-striato-pallido-thalamo-cortical (CSPTC) loop. The most prominent projections to the striatum arise from the motor cortex.

All major projections in this basic circuitry (Fig. 76.1) are glutamatergic, except for the projections from the basal ganglia toward the thalamus, which are GABAergic. The glutamatergic neurons within each of the major components of the circuit are under inhibitory control by GABAergic interneurons. In addition, four groups of densely packed neurons provide diffuse projections to all areas of the brain to modulate their functions: cholinergic neurons in the basal forebrain and brain stem, dopaminergic neurons in the substantia nigra and ventral tegmental area, noradrenergic neurons in the locus ceruleus, and serotonergic neurons in the raphe nuclei. The broken arrows in Fig. 76.1 indicate the four neurotransmitter-specific projection systems. The relay of information from one neuron to another across these neurotransmitter-specific projection systems is described next.

## Synaptic Neurotransmission

Dendrites create a network of fibers providing the neuron with input from other cells (Fig. 76.2). The cell integrates these different inputs through modulation of the membrane potential, or at the level of the nucleus (regulation of gene expression). One function of the cell body is the synthesis of all cell-specific receptors and enzymes needed for neurotransmitter production.

**Figure 76.2.** Anatomy of the neuron: the compartments of a typical neuron and the four major mechanisms of synaptic neurotransmission (1–4). See text for details.

The axon is the output station of the neuron. The axon can be short (local circuit neuron) or long (projection neuron). If a deviation from the resting membrane potential is above a certain threshold, an *action potential* is created and travels downstream rapidly. The nerve terminal is the widened terminal part of the axon. It provides a small area of close contact with dendrites of neighboring cells: a synapse. Variations of this typical scheme include synapses between two axons, two dendrites, and neurotransmitter release in medial parts of the axon (varicosities, boutons).

The presynaptic neuron, which releases the neurotransmitter into the synapse, may express two types of proteins that affect synaptic communication (Fig. 76.2): *Membrane-bound receptors* bind the intrinsic neurotransmitter (autoreceptor) or transmitters of neighboring neurons (heteroreceptor) and affect the cell via intracellular messengers. One response, for example, is the modulation of neurotransmitter release (Langer, 1997). *Membrane-bound reuptake transporters* pump the released neurotransmitter back into the cell (Amara, 1995; Lester et al., 1996).

The neuron receiving the input (postsynaptic cell) can be modulated via two different types of receptors (Fig. 76.2): *Fast-acting, class I (ionotropic) receptors*: The neurotransmitter binds to the receptor protein and within milliseconds leads to a change in the permeability of the associated ion channel, allowing the influx of ions such as  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ ,  $\text{K}^+$ , or  $\text{Cl}^-$ . *Slow-acting, class II (G-protein-coupled) receptors*: The neurotransmitter binds to the receptor protein and thereby changes the protein conformation. This change is relayed to an associated G-protein, so-called because it binds guanidine triphosphate (GTP) in order to be activated. G-proteins regulate two major classes of effector molecules: ion channels and second messenger generating enzymes.

## The Major Neurotransmitter Systems

The major neurotransmitter systems can be divided into two groups based on their anatomic distribution. The first group comprises the cholinergic, serotonergic, noradrenergic, and dopaminergic neurons. These four systems originate from small groups of neurons, densely packed in circumscribed areas of the forebrain or

brain stem, and that project to their target areas typically by long-ranging projection fibers. Because these neurotransmitter-specific projection systems reach selected neural systems, their modulation leads to more circumscribed effects. These four systems are presented initially, as they are of greatest relevance to the action of commonly used psychotropic drugs.

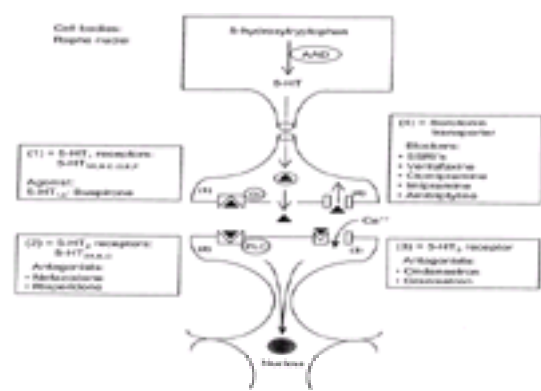

The second group includes the glutamatergic and GABAergic systems. Their neurons are by far the most prevalent and widely distributed types in the human brain. The widespread distribution of these two neurotransmitter systems has functional implications, as the modulation of glutamatergic and GABAergic neurotransmission affects many neural systems. These two systems are also relevant to psychopharmacology: for example, certain psychotropics (e.g., the benzodiazepines) and drugs of abuse (e.g., ethanol) act on GABAergic systems, and novel agents targeting the glutamate pathways are being tested for the treatment of psychotic disorders.

### Serotonergic Neurotransmission

Most serotonergic cells overlap with the distribution of the raphe nuclei in the brainstem. A rostral group (B6–8 neurons) projects to the thalamus, hypothalamus, amygdala, striatum, and cortex. The remaining two groups (B1–5 neurons) project to other brainstem neurons, the cerebellum, and the spinal cord.

Serotonin acts at two different classes of receptors: at an inotropic receptor (5-HT<sub>3</sub> receptor) or at slower acting receptors, coupled either to phospholipase C (5-HT<sub>2</sub> receptors) or to G-proteins (5-HT<sub>1,4-7</sub> receptors) (Julius, 1991).

The 5-HT<sub>1</sub> receptors (5-HT<sub>1A,B,C,D,E,F</sub>) (Fig. 76.3) are coupled to G<sub>i</sub> and lead to a decrease of cyclic AMP. The 5-HT<sub>1A</sub> receptor is also directly coupled to a K<sup>+</sup> channel leading to increased opening of the channel. The 5-HT<sub>1</sub> receptors are the predominant serotonergic autoreceptors. The atypical anxiolytic buspirone acts as an agonist at the 5-HT<sub>1A</sub> receptor.

**Figure 76.3.** Serotonergic neurotransmission.

5-HT<sub>2</sub> receptors (5-HT<sub>2A-C</sub>) are coupled to phospholipase C and lead to a variety of intracellular effects (mainly depolarization). The 5-HT<sub>2</sub> receptor may be important in mediating the therapeutic effects of agents as varied as risperidone and nefazodone. Three receptors (5-HT<sub>4,6&7</sub>) are coupled to G<sub>s</sub> and activate adenylate cyclase.

The 5-HT<sub>3</sub> receptor is the only monoamine receptor coupled to an ion channel, probably a Ca<sup>2+</sup> channel. It is found in the cortex, hippocampus, and in the area postrema, where it mediates nausea and emesis. It is typically localized presynaptically and regulates neurotransmitter release. Newer antiemetics and antimigraine drugs have effects at the 5-HT<sub>3</sub> receptor site (Fig. 76.3).

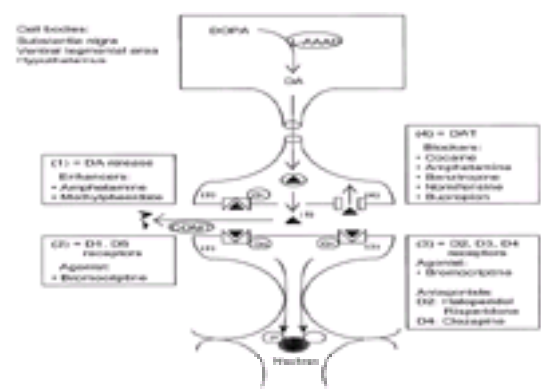

Serotonin is removed from the synapse by a high-affinity serotonin uptake site that is capable of transporting serotonin in either direction, depending on the concentration. The serotonin transporter is the primary target site for several antidepressants, including the selective serotonin reuptake inhibitors (SSRIs), venlafaxine, and tricyclic antidepressants such as clomipramine and, to a lesser extent, imipramine and amitriptyline (Fig. 76.3).

Serotonin is linked to many brain functions because of the widespread serotonergic projections and heterogeneity of the serotonergic receptors (Jacobs and Azmitia, 1992; Lucki, 1998). For example, modulation of serotonergic receptors and the reuptake site is beneficial (among others) in the treatment of anxiety, depression, obsessive-compulsive disorder, and schizophrenia (Murphy et al., 1998).

### Dopaminergic Neurotransmission

Dopaminergic neurons can be divided into three major groups based on the length of their efferent fibers: (a) ultrashort systems in the retina and olfactory bulb; (b) intermediate-length systems originating in the hypothalamus and projecting, among others, to the pituitary gland; and (c) wide-ranging systems originating from two areas, the substantia nigra (SN) and the ventral tegmental area (VTA). The SN neurons (also called A9 neurons) project to caudate and putamen, whereas the VTA neurons (also called A10 neurons) project to limbic areas such as nucleus accumbens and amygdala (i.e., mesolimbic projections) and several cortical areas such as frontal, cingulate, and entorhinal cortex (i.e., mesocortical projections).

Dopamine is released into the synapse from vesicles (Fig. 76.4); this process is facilitated by the stimulants methylphenidate and amphetamine.

**Figure 76.4.** Dopaminergic neurotransmission.

Dopamine acts at two different classes of dopamine receptors in the CNS, the D<sub>1</sub> receptor family and D<sub>2</sub> receptor family (Fig. 76.4) (Baldessarini and Tarazi, 1996). The D<sub>1</sub> receptor family includes the D<sub>1</sub> and D<sub>5</sub> receptors. Both are coupled to G<sub>s</sub> (G-stimulating) and lead to an increase of cyclic AMP. The D<sub>2</sub> receptor family includes the D<sub>2</sub>, D<sub>3</sub>, and D<sub>4</sub> receptors. All are coupled to G<sub>i</sub> (G-inhibitory) and lead to a decrease of cyclic AMP. There is a predilection of the different dopamine receptors for expression in specific brain areas (e.g., D<sub>1</sub> receptors are found in the striatum and cortex, D<sub>2</sub> receptors in the striatum and pituitary gland, and D<sub>3</sub> receptors in the nucleus accumbens). Dopamine receptor blockade is the major target of antipsychotic drugs, particularly at D<sub>2</sub> sites (Fig. 76.4). Presynaptic dopaminergic receptors are typically of the D<sub>2</sub> type and found on most portions of the dopaminergic neuron (as autoreceptors). They regulate DA synthesis and release, as well as the firing rate of DA neurons. Autoreceptors are five to 10 times more sensitive to DA agonists than postsynaptic receptors.

Dopamine is removed from the synapse by two mechanisms: first, catechol-O-methyl-transferase (COMT) degrades intrasynaptic DA. Second, the dopamine transporter (DAT) (Fig. 76.4), a Na<sup>+</sup>/Cl<sup>-</sup> dependent neurotransmitter transporter, transports DA in either direction, depending on the concentration gradient. Stimulant drugs such as amphetamine and cocaine potently block the DAT.

Dopamine affects several brain functions primarily by modulation of other neurotransmitter systems (Missale et al., 1998). Dopaminergic neurons of the SN project to the striatum and modulate the function of striatal GABAergic neurons. Dopaminergic projections of the VTA to limbic structures such as the nucleus accumbens are known to be involved in reward behavior and the development of addiction to drugs such as ethanol, cocaine, nicotine, and opiates (Diana, 1998; Koob, 1998). Dopaminergic projections from the VTA to the cortex play a role in the fine-tuning of cortical neurons (i.e., better signal-to-noise ratio) (Goldman-Rakic, 1998).

#### Noradrenergic Neurotransmission

About half of all noradrenergic neurons (i.e., 12,000 on each side of the brain stem) are located in the locus ceruleus. They provide the extensive noradrenergic innervation of cortex, hippocampus, thalamus, cerebellum, and spinal cord. The remaining neurons are distributed in the tegmental region. They innervate predominantly the hypothalamus, basal forebrain, and spinal cord.

Norepinephrine is released into the synapse from vesicles; amphetamine facilitates this release (Fig. 76.5). Norepinephrine acts in the CNS at two different types of noradrenergic receptors, a and b. Adrenergic a receptors can be subdivided into a1 receptors (coupled to phospholipase and located postsynaptically; prazosin is a typical antagonist) and a2 receptors (coupled to G<sub>i</sub> and located primarily presynaptically; clonidine and guanfacine are potent agonists, and yohimbine an antagonist) (Fig. 76.5) (Insel, 1996). Adrenergic b receptors in the CNS are predominantly of the b1 subtype. b1 Receptors are coupled to G<sub>s</sub> and lead to an increase of cyclic AMP.

Figure 76.5. Noradrenergic neurotransmission.

Norepinephrine is removed from the synapse by COMT and the norepinephrine transporter (NET), a Na<sup>+</sup>/Cl<sup>-</sup> dependent neurotransmitter transporter. Once internalized, NE can be degraded by the intracellular enzyme monoamine oxidase (MAO).

Noradrenergic projections modulate sleep cycles, appetite, mood, and cognition by targeting the thalamus, limbic structures, and cortex. These functions are targets of antidepressant drugs, which act via blockade of the norepinephrine transporter (Fig. 76.5) (Charney, 1998). Also, the locus ceruleus (LC) receives afferents from the sensory systems that monitor the internal and external environments. The widespread LC efferents lead to an inhibition of spontaneous discharge in the target neurons.

#### Cholinergic Neurotransmission

Cholinergic neurons in the central nervous system are either wide-ranging projection neurons or short-ranging interneurons. Projection neurons in the basal forebrain (septum, diagonal band, nucleus basalis of Meynert) project to the entire cortex, hippocampus, and amygdala, and projection neurons located in the brain stem project predominantly to the thalamus. Cholinergic interneurons in the striatum modulate the activity of GABAergic striatal neurons.

Acetylcholine acts at two different types of cholinergic receptors. Muscarinic receptors bind ACh as well as other agonists (muscarine, pilocarpine, bethanechol) and antagonists (atropine, scopolamine). There are at least five different types of muscarinic receptors (M1 to M5). All have slow response times. They are coupled to G-proteins and a variety of second messenger systems. When activated, the final effect can be to open or close channels for K<sup>+</sup>, Ca<sup>2+</sup>, or Cl<sup>-</sup> (Bonner, 1989).

Nicotinic receptors are less abundant than the muscarinic type in the CNS. They bind ACh as well as agonists such as nicotine (Fig. 76.6) or antagonists such as d-tubocurarine. The fast-acting, inotropic nicotinic receptor allows influx of Na<sup>+</sup> > K<sup>+</sup> > Ca<sup>2+</sup> into the cell.

Figure 76.6. Cholinergic neurotransmission.

Acetylcholine is removed from the synapse through hydrolysis into acetyl CoA and choline by the enzyme acetyl cholinesterase (AChE).

Acetylcholine modulates attention, novelty seeking, and memory via the basal forebrain projections to the cortex and limbic structures. Anticholinergic delirium and Alzheimer's disease are examples of a cholinergic deficit state (Geula, 1998; Giacobini, 1998). Furthermore, cholinergic interneurons modulate striatal neurons by opposing the effects of dopamine, a function that is exploited therapeutically when using anticholinergic agents such as bethanechol or trihexyphenidyl to treat the extrapyramidal side effects associated with antipsychotics (Fig. 76.6).

#### Gabaergic Neurotransmission

GABAergic neurons can be divided into two groups (Fig. 76.7): (a) Short-ranging neurons (also called interneurons or local circuit neurons) in the cortex, thalamus, striatum, cerebellum, and spinal cord; and (b) medium- and long-ranging neurons in the basal ganglia, septum, and substantia nigra.

**Figure 76.7.** GABAergic neurotransmission.

GABA acts at two types of receptors, the GABA<sub>A</sub> and GABA<sub>B</sub> receptors.

The GABA<sub>A</sub> receptor is a receptor-channel complex comprised of five subunits ([Lüddens and Korpi, 1996](#)). Activation leads to the opening of the channel, allowing Cl<sup>-</sup> to enter the cell, resulting in decreased excitability. Five distinct classes of subunits and multiple variations in the composition of the GABA<sub>A</sub> receptor are known. The receptor can be modulated by benzodiazepines at the α subunit and barbiturates and ethanol near the Cl<sup>-</sup> channel ([Fig. 76.7](#)).

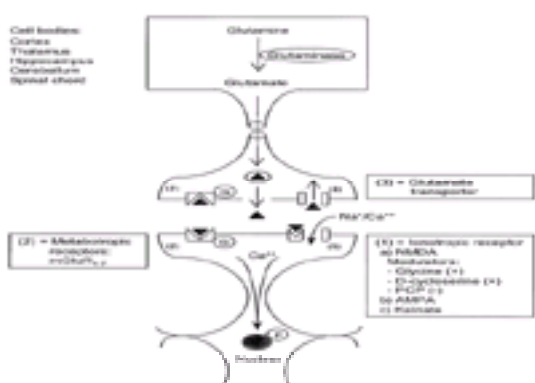

The GABA<sub>B</sub> receptor is a G-protein–coupled receptor with similarity to the metabotropic glutamate receptor ([Bettler et al., 1998](#); [Kaupmann et al., 1997](#)). The GABA<sub>B</sub> receptor is linked to G<sub>i</sub> (decreasing cyclic AMP and opening of K<sup>+</sup> channels) and G<sub>o</sub> (closing Ca<sup>2+</sup> channels). GABA is removed from the synapse by a sodium dependent GABA uptake transporter ([Fig. 76.7](#)).

Cortical and thalamic GABAergic neurons are crucial for the inhibition of excitatory neurons. GABAergic agonists such as benzodiazepines or barbiturates are efficacious in the treatment and prevention of seizures ([Bazil and Pedley, 1998](#)). Furthermore, modulation of GABA<sub>A</sub> receptors is beneficial in the treatment of anxiety disorders, insomnia, and agitation—most likely because of a general inhibition of neuronal activity.

### Glutamatergic Neurotransmission

Glutamatergic neurons are widely distributed throughout the entire brain. Prominent glutamatergic pathways are the cortico-cortical projections, connections between thalamus and cortex, and projections from cortex to striatum (extrapyramidal pathway) and to brain stem/spinal cord (pyramidal pathway) ([Ozawa et al., 1998](#)).

Glutamate acts at three different types of ionotropic receptors ([Fig. 76.8](#)) and at a family of G-protein–coupled (metabotropic) receptors ([Fig. 76.8](#)) ([Nakanishi, 1992](#); [Nakanishi et al., 1998](#); [Vandenberg, 1998](#)).

**Figure 76.8.** Glutamatergic neurotransmission.

Binding of glutamate to the ionotropic receptor opens an ion channel allowing the influx of Na<sup>+</sup> and Ca<sup>2+</sup> into the cell. NMDA receptors bind glutamate and *N*-methyl-d-aspartate. The receptor is comprised of two different subunits: NMDAR1 (seven variants) and NMDAR2 (four variants). The NMDA receptor is highly regulated at several sites. For example, the receptor is virtually ineffective unless a ligand binds to the glycine site and it is blocked by binding of ligands (e.g., ketamine and phencyclidine = PCP) to the PCP site inside the channel. AMPA receptors bind glutamate, AMPA, and quisqualic acid, whereas kainate receptors bind glutamate and kainic acid.

The metabotropic glutamate receptor family includes at least seven different types of G-protein–coupled receptors (mGluR1-7). They are linked to different second messenger systems and lead to the increase of intracellular Ca<sup>2+</sup> or the decrease of cyclic AMP. The increase of intracellular Ca<sup>2+</sup> leads to the phosphorylation of target proteins in the cell.

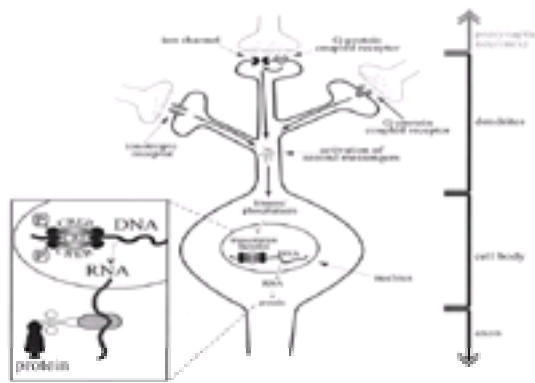

Glutamate is removed from the synapse by high-affinity reuptake; two transporter proteins are expressed in glial cells and one in neurons ([Fig. 76.8](#)).

Glutamate has an effect on many brain functions. For example, glutamatergic neurons and NMDA receptors in the hippocampus are important in the creation of long-term potentiation, a crucial component in the formation of memory ([Wilson and Tonegawa, 1997](#)). Excess stimulation of glutamatergic receptors, as seen in seizures or stroke, can lead to unregulated Ca<sup>2+</sup> influx and neuronal damage ([Coyle and Puttfarcken, 1993](#); [Dingledine et al., 1990](#); [Loscher, 1998](#)). Decreased glutamatergic function is thought to be involved in the creation of psychotic symptoms. Phencyclidine and ketamine can induce psychotic symptoms and *d*-cycloserine or glycine can decrease psychotic and/or negative symptoms in schizophrenia ([Farber et al., 1999](#); [Goff et al., 1999](#); [Heresco-Levy et al., 1999](#)).

### Intracellular Information Processing

Each neuron is the target of many projections from local and distant neurons. These influences are integrated at the level of the cell membrane and cell nucleus. The neurotransmitter-mediated activation of ion channels in the cell membrane can lead to an increase or decrease of the resting membrane potential. This may lead to the creation of an action potential. At the level of the cell nucleus, the various receptors and ion channels expressed on the cell membrane may influence gene and protein expression.

Gene expression is regulated by transcription factors that bind to specific sequences of the DNA in the nucleus ([Fig. 76.9](#)); therefore, membrane-bound receptors or ion channels in distal parts of the neuron must be able to activate intraneuronal signal transduction pathways that can span long distances and translocate to the nucleus. Because proteins assemble the neuron and determine neuronal properties, gene expression regulates neuronal function and may cause malfunction. Many psychopharmacologic agents with delayed therapeutic effects are thought to produce their therapeutic benefits through modulation of gene expression ([Duman et al., 1997](#); [Hyman and Nestler, 1996](#)).

**Figure 76.9.** Intracellular information processing. Neurotransmitters released from the presynaptic neuron activate receptors at the postsynaptic neuron. Second messengers either enter the neuron (e.g.,  $\text{Ca}^{2+}$  through ligand-gated ion channels) or are newly synthesized inside the neuron (e.g., G-protein-coupled receptors stimulate adenylate cyclase and the synthesis of cyclic AMP). Neurons usually have multiple receptor types and are able to integrate information from a variety of synaptic inputs. Second messengers stimulate protein kinases and protein phosphatases to control the state of phosphorylation of various proteins inside the neuron. Transcription factors such as CREB are regulated by kinases and phosphatases. A high level of discrimination is observed, although some transcription factors integrate information from different second messenger pathways. Thus, kinases and phosphatases regulate groups of genes under the control of specific transcription factors. Inset: Phosphorylation of CREB stimulates the transcription from DNA into RNA, which is transported out of the nucleus and translated (with ribosomes and tRNA) into protein.

Release of neurotransmitters from the presynaptic neuron into the synapse activates receptors on the postsynaptic neuron ( Fig. 76.9). Ions such as calcium enter the cell and act as second messengers on activation of ionotropic receptors. Activation of G-protein-coupled receptors facilitates the opening of neighboring ion channels or the synthesis of second messengers such as cyclic AMP. Second messengers (calcium, cyclic AMP) regulate the activity of protein kinases (proteins that transfer phosphate groups to a substrate protein) and phosphatases (proteins that remove phosphate groups from a substrate protein). In all cases investigated to date, the activation of neurotransmitter receptors changes the state of phosphorylation of neuronal proteins.

The transcription factors are one group of proteins regulated by phosphorylation. Transcription factors operate by recruiting the transcription initiation complex and RNA polymerase to particular genes. The RNA polymerase then transcribes the DNA template into an RNA molecule, which is translated into protein outside the nucleus.

Among the best-studied transcription factors in the brain is the  $\text{Ca}^{2+}$ - and cyclic AMP-responsive element binding protein (CREB) ( Montminy et al., 1990). The study of CREB has provided us with an insight into the complex consequences of transcription factor activation and gene expression on higher brain function. A variety of signal transduction pathways are integrated into CREB-mediated gene expression, such as those activated by  $G_s$ -proteins, ionotropic receptors or growth factors. Cyclic AMP-responsive element binding protein is activated by phosphorylation and regulates the expression of several target genes (e.g., genes for peptide neurotransmitters, enzymes involved in neurotransmitter synthesis, and growth factors). The discovery that CREB plays a vital role in processes such as learning and memory provided a link between gene regulation and cognitive function ( Frank and Greenberg, 1994; Stevens, 1994).

Small but persistent abnormalities in neurotransmission can have far-reaching consequences because neurotransmitters and receptors influence gene and protein expression in the brain. An understanding of signal transduction pathways and transcription factors such as CREB is instrumental in providing us with new therapeutic avenues in psychopharmacology.

#### [Chapter References](#)

The now-famous clinical trial conducted by [Charles Bradley \(1937\)](#) is often cited as the beginning of pediatric psychopharmacology. In that study, the racemic mixture of levoamphetamine and dextroamphetamine (Benzedrine) was administered openly to a group of 30 children with mixed behavioral and emotional symptoms. Bradley and colleagues observed that the children characterized as “noisy, aggressive and domineering” were calmer and more manageable. In the same issue of the *American Journal of Psychiatry*, [Molitch and Eccles \(1937\)](#) reported what may be the first placebo-controlled study in child psychiatry. Ninety-three boys described as juvenile delinquents were randomly assigned to gradually escalating doses of Benzedrine or placebo. The Benzedrine group showed dose-related improvements across a range of measures on learning, motor control, and short-term memory that exceeded the improvements in the placebo group. The field of pediatric psychopharmacology has made steady but slow progress since this pioneering work.

Despite clear progress in some areas, there are important gaps between research and clinical practice. For example: (a) There have been over 100 placebo-controlled studies on the efficacy of methylphenidate in the treatment of attention deficit hyperactivity disorder (ADHD), yet only a few studies have evaluated long-term effects ([MTA, 1999](#)). (b) For serious psychiatric disorders such as autism, empiric support for the use of any medication remains meager, leaving clinicians and families with inadequate guidance on how best to treat affected children. (c) Despite the demonstrated efficacy and safety of selective serotonin reuptake inhibitors (SSRIs) in the treatment of children and adolescents with obsessive-compulsive disorder (OCD), little is known about the appropriate duration of treatment. (d) Based on an evaluation of prescribing trends in three large health care systems, methylphenidate use among children 2 to 4 years of age increased from 1 to 5 per 1,000 in 1991 to 4 to 11 per 1,000 in 1995 ([Zito et al., 2000](#)). This twofold to threefold increase, depending on the health system under consideration, stands in sharp contrast with the lack of clinical research with methylphenidate for this age group. Clearly, the empiric foundations for pediatric psychopharmacology are not yet fully anchored. Over the past decade, however, there have been several initiatives that are likely to have a substantial impact on the pace of progress in the field.

The purpose of this chapter is to present general principles of clinical psychopharmacology in pediatric populations. Following the discussion of seven overarching principles, the chapter reviews the major classes of psychotropic medications and current approaches to their use in children and adolescents. Drugs within the major classes are considered in terms of their pharmacology, side effects, clinical applications and management, and available empiric support. Pharmacokinetic aspects, including drug interactions, as well as mechanisms of action and other pharmacodynamic issues are considered only briefly here, because such topics are dealt with in depth in the preceding and complementary chapter. Throughout this chapter, the reader is referred to [Table 77.1](#), in which the most salient information for each drug class and its specific agents is summarized.

**Table 77.1. Psychotropic Agents Used in Children and Adolescents**

## SEVEN GUIDING PRINCIPLES

### The Role of Development

There is general recognition that development can have a major impact on pharmacologic effects ([Vitiello and Jensen, 1995](#)). Thus, children and adults may show divergent responses to psychotropic drugs. The sources of these differences, as elaborated in the preceding chapter, are manifold. First, children often metabolize and eliminate drugs from the body more quickly than adults, resulting in shorter drug half-lives. This is apparently owing to a larger liver:total body ratio and more efficient glomerular filtration rate in children as compared to adults. One practical implication of these pharmacokinetic differences is that in order to achieve therapeutic serum levels, when compared to adults, children may require higher weight-adjusted dosages (expressed in mg/kg amounts) ([Vitiello et al., 1988](#)). In addition to pharmacokinetic considerations, there can be age effects on drug action as well because the central nervous system undergoes substantial developmental change during childhood.

These developmental changes in neurochemical systems can influence both therapeutic response and side effect profile. For example: (a) Compared to adults, adolescents have a higher risk of dystonic reactions to neuroleptics ([Lewis, 1998](#)). (b) Prepubertal children appear to be at a higher risk for the activating side effects of the selective serotonin reuptake inhibitors (SSRIs) ([King et al., 1991](#)). (c) Developmental differences in the maturation of noradrenergic pathways may explain, at least in part, why tricyclic antidepressants are less effective in children with depression as compared to adults ([Martin et al., 2000a](#)). Taken together, these findings suggest that the three major neurochemical systems that are manipulated by psychotropic drug treatments (dopaminergic, serotonergic, and noradrenergic,

respectively) are subject to age effects.

Federal policy initiatives have been instituted to promote studies specific to pediatric populations in recognition of these developmental influences ( [Riddle et al., 1998](#)). First, Congress passed in 1997 the Food and Drug Modernization Act (FDAMA), which offers pharmaceutical companies an additional 6 months of market exclusivity for products that are evaluated in children. For some drugs, this 6-month extension represents a powerful financial incentive. A second policy initiated by the Food and Drug Administration (FDA) requires pharmaceutical companies to evaluate new products in children if they are likely to be used in this population when released into the marketplace ([FDA, 1999](#)). A third and related important development has been the commitment of federal funds by the National Institute of Health for the establishment of research networks to conduct large-scale, multisite studies in pediatric populations. The combined impact of these initiatives makes it likely that in the coming years much more will be known about the safe and appropriate use of psychotropic drugs in youngsters, and about the effects of development on drug response.

### **The Limits of Categorical Diagnoses and Comorbidity as the Norm**

The second principle acknowledges the limitations of psychiatric diagnoses and of the current nosological system of classification. Most psychiatric disorders in childhood are probably heterogeneous with respect to etiology. This presumption is supported by the high frequency of comorbidity in child psychiatry observed both in clinical ([Biederman et al., 1991](#)) and community samples ([Angold et al., 1999](#)). The extent to which these mixed syndromes represent a variant of a given disorder is often unclear, but may be relevant to drug response. For example, in childhood OCD, tics are a common comorbid feature. Emerging data suggest that the tic-related form of OCD is phenomenologically different from non-tic-related forms of the disorder ( [Leckman et al., 1998](#)). In addition, the presence of tics appears to be associated with a lower probability of positive response to monotherapy with an SSRI ( [McDougle et al., 1994](#); [Scahill et al., 1997](#)). Along the same lines, children with developmental disabilities accompanied by hyperactivity, impulsiveness, and distractibility appear to have a lower rate of positive response than typically developing children with attention deficit hyperactivity disorder (ADHD) ( [Aman et al., 2000](#)). Developmentally disabled children also may have a higher rate of adverse events with stimulant treatment ([Handen et al., 1994](#)). Thus, etiologic heterogeneity may explain differences in clinical response. These issues underscore the importance of large treatment studies to identify clinically meaningful subgroups and predictors of positive and negative response.

### **Target Symptoms and the Integration of Data from Multiple Informants**

This principle concerns the importance of pretreatment assessment and the identification of target symptoms. Given how commonly psychiatric comorbidity is observed in children with mental disorders, the identification of target symptoms for pharmacologic intervention may be easier said than done. One of the practical challenges in child psychiatry is the requirement of gathering information from multiple sources, including the child and parents at a minimum, and the child's teacher or other caregiver as well in many cases. Obtaining data from multiple sources can be aided by the use of behavioral checklists, child self-reports, and clinician ratings. Behavioral checklists completed by parents and teachers permit comparison of the current patient to a normative sample. Clinician-rated instruments can assist in establishing a pretreatment baseline of symptom severity. Some checklists and clinician-rated instruments also can be used to measure change over time. Although checklists and rating instruments can be extremely useful in the evaluation phase and to measure change over time, they cannot replace the clinical interview and direct observation of parent and child. A closely related challenge is the integration of all available information, in order to identify the most pressing target symptoms and select the most appropriate medication in combination with other needed interventions.

### **Adverse Effects: Monitoring Risks and Benefits**

The dramatic increase in the availability of new psychotropic drugs, their expanded use in pediatric populations, and the uncertain impact of psychotropic medications on development underscore the importance of ongoing assessment of adverse effects. At present, there is no clear consensus on the best method of eliciting information about adverse events that occur in the context of pharmacotherapy. This lack of consensus is not limited to child psychiatry; it extends to adult psychiatry as well as other areas of medicine. Three approaches have been described: (a) use of an open-ended general inquiry; (b) the use of general inquiry augmented by a set of drug-specific queries or checklist; or (c) the use of a detailed review of body systems ( [Levine and Schooler, 1986](#)). At the center of this debate are concerns about sensitivity, specificity, and efficiency. The use of a detailed review of systems by an experienced clinician is unlikely to miss adverse effects of medication (i.e., high sensitivity). However, some experts express concern that this method may produce unacceptably high number of false positive responses. If true, this low specificity would come at a great cost in clinician time.

On the other hand, the open-ended general inquiry gives the parent and child an opportunity to express any concern that may have emerged since starting the medication or the last visit. Based on the assumption that parents and children notice important changes in behavior and/or health status, responses to the open-ended inquiry are likely to be clinically meaningful—even if they are not drug-related. The high specificity may result in missed adverse events (i.e., low sensitivity) because parents and children may not detect subtle adverse effects.

Until more is learned about the best method of eliciting data on adverse effects, appropriate clinical practice entails the combined use of an open-ended inquiry followed by a brief set of drug-specific side effects and safety concerns. In the pages that follow, we list the side effects associated with each of the medications presented. Additional safety concerns are also presented in [Table 77.1](#). Other fundamental issues to be covered in contemporary medication management of children include questions about concomitant medications, intercurrent illness, and other medical contacts since the previous visit. The need for vital sign and height and weight monitoring for neurologic examination, electrocardiogram, laboratory tests and drug levels, are medication-specific and described in appropriate sections that follow.

### **The Role of Caregivers and the Meaning of Medication**

The collaboration of the child's family is essential, and active engagement of the family is critical to the success of treatment interventions, pharmacologic or otherwise. A detailed discussion with the parents and child concerning the recommended medication, as well as an examination of the alternative treatments are necessary parts of initiating psychopharmacologic treatment. In addition, the family and child (to the extent possible) also should be partners in the final selection of medication. Once chosen, the dose schedule, side effects, anticipated results on target symptoms and the time to effect warrant explicit review. This discussion gives an opportunity to evaluate and, if needed, temper unrealistic expectations about the medication. Depending on the medication, it may be necessary to establish a contingency plan to manage specific side effects prior to their occurrence, such as being prepared to start benzotropine for a child who develops dystonia when started on a potent antipsychotic such as haloperidol. Children, and to a lesser extent adolescents, are dependent on their parents to administer medications, so that parental endorsement of the treatment plan is both ethically sound and practical. Failure to involve parents in the decision-making process may threaten treatment compliance, which in turn may undermine the success of the intervention ( [Lewis, 1995](#)). Attention also should be paid to the meaning that taking medication has for the child and family. Exploration of these issues may reveal a sense of failure on the part of the child or family. Some children may express concern that having to take medication implies that they are “crazy” or “weird.” These issues should be identified and addressed prior to initiating treatment. Even when handled prior to treatment, however, these issues often reemerge and require attention over the course of treatment.

### **Psychopharmacology in Context and the Combination of Therapeutic Modalities**

Psychotropic medications, no matter how effective, are often but one element in a multimodal treatment plan that includes other individually tailored interventions. This overarching principle, which may seem self-evident to clinicians accustomed to the concurrent use of various approaches in their practice, has become a focal point for research and practice guidelines. For example, a recent large-scale study required the failure of a brief psychotherapeutic intervention before proceeding to randomization to medication or placebo ( [RUPP, 2001](#)). The recently published practice parameters for pediatric OCD ( [King et al., 1998](#)) address questions of timing and sequence of interventions, such as when to use one modality (e.g., behavioral therapy) versus a combined medication approach. Finally, the ongoing NIMH-sponsored treatment of adolescents with depression study (TADS) is an example of formal testing of the separate and combined effects of medication and psychotherapeutic interventions.

### **Empirically Informed Evidenced-Based Clinical Decision Making**

A final principle is that treatment plans should be grounded on available empiric evidence. As the database of pediatric psychopharmacology expands, the value of this principle will become even more pressing and place a higher demand for clinicians to stay abreast of research findings. The International Algorithm Project has put forth a simple method for ranking available treatments according to their level of empiric support ( [Jobson and Potter, 1995](#)): *Class A* includes medications with good empiric support, based on consistently positive results in randomized controlled trials (RCTs). *Class B* consists of drugs with fair empiric support showing positive, but inconsistent, results in RCTs or positive results from small sample trials. *Class C* includes drugs with minimal empiric support, based primarily on accumulated clinical

experience from case reports and open-label studies. As examples relevant to pediatric psychopharmacology, *A level* of empiric support exists in the case of: stimulants for ADHD; fluvoxamine for OCD and other anxiety disorders of childhood; sertraline for OCD; fluoxetine for depression; and haloperidol and pimozide for tic disorders. *B level* of support exists for: sertraline for depression; clonidine for tics; guanfacine for ADHD; and fluoxetine for OCD. This ranking system clearly reflects the state of the science at a particular point in time. Given the rapid pace of development in pediatric psychopharmacology, clinicians have a responsibility to remain up to date with the empiric evidence to ensure the best possible match between target symptoms and treatment options.

## SPECIFIC DRUG TREATMENTS

### Stimulants

#### CLINICAL APPLICATIONS AND EMPIRIC SUPPORT

The stimulants, especially the short- and long-acting forms of methylphenidate and amphetamine, are first-line treatments for attention deficit hyperactivity disorder. In its classic form, ADHD is characterized by inattention, impulsiveness, and hyperactivity, although current convention includes primarily inattentive and impulsive/hyperactive subtypes (APA, 1994). Epidemiologic studies indicate that ADHD is relatively common in childhood, affecting 2% to 10% of school-aged children (Costello et al., 1996; Wolraich et al., 1998). Boys are affected more often than girls. It persists into adolescence in a majority of cases (Biederman et al., 1996), and into adulthood in as many as 30% to 40% of cases (Faraone et al., 2000). Studies of clinical populations indicate that the symptoms of ADHD are among the most common reasons for referral of children to mental health agencies (MTA, 1999). Nonetheless, there also are a substantial number of affected children who are not receiving treatment (Scahill and Schwab-Stone, 2000). Given the high prevalence of ADHD in school-age children, the potential for long-term functional disability and the high health-related costs associated with the disorder (Leibson et al., 2001), ADHD is a major public health concern.

The most commonly used stimulants for the treatment of ADHD include methylphenidate, dextroamphetamine and the mixed preparation of d,l-amphetamine (Pliszka, 1998; Spencer et al., 2000). Immediate-release methylphenidate has been studied more carefully than the other stimulants and remains the most commonly used agent in clinical practice (Safer et al., 1996). Although less well studied, the amphetamine products and extended-release formulations of methylphenidate have short-term efficacy and safety profiles that are comparable to methylphenidate (Elia et al., 1991; Pelham et al., 1990).

The empiric basis for the use of stimulants in children with ADHD rests on findings from hundreds of short-term, randomized, placebo-controlled studies conducted over the past 30 years (Spencer et al., 2000). Results from controlled studies over the last decade provide additional information about dose response, similarities, and differences in response across stimulant preparations, and the importance of regular clinical monitoring to achieve optimal response. Rapport and colleagues (Rapport and Denney, 1997) conducted a dose-response study in 76 subjects (66 boys and 10 girls) between the ages of 6 and 11 years. The 5-week study used four dose levels of methylphenidate (5, 10, 15, and 20 mg given twice daily (BID)) and placebo given in random order in a crossover design. All dose levels of active medication were superior to placebo. In addition, there was a clear linear trend, such that classroom behavior and the number of completed assignments improved with each increase in dose; however, the incremental improvement was smaller as the dose moved above the 10-mg dose level.

In order to compare methylphenidate and *d*-amphetamine, a placebo-controlled, crossover study was conducted in 48 boys between 6 and 12 years of age (Elia, 1991). Subjects were treated with methylphenidate, *d*-amphetamine or placebo in random order for 3 weeks in each treatment condition. During each condition the dose was increased on a weekly basis (e.g., methylphenidate doses for children under 30 kg of body weight were 12.5, 20, and 35 mg at breakfast and lunchtime for the respective weeks). Based on a global rating of response, 79% of the subjects showed a positive response to methylphenidate and 88% showed a positive response to *d*-amphetamine. Only two of the 48 subjects failed to respond to one or the other stimulant.

Pelham and colleagues (Pelham et al., 1990) evaluated the extended release products methylphenidate SR, *c*-amphetamine spansule, and pemoline in a crossover study that also included immediate release methylphenidate (10 mg morning and noon) and placebo. The sample consisted of 22 boys between the age of 8 and 13 years. The dose of active drug was fixed at 10 mg methylphenidate twice a day (approximately 0.3 mg/kg per dose) for the immediate release product, with equivalent doses of the extended release preparations. For example, 20 mg of the sustained release methylphenidate, 10 mg of *d*-amphetamine spansule or 56.25 mg of pemoline were given in the morning only. To maintain the blind across treatments, placebo was given at noon during the extended release treatment periods. Each treatment condition lasted 3 to 6 days. All forms of stimulant were superior to placebo on several outcomes, with only minor differences across preparations.

To date, only methylphenidate has been evaluated in long-term studies (MTA, 1999). With its sample size of 576 children, the Multimodal Treatment Study (MTA) of children with attention deficit hyperactivity disorder provides convincing evidence for the long-term benefits of methylphenidate. In the MTA study, children between 7 and 10 years of age were randomly assigned to one of four treatment groups: medication management ( $N = 144$ ; primarily methylphenidate administered in a systematic fashion with close monitoring); an intensive behavioral treatment program ( $N = 144$ ); combined medication management and the same behavioral treatment program ( $N = 145$ ); or community care, which served as the control group ( $N = 146$ ). The MTA research sites provided treatment to three of these groups, including the medication management group, the behavioral therapy only group and the combined medication plus behavioral therapy group. The community care group received treatment from self-selected practitioners. In most cases (84 of 146, or 58%), community care consisted of methylphenidate given on a twice-daily schedule. After 14 months of treatment, all four groups showed improvement compared to baseline. Comparisons across the four groups showed that the combined treatment group and the medication management group did significantly better than the community care group across a range of outcomes.

Several potentially important differences emerged when community care was compared to medication management provided by the MTA sites. First, community practitioners most often administered methylphenidate on a twice-daily schedule, compared to three times per day in the MTA-treated groups. Among the children randomly assigned to community care, 33% ( $N = 48$ ) stopped taking medication during the study period. Not surprisingly, this group showed the least improvement on the primary outcome measures. By contrast, only 3% ( $N = 18$ ) of the research medication management groups (both medication only and medication plus behavioral treatment) discontinued medication during the study. Finally, in the MTA medication management groups, follow-up visits were more frequent and parent and teacher ratings were used in a systematic way to inform clinical decision-making.

Taken together, the results of these studies suggest that stimulants are effective for short- and long-term treatment of children with ADHD. When considering group effects, stimulants appear to be equally beneficial, but individual patients may respond better to one preparation over another. The limited effectiveness of stimulants observed in the community care group of the MTA suggests that close clinical monitoring with dose adjustments based on systematic assessment of therapeutic and side effects contributes to compliance and optimal results.

#### MECHANISM OF ACTION

Although stimulants have become the standard treatment for ADHD, their mechanism of action is not clearly understood. In addition, the mechanism of action for amphetamines and methylphenidate may be slightly different (Solanto, 1998). Methylphenidate promotes release of stored dopamine and blocks the return of dopamine at presynaptic dopamine transporter sites. Amphetamines also block dopamine reuptake at the transporter, but appear to promote the release of newly synthesized dopamine more selectively. These combined effects enhance dopamine function in striatum and, at least indirectly, in the prefrontal cortex. It is also clear that both methylphenidate and the amphetamines affect the norepinephrine (NE) system (Biederman and Spencer, 1999). For example, both compounds decrease the firing rate in the locus ceruleus (LC), although amphetamine appears to be more potent in this action. Whether the effect on the NE system is facilitative or inhibitory is not clear at present. Nonetheless, these combined effects appear to be essential to the clinical effects of the stimulants, as drugs with more selective action (e.g., guanfacine or desipramine) tend to have smaller clinical effects.

#### PHARMACOKINETICS

Immediate release formulations of methylphenidate, dextroamphetamine, and the combined levoamphetamine and dextroamphetamine preparation are readily absorbed and show behavioral effects 30 to 60 minutes after ingestion. The peak level of immediate release methylphenidate occurs approximately 90 to 150 minutes after ingestion and the clinical effects last 3 to 5 hours. The immediate release amphetamine products achieve peak levels between 1 and 3 hours, with duration of action of 5 to 7 hours. Based on blinded studies in a research classroom setting, the d,l-amphetamine preparation appears to have a slightly longer duration of action than standard *d*-amphetamine (Swanson et al., 1998). Methylphenidate and amphetamine are broken down in the liver, and both the parent compound and its metabolites are excreted in the urine within 24 hours. Several newly developed sustained release products have been introduced, offering a range of options for clinical management of children and adolescents with ADHD. Published data on these new sustained release products are not yet available. Because some children may respond better to preparations with faster or slower onset of action, the rate of absorption may influence the choice of a particular agent. Individual

manufacturer's materials should be reviewed before prescribing these agents.

### SPECIFIC STIMULANTS AND CLINICAL MANAGEMENT

There has been considerable debate over whether stimulant dose should be weight-based or a fixed-dose ( [Greenhill et al., 1996](#); [Pliszka, 1998](#)). At least in part, this controversy can be traced to early research suggesting that lower doses, such as 0.3 mg/kg per dose, were optimal for enhancing cognitive performance, whereas higher doses (0.6 mg/kg per dose or higher) were more effective for behavioral control ( [Sprague and Sleator, 1977](#)). Subsequent studies have not supported this view. For example, a convincing linear dose-response was demonstrated across a range of outcomes in a placebo-controlled, crossover study involving 76 children and four dose levels of methylphenidate ( [Rapport and Denney, 1997](#)). Nonetheless, individual children may indeed show variability in response across a range of dose levels. Other children may show an orderly dose-response up to a threshold, above which there is little additive benefit. Thus, the mg/kg calculation can be used as a crude guide to calculate the starting dose of 0.3 mg/kg per dose and to a usual ceiling dose (e.g., 0.8 mg/kg per dose). Thereafter, the dose can be increased to establish an optimal response. For example, school-age children can be started on 5 mg thrice daily (TID) (just before breakfast, just before lunch, and 3 to 4 PM). The dosage may be increased to 10 mg BID (morning and noon) and 5 mg after school after 5 to 7 days. Subsequent increases are based on clinical response and emergence of side effects. The third dose typically remains half (or even less) of the first and second doses so as to minimize *rebound* effects and possible interference with sleep ( [Greenhill et al., 1996](#)).

To determine the optimal daily dose of methylphenidate, it is essential to get feedback from both parents and teachers. In the MTA study, children were seen weekly when starting the medication to monitor progress and side effects. The study used daily ratings to assist with the assessment of response. Although this is not feasible in clinical practice, clinicians may elect to pace dose increases with the collection of parent and teacher ratings. For example, in the first month of treatment, clinicians may increase the dose on a weekly basis. Collection of parent and teacher ratings prior to each increase would allow comparisons across dose levels. This information could be integrated with side effect data in order to select the optimal dose.

A similar approach can be used with *d*-amphetamine and *d,l*-amphetamine. These two drugs are dosed similarly to one another, but because of their greater (twofold) potency, they are used at half the methylphenidate dose. Moreover, owing to their slightly longer duration of action, the amphetamines are typically given twice a day—morning and noon. The initial dosage may be a single 2.5-mg dose in younger children or a 5-mg dose in older children. After 5 to 7 days, the medication may be raised 5 mg BID in younger children and 10 mg BID in older children. Thereafter, the dosage may be raised every 5 to 7 days to a total of 15 to 20 mg per day in younger children, and 40 mg per day in older children.

Until recently, methylphenidate sustained release, *α*-amphetamine spansules and pemoline were the only available long-acting formulations. Several new extended release products—two formulated with methylphenidate and one with *d,l*-amphetamine—have entered the market place. These longer-acting preparations are generally considered as effective as the immediate release compounds, and published results with them are forthcoming. The advantage of the long-acting preparations is that children do not need to take a dose in school, which may enhance compliance. The longer duration formulations may minimize the behavioral rebound often seen with immediate release formulations. The use of pemoline is declining since the introduction of these new extended release compounds, and given concerns about its potential hepatotoxicity.

### SIDE EFFECTS

Growth retardation, presumed to be secondary to stimulant-induced appetite suppression, has been a common concern among clinicians and families alike. Based on data from a large cohort of clinic cases treated with stimulants, Spencer and colleagues contend that slowed growth may be temporary, and that children with ADHD may be shorter than their age mates before puberty, but “catch up” in adolescence ( [Spencer et al., 1998a](#)). Appetite suppression often can be managed by giving stimulant medications with food or immediately after meals. Height and weight should be monitored regularly in children treated with stimulants, and tracked during long-term maintenance on population-normed weight- and height-for-age charts.

Other common side effects include sleep disturbance, depressed mood, stomachaches, over-focusing on details, tics and mannerisms, and picking at skin. Insomnia can be difficult to sort out, because many children with ADHD have sleep difficulties prior to receiving stimulant medications. Rebound effects associated with stimulant withdrawal may compound preexisting sleep problems. Thus, the child's sleep history should be documented prior to treatment and monitored throughout. As noted, it is common practice for the third dose of methylphenidate to be lower than the first two in order to minimize a possible rebound effect. The use of clonidine as an aid for sleep has been proposed, yet remains a controversial practice ( [Wilens et al., 1999](#)).

Results from case reports and controlled studies suggest that exposure to stimulants can be associated with the emergence of tics ( [Borcherding et al., 1990](#)) or the worsening of preexisting tics ( [Law and Schachar, 1999](#)). However, several recent studies have also shown that tics do *not* invariably worsen when children with ADHD and comorbid tic disorders are treated with stimulants ( [Castellanos et al., 1997](#); [Gadow et al., 1995](#)). Nonetheless, children with tic disorders should be monitored carefully when treated with stimulants. Dose reduction may be sufficient, but discontinuation may be warranted in some cases ( [Law and Schachar, 1999](#)).

### Antipsychotics

#### CLINICAL APPLICATIONS AND EMPIRIC SUPPORT

Antipsychotics were introduced to adult psychiatry in the early 1950s and were used in children shortly thereafter. The antipsychotics can be classified according to chemical family, such as phenothiazines or butyrophenones. Alternatively, they may be classified according to the relative potency of their dopamine blockade. Chlorpromazine and thioridazine are low-potency drugs in that relatively high doses are required to achieve usual therapeutic effects. By contrast, haloperidol and fluphenazine are high-potency dopamine blocking drugs. It is becoming commonplace to classify antipsychotics as typical or atypical with the introduction of clozapine and a short list of newer compounds. Pediatric uses of antipsychotics include the treatment of psychosis, severe behavioral problems associated with autism and other developmental disorders, aggression, tics, and as an adjunctive treatment in bipolar illness and OCD.

#### TYPICAL ANTIPSYCHOTICS

##### *Chlorpromazine*

Chlorpromazine (Thorazine), an aliphatic agent, was the first antipsychotic used in children with severe behavioral disturbances. With the introduction of newer agents, the use of chlorpromazine has declined, although it is still routinely used for the acute management of agitation or aggression, when it can be administered through either oral or intramuscular (IM) routes. When used IM, careful caution must be paid to vital signs, as significant hypotension can occur even at seemingly low doses (e.g., <25 mg).

##### *Thioridazine*

Thioridazine (Mellaril), another low-potency phenothiazine in the piperidine chemical family, was among the most commonly used antipsychotics in pediatric populations until recently. The recommended dosage for treating psychosis or severe behavioral dyscontrol in 3- to 12-year-old children is 0.5 to 3.0 mg/kg per day, given in two or three divided doses ( [McClellan and Werry, 1994](#)). In addition to the introduction of the atypical neuroleptics, recent case reports indicating that thioridazine can prolong cardiac conduction times, particularly the QTc interval, have led to decline in its use, and to an advisory “black box” label from the FDA, advising to use the agent only in special clinical situations.

##### *Haloperidol*

Haloperidol (Haldol) is a butyrophenone that is structurally unrelated to the phenothiazines. It represents the prototype of a high-potency typical antipsychotic. It has been used to treat children with psychosis, aggressive behavior, tics, and behavioral dyscontrol associated with autism since its introduction in the early 1960s ( [Anderson et al., 1989](#); [Shapiro et al., 1989](#)).

Compared to the low-potency antipsychotics, haloperidol is much more likely to cause extrapyramidal symptoms (EPS), but is less sedating. The dose of haloperidol varies according to the target symptoms. For example, in school-age children with tics or severe behavioral dyscontrol associated with autism, the dose is typically in the range of 0.75 to 2.5 mg per day ( [McDougle et al., 2000](#); [Scahill et al., 2000](#)). By contrast, doses in the range of 10 may be used to deal with an acute psychotic

episode ([Spencer et al., 1992](#)).

### *Fluphenazine*

Fluphenazine (Prolixin) is a piperazine phenothiazine. It is not approved for children under the age of 12 years, and has not been well studied in pediatric populations. At low dosages (0.04 mg/kg per day) fluphenazine decreased aggression, hyperactivity, and stereotypies in an open-label study of 12 children with pervasive developmental disorder (PDD) ([Joshi et al., 1988](#)). At a mean dose of 7 mg per day in divided doses (range, 2 to 15 mg per day) fluphenazine reduced tics and was favored over haloperidol by most patients ([Goetz et al., 1984](#)). This open-label trial of 21 patients with Tourette's syndrome (TS) included both children and adults, but results were not separately reported by age group.

### *Thiothixene*

Thiothixene (Navane) is a thioxanthene derivative. It is structurally unrelated to the phenothiazines or the butyrophenones. It is approved for the treatment of psychosis in children over the age of 12 years. The available evidence in children under age 12 indicates that thiothixene is less sedating than are low-potency neuroleptics, and that it may have a lower risk of extrapyramidal symptoms (EPS) than high-potency neuroleptics such as haloperidol ([Realmuto et al., 1984](#)).

### *Pimozide*

Pimozide (Orap) is a diphenylbutylpiperidine. It is not related to the phenothiazines or haloperidol. It is a potent blocker of dopamine at the D<sub>2</sub> postsynaptic receptors, and it is used to treat tics in TS. In placebo-controlled studies involving both children and adults, pimozide has been shown to be superior to placebo in reducing tics ([Shapiro and Shapiro, 1984](#)). It also has evaluated in head-to-head trials with haloperidol. These studies suggest that pimozide is equivalent to haloperidol with respect to tic suppression, and that it has a more favorable side-effect profile ([Sallee et al., 1994](#); [Shapiro et al., 1989](#)).

## ATYPICAL ANTIPSYCHOTICS

### *Clozapine*

Clozapine (Clozaril) is a dibenzodiazepine derivative. It is chemically unrelated to any of the typical antipsychotic drugs. Soon after it was introduced in 1960, its effectiveness in treatment-resistant patients with schizophrenia was recognized, but initial enthusiasm waned following the report of fatal agranulocytosis in a series of cases in Europe. Two open studies ([Frazier et al., 1994](#); [Siefen and Remschmidt, 1986](#)) and one controlled comparison with haloperidol ([Kumra et al., 1996](#)) have been carried out in pediatric populations. Collectively, these studies included 53 patients from ages 6 to 18 years. Clozapine was effective in 30 of 53 (56%) of these patients. This figure is impressive considering that this was a group of treatment-resistant patients. In the controlled trial, doses ranged from 125 to 525 mg/day given in divided doses. Although there were no reports of EPS, several serious side effects were observed, most notably seizures ( $N = 1$ ) and hematopoietic abnormalities ( $N = 4$ ). Weight gain is a frequently observed complication of clozapine treatment. Owing to differences in the duration of the studies, however, it is not possible to aggregate data across them. A retrospective comparison of clozapine ( $N = 20$ ), olanzapine ( $N = 13$ ), and risperidone ( $N = 38$ ) in adults indicated that clozapine and olanzapine confer a higher risk for weight gain than risperidone. Using a 10% increase in body weight as a threshold, 40% in the clozapine group, and 30% of patients treated with olanzapine had excessive weight gain. These rates were significantly greater than the 10% of patients in the risperidone group. In addition, the absolute increase in weight was significantly greater for the clozapine group compared to the risperidone group. The olanzapine and risperidone groups were not different in mean weight increase ([Wirshing et al., 1999](#)).

### *Risperidone*

Risperidone (Risperdal) was the second atypical antipsychotic to be released to the US marketplace. It is a benzisoxazol derivative that has some pharmacologic features in common with clozapine. It has not been associated with agranulocytosis. Large multisite studies in adults with schizophrenia have shown that risperidone is an effective antipsychotic with low EPS liability ([Marder and Meibach, 1994](#)). Unlike clozapine, it is associated with an increase in prolactin, suggesting more potent D<sub>2</sub> blockade. The risk of EPS increases in a dose-dependent manner at doses above 6 mg per day. This apparent threshold effect is presumed to be owing to a saturation of 5HT<sub>2</sub> receptors, followed by an increase in D<sub>2</sub> binding ([Kapur et al., 1995](#)).

To date, most studies with risperidone in pediatric populations have been limited to open-label studies in small samples. Findings from these studies suggest that risperidone may be useful for the treatment of children and adolescents with thought disorder ([Armenteros et al., 1997](#)), behavioral dyscontrol in PDD ([Fisman and Steele, 1996](#); [McDougle et al., 1997](#)), and tic disorders ([Lombroso et al., 1995](#)).

A recent placebo-controlled study of 20 subjects with conduct disorder, age 6 to 14 years of age, showed that risperidone reduced aggression by 42%, compared to 4% for placebo ( $P < 0.05$ ) ([Findling et al., 2000a](#)). In a placebo-controlled study of risperidone that included both children and adults, risperidone was superior to placebo for the treatment of tics in TS ([Scahill, 2001](#)). Thirty-four subjects (26 children and eight adults) were randomly assigned to placebo or risperidone. After 8 weeks of treatment with doses ranging from 1 to 2 mg per day in the pediatric sample, risperidone was associated with a 36% improvement on a clinician-rated measure of tic severity, which was significantly better than the 9% in the placebo group ( $P < 0.01$ ). Extrapyramidal symptoms were not observed in this study. Weight gain averaged 3.1 kg in the active treatment group compared to no change in the placebo group ( $P < 0.05$ ). Treatment emergent social phobia was observed in two cases in the risperidone group, which has been reported by others ([Hanna et al., 1999](#)).

Risperidone has also been compared to pimozide in a randomized, double-blind trial ([Bruggeman et al., 2001](#)). In that study, risperidone and pimozide were similar in their positive effects, with reductions in tic severity of 44% and 47%, respectively. Not surprisingly, the pimozide group reported more EPS. Weight gain was greater in the risperidone group (4.5 compared to 2.7 kg). Dose ranges were similar; up to 6 mg per day for each drug. The study included 50 subjects in total, but only 17 were in the pediatric age group. Results in the pediatric sample were not reported.

Several other controlled studies of risperidone are under way and published reports will be available in the near future. For example, the RUPP Autism Network recently completed a placebo-controlled study of risperidone in 101 children with autism accompanied by aggression, self-injurious behavior, and/or irritable and explosive behavior (the study's design and assessment methods are described in [Arnold et al., 2000](#); Scahill et al., in press). In most of these studies, the drug was initiated at 0.5 mg per day and increased by 0.5 mg every 5 to 7 days to a range of 1 to 3.5 mg per day in two divided doses. Findling and colleagues (2000a) started smaller children (i.e., less than 50 kg) at 0.25 mg per day and 0.5 mg for larger subjects. The dose ranged from approximately 1.0 to 2.5 mg per day given in a single morning dose.

### *Quetiapine*

Although not chemically related to clozapine, quetiapine (Seroquel) resembles clozapine in its receptor occupancy profile. It has low activity at D<sub>2</sub> receptors. Because it is a relatively low-potency drug at the 5HT<sub>2</sub> sites as well, it does not show the threshold effect observed with risperidone. Thus, even at high doses, quetiapine has low EPS liability and shows only transient rises in prolactin. As with the other available atypical neuroleptics, quetiapine has demonstrated safety and efficacy for the treatment of adults with schizophrenia. Only limited data are available on its use in children and adolescents. Preliminary results suggest that quetiapine may be useful for the treatment of psychotic symptoms in adolescents ([McConville et al., 2000](#)). Less promising results were reported in an open-label study of six adolescents with pervasive developmental disorder ([Martin et al., 1999](#)). In that study, only two of six subjects showed a positive response on global measures of behavior.

### *Olanzapine*

Olanzapine (Zyprexa) is another agent with atypical features that are preserved only in the lower dose range (<20 mg/day). The use of olanzapine has been described in open-label series of children and adolescents with treatment-resistant schizophrenia ([Kumra et al., 1998](#)), and more recently as a single ([Frazier et al., 2001](#)) or adjunctive ([Chang and Ketter, 2000](#)) agent for the treatment of juvenile bipolar disorder. Together with clozapine, olanzapine has shown the highest propensity for morbid weight gain in adults ([Allison et al., 1999](#); [Wirshing et al., 1999](#)). The high risk of weight gain associated with these agents is a pressing concern for children and adolescents and warrants more study.

## Ziprasidone

Ziprasidone (Geodon), the most recently released atypical antipsychotic medication, also has been shown to be effective in adults with schizophrenia ( [Bagnall et al., 2000](#)). Like risperidone, it is a potent blocker at the D<sub>2</sub> and 5-HT<sub>2</sub> sites. Compared to risperidone, however, much larger doses are required to achieve an antipsychotic effect. For example, the usual dose of risperidone in adults with schizophrenia is 6 mg per day. By contrast, the dose of ziprasidone is typically in the range of 80 to 160 mg per day in two divided doses ( [Tandon, 2000](#)). There is one published study of ziprasidone in a pediatric population. In that trial, 28 children (age 7 to 17 years) with TS or chronic motor tic disorder were randomly assigned to placebo ( N = 12) or ziprasidone ( N = 16) under double-blind conditions. The mean dose of ziprasidone was 30 mg per day in divided doses. Using the same outcome measure mentioned for the risperidone study in TS, ziprasidone was associated with a 35% improvement in tic severity, compared to a 7% decline in the placebo group ( *P* < 0.05) ( [Sallee et al., 2000](#)). Common side effects included moderate sedation (one subject), mild sedation (11 subjects), insomnia (four subjects), and akathisia (one subject). There were no changes in laboratory values, cardiac conduction times, or body weight in the ziprasidone group. Its apparent limited effect on weight gain makes of ziprasidone a welcome addition to the antipsychotic armamentarium, although larger studies are needed to confirm this initial impression.

### MECHANISM OF ACTION

The principal therapeutic action of the typical antipsychotics is to block postsynaptic D<sub>2</sub> receptors ( [Findling et al., 1998](#)). The observed differences across traditional antipsychotics are presumably related to the regional specificity of the D<sub>2</sub> blockade (striatum versus limbic structures), and the effects on other neurotransmitter systems. By contrast, the atypical antipsychotics block both dopamine and serotonin postsynaptic receptors to varying degrees. The addition of postsynaptic 5-HT blockade appears to lower the risk of EPS and perhaps of tardive dyskinesia (TD) as well. It may also contribute to beneficial effects on negative symptoms of schizophrenia, although this remains a matter of controversy. Some investigators argue that the beneficial effects of the atypicals on negative symptoms have yet to be demonstrated in a convincing manner, whereas others concede that these agents can improve negative symptoms, but contend that 5HT<sub>2</sub> blockade may not be the underlying mechanism involved.

Antipsychotic medications also have anticholinergic and antihistaminergic effects, and block adrenergic pathways as well. These additional pharmacologic properties probably do not contribute to the therapeutic effects of the antipsychotic drugs, but do have an impact on their side-effect profiles. For example, low-potency neuroleptics such as chlorpromazine and thioridazine cause more sedation, dry mouth, and constipation, presumably owing to antihistamine and anticholinergic effects. Their propensity to cause hypotension may be related to  $\alpha$ -adrenergic blockade.

### SIDE EFFECTS

Extrapyramidal symptoms (e.g., dystonic reactions, rigidity, and akathisia) are more common with the high-potency neuroleptics. In addition to EPS, side effects of the typical antipsychotic drugs in children and adolescents include cognitive blunting, school phobia, weight gain, and depressed mood. Drowsiness is a common side effect with the low-potency antipsychotic agents, but may occur in the high-potency antipsychotics as well. Anticholinergic side effects such as dry mouth, constipation, and blurred vision also should be monitored. As noted, thioridazine, pimozide, and other antipsychotics can prolong cardiac conduction times to varying degrees. Indeed, recent guidelines suggest that electrocardiograms be obtained at baseline and during maintenance treatment with antipsychotics ( [Gutgesell et al., 1999](#)).

Although the atypical antipsychotics are less likely to cause EPS, they are not free of adverse effects. Clozapine is associated with a low risk of agranulocytosis. For this reason, it is only used in treatment-resistant schizophrenia. Other side effects of clozapine include lowered seizure threshold and tachycardia. An adverse effect that has been recurrently reported for clozapine, olanzapine, quetiapine, and risperidone is weight gain. Although the number of subjects studied remains relatively small, all available studies in pediatric samples with these agents have reported weight gain. In the two placebo-controlled studies with risperidone, weight gain was significantly greater in the active treatment group as compared to placebo, posting 4.3 kg in one study ( [Findling et al., 2000a](#)) and 3.1 kg in the other ( [Scahill, 2001](#)). When followed for longer periods of time, the weight gain can be substantial ( [Kelly et al., 1998](#); [Martin et al., 2000b](#)). Adult studies suggest that weight gain is likely to be greatest with clozapine, followed by olanzapine, risperidone, and quetiapine ( [Allison et al., 1999](#)). Thus far, and for reasons that are not clear, ziprasidone has not been associated with weight gain. The mechanism for weight gain appears to be through an increase in appetite, which may be owing to interference with the satiety mechanism. The health consequences of obesity can be significant. For example, case reports suggest that olanzapine may contribute to increased serum triglycerides ( [Osser et al., 1999](#)) and drug-induced Type II diabetes ( [Wirshing et al., 1998](#)). Rare cases of hepatotoxicity have been reported with risperidone, prompting some investigators to recommend periodic measurement of liver enzyme levels during maintenance treatment ( [Kumra et al., 1997](#); [Landau and Martin, 1998](#)).

### Tardive Dyskinesia

The risk of tardive dyskinesia (TD) increases as a function of dose and duration, but it may occur with brief exposures as well. Tardive dyskinesia has been reported in pediatric patients, but it does not appear to be common ( [Riddle et al., 1987](#)). Thus, children and adolescents treated with antipsychotics should be monitored for abnormal movements. The largest systematic study to date ( [Campbell et al., 1997](#)) raises questions regarding the difficulty in distinguishing between TD and withdrawal dyskinesia (WD). In that study, 30% of children between the ages of 2 and 8 years showed persistent dyskinesic movements for up to 3 months of follow-up after a planned withdrawal from haloperidol. Questions of how and when to discontinue antipsychotic medication are critical ones, but data to guide clinical decisions are limited. To minimize WD, dose reductions should be done gradually while evaluating changes in symptom severity. In autism and tic disorders, discontinuation may be considered annually for cases in which good control has been achieved. If symptoms persist, the maintenance dose of the neuroleptic should be reduced to the lowest possible one sufficient to maintain symptomatic control and minimize overall exposure ( [McClellan and Werry, 1994](#)). Based on the collective experience with clozapine, the newer atypicals may also have a lower risk of TD. More study is needed, such as long-term follow-up of clinical samples treated with atypical antipsychotics and careful postmarketing surveillance of these agents in pediatric populations.

Neuroleptic malignant syndrome (NMS) is a rare adverse effect that has been associated with the typical antipsychotics. Characterized by high fever, autonomic instability, and muscle breakdown (reflected by elevated creatine phosphokinase (CPK) titers), it can pose a life-threatening risk. Indeed, a disease-fatality rate of 9% has been reported for children and adolescents ( [Silva et al., 1999](#)). Discontinuation of the agent involved is usually all that is required, highlighting the importance of early identification of the condition. In severe cases, IV fluids are needed, and some authors have advocated the use of dantrolene or bromocriptine to maximize recovery.

### Antidepressants

The antidepressants include a group of chemically diverse compounds that have been shown to be effective in the treatment of adults with major depression. More recently, several antidepressants have been used in the treatment of adults with a range of other disorders, including OCD, generalized anxiety disorder (GAD), panic disorder, social phobia, and posttraumatic stress disorder (PTSD). These broader clinical applications likewise are being implemented with increasing frequency in the pediatric population, even though the level of empiric support varies widely, and depends largely on the disorder under consideration. Antidepressants can be classified according to: (a) chemical similarity (such as tricyclics compounds, and within these, secondary or tertiary amines); (b) primary mode of action (such as the SSRIs, selective norepinephrine reuptake inhibitors, or monoamine oxidase inhibitors); and (c) miscellaneous, newer antidepressants (e.g., bupropion, venlafaxine, or nefazodone).

### Tricyclic Antidepressants

#### CLINICAL APPLICATIONS AND EMPIRIC SUPPORT

Tricyclic antidepressants (TCAs) have been used to treat several psychiatric disorders of childhood over the past three decades, including depression ( [Puig-Antich et al., 1987](#)), ADHD ( [Biederman et al., 1989](#)), OCD ( [DeVeauugh-Geiss et al., 1992](#)), separation anxiety disorder ( [Klein et al., 1992](#)), and enuresis ( [Werry et al., 1975](#)). Although TCAs have been used frequently in clinical practice, evidence for their efficacy in treating children with these psychiatric disorders is inconsistent. For example, a series of carefully conducted controlled trials have consistently failed to show the superiority of any TCA over placebo in the treatment of child- and adolescent-onset depression. This poor track record stands in marked contrast to the more compelling results in adult depression ( [Martin et al., 2000a](#)). The use of TCAs in non-OCD anxiety is equivocal. One recent study found imipramine superior to placebo in the treatment of separation anxiety ( [Bernstein et al., 2000](#)), but an earlier report found no differences between the treatment conditions ( [Klein et al., 1992](#)). In contrast to these respectively disappointing or inconclusive findings in

depression or separation anxiety, double-blind, placebo-controlled studies have demonstrated the efficacy of desipramine in children with ADHD ( [Biederman et al., 1989](#); [Singer et al., 1995](#)), and of clomipramine for the treatment of OCD in children and adolescents ( [DeVeauugh-Geiss et al., 1992](#)). Clomipramine also has been used in the treatment of children with autism accompanied by OCD-like symptoms. In a crossover study, clomipramine was superior to desipramine and placebo in reducing repetitive behaviors ( [Gordon et al., 1993](#)). Intravenous administration of clomipramine has shown promise in adults and, to a lesser extent, in adolescents with refractory OCD ( [Koran et al., 1998](#); [Sallee et al., 1998](#)).

#### MECHANISM OF ACTION

To varying degrees, the TCAs inhibit the reuptake of NE by presynaptic neurons. Over time, this pharmacologic effect is presumed to enhance noradrenergic neurotransmission. Among the TCAs, desipramine is the most selective in its capacity to block NE reuptake. This highly selective property of desipramine is presumed to play a role in its effectiveness in ADHD. Based on the favorable effects of desipramine in ADHD, there is interest in other compounds, such as tomoxetine, which have highly selective norepinephrine reuptake inhibiting properties ( [Spencer et al., 1998b](#)). Unlike desipramine, however, tomoxetine does not appear to prolong cardiac conduction times. Clomipramine is unique among the TCAs in that it is a potent inhibitor of serotonin reuptake. This property is presumed to explain the superiority of clomipramine over desipramine for the treatment of OCD ( [Leonard et al., 1989](#)).

#### PHARMACOKINETICS

Serum levels of TCAs can show wide variation across individuals taking the same oral dose because of genetic differences in CYP 450 enzyme activity. Thus, therapeutic levels for the TCAs are not well established in pediatric populations. Serum levels may be useful, however, to identify children with low or rapid metabolic activity, rule out toxicity, and assess compliance.

#### CLINICAL MANAGEMENT

An ECG, pulse, and blood pressure should be obtained prior to starting any of the TCAs. A medical and family history that focuses on syncope in the child, as well as episodes of syncope or sudden death in close relatives may be informative. Evidence of a normal physical examination within the past year also should be documented. The typical dose range for TCAs in children is up to 5 mg/kg per day for imipramine, 2.5 mg/kg per day for nortriptyline, and perhaps somewhat higher (3 mg/kg per day) for clomipramine. Imipramine may be started at a dosage of 25 mg and increased every 4 or 6 days in similar increments to 100 to 150 mg per day. In younger children, nortriptyline is typically introduced with a 10-mg dose, with increases every 4 to 6 days to a range of 50 to 75 mg per day in divided doses. Clomipramine is usually started at a dose of 25 mg, with gradual increases every 4 or 6 days to a maximum of 100 mg per day in younger children and 150 mg in older children. For all of the TCAs, repeat vital signs and electrocardiograms (ECGs) should be obtained during the dose adjustment phase and when the maintenance dose has been achieved. As part of the informed consent process, potential cardiac effects and the reason for repeat ECG monitoring should be discussed with the family and child in a developmentally appropriate manner. A heart rate corrected QT interval (QTc) above 460 ms, QRS complex longer than 120 ms, or PR interval greater than 200 ms ( [Gutgesell et al., 1999](#)) warrant dose reduction followed by a repeat ECG. Exceeding these parameters should prompt treatment reevaluation and perhaps discontinuation. For cases showing clinical benefit and persistent ECG abnormalities, consultation with a pediatric cardiologist is in order.

#### SIDE EFFECTS

The TCAs are associated with a range of side effects, including sedation, dizziness, dry mouth, excessive sweating, weight gain, urinary retention, tremor, and agitation. Lowering the dose, changing dose schedules, or switching between secondary and tertiary amines often can help manage these effects. For example, to deal with sedation, the medication could be given twice a day, with the higher dose in the evening. Switching between TCAs can be helpful at times: For example, imipramine (a tertiary amine) can be changed to nortriptyline (a secondary amine) in an effort to minimize sedation or constipation. Despite the evidence showing the efficacy of clomipramine for OCD and desipramine for ADHD, the TCAs appear to be declining in use ( [Ryan and Varma, 1998](#)). This trend is largely owing to the side effect profile and potential for serious adverse effects; the rare possibility of sudden death related to tachyarrhythmias is the most ominous. Originally reported in cases treated with desipramine, the series of case reports that accrued over ensuing years has led some (but not all) experts to recommend avoiding TCAs in the pediatric population ( [Werry et al., 1995](#)). The combination of: (a) stepwise dosing within clear weight-adjusted margins; (b) careful ECG monitoring; (c) full disclosure of the risk:benefit ratio in the treatment planning process; and (d) their selective use in nonresponders to first-line agents, provides a rational basis for keeping these important compounds in the child psychiatric armamentarium.

#### INTERACTIONS

Hepatic enzymes in the cytochrome P450 system (CYP 450) metabolize the TCAs, like most other psychotropic drugs. Several psychotropic (fluoxetine, fluvoxamine, paroxetine) and nonpsychotropic drugs (ketoconazole, cimetidine, erythromycin) inhibit the action of one or more of these hepatic enzymes. Inhibition of the enzyme specific for metabolizing the TCA can result in toxicity ( [Flockhart and Oesterheld, 2000](#)). For example, the commonly used broad-spectrum antibiotic erythromycin is a potent inhibitor of CYP3A4. Clomipramine is a substrate for this enzyme. The addition of erythromycin to ongoing treatment with clomipramine causes a dramatic rise in the level of the latter, with an attendant increase in the risk of adverse effects. This mechanism also has been exploited as a therapeutic maneuver in refractory OCD. When added to ongoing treatment with clomipramine, fluvoxamine (also an inhibitor of CYP3A4) reduces the metabolism of clomipramine and causes substantial increase in drug level. To date, only case reports showing benefit in refractory cases have been published. The proposed mechanism for the reported benefit in refractory cases is the rise in the parent compound, clomipramine, which is more selectively serotonergic in its action than the noradrenergic metabolite, desmethylclomipramine. Because this combination increases the risk of typical side effects of clomipramine, as well as the risk of prolonged cardiac conduction times and of seizures, this combined approach is reserved for refractory cases only.

#### Selective Serotonin Reuptake Inhibitors

The SSRIs are a group of chemically unrelated compounds that potently inhibit the return of serotonin into presynaptic neurons. Currently marketed SSRIs include fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram. In contrast to clomipramine, which inhibits the reuptake of both NE and serotonin, these newer compounds are more restricted in their reuptake of serotonin; therefore, their denotation as selective.

#### CLINICAL APPLICATIONS

All of the SSRIs in current use are approved for use in the treatment of adults with OCD. With the exception of fluvoxamine, the SSRIs also are approved for use in adults with major depression. More recently, paroxetine and sertraline have been approved for adults with anxiety disorders, and sertraline for PTSD. In pediatric populations, the FDA has approved fluvoxamine and sertraline for the treatment of OCD.

#### EMPIRIC SUPPORT

The introduction of the SSRIs, starting with fluoxetine in the late 1980s, has had a dramatic impact on the practice of pediatric psychopharmacology. Compared to the TCAs, monotherapy with the SSRIs is relatively simple. As a group, these medications are generally well tolerated, typically can be given once a day, and do not require blood level monitoring or ECGs. Following the early clinical trials with clomipramine and fluoxetine in children and adolescents ( [DeVeauugh-Geiss et al., 1992](#); [Leonard et al., 1989](#); [Riddle et al., 1992](#)), several large placebo-controlled clinical trials with sertraline ( [March et al., 1998](#)) and fluvoxamine ( [Riddle et al., 2001](#)) in OCD; with fluoxetine ( [Emslie et al., 1997](#)) and paroxetine (Keller et al., 1998) in depression, and with fluvoxamine in non-OCD anxiety disorders ( [RUPP, 2001](#)), have been conducted in pediatric populations. In each of these studies, the SSRI was superior to placebo in the primary outcome measure of interest.

#### OBSESSIVE-COMPULSIVE DISORDER

Sertraline and fluvoxamine have been evaluated in randomized, multisite, placebo-controlled trials of parallel groups. Using the Children's Yale-Brown Obsessive Compulsive Scales (CYBOCS) as the primary outcome measure, both drugs were superior to placebo in improving obsessive-compulsive symptoms. Sertraline was evaluated in 187 subjects ranging from 6 to 12 years of age. In that study, an average daily dose of 167 mg of sertraline was associated with at least a 25% improvement in the CYBOCS score in 53% of subjects, compared to 37% for placebo ( $P = 0.03$ ) ( [March et al., 1998](#)). In 120 children between the ages of 8 and 17 years, fluvoxamine at a mean daily dose of 165 mg was effective in 42% of children, compared to 26% among those treated with placebo ( $P = 0.06$ ) ( [Riddle et al.,](#)

[2001](#)). Based on open-label follow-up data, beneficial effects were maintained for several months in a majority of subjects (Walkup, personal communication).

An open-label study of paroxetine in pediatric OCD revealed not only promising results ([Rosenberg et al., 1999](#)), but also interestingly, reductions in thalamic volume ([Gilbert et al., 2000](#)) and caudate glutamate levels ([Rosenberg et al., 2000](#)), which paralleled clinical response. Two small placebo-controlled studies provide additional support for the efficacy of fluoxetine in OCD ([Kurlan et al., 1993](#); [Scahill et al., 1997](#)). Finally, one open-label study with citalopram has been done in children with OCD ([Thomsen, 1997](#)). In that study, 23 subjects were treated with 10 to 40 mg per day of citalopram for 10 weeks in an open-label fashion. Eleven of 23 subjects showed a clinically meaningful positive response (30% improvement or more). Five patients showed little or no response, and the remaining seven showed a partial response.

Taken together, these data suggest that the SSRIs are effective for the treatment of OCD in children and adolescents; however, the magnitude of response may not be large. In addition, some children with OCD may show only a partial response to an adequate trial of an SSRI. For example, approximately 40% of the subjects in the multisite sertraline study showed less than a 25% improvement in obsessive-compulsive symptoms ([March et al., 1998](#)). This observation indicates that clinicians should remind parents and patients not to have unreasonably high expectations for SSRI treatment. The problem of partial response raises questions about whether to switch to another SSRI or clomipramine, or embark on one of several augmentation medication strategies. Although not well studied in children, two studies have shown that the addition of low-dose haloperidol ([McDougle et al., 1994](#)) or risperidone ([McDougle et al., 2000](#)) to an SSRI can be effective in adults with refractory OCD. When evaluated in rigorously controlled studies, no other pharmacologic addition strategies have been effective in refractory OCD. These strategies have included, drugs such as lithium and buspirone among others, both of which enhance serotonergic function. Case reports suggest that the addition of clonazepam may be useful in some cases ([Leonard et al., 1994](#)) and combined treatment with an SSRI and clomipramine also may be useful ([Figueroa et al., 1998](#)). In view of the inadequate support for combined pharmacotherapy in children with refractory OCD, other interventions should be considered. For example, cognitive-behavioral therapy (CBT) has shown promise in children and adolescents with OCD ([March et al., 1994](#); [Scahill et al., 1996](#)). Further study in combined medication approaches and the combined use of CBT with medication for the treatment of children and adolescents with OCD are needed.

## DEPRESSION

Fluoxetine, sertraline, and paroxetine have each been studied for the treatment of depression in children and adolescents. The landmark fluoxetine study by Emslie and colleagues (1997) was the first to show superiority of an antidepressant over placebo for the treatment of depression in children and adolescents. A placebo-controlled, multicenter trial comparing paroxetine, imipramine, and placebo was completed recently ([Keller et al., 2001](#)). Paroxetine was found to be superior to placebo, achieving a 63% response rate, compared to 46% in the placebo group. By contrast, the response rate in the imipramine group was 50%, which was not statistically different from placebo. Imipramine was associated with common TCA side effects and with a high rate of premature discontinuations. Two open-label sertraline studies ([Ambrosini et al., 1999](#); [Tierney et al., 1995](#)) with a combined sample of 80 subjects showed promising preliminary results. An industry-sponsored, placebo-controlled study of sertraline is now under way and should provide definitive results. Collectively, these data suggest that the SSRIs are the first-line agents for the treatment of depression in children and adolescents. In support of this conclusion, the recently published Texas algorithm for depression in children and adolescents recommends fluoxetine as the first-line drug ([Hughes et al., 1999](#)).

## NON-OBSESSIVE-COMPULSIVE ANXIETY DISORDERS

To date, only fluvoxamine has been evaluated in the treatment of children and adolescents with non-OCD anxiety disorders. In a multisite study sponsored by the National Institute of Mental Health ([RUPP, 2001](#)), 128 subjects between the ages of 6 and 17 years were randomly assigned to placebo or fluvoxamine after a 3-week psychoeducational intervention. The primary outcome measure was the Pediatric Anxiety Rating Scale (PARS), a new scale developed specifically for the trial ([Walkup and Davies, 1999](#)). After 8 weeks of treatment, children in the fluvoxamine group showed a 52% improvement (mean decrease in PARS from 18.7 to 9.0) compared to 16% improvement (mean decrease from 19.0 to 15.9) for the placebo group ( $P < 0.001$ ). The dose began at 25 mg per day, with a planned increase to 25 mg twice a day after 4 days. The dose schedule continued upward in 25-mg increments every 4 to 5 days as tolerated. The findings from this study provide support for the efficacy and large effect size of fluvoxamine in the treatment of generalized anxiety disorder, social phobia, and separation anxiety. This study also paves the way for the study of the other SSRIs and combination treatments (medication and psychotherapy) in non-OCD anxiety disorders.

## MECHANISM OF ACTION

The SSRIs interfere with the return of serotonin into the presynaptic neuron by blocking the serotonin transporter located on presynaptic nerve terminals. Over time, this blockade leads to a desensitization of the serotonin autoreceptors, which typically exert an inhibitory influence on serotonin release. With continued blockade of the transporter, the desensitized autoreceptors do not exert their usual inhibitory influence and serotonergic function is enhanced. Based on a series of animal studies, Blier and colleagues suggest that the main location of the enhanced serotonergic function appears to be the hippocampus in depression, and the orbital frontal cortex in OCD ([Blier and de Montigny, 1998](#)).

## PHARMACOKINETICS

All five SSRIs have relatively long half-lives, permitting single daily dosing. Fluvoxamine, which has the shortest half-life, is sometimes given on a twice-daily schedule. A recent pharmacokinetic evaluation of paroxetine showed that children metabolize the medication faster than adults ([Findling et al., 1999](#)). Despite the shorter half-life in the pediatric population, these investigators still recommend once-daily dosing for paroxetine. The pharmacokinetic profiles of the other SSRIs in pediatric populations have not been documented. In adults, fluoxetine and citalopram have the longest half-lives of currently available SSRIs, with estimates of 48 to 72, and 33 hours, respectively. In addition, fluoxetine has an active metabolite (norfluoxetine) with an elimination half-life of 7 to 14 days. Both fluoxetine (primarily norfluoxetine) and paroxetine are potent inhibitors of CYP 2D6. Because both paroxetine and fluoxetine are 2D6 substrates, they inhibit their own metabolism, resulting in nonlinear kinetics at higher doses.

## CLINICAL MANAGEMENT

### Fluoxetine

Fluoxetine (Prozac) is available in a 10-mg scored tablet, a 20-mg capsule, and a 20-mg/5 mL liquid preparation. A typical starting dose for school-age children is 5 to 10 mg per day; smaller children may start at 2.5 mg per day. Given its long half-life, fluoxetine should be increased slowly (weekly or even at 2-week intervals) to avoid "overshooting" the optimal dose. The usual dose range for children and adolescents is 5 to 40 mg per day, although some children and adolescents may require higher doses.

### Sertraline

Sertraline (Zoloft) is available in 25-, 50-, and 100-mg tablets that can be broken in half easily. Treatment might start with a 12.5- to 25-mg dose, with similar weekly increments to a range of 50 to 150 mg in children. Higher dosages may be required in older adolescents. A recent, multiple dose study in adults with OCD showed that some patients respond to relatively low doses of sertraline ([Greist et al., 1995](#)). Thus, clinicians should review therapeutic response during the dose adjustment phase to determine whether additional increases are needed, rather than using an automatic dose schedule.

### Fluvoxamine

Fluvoxamine (Luvox) is available in 25-, 50-, and 100-mg scored tablets. Treatment usually begins at 12.5 to 25 mg per day and is increased by 25 mg on a weekly basis. The typical dose range is 50 to 200 mg per day. Although the double-blind trial in children and adolescents with OCD used a rapid dose escalation with increases every 3 days ([Riddle et al., 2001](#)), the more recent RUPP anxiety study used a slower upward adjustment ([RUPP, 2001](#)). This study started with 25 per day and increased to 25 mg twice a day within the first week. Thereafter, the dose was increased in 25-mg steps each week as tolerated. This schedule is more in keeping with current clinical practice ([Grados et al., 1999](#)).

### Paroxetine

Paroxetine (Paxil) is available in 10-, 20-, and 30-mg tablets that can be broken in half, as well as in an oral suspension (10 mg/5 mL). The typical starting dose is 5 to

10 mg per day, with weekly increases to a total daily dose of 10 to 40 mg.

### *Citalopram*

Citalopram (Celexa) is available in 10- and 20-mg scored tablets, as well as a liquid preparation. As noted, there is only one study in pediatric populations, in which 23 children with OCD were treated openly for 10 weeks at doses ranging from 10 to 40 mg per day. Based on experience with the other SSRIs, a reasonable starting dose is 5 mg per day, with increases on weekly or 2-week intervals, to a maximum of 40 mg per day.

### *SIDE EFFECTS*

The SSRIs are generally well tolerated as a group, and potentially serious side effects such as alterations in cardiac conduction times or seizures have not been reported in the usual dose range. In addition to their propensity for cytochrome P450-based drug interactions ( [Oesterheld and Flockhart, 2000](#)), common side effects of the SSRIs in children and adolescents appear to be behavioral activation and GI complaints such as nausea or diarrhea. Signs of behavioral activation include motor restlessness, insomnia, impulsive, and/or disinhibited behavior. It may occur early in treatment, with dose increases ( [King et al., 1991](#)), or following the addition of drugs that inhibit the metabolism of the SSRI (e.g., cimetidine). The potential for behavioral activation early in treatment underscores the importance of starting at low doses and moving upward slowly. As with other antidepressants, hypomania and full manic activation also have been reported. For example, in a series of 33 children and adolescents being treated for depression, two cases of sertraline-induced mania were reported ( [Tierney et al., 1995](#)). Other side effects include diarrhea, nausea, heartburn, decreased appetite, and fatigue. Sexual side effects, which are relatively common in adults, also should be considered in sexually active adolescents.

There have also been reports of suicidal ideation and self-injurious behavior with fluoxetine ( [King et al., 1991](#)). Whether fluoxetine confers greater risk for suicidal ideation than the other SSRIs or whether the SSRIs carry a higher risk for suicidal ideation than other antidepressant classes is unlikely. As with all antidepressants, especially when treating depression, clinicians should monitor suicidal thought and self-injurious potential in any child or adolescent treated with an SSRI.

### *SELECTIVE SEROTONIN REUPTAKE INHIBITOR DISCONTINUATION SYNDROME AND DURATION OF THERAPY*

A flu-like syndrome characterized by dizziness, moodiness, nausea, vomiting, myalgia, and fatigue occurring in association with the withdrawal or acute discontinuation of shorter-acting SSRIs such as paroxetine, fluvoxamine, and sertraline has been described ( [Black et al., 2000](#)). Recently, a controlled discontinuation study in 220 adults compared the withdrawal effects of fluoxetine, paroxetine, and sertraline: Paroxetine and sertraline were associated with irritability, agitation, fatigue, insomnia, confusion, dizziness, and nervousness on abrupt withdrawal, but fluoxetine was not ( [Rosenbaum et al., 1998](#)). The long half-life of fluoxetine and norfluoxetine presumably results in a gradual "autotaper," even when the oral dose is stopped abruptly. Based on these results, a slow withdrawal of the shorter-acting SSRIs is warranted. Citalopram has a 33-hour half-life, but no known active metabolites. Sudden discontinuation of citalopram also should be avoided in the absence of data on adverse effects following abrupt withdrawal.

Another clinical issue that often arises in the course of treating children and adolescents with an SSRI concerns the duration of treatment. Studies of adults with depression suggest that an episode of depression typically lasts 9 months to 1 year. Based on this evidence, the duration of treatment for depression can be set at a 1-year minimum. For OCD and anxiety disorders, however, there are no data on which to base duration of treatment. A recent review on OCD suggests discontinuation after a relatively symptom-free period of 8 to 12 months ( [Grados et al., 1999](#)). A long-term follow-up study of 54 children and adolescents with OCD found that 70% ( $N = 39$ ) remained on medication for more than 2 years ( [Leonard et al., 1993](#)). Given the potential for chronicity in OCD, children and parents should be informed that symptoms might return following a planned SSRI discontinuation. Clearly, more study is needed on the matter of SSRI treatment duration in pediatric populations.

### *DRUG INTERACTIONS*

The SSRIs are increasingly common in clinical practice because of their multiple clinical applications, ease of use, and perceived safety. In addition, the use of combined psychotropic medications seems to be on the rise. These trends underscore the importance of monitoring drug–drug interactions in clinical practice. All of the SSRIs have the potential for such interactions because they all inhibit one or more of the CYP isoenzymes. As illustrated previously, inhibition of the enzyme system responsible for metabolizing an active drug raises its serum level, thereby enhancing its beneficial or deleterious effects. For example, oculogyric crises and other dystonic reactions have been reported in youngsters when an antipsychotic was added to ongoing treatment with paroxetine ( [Horrigan and Barnhill, 1994](#); [Lombroso et al., 1995](#)). The adverse event reported by Lombroso and associates (1995) was probably the result of paroxetine's inhibition of CYP2D6, the enzyme that metabolizes risperidone. (For a more detailed discussion of drug interactions, interested readers are referred to the previous chapter.)

### **Other Antidepressant Medications**

#### *Bupropion*

Bupropion (Wellbutrin) is unrelated to all other available antidepressants. Although its mechanism of action is unclear, it appears to have both dopaminergic and noradrenergic effects. It is approved for the treatment of depression and smoking cessation in adults. Although bupropion has not been studied for depression in children or adolescents, it has been evaluated in controlled studies for the treatment of ADHD. A placebo-controlled trial of bupropion in 72 children with ADHD showed its superiority over placebo in the treatment of ADHD, although the treatment effect was smaller than that usually seen with stimulants ( [Conners et al., 1996](#)). The dose of bupropion (3 to 6 mg/kg per day) ranged from 50 to 200 mg per day in divided doses. The findings of this study are consistent with previous placebo-controlled studies ( [Casat et al., 1987](#)), and a direct comparison with methylphenidate ( [Barrickman et al., 1995](#)). In a recent open-label study conducted in 24 adolescents (11 to 16 years old) with comorbid ADHD and depression, sustained release bupropion was associated with improvements in both conditions in 58% ( $N = 14$ ), depression only in 29% ( $N = 7$ ), and ADHD alone in 4% ( $N = 1$ ), suggesting that further studies of this monotherapy appear warranted for these commonly comorbid conditions ( [Daviss et al., 2001](#)).

Side effects of bupropion include agitation, insomnia, skin rashes, nausea, vomiting, constipation, and tremor. Bupropion also may reduce the seizure threshold in a dose-dependent fashion; therefore, daily doses should not exceed 300 mg in children, and no single dose should be higher than 150 mg. Bupropion (Wellbutrin) is available in 75- and 100-mg tablets, and 100- and 150-mg sustained release (SR) tablets. Treatment is usually on a TID basis given the agent's short half-life, although BID dosing is possible with the SR preparations.

#### *Venlafaxine*

Venlafaxine (Effexor) is an agent that selectively inhibits serotonin reuptake at lower doses (<150 mg/d). It acts on both NE and serotonin reuptake at the higher dose range. To date, there is one placebo-controlled trial in children with depression. The study, which included 32 youngsters, found that the drug was no better than placebo in relieving depression ( [Mandoki et al., 1997](#)). The lack of a significant result may well relate to the small sample size, suggesting that larger studies are warranted. Indeed, a large multisite, industry-sponsored study is currently underway.

Venlafaxine is available in 25-, 37.5-, 50-, 75-, and 100-mg tablets, and in 37.5-, 75-, and 100-mg extended release (XR) capsules. Dosing is started with the smallest dose given at bedtime, and with attention to early sedation and dizziness, before moving to a twice-daily regimen. At higher doses (>150 mg/d), venlafaxine can be associated with diastolic hypertension, an effect that is clearly dose-dependent in nature.

#### *Nefazodone*

Nefazodone (Serzone) is a potent 5HT<sub>2a</sub> postsynaptic antagonist and a moderate serotonin and norepinephrine reuptake inhibitor. The clinical importance of this novel mechanism is not entirely clear, but nefazodone has been shown to be effective in the treatment of adults with major depression, especially when accompanied by prominent anxiety features. The pharmacokinetic properties of nefazodone have been studied in an 8-week trial of 28 children and adolescents. The kinetic profile was shown to be similar to that in adults, and 19 of 28 subjects were rated as clinically "much" or "very much improved" on a global impression scale ( [Findling et al., 2000b](#)). Based on these findings, an industry-sponsored, placebo-controlled in children 12 to 18 years old has been undertaken, with results still pending. Nefazodone is available in 50-, 100-, 150-, 200-, and 250-mg tablets. Dosing is divided into a twice-daily regimen, usually "weighed" toward bedtime given the agent's

sedating properties.

Several other new antidepressants have entered or will soon be introduced into the marketplace, including mirtazapine, tomoxetine, reboxetine, and various selective monoamine oxidase inhibitors (MAOIs). Data on the use of these newer agents in the pediatric population are not yet available.

## Mood Stabilizers

The prototype for the chemically unrelated drugs in this class is lithium, which has been used in the treatment of bipolar illness for nearly 50 years. Other medications that are currently on this growing list include valproate, carbamazepine, lamotrigine, gabapentin, and topiramate. Of these, only valproate and carbamazepine have been carefully studied in adults. Encouraging preliminary data are available for lamotrigine and topiramate. By contrast, empiric data for any of the mood stabilizers are scarce in the pediatric population ([Davanzo and McCracken, 2000](#)).

Data from clinical samples indicate that cases of bipolar illness resembling the adult form of the disorder can be observed in children and adolescents ([Fristad et al., 1992](#); [Strober et al., 1995](#)); however, some investigators contend that the clinical presentation of bipolar disorder in childhood may have important differences from the classic presentation in adults. In an effort to guide practice, these authors favor an expanded definition of the bipolar phenotype in children. For example, some argue that discrete episodes of mania may be harder to identify in children and adolescents ([Geller and Luby, 1997](#)). The notion that bipolar disorder resides on a spectrum encompassing the full syndrome and a cluster of related, albeit milder symptoms is supported by observations in community and clinical samples ([Lewinsohn et al., 1995](#)). What is less clear, however, is whether this wider phenotype is responsive to mood stabilizing medications. Nonetheless, the mood stabilizers are being increasingly used to treat a broad range of symptoms, including irritability, mood lability, aggression, and bipolar disorder.

### LITHIUM

Although controlled data in pediatric populations are scarce, accumulated evidence from case reports and open studies suggest that lithium is safe and effective for the treatment of children and adolescents with bipolar illness or severe aggressive behavior ([Davanzo and McCracken, 2000](#)).

#### *Clinical Applications and Empiric Support*

Lithium was compared to placebo in a crossover study of six children with various psychiatric diagnoses, including ADHD, major depression, and a "mixed" bipolar disorder ([McKnew et al., 1981](#)). Only the two subjects diagnosed with bipolar illness showed a clearly positive response to lithium. Other early lithium studies showed promising results among children ([Carlson et al., 1992](#); [Younes et al., 1986](#)). Geller and colleagues (1998) conducted the first placebo-controlled study of lithium in youngsters, including 25 adolescents with various forms of bipolar illness and comorbid substance abuse. Although lithium was associated with improvements in overall functioning and substance abuse, there was no difference between active and placebo groups on measures of manic or depressive symptoms. The failure of lithium to separate from placebo on the core bipolar symptoms may be owing to the small sample size ( $N = 12$  in active group,  $N = 13$  in placebo). Taken together with the small studies cited in the preceding, these data provide only modest support for the use of lithium for the short-term treatment of mixed bipolar illness in children and adolescents.

In a long-term naturalistic observations study, 59 children with a mean age of 10.9 years who were diagnosed with classic bipolar disorder and treated with lithium were followed for up to 10 years ([DeLong and Aldershof, 1987](#)). All patients were evaluated on and off the medication during planned discontinuation periods. Lithium was effective in 39 of 59 patients with bipolar disorder, showing both short-term and enduring benefits. In an 18-month naturalistic follow-up study, 24 of 37 adolescents with bipolar I disorder showed long-term benefit from lithium treatment ([Strober et al., 1990](#)). The 13 adolescents, who discontinued lithium treatment during the first year, were 20 times more likely to relapse than those who remained on maintenance therapy (12 of 13 versus nine of 24, respectively). These two studies provide support for the benefit of lithium prophylaxis in children and adolescents with classic bipolar disorder.

#### *Other Clinical Applications: Aggression and Self-Injury*

Lithium was superior to placebo in reducing the frequency of aggression in 66 nonpsychotic male prisoners (16 to 24 years old); however, 14 or nearly half of the 33 subjects on active medication withdrew from the study owing to adverse effects ([Sheard et al., 1976](#)). A study comparing haloperidol, lithium, and placebo in 61 treatment-resistant aggressive children (5 to 13 years old) found that after 4 weeks of inpatient treatment, both haloperidol and lithium were superior to placebo in reducing aggressive behavior; lithium was associated with fewer side effects ([Campbell et al., 1984](#)). More recently, lithium was found to be superior (16 of 20 responders) when compared to placebo (six out of 20) in the treatment of aggressive behaviors in hospitalized children with conduct disorder ( $P = 0.004$ ) ([Malone et al., 2000](#)). By contrast, the experience in the treatment of self-injurious behaviors in children with developmental disorders generally has been disappointing ([DeLong and Aldershof, 1987](#)).

#### *Mechanism of Action*

Lithium affects several neurochemical systems, including the function of serotonin, NE, and dopamine. However, its main actions seem to be mediated by effects on intracellular signaling processes, and specifically, the phosphatidylinositol and protein kinase C pathways ([Manji and Lenox, 1998](#)).

#### *Pharmacokinetics*

Lithium is readily absorbed from the gastrointestinal tract, with peak levels occurring 1 to 3 hours after oral ingestion. It is not metabolized in the liver, and the kidneys excrete approximately 95% of the ingested drug. The half-life in adults is approximately 24 hours, slightly longer than the 18 hours reported in children ([Vitiello et al., 1988](#)). This shorter half-life in children is probably owing to faster glomerular filtration rates.

#### *Clinical Management*

Dosages in the range of 10 to 30 mg/kg per day are typical for children under 12 years of age; thus, a 30-kg child would receive 900 mg per day in divided doses. Older adolescents are likely to be treated in the range of 1,200 to 1,800 mg per day during acute mania. Maintenance doses typically are lower. The optimal serum level range is in the range of 0.6 to 1.1 mEq/L. Lithium is available in tablet, capsule, and liquid (lithium citrate) forms. In outpatient settings, the dose typically is started at 300 mg twice a day for children, up to 600 mg twice a day for older adolescents. Trough lithium levels can be checked after 4 to 6 days, and adjustments in dose made as necessary ([Geller and Luby, 1997](#)). When used to treat bipolar illness, the clinical benefit of lithium may be evident within 10 to 14 days of reaching therapeutic serum level in some cases, although as many as 4 to 6 weeks of treatment may be required ([Kowatch et al., 2000](#)).

Prior to initiating a trial of lithium, a child should have a physical examination, including screening laboratory tests such as complete blood count, electrolytes, blood urea nitrogen, creatinine, and thyroid indices. Because the kidneys excrete lithium, it is generally not recommended in children with compromised renal function. The risk of glomerular damage with long-term lithium treatment appears to be minimal, but polyuria and polydipsia are relatively common because of lithium's effect on tubular reabsorption. In a few cases, nephrogenic diabetes insipidus can occur, which may warrant discontinuation. Current recommendations include repeat laboratory tests at 6-month intervals. Lithium levels should be monitored owing to its narrow therapeutic range. Levels also should be obtained when the patient's clinical status changes, if side effects occur, and routinely at 3- to 6-month intervals. Salivary lithium levels can be measured, but do not accurately predict serum levels ([Vitiello et al., 1988](#)). Serum levels should be drawn 4 to 6 days after a dose adjustment to ensure that a steady state has been achieved, and 12 hours after the previous dose to ensure a trough reading.

#### *Toxicity and Side Effects*

Lithium appears to be generally well tolerated in children and adolescents. The most common side effects may be nausea, tremor, polyuria, polydipsia, and enuresis. Other relatively frequently reported side effects include diarrhea, acne, abdominal distress, cognitive dulling, hair loss, and weight gain. The signs of lithium toxicity include tremor, blurred vision, nausea, diarrhea, ataxia, hyperreflexia, and dysarthria, which can occur at serum levels of 1.4 mEq/L or higher. Parents and children should be educated about the importance of adequate fluid intake because dehydration can increase lithium levels and may induce toxicity. At serum levels above 2.5 mEq/L, multiple organs may be affected and toxicity may prove fatal. Symptoms of acute overdose include nausea, vomiting, stupor, choreoathetosis, convulsions, and coma. Lithium, like valproate and carbamazepine, has been associated with increased occurrence of birth defects; therefore, contraception should be ensured in

sexually active teenage girls treated with any mood stabilizer.

#### *Drug Interactions*

Carbamazepine, nonsteroidal antiinflammatory drugs, tetracycline, and thiazide diuretics can all increase lithium levels when given concomitantly and therefore should be used cautiously. By contrast, theophylline and caffeine promote lithium excretion, resulting in lower serum levels.

#### **VALPROATE**

##### *Clinical Applications and Empiric Support*

Valproate is an anticonvulsant that has been shown to be an effective mood stabilizer in adults. The most commonly used formulation of valproic acid, divalproex, is an enteric-coated preparation containing valproic acid and sodium valproate in equal parts. In the pivotal three-group study demonstrating its efficacy in adult mania, divalproex ( $N = 69$ ) was compared to lithium ( $N = 36$ ) and placebo ( $N = 74$ ) (Bowden et al., 1994). Forty-eight percent of those subjects randomized to divalproex showed a positive response, which was significantly better than the 25% response rate in the placebo group, and no different from the 49% response rate in the lithium group. Largely based on these adult data, clinicians have increasingly resorted to divalproex in the treatment of a range of problems in children and adolescents, including bipolar illness and explosive behavior.

Until recently there were only case reports of divalproex use in pediatric populations (Kastner et al., 1990; Papatheodorou et al., 1995). In addition to the small number of subjects, these early observational reports studied treatment in a heterogeneous group of patients, making it impossible to merge data across studies.

Three recent studies provide useful, albeit preliminary, information about the use of divalproex in pediatric populations. In two related studies, valproate was evaluated in 30 adolescents with labile mood and explosive behavior. The first study was a 5-week, open-label trial involving 10 adolescents aged 15 to 18 years (Donovan et al., 1997). All 10 had a disruptive behavior disorder diagnosis, such as oppositional defiant disorder, conduct disorder, ADHD accompanied by school expulsion, defiance of rules, and petty crimes. Although labile mood was an entry criterion, none of the subjects met criteria for bipolar disorder. All 10 subjects showed a decline in the number and intensity of outbursts, as well as improvements in mood lability. Using similar ascertainment and entry criteria, the same investigators evaluated divalproex in a placebo-controlled, crossover trial of 20 patients (age range 10 to 18 years) (Donovan et al., 2000). During the first 6 weeks, eight of 10 subjects on divalproex showed a positive response, compared to none of 10 in the placebo group. Moreover, six of seven subjects who were randomly assigned to the placebo-first group showed a positive response to divalproex in the second phase of the study.

The use of divalproex in juvenile bipolar disorder was recently reported in a randomized, open-label trial comparing the drug ( $N = 15$ ) to lithium ( $N = 13$ ) and carbamazepine ( $N = 13$ ) (Kowatch et al., 2000). The initial sample of 42 children and adolescents, between the ages of 8 and 18 years, included 20 subjects with bipolar I and 22 with bipolar II disorder. Using a response criterion of 50% improvement or greater on the Young Mania Rating scale, divalproex was associated with a 53% response rate, compared to 38% for both carbamazepine and lithium ( $P = 0.06$ ). Although this study found a higher effect size for valproate (1.63) than for lithium or carbamazepine (1.06 and 1.00, respectively), small sample sizes urge caution when interpreting these seemingly large effects. Furthermore, divalproex has yet to be studied in a controlled fashion for this indication.

In conclusion, these emerging data provide a modest level of support for the use of divalproex in the treatment of children and adolescents with bipolar disorder and disruptive behavior accompanied by explosive outbursts and mood instability. Larger studies in equally well-characterized samples are needed to confirm these preliminary results.

##### *Mechanism of Action*

Divalproex has multiple pharmacologic effects and the details of its therapeutic actions are not fully known. It is clear that divalproex enhances GABA transmission through increased synthesis and release. Given the inhibitory role of GABA in the brain, this effect may account for the drug's anticonvulsant and antimanic effects. Based on animal studies, it has been proposed that divalproex shares with lithium a capacity to inhibit the protein kinase C signaling pathway (Manji and Lenox, 1999). This intracellular biochemical pathway plays a fundamental role in neuronal activity, transmitter release, and ultimately gene expression in the brain. Inhibition of protein kinase C is presumed to contribute to the antimanic effects of both drugs.

##### *Clinical Management*

Dosing in adolescents followed on an outpatient basis could start with 250 mg twice daily, and increase every three to five days in 250 to 500 mg increments, to a target dose of 20 mg/kg per day in two to three divided doses. Younger children might start with half the starting dose used in adolescents and move up in 125 to 250 mg increments. Levels should be checked after two weeks or sooner if a more aggressive dose schedule is used. Target serum levels are in the range of 85 to 110 (mg/L) (Kowatch et al., 2000).

Common side effects included nausea and sedation. Others include vomiting, increased appetite and weight, tremor, asthenia, dizziness, hair loss, and thrombocytopenia. There also have been reports of polycystic ovary disease in women treated for seizure disorders, manifested clinically by hyperandrogenism, accelerated weight gain, and menstrual and lipid profile irregularities (Isojarvi et al., 1993). The role of divalproex in these adverse endocrine effects is unclear and a matter of some debate, especially among teenage girls (Davis et al., 2000). Although rare, divalproex also has been associated with hepatic failure, and with fatal hepatitis in children under the age of 2. There is also a small risk of pancreatitis early in treatment. Clinical management involves monitoring weight, appetite, energy level, evidence of bruising, and of androgenism in girls. Liver enzymes and amylase levels should be obtained within the first month of treatment and periodically during chronic treatment (Davanzo and McCracken, 2000).

#### **CARBAMAZEPINE**

##### *Clinical Application and Empiric Support*

Carbamazepine is an anticonvulsant that has been used in adults for a variety of neurologic and psychiatric disorders, including seizures, trigeminal neuralgia, and bipolar disorder. It has proven effective in the treatment of lithium-resistant mania and impulsive behavior in adults. Case series and open-label studies in children have included bipolar disorder (Hsu, 1986; Kowatch et al., 2000; Woolston, 1999), aggression (Kafantaris et al., 1992), and treatment-resistant ADHD (see metaanalysis by Silva et al., 1996). To date, however, the one controlled carbamazepine trial in youngsters failed to show its superiority over placebo for the treatment of aggression among 5- to 12-year-old inpatients diagnosed with conduct disorder (Cueva et al., 1996).

##### *Clinical Management*

Carbamazepine is slowly absorbed, and peak plasma concentrations are achieved within 2 to 8 hours following oral administration. It is supplied in 100-mg (chewable) and 200-mg tablets, and in an oral suspension of 100 mg/5 mL. The initial oral dose for children ages 6 to 12 is 100 mg daily, and can be increased at weekly intervals by 100 to 200 mg. The usual maintenance dose is 10 to 20 mg/kg per day, administered in divided doses (BID or TID). Frequent dose adjustments, especially early in treatment, are common given the drug's short half-life following the induction of its own metabolism ("autoinduction"), a phenomenon related to microsomal enzyme activation.

Although the clinical utility of therapeutic plasma levels for children with mood disorders is unclear, plasma concentrations for anticonvulsant effect are in the range of 4 to 14 mg/mL, and these guidelines may be useful during dose adjustment and in order to prevent toxicity. Plasma levels should be obtained 2 to 4 days after achieving a steady-state plasma concentration. Baseline CBC, including platelet count, should be followed periodically. In addition to drug pharmacokinetic interactions, potential side effects include sedation, rash, leukopenia, and more rarely, aplastic anemia and thrombocytopenia.

Given the lack of controlled studies, the multiple drug-drug interactions, and its potentially serious side effects, carbamazepine should be considered as a second- or third-line mood stabilizer in the treatment of children and adolescents, and may be particularly useful in the context of morbid weight gain associated with lithium,

divalproex, or atypical antipsychotics.

#### OTHER (THIRD-GENERATION) ANTICONVULSANTS

Three new anticonvulsants recently approved for the treatment of epilepsy in adults have become the focus of interest as potential mood stabilizers. Although their efficacy in adults with psychiatric disorders is not yet established, and only case reports on their use in pediatrics are available to date, they are briefly reviewed here, because it is likely that they will be used increasingly in the coming years.

##### *Lamotrigine*

Lamotrigine (Lamictal) is an agent with a bimodal spectrum of efficacy; it has been used in the treatment of both depressed and manic symptoms, and may be especially useful among rapid cycling patients. Lamotrigine was reported as an effective augmenting intervention to valproate in 16 of 22 (72%) adolescents with bipolar depression ([Kusumakar and Yatham, 1997](#)). Of serious pediatric concern is the risk of skin rash reported in patients treated with lamotrigine, an effect that seems to be both dose- and age-related. The rash usually is mild and seen within the first months of treatment, but it can develop into full-blown Stevens-Johnson syndrome, a potentially lethal condition associated with widespread skin sloughing. Until additional safety and efficacy data become available, the use of this agent cannot be presently justified among children and adolescents except in the most extreme, treatment-refractory cases.

##### *Gabapentin*

Gabapentin (Neurontin) is of interest because it undergoes virtually no hepatic metabolism in addition to preliminary adult studies showing its efficacy as an antimanic agent. It is excreted largely unaltered by the kidneys and poses no serious drug interactions. However, despite a benign side-effect profile among adults, aggressive behavior and worsening hyperactivity have been reported among 12 children receiving gabapentin for the treatment of seizure disorders ([Davanzo and McCracken, 2000](#)). Consequently, its use as a mood stabilizer for children cannot be recommended until its efficacy and side-effect profile are better established through appropriate trials.

##### *Topiramate*

Topiramate (Topamax) is a glutamate release antagonist and a GABA reuptake inhibitor. It has been used in adults as an adjunctive intervention, usually in combination with traditional mood stabilizers or with atypical antipsychotics ([Chengappa et al., 1999](#)). The report of weight loss with topiramate in these initial studies is interesting. This side effect may offset the weight gain associated with atypical antipsychotic use if topiramate proves useful as a mood stabilizer. Topiramate may be associated with cognitive blunting and word retrieval difficulties, a concern that may limit its use in children.

#### **$\alpha$ 2-Adrenergic Agents**

The  $\alpha$ 2-adrenergic agents (clonidine and guanfacine) are approved for use only in adults with hypertension. Beginning with the early studies of clonidine for the treatment of TS, these drugs have become increasingly common in child psychiatry for treating tics, ADHD, and aggressive behavior in children ([Newcorn et al., 1998](#)). Indeed, between 1991 and 1995, the largest rise in the rate of psychotropic drugs used in preschoolers was for clonidine, with a 28-fold increase in one large database ([Zito et al., 2000](#)).

#### CLONIDINE

##### *Clinical Applications and Empiric Support*

There are only two controlled studies of clonidine (Catapres) in the treatment of tics, both of which included children and adults. In the first, clonidine was no better than placebo in suppressing tics ([Goetz et al., 1987](#)); however, a subsequent slightly larger trial proved it superior to placebo, producing approximately 35% improvement in tic severity ([Leckman et al., 1991](#)). Similarly, findings in ADHD have also been inconsistent: Clonidine provided modest benefit for ADHD in an early study involving 10 children in a placebo-controlled discontinuation study ([Hunt et al., 1985](#)). These findings were not replicated in a crossover study in which 34 children received desipramine, clonidine, and placebo in random order. Desipramine, but not clonidine, was superior to placebo on a parent measure of ADHD symptoms ([Singer et al., 1995](#)).

Taken together, these findings suggest that clonidine has modestly beneficial effects for ADHD symptoms and tics. These results also point out the potential limitations of small studies, even when a controlled design is used. One study shows benefit, but the next study fails to replicate the findings.

It is in this context that the multisite Treatment of ADHD in Children with Tourette's Syndrome (TACT) study was undertaken (Kurlan and McDermott, submitted). In this study, 136 children (7 to 14 years old) with ADHD and a chronic tic disorder were randomized to one of four treatments: clonidine, methylphenidate, clonidine + methylphenidate, or placebo. All three active treatments were superior to placebo on teacher and parent measures of ADHD. In evaluating the pattern of response across treatments, the investigators concluded that methylphenidate had superior effects on attention, and that clonidine had greater impact on impulsiveness and hyperactivity. Thus, the combination of clonidine + methylphenidate provided fuller coverage of ADHD symptoms in this population and produced the largest change from baseline. Tics generally declined in all active treatment groups. For 35% ( $N = 13$ ) of those children randomized to treatment with stimulant alone, however, the increase in tics limited further dose increases.

At doses averaging 0.26 mg per day for clonidine and 25.9 mg for methylphenidate, there were no serious side effects and no evidence of cardiac conduction problems with either drug alone or the combination. Sixty-four percent of the subjects receiving clonidine complained of sedation, with 42% describing moderate to severe problems with sedation. These sedative side effects limited dose increases in over half of the subjects treated with clonidine.

This study is important in several regards. First, it is the first large-scale study to evaluate a combined pharmacotherapy in children with a psychiatric disorder.

Second, it provides valuable efficacy and safety information about a treatment combination that is becoming commonplace in the field. Concern about the safety of this combination heightened following the death of three children being treated with clonidine and methylphenidate. Although a careful review of these cases concluded that neither drug nor the combination was responsible for the deaths of these children, controversy about this drug combination in children continues ([Wilens et al., 1999](#)). Given the sample size, this study cannot answer questions concerning the occurrence of rare adverse events, but the results do provide support for the efficacy and safety of this combined treatment approach. The high rate of sedation associated with clonidine in this sample confirms the narrow dose range of the agent.

Third, this study adds to the list of other recent controlled studies showing that tics do not invariably increase when children with TS are treated with stimulants. Nonetheless, this was a dose-limiting side effect in one-third of the subjects treated with methylphenidate alone.

#### GUANFACINE

Guanfacine (Tenex) is an  $\alpha$ 2-agonist that is similar to clonidine. It was developed as an antihypertensive agent. Interest in guanfacine has been prompted by three observations. First, compared to clonidine, it is less sedating. Second, it has longer half-life than clonidine. This longer duration of action could translate into a need for fewer doses per day and a lower risk of rebound effects. Third, accumulated data from a series of animal studies provides compelling evidence that guanfacine is more specific in action than clonidine ([Arnsten, 1997](#)). Until recently, there were only three open-label studies of guanfacine involving a total of 38 children ([Chappell et al., 1995](#); [Horrigan and Barnhill, 1995](#); [Hunt et al., 1995](#)). All three studies showed promising results for guanfacine in the treatment of ADHD. The study by Chappell and colleagues (1995) also reported that guanfacine had a modestly beneficial effect on tics.

The first placebo-controlled study of guanfacine in children included 34 subjects (17 in each treatment group) with ADHD symptoms and a tic disorder ([Scahill et al., 2001](#)). After 8 weeks of treatment at doses ranging from 1.5 to 3.0 mg per day given in three divided doses, the guanfacine group showed a 37% improvement in a teacher rating of classroom behavior compared to an 8% change in the placebo group ( $P < 0.001$ ). Similar results were observed for teacher ratings of inattention as well as hyperactivity and impulsiveness. Nine of 17 subjects in the guanfacine group were blindly rated as "much improved" or "very much improved," compared to 0 of

17 in the placebo group ( $P < 0.001$ ). Both groups showed modest improvement on parent-rated behavior. The 27% drop in the guanfacine group was not significantly different from the 21% drop in placebo. Children with marked tic severity were excluded from the trial because the target symptoms in this study were inattention, hyperactivity, and impulsiveness. Nonetheless, guanfacine also was associated with a 31% drop in a clinician-rated measure of tic severity, compared with 0% improvement in the placebo group ( $P = 0.05$ ).

Side effects generally were mild. One subject withdrew from the study owing to moderate sedation. Six other subjects complained of mild sedation, which resolved with continued treatment or dose decrease. Other complaints included mid-sleep awakening in three subjects, dry mouth ( $N = 4$ ), constipation ( $N = 2$ ), and loss of appetite in the morning ( $N = 2$ ). Weight was stable in both groups and there were no alterations in clinical laboratory results, including cardiac conduction parameters. The mean resting diastolic blood pressure showed an eight-point decline at midpoint in the guanfacine group that returned to baseline by the 8-week mark. There was no difference between groups on blood pressure measured from the supine to standing position. In a case by case review, six subjects in the guanfacine group showed a one-standard deviation drop (10 mm of Hg) in resting systolic or diastolic blood pressure at one visit, compared to two subjects in the placebo group ( $P = 0.11$ ). No subject showed such a reduction in blood pressure at more than a single visit.

In conclusion, these preliminary results suggest that guanfacine is a safe and effective treatment for children with ADHD and tics. The 37% improvement in teacher-rated behavior is less than the 50% to 60% improvement reported in most stimulant trials, but is similar to the level of improvement observed in other nonstimulant studies ([Biederman et al., 1989](#); [Conners et al., 1996](#); [Feigin et al., 1996](#)). Given that two-thirds of the subjects in the guanfacine trial had failed prior stimulant treatment, the results observed in this sample may not be comparable to the findings of other nonstimulant trials.

#### MECHANISM OF ACTION

The traditional view is that clonidine regulates central noradrenergic activity through its agonist effects on presynaptic  $\alpha_2$  receptors in the LC. Clonidine is indeed ten times more potent than guanfacine in reducing LC firing and inhibiting NE release. In addition to weaker presynaptic effects, accumulated data from studies in primates show that guanfacine has direct stimulating effects on postsynaptic  $\alpha_2$  receptors located in prefrontal cortex (PFC) ([Arnsten, 1997](#)). These animal studies have established that this pharmacologic mechanism improves PFC function. This action is likely to be relevant for the treatment of ADHD given the fundamental role of the PFC in attention and working memory.

#### CLINICAL MANAGEMENT

Clonidine comes in 0.1-, 0.2-, and 0.3-mg tablets. In school-age children, the starting dose is typically 0.05 (one-half of a 0.1-mg tablet) at bedtime. The dose is then increased in 0.05 mg increments every 3 to 5 days as tolerated to a maximum of 0.2 mg per day [e.g., 0.05 mg four times daily (QID)] in prepubertal children, and 0.3 mg in teenagers. To ensure even behavioral effects blood levels across the entire day, clonidine is typically given three to four times per day. Clonidine transdermal patches (Catapres TTS) delivering 0.1, 0.2, and 0.3 mg per day are available, but they have not been well studied in youngsters, and may have erratic absorption from the skin. The typical starting dose of guanfacine is 0.5 mg at bedtime, with 0.5 mg increases every 3 to 5 days to a total of 1.5 to 3.0 mg per day in three divided doses.

The side effects of clonidine and guanfacine are similar, although guanfacine appears to be better tolerated. The most common side effects include sedation, dizziness, irritability (especially when the medication wears off), and mid-sleep awakening. Hypotension is generally not a problem with either drug in children and adolescents, but warrants monitoring, particularly in the dose adjustment phase. A related concern with clonidine is the well-documented phenomenon of rebound hypertension following precipitous withdrawal ([Leckman et al., 1986](#)). In adults with high blood pressure, however, abrupt discontinuation of guanfacine did not result in rebound hypertension ([Wilson et al., 1986](#)). Nonetheless, abrupt discontinuation of either drug should be avoided. There is incomplete consensus in the field regarding the need for electrocardiograms in children and adolescents treated with the  $\alpha_2$ -agonists. A recent statement from the American Heart Association indicates that no cardiovascular monitoring other than blood pressure and pulse is required for clonidine and guanfacine ([Gutgesell et al., 1999](#)).

#### Other Agents Used in the Treatment of Children with Psychiatric Disorders

Many other agents are used in pediatric psychopharmacology. This final section briefly reviews six additional compounds. These drugs are included here because of their potential clinical usefulness, or prompted by the familiar sequence in our field: media clamor about a particular drug based on a case report, which is followed by disappointing results on careful evaluation. This sequence has recently been played out by secretin for the treatment of autism.

#### CLONAZEPAM

Clonazepam (Klonopin) is a long-acting benzodiazepine that is approved as an anticonvulsant. In adults it is also used to treat anxiety disorders and as an adjunctive treatment for tics. A study of 15 prepubertal children showed that clonazepam could be useful in anxiety disorders in some children; however, side effects—including disinhibition, irritability, and drowsiness—were common and problematic ([Graae et al., 1994](#)). Given these results, clonazepam does not appear to be a first-line agent for the treatment of anxiety disorders in pediatric populations, although it can be useful as an adjunctive intervention, especially on a time-limited basis. Treatment can begin with 0.25 mg in the morning and increasing to 0.25 mg twice daily after 3 to 4 days. Thereafter, the dose may be increased slowly to a maximum of 2 mg per day in divided doses. Clonazepam should be tapered gradually when discontinued. As with other benzodiazepines, long-term use can be associated with dependence, albeit less commonly than with shorter-acting agents. Children treated for more than 4 weeks should be gradually tapered when coming off of the drug to limit the rebound anxiety associated with abrupt withdrawal.

#### BUSPIRONE

Buspirone (BuSpar) is an atypical anxiolytic drug that is unrelated to the benzodiazepines. It acts as a 5-HT<sub>1A</sub> agonist, which results in a presynaptic release of serotonin ([Velosa and Riddle, 2000](#)). In an initial study, buspirone (10 to 20 mg per day in two divided doses) was associated with significant improvement in anxiety symptoms, as measured by a global scale ([Simeon et al., 1994](#)). This improvement was evident within 3 to 4 weeks of starting the medication. Side effects included weariness, sleep disturbance, abdominal discomfort, and headache. In a group of 25 hospitalized children with anxiety and aggressive behavior, improvement in anxiety and aggression was noted in about 75% of the cases ([Pfeffer et al., 1997](#)). Approximately 16% ( $N = 8$ ) worsened and four developed hypomania. Another open-label study was conducted in 22 subjects with pervasive developmental disorders with prominent anxiety symptoms. The subjects, who ranged in age from 6 to 16 years, were treated with 15 to 45 mg per day given on a three times per day schedule. After 8 weeks of treatment, 16 of the 22 subjects showed a clinically significant improvement in a global measure of anxiety ([Buitelaar et al., 1998](#)). Side effects included mild activation in two subjects, nausea in one, and orofacial movements in another, the last of which resolved when the drug was discontinued.

The typical starting dose is 5 mg three times per day, with gradual increases weekly to 45 mg per day (15 mg TID). In younger children, buspirone may be initiated at 2.5 to 5 mg per day and increased thereafter every 3 to 4 days to a total of 20 to 30 mg per day in three divided doses. Buspirone should be discontinued in the absence of improvement after 8 weeks.

#### ANTIENURETIC AGENTS: DESMOPRESSIN, OXYBUTYNIN, AND TOLTERODINE

Desmopressin (DDAVP) is synthetic antidiuretic hormone (ADH), a powerful inhibitor of the production of urine. It can be administered orally or via intranasal spray. One review suggested that desmopressin helps approximately 25% of children who use it, with minimal risk of adverse effects ([Thompson and Rey, 1995](#)). The beneficial effects often do not endure over time, although desmopressin is usually well tolerated. The most effective treatment for enuresis is the use of behavioral interventions, such as a “pad and buzzer” or a “moisture alarm.” However, DDAVP can be a useful short-term adjunct, as in the facilitation of sleepovers or overnight camp stays. Antimuscarinic agents occasionally can be useful for longer-term pharmacologic management of enuresis, usually in cases unresponsive or only partially responsive to behavioral interventions. Alternatives to the time-tested use of low-dose (25- to 50-mg HS) imipramine ([Werry et al., 1975](#)) include oxybutynin (Ditropan) or the less sedating tolterodine (Detrol). Beneficial effects usually disappear rapidly on drug discontinuation, as is the case of other pharmacologic interventions for enuresis.

#### SECRETIN

Secretin is a peptide that regulates pH in the small intestine. It is approved only as a diagnostic probe to assess pancreatic function. The dramatic and much publicized response of a single infusion of secretin in a child with autism produced considerable interest and hope for this treatment, but subsequent results from

placebo-controlled studies with pervasive developmental disorders cast serious doubt on its usefulness for this population ( [Sandler et al., 1999](#); [Volkmar, 1999](#)).

**Acknowledgments.** *This work was supported, in part, by Scientist Career Development Award K01 MH01792-01 to Andrés Martin, by Public Health Service grants M01 RR06022, 5P01 HD1DC35482 and 5P01 HD03008, and by a National Institute of Mental Health Research Unit on Pediatric Psychopharmacology, contract MH97 CR0001 to Yale University. ### HISTORY

The monumental work of Sigmund Freud looms so large in the field of dynamic psychiatry that students in the 21st century easily equate Freudian psychoanalysis with dynamic psychiatry. However, it is useful to place psychodynamic psychiatry in a broader context both historically and epistemologically. [Gabbard \(1990\)](#) describes the several uses of the term *dynamic* in the late 19th century by Leibniz, Herbart, Fechner, and the renowned neurologist Hughlings Jackson. In their usage dynamic was contrasted with static. It referred to changing states of consciousness and physiologic processes as opposed to anatomic structures. Dynamic encompassed the concept mental energy. It implied functional rather than fixed organic impairment. In the 20th century dynamic psychiatry—with its emphasis on the patient's subjective experience, the workings of unconscious psychological processes, and the patient's unique inner life—was contrasted with *descriptive* psychiatry, which strove to categorize patients according to observable behavior.

Psychodynamic psychotherapy of children began with [Freud's publication \(1909/1955\)](#) of the case of “Little Hans.” Freud's interest was not the treatment of children but the centrality of childhood experience in shaping the adult psyche. Although he sought to “reconstruct” childhood experience from the analysis of adults, he encouraged his students to observe children for “a more direct and less round about proof” of the existence of infantile sexuality. It was in this context that Freud came to supervise the analysis of “Little Hans” by Hans' physician father.

Hermine Hug-Hellmuth was the first to undertake psychoanalytic therapy of children and adolescents. Her paper, “On the Technique of Child-Analysis” (1921), surveys technical issues in the psychodynamic treatment of children recognized as core issues to this day. She notes that the child does not come of his own accord. She advises against a judgmental stance or the giving of direct commissions and prohibitions. Hug-Hellmuth demonstrates her engagement of the child in “talking over things together.” She introduces the role of an educational method founded on psychoanalytic knowledge. Hug-Hellmuth examined the multiple ways in which work with children and adolescents differs from that with adults, including the complexities of the relationship between the analyst and the child's parents. Her observation that the child's spontaneous play could stand in the place of the verbal communications of the adult to reveal unconscious conflict was most significant for the development of psychodynamic therapy with children. Further, she observed that fully conscious avowal of analytic understanding was not a prerequisite for therapeutic effect in children.

[Melanie Klein \(1932\)](#) and [Anna Freud \(1946\)](#) emerged as the founders of two distinct schools of child psychoanalysis. Klein coined the term “play analysis,” emphasizing the child's play as equivalent to free association in adult analysis. Her methods encouraged early, deep interpretations and minimized the analyst's contact with parents and teachers. Anna Freud's long career from the 1920s to her death in 1982 allowed for significant evolution in her ideas regarding psychodynamic treatment of children and adolescents. Trained as a teacher, she was interested in the “educative” functions of the analyst in addition to the interpretive functions. Her work on ego mechanisms of defense ([Freud, 1936](#)) led to the development of defense analysis of children and adolescents. Her attention to observing the developmental process in children led her to conceptualize interweaving lines of development ([Freud, 1965](#)). Emigrant analysts in the wake of World War II brought both Kleinian and Freudian ideas to America. Child analytic training took root in the United States, allowing child psychoanalysts to play a major role in the training of child and adolescent psychiatrists in psychodynamic therapy.

Two distinctly American therapeutic traditions, admittedly influenced and stimulated by the frisson of psychoanalytic thought, have contributed their own unique emphases to the field of dynamic psychotherapy with children, particularly play therapy. Recognition of the contributions of the dynamic play therapy developed within the child guidance movement ([Allen, 1942](#)) and client-centered therapy ([Rogers, 1951](#)) reminds one not to equate “psychoanalytic” and “psychodynamic.” Homegrown American psychodynamic therapists such as Frederick Allen and Carl Rogers sought to counteract the impact of the American behaviorist tradition. Allen wrote:

The behaviorists advanced the belief that a child with relatively normal equipment could be made into anything parents wanted him to be if they exercised their power, adequately and intelligently, in the first few years of the child's life. The child was seen as little more than a by-product of another's desire. . . . This created a distortion of a parent's sense of responsibility . . . [and a] failure to appreciate the nature of growth and the participation of both child and parent in the child's development ([Allen, 1942](#)).

Allen regarded the child

as an individual who could be helped to grow and to become a person in his own right . . . the child was included as an active participant in the relationship designed to help him. Instead of being seen as an object to be changed, he was accepted as a human being with the capacity to change ([Allen, 1942](#), p.12).

The child's exercise of free expression, a here-and-now focus, and the rapport in the relationship between patient and therapist were emphasized as “nondirective” therapy developed through the work of [Axline \(1947\)](#) and [Dorfman \(1951\)](#).

### DEFINITION

Psychotherapy has been defined as a treatment that ameliorates psychopathologic conditions, functional impairments, and developmental disturbances by means of psychological processes and a therapeutic relationship with a trained therapist ([Gabbard, 1997](#); [Werry and Andrews, 1996](#)). In the treatment of children and adolescents these three elements—psychopathology, psychological processes, and the therapeutic relationship—should be considered in the context of the patient's social environment and ongoing development ([Brent and Kolko, 1998](#)). Psychodynamic psychotherapy aims at bringing about change in psychological processes that are largely unconscious but can be inferred from observable phenomena, such as physical actions or speech acts. The processes determining the inner world of subjective experience are of particular interest. The plethora of unconscious processes of which the human brain is capable allows for great diversity of focus for dynamic psychotherapy.

Psychodynamic therapy capitalizes on the observation that human beings are psychologically changed by relationships with other human beings. Psychodynamic technique utilizes two aspects of human relationships to achieve this mutative effect. Particular attention is paid to *transference*, the unconscious displacement onto the therapist of patterns of feelings, thoughts, and behavior originally experienced in relation to significant figures during childhood. The manifest or “real” relationship between the therapist and patient also is used to further the aims of the treatment.

The psychodynamic therapist conceptualizes psychopathologic conditions, functional impairments, and developmental disturbances in terms of the inferred unconscious psychological processes based on the symptoms and the patient's history. Similarly, social context, and developmental and maturational factors are evaluated for both their role in the etiology of the condition and potential interventions in the social environment that would affect the patient's unconscious, internal psychological functions.

## THEORETICAL BASIS

Psychodynamic therapy requires as a foundation a theory of the functioning of the unconscious mind and the internal experience of the individual as well as a theory of the psychological impact of human relationships. Psychoanalysis provides a rich tradition of observation and theory on which dynamic therapists can draw. Sigmund Freud was a research neuroscientist at the cutting edge of his era before he turned to the clinical practice of neurology and eventually psychiatry. Although he recognized that the research methods of his time did not allow for a full explication of the neuronal base of psychic events, he endeavored to keep his psychological theories consistent with biology. For instance, Freud conceptualized the mind as interplay of excitatory (drive) and inhibitory (defense) phenomena. Greatly influenced by the Darwinian theories of the German zoologist Carl Claus, with whom he trained ( [Ritvo, 1990](#)), Freud sought to construct a developmental framework for his psychology, an approach that put the psychic phenomena of childhood in the spotlight and paved the way for child psychotherapy. Psychoanalytic psychology as a theory of adaptation of the organism to its environment derived from these Darwinian roots, as did the "libidinal drive" as an aspect of the innate striving for survival and reproduction and the concept of conflicting forces within the mind.

[Freud \(1917/1963\)](#) used the Darwinian concept of a *complemental series* to position himself as a centrist in the nature–nurture controversy over the origins of psychopathology with severe constitutional deficits at one end of the spectrum of pathogenic etiology and severely traumatic experiences at the other. The psychodynamic therapist utilizes the complemental series to evaluate the interaction and impact of nature and nurture on the patient's pathology.

In dynamic theory the mind is not seen as a blank slate at birth but rather as endowed with the biological potential to develop psychic structure given an adequate environment. *Internalization* denotes the process by which experiences with the external world, usually in the realm of relationships, form stable intrapsychic structures or capacities. Once a process is internalized it no longer requires an external stimulus for its function to be executed. *Identification*, the psychological process by which one individual becomes like another, is a familiar mechanism of internalization.

Unconscious psychological processes may be considered as primary determinants of the inner world of subjective experience. The individual's total subjective experiential world, including thoughts, feelings, and fantasies as well as perceptions of the external world, regardless of whether they accurately reflect the external world as viewed by another observer, has been designated *psychic reality*. The dynamic therapist attempts to grasp the patient's psychic reality and convey to the patient an interest in understanding his experience of himself.

A primary tenet of psychoanalysis is *psychic determinism* (Moore and Fine, 1990), the principle that nothing in the mind happens by chance or in a random way. All psychic acts and events have meanings and causes and can be understood in terms of psychic earlier events. The mind retains experiences and is shaped by them. Conscious thoughts and overt behaviors provide observable clues to their underlying unconscious psychic determinants. A corollary hypothesis, *overdeterminism* or *multideterminism*, states that a psychic event (e.g., a symptom), is typically caused by more than one factor and may serve more than one purpose in the psychic framework. The multidetermined nature of symptoms provides the psychodynamic therapist with more than one way to approach a symptom. The clinical flexibility is very appealing to the practitioner but frustrating to researchers who seek standardization of method.

The concept of multideterminism is further refined in dynamic theory by the observation that the multiple determinants of a particular observable psychic phenomenon are frequently in opposition or *conflict* with one another. Psychodynamic theorists have identified several types of psychic conflict. *External conflicts* denotes the conflicts that arise between the child and the environment; the consequent frustration demands management by the child's psyche. External conflicts are most evident in early childhood when the infant or toddler has little internal restraint and struggles with the caretaker over such matters as bedtime or playing with an electrical plug. As prohibitions become internalized, the conflicts become *internal*. Not all conflicts are caused by prohibitions. Conflicts may arise between competing urges, thereby creating ambivalence. For example, conflicts arise between urges toward passive-dependence and active-mastery. An internal conflict may or may not become a fully *internalized conflict*. An internalized conflict is conceptualized as continuing in the individual's psyche when environmental forces that triggered the initial internal conflict no longer exist.

Freud realized that a conceptual tool was needed to provide an orienting and systematizing framework for clinical data and hypotheses about unconscious phenomena and subjective experience. He termed such a tool "metapsychology" and offered several different models as he strove to find a conceptual frame that accommodated all his data. The most lasting of Freud's metapsychological frameworks was a structural theory, *the tripartite model*, which divides mental functions into *id*, *ego*, and *superego*. *Id* is a concept that encompasses the mental representations of the instinctual drives ( [Ritvo and Solnit, 1995](#)). *Drive* is a term applied to a stimulus arising within the individual that arouses the mind and incites mental activity. The term *ego* encompasses all the capacities of the mind to manage and channel the arousal and activity incited by the drives. Freud, with an apt metaphor, says of ego

in its relation to the id it is like a man on horseback, who has to hold in check the superior strength of the horse. . . . Often a rider, if he is not to be parted from his horse, is obliged to guide it where it wants to go; so in the same way the ego is in the habit of transforming the id's will into action as if it were its own ( [Freud, 1923/1961](#), p.25).

Superego functions conceptualize the inner voice of conscience, which maintains ideals and values, observing and criticizing any shortfall of the self.

For many students *id* is difficult to conceptualize and to recognize in the clinical situation. "Id" did not make its way into the vernacular to the extent that "ego" did, nor is "drive" or "internal stimulus" as close to a common usage as "conscience," which makes "superego" more accessible to the untutored ear. The internal stimuli that are most familiar to the average person are feelings. Because emotions arise from genetically endowed, physiologic response patterns, they are an early, although in psychoanalytic theory not primary, step in the pathway to arousal and mental activity. In psychoanalytic parlance affects serve a signal function triggering ego efforts to manage drives. The drives themselves may be thought of as genetically endowed motivational states. Commonly we think of these as urges, needs, wishes, and desires.

Advances in neuropsychology and genetics may eventually allow the enumeration of drives on the basis of their genetic and neuronal determinants, but to date the conceptual organization of the drives is speculative and incomplete. The classical Freudian nomenclature works with a dualistic system of an aggressive and sexual drive. The sexual or *libidinal* drive includes affiliate and pleasure seeking urges. A child who enjoys being bathed by the parent and having his or her naked body admired is displaying a derivative of the libidinal drive. The pleasure the child takes from the sensuous experience of the water would also be a libidinal drive derivative. The aggressive drive in its broad connotation includes impulses toward self-assertion and the desire to prevail in one's wishes. This urge to prevail brings forth the more colloquially recognized aspect of the aggressive drive when in the face of frustration the urge to prevail becomes an urge to subjugate or destroy the perceived source of frustration. Pleasure in motoric or mental activity is an aggressive drive derivative at a basic level. Because pleasures sought in response to libidinal drive inevitably run into some requirement for delay or other frustration in the external world, aggressive and libidinal drives are intimately related; ego mechanisms must develop to regulate aggressive drives if libidinal drives are to be satisfied. A clinical formulation in this metapsychological model that failed to assess the role of aggressive drive in symptom formation would not be complete.

Many theorists and clinicians have been dissatisfied with Freud's dual drive approach. When using conceptual models other than the tripartite model they postulate other motivating forces within the individual. For example, [Miller \(1996\)](#), applying Kohut's *self-psychology* to children, proposes three primary drives: the drive toward internal integration, the will to do, and the need for others. Whichever conceptual framework is utilized, dynamic psychotherapy sees the individual's motivations, impulses, and desires as important determinants of subjective experience, mental functioning, and behavior.

In the tripartite model of the mind, ego includes all the mental capacities available to the individual for regulation of the internal milieu and adaptation to external reality. Ego's task is to optimize pleasure and gratification of wishes and needs while maintaining internal equilibrium, the health of the body, good relations with the external world, and peace with superego. Although ego includes all the mental capacities for engaging with external reality, it also focuses on internal reality. As with *id*, there is no single psychodynamic approach to describing or organizing all the phenomena that can be subsumed in the concept ego. One approach defines basic categories of ego functions: reality testing, object relations, regulation of affect, thought, defensive activity, autonomous functions, and synthetic or integrative functions. Work with children requires examining each of these functions in the context of the child's age and developmental accomplishments.

In the broad range of psychological theories, defensive ego activity and the capacity for object relations are conceptualizations of mental functioning most uniquely attributable to psychodynamic theory. *Defense* is a term describing ego efforts to protect against *internal* dangers. From experience with loved persons on whom the child is entirely dependent for survival, the child internalizes the displeasure expressed by the caretaker toward unacceptable drive derivatives, such as biting the nipple when nursing, and identifies with the pleasure expressed toward socially acceptable drive derivatives, such as biting and chewing finger foods. Ego is challenged to restrain prohibited expressions and promote approved expressions of inner urges once this process of internalizing permissions and prohibitions has

begun. Psychoanalytic observations reveal how fear of the disappearance or loss of the loved caretaker, the “object” of object relations, generates a need for defensive maneuvers. The psychological maneuver by which the inhibition is accomplished is termed a *mechanism of defense*. The fear shifts from fear of loss of the object itself to fear of loss of the object's love with increasing ego maturity and development in an environment of “good enough” parenting. Fear of loss of body integrity, often referred to as castration anxiety, enters the signaling system with further development. Finally, as superego functions and ego ideals develop, unpleasant affects of shame, guilt, and remorse stimulate restraint. Intense anxiety and mobilization of powerful and often primitive defenses occur when coping capacities are on the verge of being overwhelmed by massive overstimulation or frustration, for example, with acute or chronic trauma or the upsurge of urges associated with the onset of puberty.

Defense mechanisms are typically unconscious, automatic, psychological processes. The individual does not consciously choose to institute a defense; however, an individual can learn to recognize defensive activity as it occurs through dynamic psychotherapy, psychoanalysis, or self-analysis ( [Gray, 1994](#)). Anna Freud's classic, *The Ego and the Mechanisms of Defense* (1936) enumerated several patterns of defense already in the analytic literature: regression, repression, reaction formation, isolation, undoing, projection, introjection, turning against the self, reversal, and sublimation. To these she added: turning passive to active, denial, intellectualization, displacement, identification with the aggressor, and altruistic surrender. Following that publication, effort was devoted to developing a comprehensive catalog of defense mechanisms. Clinical observation eventually led to the conclusions that any aspect of ego functioning may be used in the service of defense and the attempt to delineate a comprehensive list of specific mechanisms was impossible and potentially misleading in its reductionism. Nonetheless, children use certain mechanisms with sufficient frequency that it is of value to psychodynamic child therapists to be able to recognize them in the clinical situation ( [Table 78.1](#)).

Denial: The disavowal of intolerable external reality factors or of thoughts, feelings, wishes, or needs that are apparent to an observer.
Displacement: The transfer of emotions, ideas, or wishes from the original object to a more acceptable substitute.
Externalization: The attribution of internal conflicts to the external environment and a search for environmental solutions. In therapy the person of the therapist is used to represent one or the other part of the patient's personality structure.
Reaction formation: The adoption of affects, ideas, or behaviors that are the opposites of impulses harbored either consciously or unconsciously.
Repression: The exclusion of unacceptable ideas, fantasies, affects, or impulses from consciousness or the sweeping out of consciousness of what has never been conscious. Repressed material emerges in disguised form in thought, speech, and actions.
Suppression: The conscious effort to control and conceal unacceptable impulses. Suppression is the exception to the rule that defenses are unconscious processes.
Substitution: The transfer of tension from drives or affects into disturbances of bodily functions or rhythms.
Turning passive to active: The management of affects and impulses directed to a passive experience with an object, more powerful "other" (by playing out in action or story the active "other" role. This includes the process of identification with the aggressor.

**Table 78.1. Defenses Commonly Exhibited By Children In Psychodynamic Therapy**

Controversy exists both within dynamic child psychiatry and between dynamic and descriptive psychiatry regarding the degree to which defensive activity and internal conflict involve such “autonomous” ego functions as perception, motility (e.g., walking, eye–hand coordination), intention, intelligence, logical thought, speech, and language. These “autonomous” ego functions were conceptualized by [Heinz Hartmann \(1950\)](#) as relatively resistant to disturbance by intrapsychic conflict. It is clear that many disturbances in this area have their origins in constitutional variations in brain functioning. However, it is also clear from clinical material that in many children and adults these presumed autonomous functions are impacted by conflict and defense; this is no surprise to psychiatrists familiar with the way cognitive function is impaired by defensive denial. The challenge to the child and adolescent psychodynamic therapist is in the differential diagnosis. Psychological testing by a professional skilled in elucidating this distinction can be very useful at times.

Superego, the moral agency in the tripartite model, encompasses conscience, morality, critical self-observation, self-punishment, and the holding up of ideals ([Compton, 1995](#)). Although available to consciousness as moral precepts and ideals, superego functions are predominantly unconscious, out of awareness. Superego is built out of the child's desire to please adults, fear of displeasing adults and thereby losing their approval and affection, experiences of consequences from the physical and social world, and identification with the models of self-control and moral values presented by important adults. There is continuing development of a set of standards, “*ego ideal*,” epitomizing the individual's beliefs of what is right, good, or desirable. Superego only can be effective in controlling behavior in conformance with this ideal to the degree that ego capacities have developed to be deployed in thwarting and channeling unacceptable impulses. When misbehavior is the presenting complaint about a particular child, the clinician must evaluate whether the behavioral expectations of the adults are “age appropriate.” The clinician also pays attention to the meaning of the behavior rooted in the child's anxiety and conflict over drive derivatives.

Superego is a concept that describes an internal, intrapsychic phenomenon derived from object relations and experiences with the external world. The clinician observes superego functions by attending to the affects signaling pleasure and displeasure. When thought and behavior conform to the internalized standards of the developing ego ideal, the child shows pleasure in performance of daily tasks, self-esteem, happiness, or contentment. The child displays signs of humiliation, shame or guilt, and low self-esteem when thought and behavior disappoint the strictures of internalized standards and superego functions. Children frequently externalize blame as a defense against the painful affect when the negative affect or sense of being wrong is unbearable. Unfortunately, when the child lies or blames others, adults may assume that the child does not know he was bad; in these instances, the child knows but cannot tolerate the knowing. Children frequently express their guilt is through enactment in which their behavior brings about a punishment. For example, a child struggling with urges to injure a new sibling may become accident-prone.

An interesting finding from psychoanalysis is that the harshness and rigidity of an individual's superego is not directly proportional to the parent's severity or the child's experiences with the parent but rather to the intensity of the aggressive wishes and relative weakness and immaturity of the individual's ego and defenses. Parental harshness is thought to weaken superego functions because when the parent's aim is to inflict a punishment that hurts the child, either physically or through deprivation, the child becomes focused on the external struggle with the parent and is distracted from the internal struggle with shame, guilt, or remorse.

Although ego psychologists have focused on defensive ego functions, an alternative metapsychology has developed under the rubric of object relations theory. Freud's emphasis on early experience as a source of both psychopathology and transference focused interest on the earliest relationships of the human infant and toddler. This emphasis and the observational studies of young children that it spawned ( [Mahler, 1962](#); [Provence and Ritvo, 1961](#); [Spitz, 1945](#)) have reaped extensive benefit for the mental health of children. Although loosely anchored in the tripartite model of the mind, psychoanalytic object relations theories as defined by [Kernberg \(1995\)](#) are

those that place the internalization, structuralization, and clinical reactivation (in the transference and countertransference) of the earliest dyadic object relations at the center of their motivational (genetic and developmental), structural, and clinical formulations ( [Kernberg, 1995](#), p. 450).

Object relations theories use a metapsychology organized around the concept of an *internal representational world*, “a world which is only gradually differentiated in the course of development as a consequence of processes of biological and psychological adaptation” ( [Sandler and Rosenblatt, 1962](#), p. 130). The child constructs representations that enable him or her to perceive sensations arising from various sources, to organize and structure them in a meaningful way. It is useful to make a distinction between representations and images. A representation is a more or less enduring organization or schema constructed from a multitude of images, each derived from a multitude of experiential impressions. Sandler gives the example of a child who experiences many images of his or her mother—mother feeding, mother talking, mother preparing food, and so on—out of which gradually is created the mother representation encompassing the entire range of mother images, all bearing the label “mother.”

The object relations metapsychological construct of the intrapsychic representational world provides a conceptual framework for the processes of internalization. Identification is the coalescence of a self-representation with an object-representation, or a change in the self-representation so that the object-representation is duplicated. En route to a stable identification are temporary identifications and imitations with transitory changes in self-image. The object-representation used as a model in identification may be based to a degree on fantasy rather than wholly on real attributes of the object from which it derived. Identification with its duplication of the object-representation within the self-representation is seen as a step in the loosening of the dependency tie to the object.

In psychodynamic therapy special attention is given to understanding and manipulating the impact of the patient–therapist relationship on the patient's intrapsychic structures and functions. A basic concept of *transference* “refers to the way in which the patient's view of and relations with his childhood objects are expressed in his current perceptions, thoughts, fantasies, feelings, attitudes, and behavior in regard to the analyst” ( [Sandler et al., 1980](#), p. 78). The therapist can observe the transference by looking for distinctive types: transference of habitual ways of relating, current relationships, and past experiences ( [Sandler et al., 1980](#)). It is

particularly useful to examine and utilize transference onto the therapist of defensive functions. Transference is frequently used as a general term for the patient's attitudes and behavior toward the therapist and as such includes *externalizations*, which [Anna Freud \(1965\)](#) specifies as

processes in which the person of the analyst is used to represent one or the other part of the patient's personality structure. . . . The child thus re-stages his internal (intersystemic) conflicts as external battles with the analyst, a process which provides useful material ( [Anna Freud, 1965](#), pp. 41–42).

Therapists' interventions differ with each therapist's assessment of transference phenomena. [Brenner \(1982\)](#) points out that the phenomenon of transference is not unique to the therapeutic relationship but rather “ every object relation is a new edition of the first, definitive attachments of childhood.” In essence, psychodynamic theory proposes that psychologically significant relationships contribute to the individual's perceptions, thoughts, fantasies, feelings, attitudes, and behavior in all future relationships.

The patient's experience of the therapist is not limited to the transference. A portion of the therapeutic action of psychodynamic therapy is thought to rest in the experience of the *real relationship* with the therapist. The child even more than the adult has receptivity for new experiences. The psychodynamic therapist provides the child or adolescent with a new object with new potentials for internalization. The therapist strives to cultivate specific qualities, some of which may be novel to the child. These include a respectful attitude toward the child, particularly toward the child's thoughts and feelings, as well as the protection of the child's confidences from intrusion by parents or teachers. The therapist strives to be reliable and predictable in the arrangements made for meeting with the child. Most significantly the psychodynamic therapist establishes a relationship with the child that is largely unilateral in its focus so that the events of the therapy evolve primarily from the child. Unlike the relationship with parents or peers in which there is a necessary and healthy reciprocity, the focus on the child in the relationship with the psychodynamic therapist allows the internal world of the child to dominate the transactions ( [Lewis, 1997](#)). The therapist as an interested and thoughtful observer becomes a model for the child's development of the capacity for self-observation, a capacity termed either *observing ego* or *reflective function*.

Although the primary focus in the patient–therapist relationship is tipped toward the patient, psychodynamic theory does address the therapist's experience of this relationship. *Countertransference* refers specifically to intrapsychic conflicts stirred in the therapist by the patient. Generically, countertransference refers to all the reactions of the therapist to the patient. Detection of countertransference requires a “constant internal vigilance of the psychiatrist, who notes the emergence of powerful positive and negative feelings toward the patient and reflects on the possible origin of those feelings in the context of past relationships” ( [Gabbard, 1990](#)). [Marshall \(1979\)](#) operationalizes the definition of countertransference into two categories: (a) reactions arising from the therapist's unresolved internal conflicts; and (b) natural reactions to a patient's provocative behavior. [Winnicott \(1949\)](#) dubbed this second type “*objective*” countertransference, objective in the sense that virtually everyone would find the patient's behavior provocative. The challenge to the therapist when the objective countertransference is recognized is to construct a response that is both honest and therapeutic. Marshall suggests that either type of countertransference may occur consciously or unconsciously. By definition, the therapist is unaware of unconscious self-derived responses. [Table 78.2](#) lists behaviors that signal the presence of unconscious therapist-derived countertransference. Many of these same factors may be purposefully instituted as adaptations of technique, *parameters*, when clinically warranted. The therapist's task is to prevent countertransferences from distorting the treatment ( [Table 78.2](#)).

---

Excessive play with diminution of talk
Quick yielding to requests
Gratification of the child, particularly feeding and gift-giving
Any strong feeling, especially if accompanied by guilt or anxiety
“Lulling”: the altering of attention when a child plays out similar fantasies
repeatedly
Impulsive talk or action
Physical contact
Allowing parents to use child's time
Consultation with parents or others without child's involvement or agreement
Strong, unresolved feelings toward parents
Inability to involve parents appropriately
Preoccupation with changing behavior, especially as desired by parents or school

Marshall R. Countertransference in the psychotherapy of children and adolescents. *Contemp Psychoanal* 15:595-628, 1979.

**Table 78.2. Clinical Clues to Unconscious Therapist-Derived Countertransference**

*Treatment alliance* and *working alliance* are terms used to refer to “all the factors that keep a patient in treatment and which enable him to remain there during phases of resistance and hostile transference” ( [Sandler et al., 1980](#), p. 53). *Resistance* is a conceptualization of the psychological mechanisms that cling to the intrapsychic status quo and seek to prevent change. In essence, resistance is a defense against affects, undesirable self-representations, or unwanted drive derivatives that are stirred and moved toward awareness by the therapeutic process. Inherent in the treatment alliance is the patient's awareness of internal difficulties and an acceptance of the need to be helped. Children with very fragile self-esteem may refuse to enter into therapy because they cannot tolerate the recognition of their difficulties.

In child and adolescent treatments the establishment and maintenance of the alliance is more complex than in adults because of the dependence on parents to bring the child to treatment. A positive alliance with the parents sustains the child's engagement in treatment even when the child's resistance is strong. Parents can subtly oppose the child's wish to come to treatment or collude with the child's resistance. The therapist must establish and maintain a working alliance with the parents sufficient to keep the therapy going.

## CLINICAL APPROACH

The clinical application of psychodynamic theory to the treatment of children and adolescents covers a broad range of settings, participants, intensities, and combinations with other modalities of treatment such as psychopharmacology, educational remedies, family therapy, and environmental change. Individual, intensive, psychodynamic therapy, based largely on psychoanalysis but drawing as well on American client-centered therapy and the child guidance approach to individual therapy, can be used to demonstrate the fundamental techniques and practices of dynamic psychotherapy.

### Indications and Goals

Individual psychodynamic therapy formulates the intrapsychic component of the child or adolescent's condition within a developmentally attuned biopsychosocial model of dysfunction. Formulation goes beyond the simple descriptive categories of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) or *International Classification of Diseases*, 10th revision (ICD-10) to include life events and chronology related to the emergence of psychopathology, the pathophysiology of symptoms, signs, and problematic behaviors, and the developmental status, leading conflicts, and coping and adaptive mechanisms of the child ( [Robson, 1986](#); [Shapiro, 1989](#)). Individual psychodynamic therapy is most clearly indicated in cases where the patient's difficulties are the product of intrapsychic conflict and adherence to defensive solutions or object representations that are developmentally regressive. Frequently, a child's difficult behaviors are externalizations of intrapsychic conflict. Psychodynamic therapy is indicated in cases where the etiologic factors in the social environment, such as mother's pregnancy and birth of a sibling or maternal depression over the death of grandparents, have been resolved but the child's defenses have become fixed. [Anna Freud \(1968\)](#) proposes two other categories of disturbance that psychoanalysts have attempted to treat that are not generated solely from the past but from significant present circumstances. One is the child or adolescent's difficulty coping with a current developmental imperative such as entry into school or the upheaval in self-image at puberty and the adolescent shift in relationships with the parents. The focus of therapy would still be on the intrapsychic difficulties of the youth. In Anna Freud's second category the environment or the child's own constitution, such as blindness or multiple learning disabilities, presents a current and ongoing interference with development. In these cases, Anna Freud suggests, intensive individual work may be important but is unlikely to bring the youth to health without environmental interventions.

Intensive, individual psychodynamic therapy is contraindicated in cases of severe constitutional deficits such as autism, severe pervasive developmental disorder, or moderate to severe mental retardation, particularly to the degree that these disorders affect capacity for self-observation and receptive language function. Intensive treatment is contraindicated when circumstances within the family or the treatment facility cannot sustain the continuity and integrity of the therapy, especially if disruption of the therapy repeats previous traumas of loss and unpredictability for the child. Because intensive treatment places considerable strain on family resources and the child and parents' time it should not be undertaken if a less intensive treatment is adequate.

The goals of therapy extend beyond symptom relief. A primary goal is to restore psychological development to a normal path, including management of anxiety, enhanced affect regulation, improved self-esteem, increased frustration tolerance, age-appropriate autonomy, greater capacity for pleasure and satisfaction in school work and play, and better relationships with peers. Additional goals are to enhance the child's resilience and decrease the likelihood of relapse by developing the child's capacity for understanding his or her own feelings, thoughts, and the connection between feelings and behavior. The child or adolescent comes to a more sophisticated understanding of other people's thoughts, feelings, and behaviors by learning to know and observe his own mental functions. This contributes to improved interpersonal relationships.

### Opening Phase

The challenge and gratification provided by the practice of psychodynamic therapy stems in part from the requirement that the practitioner pursue diagnostic and therapeutic goals simultaneously. Thus, the psychodynamic child and adolescent psychiatrist seek to establish a psychodynamic treatment stance from the very first contact with the adult caretaker and patient. Work with children and adolescents has the additional challenge of requiring the formation of a working alliance both with the parents and patient. Although directing and observing the evaluation process, the clinician acts in a manner that respects the parental functions of the caretaker as well as the developmentally appropriate autonomy and inner experience of the child.

### THE FIRST VISIT

With adolescents, particularly older adolescents, the clinician usually meets with the patient for one or several sessions before meeting with the parents. This allows the adolescent to explore issues of trust with the clinician and demonstrates that the clinician's primary relationship is to the adolescent. For younger children, it is typical for the parents to meet with the psychiatrist to provide background data but even more importantly to establish their own trust and confidence in the psychiatrist so that they can assure the child of the appropriateness of this undertaking. It is important to explore with parents how they will prepare the child for the first visit. If the child has expressed distress over a particular symptom, the parent may explain that the doctor is there to help with that symptom. In language appropriate to the child's age, the parents ought to tell the child that the doctor is one who helps children with their feelings and worries by talking and playing with them.

### STRUCTURING THE PSYCHODYNAMIC THERAPY

The intention in individual therapy is for the therapist and child to work together separately from the parents. The child may have difficulty leaving the parent, either because for a preschooler this is within the range of age-appropriate behavior or for an older child because of underlying conflicts. Such separation difficulties require an adaptation of technique and preliminary work with the child and parent to understand and work through the issue. The idea behind working with the child without the parent in the room is to create a zone of confidentiality and psychic safety within which the child and therapist can explore feelings, thoughts, and behaviors. If the parent is present, the child's spontaneity is restrained or stimulated in part by the possible reaction from the parent. When the child is seen alone, the therapist is in a better position to see how the child has internalized the authority of the parents.

The psychiatrist should clarify to both the parents and the child that, although he or she meets with the child's parents on a regular basis, the confidentiality in this therapy is "a one-way street," which allows the psychiatrist to tell the child what the parents have said but precludes the psychiatrist reporting to the parents what the child has said or done. Children, particularly at the beginning of therapy, frequently will not report to the therapist current events that provide a context for understanding the child's talk and play within the session because children are very oriented in the present moment and are defensive against affect. A meeting or phone call from the parents is important if the therapist is to know about these events. The "one-way street" implies that the therapist will share these communications from the parents with the child. The child's understanding of the purpose of the therapist's meetings with parents develops as the therapy continues. It is the therapist's task through word and deed to help the child understand that, although the therapist tries to help the parents understand their role as parents of a child this age and with these problems, the therapist can not control the parents and will not take sides in a specific struggle between the child and parents. On the other hand, particularly with older children and adolescents, it can be pointed out that the parent has a responsibility to the child for assuring that the therapist is doing a responsible job and thus needs some report from the therapist on the progress of the work.

There are several other elements the psychodynamic therapist uses to create a special person, place, and time for dealing with feelings and worries in addition to creating a zone of confidentiality. The therapist deals with the child in a nonjudgmental and nondirective manner such as that described by [Virginia Axline \(1947\)](#) in her classic text, *Play Therapy*. In an intensive individual psychodynamic therapy, the therapist strives to relate to the child in the style [McConville \(1998\)](#) has described as the "empathic participant" who approaches the child with the wish to know "what's it like to be you." The therapist and child explore together rather than doing something *to* or *for* the child. Eventually the therapist is *with* the child as the child examines and explores his own thoughts, feelings, and conflicts. If doctor-patient relationships are conceived of as either prescriptive, collaborative, or facilitative the psychodynamic therapist eschews the prescriptive, choosing to be collaborative and facilitative.

The office must be suitably sturdy and equipped in a manner age-appropriate to the patients who will be treated in order to work nondirectively with children. A separate playroom is advantageous when working with young children who are struggling to control intensely messy or aggressive impulses. The toys do not need to be numerous or elaborate. Children's activities in a play therapy tend to fall into the following categories: games with rules, physical activities, creative projects, solo imaginary play, and imaginary play with the therapist as a participant. It is helpful to have a deck of cards, one or two simple board games such as checkers or Trouble, a Nerf or koosh ball, paper, washable markers or crayons, tape and children's scissors, a set of blocks, puppets, action figures, and dolls or animal figures. A family grouping of animals or small dolls is useful. The child can use a ferocious animal (e.g., shark, lion, or dinosaur, either a puppet or animal figure) to express aggressive urges.

The issue of limit setting will arise no matter how appropriately the office or playroom is outfitted. Common-sense limitations are necessary to protect the room, therapist, and child from physical damage. One way to understand the limits is to say, "When we are done I have to be able to clean up and have you, me, and the office/playroom back the way it was." This creates in the child's world of expression through action the same safety from real-world consequences the adult analyst on the couch enjoys when expressing himself or herself verbally. Frequently, the therapist is able to address the impulse toward an unacceptable action while redirecting its aim. Thus one might say, "You may not cut my dress when you feel like attacking but you may cut this paper I will hold. I can see you feel strong and safe when you are doing the cutting. You let me know how scary it feels to have someone attacking." The therapist tries to prevent the dangerous action without creating a physical struggle if the child cannot be redirected. It is important that the therapist not become angry, blaming, and punitive while commenting on the child's struggle over the destructive wish and maneuvering of the therapist into being the "policeman who must keep us and the office safe." It is also appropriate for the therapist to remind the child that "We must try to find words for these feelings so you can tell me about it without things getting broken." The implementation of a set starting and ending time is the most frequently imposed limitation, as [Axline \(1947\)](#) points out. The therapist's adherence to routine in keeping the time and dates of appointments on a predictable schedule is a necessary part of creating reliability and boundaries in the therapeutic relationship. The child's reaction to waiting in the waiting room for the appointed starting time and dealing with leaving the therapist at the end of the session can serve to reveal the particular child's conflicts.

### THE INTERPRETIVE SESSION: STRUCTURING THE WORK FOR THE PARENTS

Intensive individual psychodynamic therapy is initiated after a period of evaluation, crisis management, or even pharmacotherapy. It is important that the therapist and parents meet in an interpretive session or two to review the formulation of the child's diagnosis and prognosis in dynamic and developmental terms, and to discuss the recommendation for intensive treatment and necessary arrangements. Intensive therapy implies two or more sessions per week. Psychoanalysis with sessions four or five times per week is indicated when the pathologic conflicts and maladaptive, regressive defenses are longstanding and pervasive in the child's response to a wide range of circumstances. Parents understand that frequency of practice enhances the outcome and shortens the overall time course in order to acquire a foreign language or master a musical instrument. In intensive psychodynamic therapy the child undertakes to learn a new "psychological language" and develop new skills to master feelings and impulses. The patient must be helped to counteract the resistance to change that is a natural mechanism for maintaining stability. The wise therapist is cautious in predicting the duration of treatment. Much depends on the stability of the environment and degree of current destabilizing stresses. What are the burdens and constraints on the parents in terms of effort and expense that might limit the duration of treatment? Parents should be told that intensive individual psychodynamic therapy is generally measured in years, not weeks or months. Shorter intense treatments are adaptations to specific circumstances undertaken after weighing the risks and benefits over other treatment modalities.

The frequency and purpose of parent sessions also must be discussed. As third-party coverage for intensive psychotherapy has diminished in the past 20 years, the tendency has been to decrease the parent visits in order to maximize the resources available for the child's visits, a short-sighted solution, especially with younger children. The parents and therapist need to meet to maintain an alliance and avoid undermining splits and competition for the child. Helping parents to make changes

in day care, bedtime rituals, family modesty, and discipline facilitates recovery of a healthy developmental trajectory more rapidly in the younger child.

### *BEGINNING THE PROCESS OF INTERPRETATION*

Interpretation is the process whereby the therapist, by expressing in words what he or she has come to understand about the patient's mental life, helps the patient to observe and understand his or her inner life in a new and more complete way (Moore, 1990). The therapist engages the child or adolescent in the act of observation by making *attention statements* (Lewis, 1974), comments that draw the patient's conscious attention to the content of his actions or verbalizations (Chapter 79). Beginning with ego syntonic and nonthreatening content, the therapist provides verbal commentary on the child's play, reflecting back the child's anxieties, judgments, or wishes. As the therapeutic alliance develops, the therapist begins to draw the patient's attention to coincidences, paradoxes, and remarkable absences of affects, topics, or persons who ought to be central to the child's experience.

### **Middle Phase**

Whereas the initial and termination phases may last several weeks to months, the middle phase of treatment lasts months to years. Intrapsychic structure is created or remodeled, new defenses are developed, and old patterns of response are relinquished during the middle phase.

### *THE CHILD IN THE MIDDLE PHASE*

The middle phase begins when the patient has taken in the structure of the treatment: the therapist's nonjudgmental attitude, regularity of appointment times, and maintenance of confidentiality. The patient implicitly knows that a goal of the treatment is to understand the way she or he feels and behaves, that everything she or he says or does is to be considered in the therapy. The child's play or the older child's conversation and behavior are part of the associative process revealing the patient's intrapsychic state. It does not meet the criteria of free association in adult psychoanalysis because the child's capacity for introspection is limited and the child is not instructed to say whatever comes to mind. The child or adolescent tends to maintain a consciously goal-directed stance (e.g., winning the game of checkers). This goal-directedness creates considerable tension between the child's tendency to become absorbed in the play and the capacity to self-observe. The therapist's verbalizations about the play model the observing function as well as clarify the dynamic functions of the play for the child.

The transition in late childhood and early adolescence from playing in therapy to sitting and talking reflects a developmental move from expression through action to enhanced verbal communication. Superego development contributes to this process with increasing superego autonomy and constriction in primary process expression to meet an increasingly mature ego ideal. Often in this transitional stage the patient will fiddle with objects in the office; draw or play cards; or bring in homework, magazines, books, or a pocket full of gadgets to allow an action outlet or focus that is not threatening in its pull back toward childhood play. In this period the therapist needs to allow the patient to establish a comfortable blend of action and verbal expression while being alert for the ways in which either might be used as a resistance.

Resistance is an inevitable aspect of a psychodynamic therapeutic process. Lewis and Blotcky (1997) describe three categories of resistance: active, passive, and compliant. The actively resistant patient expresses overt objections to the treatment, such as opposition to coming to appointments and complaints about interference in his or her life. The passively resistant youth may be stubbornly silent, withholding, and plead boredom. The compliant patient is described as eager to do the right things, to give "lip service" but without emotional engagement. These may be thought of as "macroresistances," appearing as an overarching response to treatment. One also finds "microresistances," moment-to-moment rejections of the therapist's offered interpretations. The child may demonstrate these by shutting down, a sudden shift of focus or behavior, or an eruption of disinhibited behavior. By observing these "microresistances," the therapist can measure the intensity of the superego in opposing awareness of the mental contents the therapist was seeking to bring to the patient's conscious awareness or the weakness of the ego when it loses control of the drive.

The patient continues to develop a relationship with the therapist during this middle phase, in addition to bringing forward the content of his inner experience. A true transference occurs, that is, the patient experiences in the current relationship with the therapist fixated conflicts, superego projections, and object representations that stem from previous experiences with the parents. The transference is affected and modified by the developmental achievements or delays of the patient. The child patient differs from the adult patient because the child is still living with the parents, who continue to exert influence over the patient. The patient may make a simple, current displacement rather than a deep transference to the therapist. The child is not the equal of the therapist because the child is still a child relating to the therapist as a child to an adult (Lewis, 1996) (Chapter 79). In addition to the emerging transference, the child or adolescent experiences the therapist as a new object for identification and satisfaction of developmental needs. The experience with an adult who respects the child or adolescent's inner life and demonstrates an approach to understanding and managing that inner life contributes significantly to the therapeutic outcome of intensive individual psychodynamic therapy.

It is important not to underestimate the contribution to the therapeutic process of the child's play and verbal self-expression, although the therapist is essential to the therapy. The play and verbalizations by expressing heretofore-unconscious mental contents in conscious communications of speech and action offer an opportunity for active mastery of components of the patient's problems apart from the specific interventions of the therapist.

### *THE THERAPIST'S MENTAL PROCESS*

The gap between the therapist's theoretical understanding of the moment-to-moment content of the therapy sessions and what it is possible to do or say at the developmental level of the child is more evident in child psychotherapy than in work with adults. Lewis (1996) describes the multistep process by which the therapist, while keeping up the play with the child, takes "mental distance," places the immediate observations into an ongoing formulation, develops an interpretation, brings the interpretation back, and presents it to the child in the context of the play and session (Chapter 79).

The therapist's interest is neither limited to nor primarily focused on the factual content of the patient's productions in the session. Even when a patient in late childhood or adolescence presents a narrative of an external event, the therapist listens for the defensive regulation of affect and drive in the narrative as well as the accuracy or potential distortions in the presentations of relationships. The therapist also assesses the patient's ability or inability to see multiple sides of the story. Referencing earlier material, the therapist considers what patterns emerge. The therapist may begin to formulate a reconstruction by thinking about how these patterns reflect a repetition of defenses and attitudes fixated by past trauma. The psychodynamic therapist continually monitors the patient's utilization of the therapist. Is the transference being manifested or is the patient turning passive to active, letting the therapist know what it feels like to be on the receiving end? Nonnarrative material is as useful in psychodynamic therapy as is narrative. In nonnarrative play the therapist observes where shifts and disruptions in the play occur in response either to frustration or the emergence of strong emotions or thoughts the child finds unacceptable. These observations inform both the content of the therapist's interpretations and their timing.

### *THE THERAPIST'S INTERPRETATIONS*

The basic process of constructing interpretations was laid out by Loewenstein (1951) and is explored comprehensively by Lewis in Chapter 79 of this volume. Interpretations may be classified as *clarifications*, *defense interpretations*, and *reconstructions*. Clarifications bring the patient's attention to bear on his or her characteristic patterns of action and interaction but do not imply a reason for the pattern. A defense interpretation picks up on the drive derivative (e.g., rivalry as an aggressive drive derivative) and points out that a defense has been instituted. The drive derivative has been changed in a way that makes it manageable and acceptable to the superego (e.g., rivalry becomes the avoidance of competition). The therapist should address the defense before addressing the drive derivative when making a defense interpretation (Freud, 1936). The defense is acceptable to the patient. It is ego-syntonic. Drawing the patient's attention to the defense reminds the patient that he or she has a way to manage the affect or drive derivative. The patient will be more likely to tolerate looking back at the intolerable drive or affect from this position of strength.

A reconstruction is an interpretation that explains current feelings, thoughts, and behaviors in terms of critical past events in the patient's life or fantasies from an earlier stage of development. Reconstructions are only offered late in the therapy process. The clinical decision to offer a reconstruction to a child or adolescent requires weighing the patient's capacity to use it to "make sense" of perplexing feelings and behaviors (Kennedy, 1971). Lewis (1996) points out that a reconstruction can be helpful to a child when it clarifies what was an essentially correct perception by the child at the time of the trauma but that has subsequently undergone distortion (Chapter 79). The therapist must consider whether a reconstruction is premature. A child too close to the trauma will reject the reconstruction in order to defend against the affects and drives the reference stirs. A reconstruction may be intellectualized or rejected because it arouses unmanageable shame or guilt.

The psychodynamic therapist must select the optimal context in addition to the level of interpretation. In play therapy the therapist decides whether to work within the

play utilizing the defensive protection displacement affords or to comment more directly to the child. If the child is playing that a tiger makes a preemptive attack on a lion, the therapist may speak about the tiger's wish to protect himself by striking first or the therapist can say to the child, "You are showing me with the tiger that you feel it is sometimes important to protect yourself by attacking first." The relationship between the child and therapist is a context for interpreting transference or externalization, clarifying the real, nontransference, relationship and offering developmental assistance. Working in the play or in the patient-therapist relationship focuses the work on events inside the treatment setting. The focus could be extended to events outside the treatment setting. The patient and therapist can discuss issues or experiences with family, peers, or school. Finally, the temporal focus may be on the past, present, or future.

#### WORK WITH PARENTS IN THE MIDDLE PHASE

Success of an intensive individual psychodynamic therapy with a child or adolescent often rests on the therapist's skill in the collateral work with the parents. The therapist must come to understand the parents' fantasies and fears about therapy, their child, and themselves as parents. Parents may come with the attitude that the therapist will redeem them from past transgressions that have affected the child. The parents may hope that the therapist will rescue the child. Alternatively, parents may see the therapist as a rival for the child's affection or as an authority figure seeking to find fault or blame the parent. Even with the most dysfunctional parent, the therapist seeks to ally with the parent's wish to be a good parent and supports the parent in those efforts. Many parents find referral for individual treatment beneficial. Where there is marital conflict the therapist tactfully explores its role in the child's difficulties. If marital therapy is indicated the parents should be referred to an appropriate clinician in order to maximize the parents' effectiveness in their parenting role, minimize the possibility that the marital conflict will disrupt the child's treatment, and protect the therapist's primary relationship with the child.

In "Problems of Termination in Child Analysis," [Anna Freud \(1957/1971\)](#) lists parental reasons for terminating treatment sooner than the Hampstead Child-Therapy Clinic recommended. Parents may be satisfied when presenting symptoms have resolved but the therapist is aware that the underlying pathologic conflicts are not stabilized. Or the parents find unacceptable transitory oppositional behaviors of the child whose therapeutic developmental gains lead to a newly achieved autonomy.

Parent work in the middle phase has the tasks of: (a) facilitating the flow of information from the parents about the child; (b) counseling and educating parents both about sensitive issues in parenting and the particular child's diagnosis, strengths, and vulnerabilities; and (c) assisting parents in advocating for the child and in case management ([Sperling, 1997](#)). The therapist must always plan interventions with parents in the context of what the therapist knows of the parents' own issues and needs. Suggestions must be given with cautious awareness that parents may resist giving up a parenting behavior or pattern of relationship with the child either because it is gratifying for the parent or represents a parental defense against negative or aggressive impulses. If such resistances are present or the parent's own conflicts can be shown to destabilize the child's progress in the therapy, the therapist has the additional task of skillfully assisting the parent to undertake therapy for herself or himself.

#### Closing Phase

The closing phase presents two distinct tasks: the decision to conclude the treatment and the *termination process* by which the treatment is ended. The psychiatrist's ability to maintain the working alliance with the patient and parents consolidates the patient's therapeutic gains and enables the patient or family to seek help in the future if needed.

#### THE DECISION TO STOP TREATMENT

Because intensive psychodynamic therapy with children and adolescents is a three-way contract ([Novick, 1990](#)) between therapist, child, and parents the conclusion may be initiated by any one, two, or all three of the parties. The optimal situation is for all three to concur that the goals of treatment have been met. A successfully completed case may be said to have "reached termination."

Premature terminations occur when there is a decision to end the therapy before the treatment goals have been met. There are two types of premature termination: disruption and interruption. Disruption refers to the decision to end the treatment because of external factors affecting any of the three parties. For example, the family may be moving or the therapist may be leaving the treatment facility. Interruption refers to a unilateral decision by one of the parties to end the treatment based on intrapsychic factors such as parents' unexamined intrapsychic conflicts aroused by the therapy. In all terminations, and particularly in the case of premature terminations, the therapist must be alert to the patient's fantasies about the reasons for ending the treatment so that they can be worked on during the termination process.

In initiating the termination process, the therapist considers the patient's ability to maintain the gains of treatment and grow in the family despite parental difficulties, the extent to which "developmental forces have been set free again and are ready to take over" ([Freud, 1957/1971](#)), and the progress the patient has made in internal consolidation of intrapsychic changes. The process of consolidation of intrapsychic changes is called *working-through* ([Chapter 79](#)).

[Sigmund Freud \(1914/1957\)](#) introduced the concept of working-through to describe the time and effort a patient requires to "become conversant with his resistance." Anna Freud describes the three major therapeutic agents of differing psychodynamic therapies in published discussions with Joseph Sandler. Abreaction is the primary therapeutic agent in client-centered play therapy. Franz Alexander's "corrective emotional experience" provides the child with a new relationship that replaces deficient past relationships. Psychoanalysis strives for a therapeutic process based on self-observation, self-awareness, and insight. Insight, according to Anna Freud, "does not occur without a working-through process," defined as the elaboration and extension into different contexts and directions of relevant interpretations. The tracing of anxieties resulting from the child's infantile perception of the world and correction of distortions of perception that were caused by the immaturity of the child's cognitive apparatus are included in her concept of working-through ([Sandler et al., 1980](#)).

#### THE TERMINATION PROCESS

All psychotherapies have a termination phase regardless of theoretical orientation ([Lewis and Blotcky, 1997](#)). Psychoanalysts give particular attention to this phase of treatment. The understanding gained of the meaning and psychological challenges to the patient inherent in "saying goodbye" are useful to the clinician in managing the conclusion of any doctor-patient relationship.

At the theoretical level, termination is conceptualized as an experience of separation and loss. The patient, parents, and therapist bring their own characteristic approaches to separation and loss to the process. Although the therapist's attention is primarily on the patient, countertransference reactions may be triggered by the loss of the patient as a real-life object. It is essential to evaluate and address the parents' needs in the face of the impending loss of the therapist as an ally.

The intrapsychic tasks for the patient are the resolution of the transference relationship and relinquishing of the real relationship with the therapist. The transference reaction to termination is colored by the patient's previous experiences with separation and loss. Ego functions may regress and symptoms recur. The therapist works to help the child verbalize feelings and ideas about the impending change and work through these reactions in light of the patient's current capacities, those appropriate to the patient's developmental level and those gained in therapy. As the patient relinquishes the real relationship with the therapist, the therapist aids the patient to internalize the therapist's functions so that the patient may carry on in developing self-understanding, particularly an ability to tolerate and examine internal conflicts and ambivalence.

The technical and practical approaches to termination are designed to promote the theoretical goals. The therapist engages the patient in *active* planning and execution of the termination seeking to avoid repetition of *passive* experiences of loss (e.g., loss of parental attention with the birth of a sibling). First, the reasons for concluding the treatment must be acknowledged and the treatment goals, child's achievements, and remaining concerns reviewed allowing the clinician, patient, and parents to gauge the patient's reaction to the impending loss. Typical reactions of children and adolescents faced with the proposition of ending therapy are: (a) fear, anger, aggression, or depression; (b) return of symptoms; (c) recapitulation of the themes of the therapy; (d) adoption of the "plan" presented; and (e) a bid to not end the therapy ([Lewis and Blotcky, 1997](#)).

Next, logistics of termination are addressed. Logistics include setting the date for the last session, deciding whether to make a clean break or a gradual diminution in the frequency of sessions, and clarifying follow-up plans. General guidelines for these decisions are tailored to the needs of the particular patient.

The clinician works to avoid precipitous endings without enough time to say goodbye and work through the patient's reactions. Optimally, the patient chooses the date by working with the therapist to understand why the patient feels one date is more suitable than another. A date at a natural time of separation, such as the end of the school year or the Christmas vacation, tends to down play the reality of the termination. This may be desirable in some circumstances but may compromise a full

working-through of the termination.

Following the model of adult psychoanalysis, many clinicians assume that therapy should be continued at the established intensity until the final session and stopped with no planned follow-up or contact. Anna Freud has seriously questioned this approach with children and adolescents ( [Sandler et al., 1980](#)). She observed that, when normal development is achieved, the child detaches himself or herself in the course of time, just as children move on from teachers and even friends. Therefore, she recommends allowing the child to reduce the frequency of visits or schedule a follow-up visit.

Classical adult psychoanalysis leaves follow-up contact up to the patient. Early follow-up is regarded as evidence of the patient's failure to resolve the transference relationship. With children and adolescents who are in psychotherapy, not analysis, one must be aware that one is working two steps removed from classical adult analysis. In conditions of significant ongoing pathology, either constitutional in the child or endemic in the family, one is well advised to establish a follow-up plan. Even in less severe cases Lewis and Blotcky point out

the clinical utility of follow-up is probably under appreciated. The follow-up process can reinforce treatment gains, provide objective assessment of any possible deterioration, sustain some continuity in the important therapist-patient relationship, and provide valuable communication between parents, clinicians, teachers and so on ([Lewis and Blotcky, 1997](#), p. 167).

All agree that it is important for the patient to feel free to return.

#### GOALS

This chapter describes the clinical process of interpretation in psychodynamic psychotherapy with children. Hypotheses concerning interpretation are mostly derived from descriptive accounts of clinical observations, few of which have been tested scientifically. Some empiric research on psychodynamic psychotherapy treatment outcome has been reported ([Target and Fonagy 1994, 1997](#)), providing evidence of improvement along various dimensions.

Reasons for this paucity of scientific validation include the complexity of the therapeutic relationship, issues of privacy and confidentiality, informed consent and ethical issues, costs of attempting such research, difficulties of controlling contingent variables, myriad of individual differences, difficulty of collecting a large enough number of subjects, and problems of matched controls. Some of the difficulties of even routine monitoring of the effectiveness of child psychotherapy are sometimes daunting ([Weiss, 1998](#)). Not surprisingly, the desire to undertake such research leaves many therapists ambivalent if not overwhelmed; hence, the paucity of scientific research in this area.

Having noted these difficulties, what can be said clinically about the technique of making an interpretation that might be useful to the clinician and helpful for the patient? The clinical goals of intensive individual psychodynamic psychotherapy may include reduction of anxiety, improvement in self-esteem, increased frustration tolerance, disappearance of symptoms, better coping strategies, appropriate independence, good relationships with peers and adults, satisfactory and satisfying schoolwork, feelings of pleasure and joy, and a sense of resumption of development.

#### HISTORICAL NOTE

Hermine Hug-Hellmuth (1871–1924), in 1920, was the first child analyst to describe a technique of child analysis, especially in the preparatory phase at a presentation she gave at the Sixth International Psychoanalytic Congress in the Hague. The paper was entitled "The Technique of Child Psychoanalysis," and was published subsequently in the *International Journal of Psychoanalysis* (1921). More recently, her paper was republished in a volume by [MacLean and Rapper \(1991\)](#). Also, a useful and lively exchange between Anne Polzer, a reviewer of MacLean's book, and the author, George MacLean, is available (Polzer and MacLean, 1992). Melanie Klein, in Berlin, was the first to develop the concept of play in therapy and made extensive use of play with interpretation, using a wide range of small toys and wooden human figure representations. Melanie Klein read her first paper in Budapest in 1919 ([Klein, 1920](#)). David Levy presented the first American report on play therapy in 1925 ([Harrison, 1980](#)). Later, in 1927, Anna Freud repeated Hug-Hellmuth's earliest account of the elements of child analysis ([MacLean and Rapper, 1991](#)). Meanwhile [Freud, in 1923](#), had stated the essential goals for treatment: "to make the best of him [or her] that his [or her] inherent capacities will allow and so to make him [or her] as efficient and as capable of enjoyment as is possible" ([Freud, 1923/1955](#)).

#### GENERAL CONSIDERATIONS

The general substrate for the method essentially involves a trusting, confidential, real relationship between a trained, motivated, caring, and accepting person who offers help to a person who needs that help. Usually there is agreement between therapist and parent about the type of theory used. Generally, opportunities are provided for the verbal expression of feelings, increasing self-knowledge, and improving self-mastery ([Karasu, 1977](#); [Langs, 1982](#); [Paolino, 1981](#)). The therapy is usually divided into periods of 30 to 50 minutes given from one to four times a week in a suitable office setting. Although numerous methods, techniques, and theories have been categorized ([London and Klerman, 1982](#)) and described ([Kazdin, 1988](#); [Varma, 1974](#)), unequivocal superiority of any one method has not been established ([Luborsky et al., 1975](#); [McDermott, 1977](#); [Schaefer 1977](#); [Wolman et al., 1978](#)).

#### BECOMING A CHILD THERAPIST

How does one become a child therapist? First, it has to be said that neither the amount nor kind of training are very reliable guides to the eventual effectiveness of a therapist: Highly trained psychotherapists often achieve no more with their patients than do those with much less experience ([Strupp and Hadley, 1979](#)). Victor Raimy once observed that "psychotherapy is an undefined technique applied to unspecified cases with unpredictable results. For this technique, rigorous training is required" (quoted in [London, 1964](#)). Supervision and continuous case conferences with acknowledged experts are the generally accepted methods of acquiring psychotherapy skills. The amount required varies with the endowment and needs of the individual psychotherapist. In a brief (8-month) longitudinal study of 12 beginning psychiatric residents, [Buckley and colleagues \(1982\)](#) found that appropriate use of clarification, confrontation, management of resistance, and the ability to deal with negative transference could be learned with supervision and experience, whereas the capacity for empathy and awareness of countertransference did not change during the period of the study ([Buckley et al., 1982](#)). There is some evidence that ordinary communication skills and empathic understanding can be taught very quickly ([Bird, 1980](#); [Ivey, 1980](#); [MacGuire, 1980](#); [Matarazzo, 1978](#)) and that the rest is experience. There is no evidence that a personal analysis must be part of psychodynamic psychotherapy training ([Marks, 1982](#)).

Specialist training in psychotherapy probably requires more time if more than one modality is being learned. [Bende and Crossley \(2000\)](#) believe that a curriculum and practicum for different therapeutic modalities, one of which would be the main modality, requires 3 years. However, mixing various therapeutic approaches during specialist training can be confusing and even "de-skilling," and may lead to therapist uncertainty in regard to one's own style ([Monaghan and Mooney, 1999](#)). It is worth noting that the single, focused learning over an extensive number of years that is required for practicing psychoanalysis does provide the psychoanalyst with a clear identity as an analyst, the acquisition of a set of specialized skills, and the opportunity to develop one's personal style.

Although a working knowledge of several different therapeutic modalities is clearly required in making an informed referral of a patient with a particular set of problems to a therapist who is a specialist in the form of psychotherapy that would be most appropriate, data on the outcome in terms of such referrals are not available.

Still, therapists who complete the initial evaluation are eventually in the position of having to make an informed decision regarding which kind of therapy is best, and who would be the appropriate therapist to undertake that treatment. More research is needed on this problem ([Seligman, 1995](#)).

## INDICATIONS

The question of when intensive individual psychodynamic psychotherapy in childhood is the treatment of choice nowadays often resolves into the question of to what degree multiple other forms of therapy are indicated and available for a particular child with a particular diagnosis. Diagnosis thus is an essential prerequisite and for this purpose must go beyond the categories of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) ([American Psychiatric Association, 1994](#)) or ICD-10 to a comprehensive developmental formulation that provides a useful basis for treatment planning ([Shapiro, 1989](#)).

Rarely does a single form of psychiatric treatment suffice for the child. In most instances, various combinations of treatment modalities are necessary, including individual psychotherapy, pharmacotherapy, behavior therapy, family therapy, educational remedies, counseling, environmental changes, group therapy, and concomitant work with the parents. For example, multimodal treatment has been found to bring about significant improvement in children with attention deficit hyperactivity disorder ([Satterfield et al., 1980](#)). Nevertheless, when psychodynamic psychotherapy is used, the commonly accepted principles of psychodynamic psychotherapy are operative no matter what other treatments are required.

Pure, solitary, intensive, individual psychodynamic psychotherapy for the child alone is indicated with confidence only when the child's problem is primarily intrapsychic and there is no other known factor amenable to treatment of any other kind. Such is rarely the case. When the child's problems are a combination of external and internal or internalized processes, and other important etiologic factors are recognized, as is often the case, intensive individual psychotherapy becomes one component of a broader treatment plan. Thus, there also may be present various ongoing current conflicts, frustrations, deprivations and losses, serious physical illness, other psychiatric diagnoses, and complex neurophysiologic disturbances that may require the addition of one or more of the previously mentioned interventions.

## INTERPRETATION AS AN ESSENTIAL ELEMENT

No matter what accompanying treatments are necessary, when individual intensive or psychodynamic psychotherapy is used, the same essential elements of the process unfold, albeit modified by the age, diagnosis, and presence of these other factors, with or without the other forms of treatment. [McDermott and Chan \(1984\)](#) described the basic requirements for psychodynamic psychotherapy for children, together with a broad description of the stages and various components of the ongoing clinical work; and [Dulcan \(1984\)](#) described brief psychotherapy with children, adolescents, and their families. This chapter focuses primarily on the particular essential elements of interpretation in intensive individual psychodynamic psychotherapy.

Intensive individual psychodynamic psychotherapy is based largely on psychoanalysis, which specifically places great importance on interpretation (making the unconscious or preconscious conscious), particularly interpretation of the transference, as the principal therapeutic agent ([Lewis, 1974](#)). This holds true whether one is treating a preschool child ([Neubauer, 1972](#)), a school-age child ([Freud, 1946/1950, 1968](#)), or an adolescent and across a wide range of diagnoses ([Witmer, 1946](#)).

More recently, [Bleiberg and colleagues \(1997\)](#) conceptualized and described "mentalization" as an initial and even key element in psychoanalytic treatment and psychodynamic psychotherapy with children. They described how to help the child enhance his or her capacity to become aware of and monitor his or her mental states and the mental states of others, thus enabling the child to manage better his or her behavior. In short, the child is helped to activate his or her ability to find meaning in behavior—his or her own behavior and the behavior of others. Classical interpretation of the unconscious as described in the following, may then follow.

Cognitive perspectives also inform psychotherapy, and some mention of cognitive-developmental and information-processing considerations are made in the sections that follow. (For a more comprehensive account of cognitive development and clinical applications, see [Chapter 12](#).)

For purposes of discussion, intensive individual psychodynamic psychotherapy can be approached as a process with three major phases: initial phase, middle phase, and termination phase.

### Initial Phase

#### *THERAPEUTIC ALLIANCE*

The major goal of the initial phase is to foster a therapeutic alliance between therapist and child. This goal is usually achieved by enabling the child to experience a nonjudgmental, understanding response to his or her behavior. The actual relationship is an important therapeutic agent in its own right, as well as the soil in which the seed of an interpretation may flourish; therefore, a positive actual relationship is encouraged.

To foster a therapeutic alliance, the child must first be given some understanding by the parents of why he or she is being brought to a therapist and what therapy is like. Essentially, the child can be told that, in addition to himself or herself, others such as parents or teachers are concerned about how the child is feeling and/or behaving and that the child's parents believe the child may be troubled or upset, possibly by something of which he or she is not aware.

Next, the parents may tell the child that talking with someone who understands children may help them and the child understand what may be troubling the child. The child can be told that the parents know of such a person, and the parents can describe the person, setting, and arrangements to the child. The child should then be encouraged to ask any questions, and the parents should be prepared and can be helped to answer truthfully and accurately.

The therapist can set the scene by first seeing the child in a suitable playroom and making sure that he or she knows by what name the child likes to be called (and that the child knows the therapist's name). The child will begin to feel understood and ally more with the therapy if the therapist can offer an early interpretative statement that provides the child with some insight yet does not arouse undue anxiety. In order to do this, a series of preparatory statements, including setting statements, attention statements, reductive statements, and situational statements, is useful ([Lewis, 1974](#)).

### Setting Statements

A child may first be told in language appropriate to the child's developmental level that this is a time set aside for the child so that he or she can allow himself or herself to think freely and begin to understand why he or she sometimes feels troubled. The child also should be told that sometimes the therapist will intervene, but with the understanding that it will always be in the interest of helping the child understand himself or herself better.

### Attention Statements

Next, the child's attention can be directed to the content of his or her actions or verbalizations. Sometimes attention is drawn to a coincidence that the child has perceived but has not, or professes not to have, registered; more frequently, attention is drawn to certain paradoxes. The immediate aim is to free the child to produce new material and consolidate existing gains ([Devereux, 1951](#)). In the course of the child's play, for example, the therapist may provide a verbal counterpart to the action being portrayed, affect that might be present, or conspicuous absence of certain persons, actions, or affects.

---

#### CASE ILLUSTRATION

An 8-year-old boy with a severe school phobia repeatedly enacted a war scene in which the general was attacked and almost killed. Many fantasies were contained in this play, but one prominent feature was the absence of any female, not only in this play item but also in any other play. After attention was drawn to this "fact," the child recognized his fear of attack from his mother, his wish to attack her, his resentment that his father was often attacked and offered him no protection, the displacement of his aggression toward his mother to his father, and his anxiety about even mentioning his mother.

This is different from a direct translation of possible symbolic representation in the play. The play characteristic to which attention is here drawn is in bold relief and capable of being understood by the child. This point is made to draw the distinction from more subtle paradoxes, which are not readily perceived, at least not by the younger child who is in the preoperational stage of cognitive development. In fact, attention statements can be easily understood by a preoperational child because they relate to more or less concrete perceptions within the play and require only short-term memory and limited "chunking" (defined as "aggregates of related, facts, concepts, or perceptions" [Chapter 12](#)).

---

## Reductive Statements

Certain statements reduce apparently disparate behavioral patterns to a common form that has hitherto not been noticed by the child. Thus, a child may manifest certain kinds of behavior whenever he or she is, say, angry. The child may not have been aware of this anger.

---

### CASE ILLUSTRATION

In the course of the treatment of a 10-year-old boy, it was noticed that there were recurring episodes of mocking, insulting, or denigrating behavior toward the therapist. Each of these episodes was related in time to one of the frequent trips away from home that the boy's mother would take. His resentment at being left behind, together with his anxiety at being left alone with his father, led to the behavior just described. This type of behavior could be reduced to a single behavioral reaction to underlying rage and anxiety precipitated by the temporary loss of his mother. When the child was told of this relationship, he reacted first of all by an intensification of the behavior pattern but subsequently was able to recognize for the first time his underlying feelings, when he stated, "My parents are always nice to me when we do fun things, but they don't help me with the serious things when I'm unhappy."

---

The child here was manifesting a more or less fixed defense, which, in the example given, was brought into sharper relief. A certain level (concrete operations) of cognitive development, including some capacity to take distance from and observe affects, must be available to the child for this to occur.

## Situational Statements

Situational statements naturally follow from those previously described. For example, the child now aware of his or her anger can be shown the situations that give rise to this anger and how in certain instances he or she has repeatedly brought about such situations, either in current relationships or the transference; however, the degree of directness with which such situational statements may be made varies with the emotional and cognitive levels of the child. Children who are in the Oedipal or pre-Oedipal phases and are at the preoperational stage of cognitive development probably need to have these statements made to them in the context of the play, either through dolls and puppets, or indirectly through some other hypothetical child or children. Children who are post-Oedipal and at the stage of concrete operations usually can be approached directly.

In the very young child, feelings seem to be almost exclusively experienced in response to an external event and seem to be viewed by the child as controlled by that external event (e.g., receiving a present produces a happy feeling, mother leaving gives rise to sad or angry feelings). Subsequently, feelings are more or less contained within the body but still not under the control of the child. Next, feelings come to be felt as part of one's self; that is, the child can conceptualize a feeling, first as a somewhat diffuse internal experience and then as multiple, different emotions that are more or less controlled as the self becomes more differentiated. During the preoperational stage, children find it difficult to experience two emotions simultaneously, perhaps because they are still tied to the immediate perception (e.g., a drawing of a face has either a smile or a down turned mouth) ([Nannis, 1988](#)). Very shortly, children can experience opposite feelings, but at first only sequentially (e.g., happy first, sad later) ([Harter, 1983](#)). Once the child is at the concrete operational stage, achieves the operations of conservation, de-centers, and is more or less freed from being tied to immediate perception, the child can then experience two opposite feelings simultaneously; that is, the child can begin to experience, understand, and tolerate ambivalence (i.e., being angry at someone he or she loves).

## Middle Phase

The essence of the middle phase of psychotherapy is the interpretation of the transference and "working through." Notwithstanding the difficulties of the initial phase, a child soon understands one of the goals of psychotherapy: the attempt to gain an understanding of the way he or she feels and behaves. After the initial phase of treatment, the child realizes that everything he or she says and does is subject to use by the therapist. Consequently, the child's play that follows is part of the associative process in the context of therapy. In certain respects, however, the developmental difference between the child and adult influences the form of these associations. The child is much more susceptible to current reality, which exerts a powerful influence on his or her play. The play is often goal directed and not freely associative. Again, the child has a tendency to act rather than think, giving at least the impression of an overemphasized aggressive transference ([Freud, 1965](#)). Further, in school-age children especially, the play is often characterized by organization, reflecting a developmental shift. Last, the child may become totally absorbed in his or her play and may then be unable to exercise an observing function.

At the same time, in addition to play, a child also communicates through most of the other elements that constitute "free association." That is, the child talks, pauses, shows affects, exhibits mannerisms, portrays attitudes, and moves about in space. It is this total picture, viewed as a whole over the course of several hours, which enables the therapist to discern or infer an associative thread. And it is this overall connection that often can be conveyed to the child.

### TRANSFERENCE

In the course of discerning this total picture, a true transference—that is, those previously fixed conflicts and compromise symptoms of the child that are now being experienced currently by the child in relation to the therapist ([Harley, 1967](#))—usually can be observed. Again, the developmental differences between child and adult modify, but do not eradicate, this emerging transference in three ways. First, to the extent that the child is normally dependent, the parents with whom the original conflict was concerned are still with the child and continue to exert their influence on the child. Second, the child is not an equal of the therapist; he or she is still a child relating to an adult as well as a patient relating to a therapist. Thus, besides the mutual respect that should exist between patient and therapist, the child also has certain expectations of the adult, such as appropriate birthday and holiday greetings and gifts ([Temeles, 1967](#)). Third, the continuing development of the child continues to modify the transference, especially during shifts from the Oedipal to post-Oedipal and eventually adolescent stages. In addition, fixations that occurred earlier may be modified with the increased range, flexibility, and shifts of defenses that occur with the development of the child.

For all these reasons, the transference in child psychotherapy is usually not freestanding and is more often unstable than the transference in the therapy of an adult. Nevertheless, to the extent that there is transference, however modified, it is available for interpretation. The more common situation in work with children is one in which a relatively simple current displacement from parent to therapist is recognized and interpreted. Even within such apparently simple displacements, however, elements of transference can be found, and they throw light on the child's current behavior when interpreted.

### RECONSTRUCTION

Linking the complexities of the child's current behavior with his or her earlier fantasies may be helpful to the child. This earlier material may be derived from the personal myth of the child or may be hypothesized from reconstruction. The striking aspect of a reconstruction is that it helps the child "make sense" out of what was previously discomfiting and/or perplexing. Further, it occasionally helps a child by confirming what was probably an essentially correct perception by the child at the time, but which has since undergone distortion. The conceptual abilities of the child are such that the child often attributes affects the child thinks he or she perceives in the parents as resulting from thoughts or wishes of his or her own. Further, the child frequently projects his or her own fantasies and affects onto the parents and subsequently acts against the parents, whom the child now regards as, say, dangerous or angry. At the same time, reconstructions are sometimes barely tolerated by the child when the child is still close to the reconstructed period. The preoperational child too may have particular difficulty in distinguishing fantasies from reality ([Piaget, 1929](#)). On the other hand, the child who is at the stage of concrete operations may have particularly strong defenses—specifically, various reaction formations, such as guilt against aggressive impulses, shame about exhibitionistic urges, and disgust when regressive impulses become threatening—and may accordingly develop a resistance to any exploration of anxiety-arousing impulses.

### PROCESS OF INTERPRETATION

Some further general points on the process of making an interpretation may now be considered. [Loewenstein \(1951\)](#), whose account would have been more complete had he placed greater emphasis on the interpretation of unconscious, or at least preconscious, material, described the following steps:

1. Show the patient that certain common elements exist in a series of events.
2. Point out the similar behavior of the patient in each of these situations.
3. Demonstrate that such behavior was manifested in circumstances that all involved, for example, competitive elements, and where rivalry might have been expected.
4. Point out that, for example, rivalry does exist unconsciously but is replaced by another kind of behavior, such as avoiding competition.

5. Show that this behavior originates in certain critical events of the patient's life and encompasses reactions and tendencies that can be grouped together.

In the stages just outlined, the interpretation of mechanism, as opposed to that of content or affect, is significant. Further, it also can be seen that there is a gradual transition from preparatory intervention, through confrontation, to an interpretation containing a genetic component. Ferenczi once described his own experiences as he proceeded in the steps just outlined:

One allows oneself to be influenced by the free associations of the patient; simultaneously one permits one's own imagination to play on these associations; intermittently one compares new connections that appear with previous products . . . without, for a moment, losing sight of, regard for, and criticism of one's own biases (quoted in [Kris, 1951](#), pp. 15–30).

Essentially, one might speak of an interactive process in the therapist involving empathy, self-observation, and clinical judgment.

The description given by [Erikson \(1940\)](#) is remarkably similar. Speculations are first derived from the observer's impressions, associations, and recollections; for example, "It was as if . . ." The observer also associates past impressions in the same child, from other children, or from data derived from the parents. The therapist reflects on the latent possibilities that the associations may possibly correspond to a genetic or associative connection in the child's mind and pictures what the child is doing under the observer's eyes and what the child is said to have done in other situations. This all leads up to the interpretation. Erikson then describes three steps in making the interpretation. First, there are observations, feelings, and reflections that lead to interpretational hints. For example, a symbolic equation or metaphor may make it possible to recognize a play act as alluding to and standing for an otherwise manifestly avoided item (a person, object, or idea), or a play arrangement may prove to represent a special effort on the part of the child to rearrange in effigy his or her psychological position in an experienced or expected danger situation. Such an arrangement usually corresponds to the child's defense mechanisms. Second, these hints are then subject to further observations and reflections and emerge as a conviction in the observer's mind in the form of the reconstruction of a genetic sequence or of a dynamic configuration pertaining to the patient's inner or outer history. Finally, the therapist may proceed to convey part of these reconstructions to the child whenever the therapist feels the time has come to do so. Erikson considers the last step to be the therapeutic interpretation.

The significant point here is the step-by-step progression in working with children implied in Erikson's statement that, "the observer may proceed to convey parts of these reconstructions to the child whenever he feels the time has come to do so" ([Erikson, 1940](#), pp. 557–671). However, it is important to keep the developmental level of the child in mind here, because massive interpretations given to a young child are more likely to be heard as interfering noises than helpful statements, with a consequent heightening of resistance and play disruption or, worse, a play inhibition.

In short, the therapist, while still engaging with the child, takes mental distance from the immediate transaction and tries to place the immediate observations into the context of what has previously taken place. The therapist can do this by a kind of mental "playback." Material from previous sessions is not only "played back" mentally, but also is translated to a higher level of abstraction, which enables the therapist to formulate to himself or herself "what is going on" as a basis for formulating an interpretation. The therapist then mentally translates this back to the level of the child and the immediate situation and makes his or her interpretation at that level.

#### GENERAL GUIDELINES FOR INTERPRETATION

##### *Multiple Appeal*

As a general rule, interpretations are probably more effective when they have "multiple appeal" ([Hartmann, 1951](#)). The therapist also decides clinically when to interpret the past, current reality, the transference, or all three.

##### *Sequence*

A number of other guidelines for the order of interpretation have been suggested. Resistances or defenses should be interpreted before the instinctual derivatives ([Loewenstein, 1951](#)). One should defer interpreting a symptom representing an important unconscious conflict until a strong therapeutic alliance has been established. One should also start with interpretation of still-mobile defense traits in preference to rigid, characterological defenses. In spite of these guidelines, individual situations may be handled in several different ways, depending on the developmental level of the child and stage of therapy. Take, for example, the following situation: An 8-year-old boy wanted to take along some tracing paper belonging to his therapist on the eve of his going on a car trip with his mother and father, the anticipation of which had already aroused considerable anxiety.

What were the possibilities here for interpretation?

1. The therapist could simply have confronted the child with his wish to take something along. At the particular stage in the therapy of this child, however, this would have been redundant, although it might have been useful as a building block, or an "attention statement" for future use.
2. The therapist could have shown the child how anxious he was about the trip with his parents, but doing so might have forced the child to face his anxiety too abruptly, with insufficient time for "working through" (see the following), and without the therapist's ongoing support.
3. The therapist might conceivably have tried to link this wish with the boy's reactions in other similar situations in which he had become anxious, but this could not be done without the previous steps.
4. The therapist also might have interpreted the patient's wishes toward the therapist for protection, but in this patient such a move might have left the patient feeling exposed and defenseless.
5. The therapist might have made the connection for the child between this coming event and earlier events in his life, but this intervention might have had little use for this particular patient, because he did not yet have a clear idea of his feelings about the coming event.
6. It might then be asked whether anything should be said at all. Something should be said, but something that will temporarily buttress the child and offer support, at the same time that both the defense and fear are being interpreted. For example, the therapist could say to the child, "How nice it will be to have something to take along, especially if you are worried about the trip." There would be no need to interpret the positive transference aspect at this point, because the movement is in a forward direction. The therapist might also decide to include an aspect of the transference, but in a supportive way. The therapist might say, for example, "I think you would like to have something of mine with you on this trip." He might then allow the child to keep the paper and reserve for a later date any further exploration of the act: "Why don't you take the paper with you? When you come back we can talk again about how you feel when you have to take a trip with your mother and father."

These examples are not meant to be recommendations of specific things to say but rather illustrations of underlying principles. The choice of level and wording depends on such factors as the diagnosis, stage of therapy, and developmental level of the child. A 6-year-old child at the beginning of psychotherapy might experience his or her anxiety on the eve of such a trip as ego-syntonic and fail to understand an interpretation of the anxiety. On the other hand, a 10-year-old who is more advanced in therapy might well experience such anxiety as inappropriate and ego-alien and might find such an interpretation useful.

##### *Timing*

An interpretation is probably well timed when the therapist thinks that the statement at that moment will help to consolidate existing gains and elicit new material ([Devereux, 1951](#)). Devereux described an interpretation as being "timely" when it is capable of being utilized by the patient, and this in turn can occur only if the patient understands it.

##### *Focus of Interpretation*

When should an interpretation be made in the play, and when should it be taken out of the play? When attention statements are made, the interpretations are clearly made "in the play." Reductive statements imply that the child is receptive to statements about himself or herself; that is, "out of the play," whereas transference interpretations in their most effective form are made quite distinctly "out of the play," given the earlier steps of preparation. (The use of play in psychotherapy with children is described extensively in [Chapter 18](#) and elsewhere) ([Beiser, 1979](#); [Buxbaum, 1954](#); [Haworth, 1964](#); [McDermott and Harrison, 1977](#); [Winnicott, 1971](#)).

##### *Tact*

Tact is required when significant developmental differences are considered. A young child may have great difficulty in tolerating ambivalence and may find it especially difficult to accept a hostile or aggressive wish or fantasy. This reluctance may be overcome by placing within a fuller context the anger, say, that is to be interpreted. For example, one might more tactfully say to a child, "It is very hard to be angry at someone you love."

[Glover \(1930\)](#) tried to be more specific with regard to tact, stating that the interpretation should be delivered as a plain statement in terms devoid of active emotional stress, to prevent an immediate, overwhelming conscious conviction on the patient's part that his or her therapist was in a state of countertransference. Glover also cautioned about the use of wit, the exploitation of the comic, and the shelter provided by technical expressions. It is usually preferable to refer to the child's parents as "mother" or "father." Only with a very young child would one use such terms as "mommy" and "daddy," and then only because they are developmentally appropriate.

#### *Wording*

Wording should be specific and concrete; the interpretation also should be worded to fit the individual situation. Again, the therapist is cautioned to avoid using the same defense mechanism the patient uses; for example, laughing things off and minimizing them. Interpretations appear to gain when they contain an element of time; for example, "now," "before," "at the age of," and "after this happened."

Wording is particularly critical with young children, not only from the point of view of the level of cognitive development but also what the child can accept in his or her dependent position with respect to the parents, and the child's own struggle against regressive pulls or progressive pushes. The child attaches greater meaning to certain words than does the adult; it is necessary for the therapist to understand these special meanings.

#### *Inexact and Incomplete Interpretation*

[Glover \(1930\)](#) distinguished between inexact and incomplete interpretations in psychoanalysis. An incomplete interpretation was termed by Glover a "preliminary interpretation." For example, one would interpret a so-called genital fantasy before an anal fantasy. He contrasted this with an inexact interpretation, when one might never interpret the anal fantasy at all. That is to say, if the interpretation of the genital fantasy was regarded as the complete interpretation, then the interpretation was *ipso facto* inexact.

An interpretation is never complete until the immediate defensive reactions following on the interpretations are subjected to investigation. The complete interpretation is really the complete treatment: "Every construction is an incomplete one. . . . As a rule he (the patient) will not give his assent until he has learnt the whole truth—which often covers a very great deal of ground" ([Freud, 1937/1964](#), pp. 257–269).

#### *COUNTERTRANSFERENCE*

In work with children, the therapist is particularly prone to countertransference phenomena. For example, there is a much greater "regressive pull" ([Bornstein, 1948](#)). The therapist must learn to recognize the feelings aroused in himself or herself so that he or she can deal with the child in a helpful way. One's own feelings are a vital instrument for understanding the child. At the same time, if the therapist is not aware of, or not clear about, the nature of his or her aroused feelings and their sources (both external and internal), he or she may be hampered in working effectively with the child. Indications that countertransference feelings may be at work include the following:

1. The therapist may fail to recognize where a child is in his or her development. Expectations then are not commensurate with the child's maturational and developmental capacities. The therapist may then experience unrealistic goals, alternating with despair.
2. The regressive pull experienced by the therapist playing and working with a child may give rise to the temptation to identify, compete, and/or act out with the child, or infantilization of the child may occur.
3. A misreading of the child's relationship to the therapist may occur, in which the relationship is seen as realistic when in fact it may be a transference from the child's feelings toward his or her parents. Therapists are usually well aware of a child's aggressive feelings but may be less aware of a child's seductiveness toward an adult (parent).
4. Remnants of the therapist's own childhood relations with his or her brothers and sisters may be an important source of the therapist's ambivalence to the child. For example, excessive concern—or lack of concern—for a child's climbing on a chair or approaching a tall column of heavy building blocks may mask an underlying wish that the child will hurt himself or herself and may be associated with guilt feelings when the child does stumble or fall. Such a feeling of guilt may come about because of the partial unsuspected fulfillment of an unacceptable wish.
5. The stirring up of old conflicts within the therapist, when exposed to certain behavior in the child, may cause anxiety in the therapist. For example, uncontrolled aggression, sex play, or masturbation may be upsetting to the therapist.
6. Sometimes the therapist may transfer old feelings from his or her own childhood onto the parents of the child. The therapist may then overidentify with the child in his or her struggle with his or her parents. Rescue fantasies may then occur. Conversely, the therapist may erroneously identify with the parents (perhaps through an identification with the aggressor mechanism) and consequently exercise unnecessary, even punitive, controls against the child who is acting too aggressively or sexually for the therapist's comfort.
7. Sometimes the therapist simply cannot understand the meaning of certain behavior in a child. Of course, there are times when all of us find some item or other of behavior inexplicable. However, the persistent drawing of a blank in understanding a repeated item of behavior should lead to the suspicion of an interference by one's own conflicts—an emotional blind spot, so to speak.
8. A therapist may find himself or herself feeling depressed or uneasy during his or her work with children. Assuming the therapist is not suffering from a true depression, the possibility exists that emotions from old conflicts have been aroused and are interfering with the therapist's functioning. Occasionally, a therapist may find himself or herself aroused and experiencing great affection for a child. This too may interfere with his or her work with the child.
9. Countertransference may be at work when the therapist permits, or even encourages, acting out in the child; for example, a therapist may suggest to a child that he or she must stand up for himself or herself and hit back. On occasion, a therapist may even feel the impulse to act out with a child.
10. A therapist may need and solicit the admiration obtained by having the child like him or her. This too may represent a deeper, unconscious need of the therapist and may not be in the best interest of the child.
11. Conversely, repeated arguing with a child may suggest that the therapist has not only become involved but also enmeshed with the child.
12. Recurring countertransference problems commonly arise in relation to specific characteristics of a child. For example, a retarded child may evoke guilt and defenses against such guilt within the therapist, or omnipotent rescue fantasies, both of which may then be acted out. Passive, hostile children may arouse anger in a therapist. Aggressive children may evoke counteraggression. Sexually attractive children and adolescents of the same or opposite sex as the therapist may threaten the therapist, leading to either vicarious and "excessive" exploitation of sexual issues or denial and avoidance.

#### *WORKING THROUGH*

It is clear that working through is necessary to sustain any therapeutic effect ([Greenacre, 1956](#)). The defensive conflicts remain somewhat structured unless they are dealt with repetitively in relation to various behaviors, events, and feelings. Historically, working through was first emphasized from the point of view of being of educative value and compared with mourning and the progressive detachment of the individual libido from the organized tensions and aims that permeated the later life. This view is insufficient.

Another concept—the corrective emotional experience—is really an aspect of working through, at least in its more modern construction. Originally, the idea involved replenishment of earlier deficiencies through the current relationship. This appealing idea unfortunately proved to be too simplistic. Among other things, it failed to take into account the power of the unconscious repetition compulsion. The concept has some merit, however, if it is modified to provide the child in the here-and-now with a reaction different from his or her previous experiences, a reaction that is now more appropriate and does not perpetuate the malignant interactions to which he or she has become accustomed. This update of the concept of course is consonant with the concept of working through. Finally, with the rise of ego psychology, the recognition of the need for consistent work with the patterns of defense and the affects related to them once more becomes paramount ([Bornstein, 1948](#)).

From a developmental point of view, working through with children poses a special problem. The chief difficulty lies in the fact that the live parents are usually present and may continue to exert a reinforcing influence on the child's original conflicts. Sometimes this interference can be alleviated by concomitant work with the parents, through some form of psychotherapy or regular meetings between the parents and the child's therapist. Occasionally, it becomes clear that the child cannot work through a conflict while in the home, and an alternative plan may become necessary, such as boarding school in the case of an older child. Now and then the difficulty is insuperable at the time, and the therapy must be interrupted until the child is in a more advantageous situation for therapy. Occasionally, it is possible to hold the

child in therapy until such a situation occurs. In some instances the child can be helped to understand the repetitive and reinforcing behavior of the parents and his or her involvement in precipitating or responding to their behavior. If the influence of the parents is not too strong, the child can be helped to modify his or her own behavior in this regard, to interrupt the vicious cycle.

### Termination Phase

The criteria for termination ideally include some actual achievement (as opposed to a "flight into health") ( [Train, 1953](#)) of the goals of therapy: reduced anxiety, improved self-esteem, increased frustration tolerance, disappearance of symptoms, better coping strategies, relative independence, good relationships with peers and adults, satisfying schoolwork, feelings of pleasure and joy, and a sense of resumed developmental progress.

In almost every instance, these achievements are judged clinically rather than measured scientifically. Clinically, there is no such thing as a perfect therapy (or for that matter, a perfect patient or therapist). Every therapy eventually stops, and when it does the child should be more or less along the road toward these laudable goals. A child may even have gained a better understanding of himself or herself and may no longer need to act out so many infantile longings, frustrations, and feelings, and may have learned instead more adaptive ways to love and be loved, for example. However, in some cases, the therapy simply stops because there is a sense of diminishing returns, the resistances are too great, the treatment is inappropriate, or for various other reasons the treatment is a failure. In one survey of terminated analytic cases ( $N = 49$ ), only 14% terminated by mutual agreement among parent, therapist, and child ( [Freud, 1971](#)).

The actual phase of termination is a useful period to explore issues of separation, reactions to loss, dependency versus independence, and anxiety about progressive developmental movements. Some children undergo a temporary regression, manifested by a reappearance of their presenting symptoms, in the face of leaving the therapist and returning, as it were, to the family. Others are able to "reconstruct" and recall the beginning of their treatment rather than reenact it through regressive behavior. A reasonable period of time is required to deal with these issues depending on the frequency, duration, and intensity of the psychotherapy. Thus, when the question of whether to terminate has been decided, preferably by mutual agreement, a termination date is set that will allow a suitable amount of time for the termination phase. This period may vary from 6 weeks to 3 months or so.

Follow-up communication is often helpful in consolidating the work of the termination phase.

## THERAPEUTIC ACTION AND THEORY

Many attempts have been made to describe the therapeutic effects of interpretation in terms of the insight achieved ( [Rothstein, 1989](#)). However, children (and adults) may achieve insight yet fail to improve emotionally or behaviorally. Further, some children (and adults) may show remarkable improvement without any evidence of insight at all. This latter phenomenon suggests that other therapeutic modes may be at work, including the beneficial effects of a loving, compassionate, respectful, and dedicated relationship, the child's feeling of being understood, and the enlightening feeling that may result from new, positive life experiences.

The particular type of interpretation that will produce a so-called therapeutic insight, that is, a structural change has been given different names, as has the actual therapeutic insight. For example, "transference" ( [Fenichel, 1945](#)) or "mutative" ( [Strachey, 1934](#)) interpretations may produce "emotional," "psychological," "immediately demonstrative" ( [Richfield, 1954](#)), or "dynamic" insights as opposed to "intellectual," "descriptive," or "neutral" ( [Reid, 1952](#)) insights. The significant point presumably is that shifts from unconscious to conscious awareness are thought to occur only after derivatives of the original feeling are recognized with an experiential sense of conviction and worked through. [Bergler \(1945\)](#) considered that the whole process of working through is centered chiefly in the correct handling and mobilization of the feeling of guilt. [Devereux \(1951\)](#) felt that an interpretation (which consists of supplying an unconscious closure element) is effective when practically all conscious and preconscious material pertaining to the neurotic gestalt has been produced. [Loewenstein \(1951\)](#) believed that the therapeutic effect is owing to a psychic process in which each of the following parts has its respective place: (a) overcoming of resistances; (b) working through; (c) remembering and reliving of repressed material; and (d) effect of the reconstruction.

Anticipated changes resulting from psychotherapy are also to some extent a function of normal development. Therefore, all of the factors that facilitate normal development also will facilitate the desired changes in psychotherapy.

The experience with the psychotherapist not only is a corrective one but also represents an oasis phenomenon for the child, who now finds himself or herself, at least temporarily, in a relatively protected, facilitating environment that enables development to proceed by reducing the impact of trauma and the acting-out tendencies in the child. Another way of putting this is to say that the child in psychotherapy finds himself or herself, at least momentarily, at a distance from the acute upset of the current developmental turmoil, whether it be a too exciting, sexualized relationship with a parent, a sadomasochistic relationship with a parent, a grief reaction at the birth of a sibling, or frightening fantasies of bodily harm.

The child is also afforded an opportunity for confirmation of his or her essentially correct perception of his or her parents, leading to a strengthening of reality testing and an increase in self-esteem. The play of the child, as well as the use of words, inasmuch as they represent an intermediate stage between action and thought, provides a handle by which the child grasps affects and is enabled to delay. Most important, the play itself undergoes a development that carries with it a significant shift from primary process to secondary process.
