The physician is obliged to tell the parents what to expect as the illness progresses. This information need not be given in full in the first interview; rather, it should be given in stages over an extended period. The goal is to give the parents information that will enable them to anticipate the child's needs at each stage. The parents usually will indicate by their questions what they need to know.

Regular contact with the parents should then be planned. The contact should take the form not of comments made in passing but of time set aside to talk, review, and listen in the privacy of an office. The physician should resist the natural impulse to avoid the parents or avoid the subject. To do this, the physician must recognize any impotence and anger he or she may feel in the face of death. The parents will come to trust the physician and feel safe expressing, if they so wish, some of their less acceptable feelings if they are sure that the physician is available and ready to listen. During these planned interviews, the physician can discuss with the parents their child's behavior, their management of the child, what to tell the child's siblings, and whether and in what way the parents would like their minister, priest, or rabbi involved. The parents should be reassured about their own handling of the situation, and the physician should feel free to share admiration for how well they are meeting the child's needs.

The physician may be asked for advice about religious rites for the sick. The practice of offering prayer with the child or administering the Sacrament of the Sick, although intended to comfort, may be anxiety arousing. Although it sometimes happens that the Sacrament of the Sick is given without the parents' consent, or even knowledge, most priests prefer to involve the parents and family first, and to have the family present in the room. However, administering the Sacrament of the Sick may cause as much upset in the family as in the child. The 1972 modification of the Sacrament of the Sick (["Ordo Unctionis," 1972](#)) does not alter very much the way in which the child might experience the ritual. Indeed, there are no specific modifications for children other than those based on the judgment of the particular priest. The physician should discuss with the parents and the priest the child's needs and how the child might experience the praying or the Sacrament before any step is undertaken.

## Talking with the Child

In regard to talking about death with the sick child, especially the young sick child, the parents' feelings and wishes must be respected. Some parents, for example, do not wish the child to be told that he or she is going to die, whereas others do. Some families need to use denial as a protective device.

There is no simple answer to the question of whether the particular child should be told. One useful approach is to discuss with the parents how they think they would respond if their dying child asked them whether he or she was going to die. There are several stages of response to such a question that might be suggested.

First, the child's reason for asking the question must be clarified. The child may be responding to the parents' or the hospital staff's anxious behavior, or the child may be concerned about such things as pain, mutilation, loneliness, and the needs of others. The child then can be given repeated opportunities to talk about what he or she is worried about.

Second, if the parents decide that they want the child to know that his or her illness is fatal, the process of telling the child about the illness and impending death should have the characteristics of a dialogue rather than of an announcement. Some children simply cannot understand and do not want to hear the truth; they should not be told. Others have to arrive slowly at the realization of the significance of their illness; it is too much for them to understand and grasp at one time.

Third, the child must be given hope. Even when the child is told that the illness is one that causes death, the child can and should be told that the physicians will do everything they can to fight the illness.

The adults must agree not only on how the child should be told but on *who* should be the first to tell him or her. Sometimes the physician is not the right person to disclose this information. A parent or a member of the clergy who is close to the child may have a more sensitive understanding of the child's needs.

A discussion of this kind with parents often helps them to express some of their own concerns. It also promotes in them a feeling of trust and of being understood, as well as a feeling that they have some control over the care of their child. Nothing is so painful to the parents as their feeling of helplessness as their child's life ebbs.

Most important, the physician who has had a dialogue with the parents is prepared to have a dialogue with the child, always keeping in close touch with the parents. The physician, for example, can convey assurance while imparting to the child as much of the truth as the parents want and the child seems ready to know. There is no blueprint answer.

The ward staff members should be clear about who has the primary responsibility for talking with the parents and child about the seriousness of the illness. If it has been agreed on by the parents that the physician should talk with the child, the physician should first establish a relationship of trust with the child. Before the physician talks with the child, he or she should make sure that someone is available to be with the child after the physician has left the room, if the child so desires. The involved staff members should be informed about how much the child knows about the illness so that the child does not receive conflicting and therefore puzzling information. Ward staff members also experience anxiety when in the presence of a dying child or such a child's family. Their natural inclination to avoid these feelings may cause them to stay away from both the child and the grieving family. Such inclinations may be better controlled if the ward staff members have the opportunity to explore and share their feelings in meetings ([Berman and Villarreal, 1983](#); [Lewis, 1962](#)).

## Specific Management of the Child Who Is Dying

[Kübler-Ross \(1972\)](#) gives a beautiful description of a dying boy's expression of his thoughts and feelings:

[The dying] boy tried to paint what he felt like. He drew a huge tank and in front of the barrel was a tiny little figure with a stop sign in his hand. This to me represents the fear of death, the fear of the catastrophic, destructive force that comes upon you and you cannot do anything about it. If you can respond to him by saying it must be terrible to feel so tiny and this thing is so big, he may be able to verbally express a sense of smallness or impotence or rage. The next picture he drew was a beautiful bird flying up in the sky. A little bit of its upper wing was painted gold. When he was asked what this was, the boy said it was the peace bird flying up into the sky with a little bit of sunshine on its wing. It was the last picture he painted before he died. I think these are picture expressions of a stage of anger and the final stage of acceptance.

This description underscores the importance of one aspect of the care of the dying child: With the parents' permission and in the privacy of his or her own room, the young child should be given the opportunity on different occasions to express his or her concerns through drawings or through play with toys and dolls ([Fig. 104.1](#) and [Fig. 104.2](#)).

**Figure 104.1.** Self-portraits done by a 4-year-old girl hospitalized with osteosarcoma. **A:** Self-portrait drawn within the first week of diagnosis. The body is intact; it is a very positive body image (i.e., profuse facial and body details, including eyelashes and hair). **B:** This portrait was drawn approximately 1 month after diagnosis. The patient was still hospitalized. Note the disintegration: The body is no longer intact, and the Broviac is highlighted, as is her stomach (she was experiencing nausea, and her Broviac became a prominent part of her experience of her body). **C:** This last drawing was done a week before death. Note the tumor looming largely in the picture. She died 3 months after diagnosis.

**Figure 104.2.** Self-portrait drawn by a school-age hospitalized patient dying of acquired immunodeficiency syndrome. The drawing expresses the child's sadness, isolation, and fears of death associated with this illness. The picture was drawn in black, and noteworthy are the major objects that appear to be floating in space with no roots, no foundation, and no sense of security. The house without a door offers no entrance or exit, implying perhaps little family support and isolation. The child is flying to heaven. He stated, "This is me flying to home in heaven in the sky."

If needed, and if the parents agree, the collaboration of a child psychiatrist here can be very helpful. The opportunity for expressive play may enable the child to exercise some control over his or her anxiety. If the child expresses concern about such problems as pain, loneliness, and fear through this play, this fact should be noted mentally by the pediatrician or child psychiatrist. At another time, the child could be reassured, without reference to the play session, that the physicians will make sure that he or she does not have pain, that there will always be someone available to help him or her, and that everything will be done to help him or her feel better.

Patients—adults and children alike—feel threatened by the passivity imposed on them by illness. Every effort must be made to give the child a feeling of active participation in treatment. The child should be informed at each stage what is being done, why it is being done, and what he or she can expect. Some feeling of hope needs to be provided. Last, the dignity of the child requires protection, and the child's privacy should be ensured.

Denial of death in a child, as in an adult, is a defense against anxiety, and it should be respected. Each person must be allowed his or her own way of dealing with the dread of death. At the same time, certain distortions should be corrected. For example, the child may require reassurance that the illness was not brought about by anything the child did (or thinks he or she did). Reactions that generate further anxiety, such as regression, should be gently but firmly controlled by the parents as well as by the hospital staff; excessive regressive behavior is uncomfortable for a child as well as for those caring for him or her.

Children vary in their capacity to deal with the inevitability of their impending death or with the diagnosis that implies impending death ( [Greenham and Lohmann, 1982](#)). Some children, particularly older children, want to know, whereas others do not want to know or cannot comprehend. In some cases, older children and adolescents possess the cognitive and emotional maturity to render them competent to take part in even the most difficult decisions in their medical care, including the decision to forego life-sustaining treatment for terminal illness ( [Leikin, 1989](#)).

### The Moribund Child

In a situation in which a child has no brain activity and is being kept "alive" by artificial methods, and there is no hope of spontaneous respiration or recovery of brain function, the physician must proceed with tact. First, before any decision is made to stop artificial life supports, the parents must be fully informed and prepared. The physician first might tell them that the child is being sustained by machines but that there is no possibility that the child will breathe on his or her own or will recover brain function; that is, the child in essence is dead. The physician should explain why this is so. In some instances, the parents have already considered the issue and will have decided to discontinue artificial life supports. Such parents also may have decided whether they want to be in the room at the time of death. Other parents may experience great anguish at the burden of deciding when to discontinue artificial respiration and also may prefer not to know exactly when it will be stopped. In a tactful way, the physician can say to such parents that there is nothing more that can be done. Then, when the parents do decide to discontinue artificial respiration, the physician should ask the parents where they want to be when it is discontinued.

The parents' wishes must be respected at all times; the child is theirs. The parents should not be rushed. It usually is their decision to make, and they need all the help they can get.

It is essential also that the parents feel a sense of unanimity with and security in the entire ward staff. Therefore, before the plan is carried out, the staff physician should discuss with all the ward staff members the steps just outlined and encourage them to express their thoughts and feelings. Parents tend to seek different answers from different staff members, and it is essential that all the staff members be aware of the way in which an individual case is being handled so that their responses do not conflict.

If the child dies suddenly without the parents being present, the parents should be informed of the death immediately, no matter what the time of day. The parents' sense of guilt at not being present when their child dies is an enormous one.

### Management of Parents During Prolonged Illness in the Child

The many different reactions that parents may have when the period of dying is one of prolonged suffering necessitate sensitive management. Some parents may request other opinions regarding prognosis or treatment. Often, they should be given this opportunity. Sometimes, however, a futile search for a magical cure may devastate a family emotionally and financially. The physician then should gently attempt to steer the parents toward a more realistic and helpful way of coping with their feelings of impotence. The physician can help parents by giving them opportunities to talk about their feelings in an accepting, nonjudgmental way. For example, parents often feel relieved when the physician reassures them that they are doing everything they can and that the physician knows how hard it is for them. The physician also can say, "Many parents have told me how at times they had wished it would all finally end, and then felt bad about thinking that. But it's a natural thought to occur. We all have many kinds of thoughts. What is important is that you have done everything that could possibly be done."

Questions may arise about child-rearing during the long period of time during which remissions occur and treatment is administered. Although the child's condition is far from normal, there often is a wish on the part of the child to feel normal. Perhaps this represents in part the child's wish that he or she no longer had the disease, that there was no longer a need for painful treatments, and that he or she could talk freely with others about feelings of frustration, anger, and resentment.

At the same time, parents may be in a quandary about how to rear the child, siblings about how to relate to the child and deal with their guilt, and teachers about how to educate and deal with the child and the other children in the classroom. Once again, there is no blueprint answer; indeed, blanket recommendations (e.g., "Treat the child normally") may only burden the parents with more conflicts and guilt. Each situation must be thought out and managed individually, taking into account the many needs of the child, the parents, and the siblings.

### Management of Siblings

Good medical management takes into account how the child's dying and death affect the child's siblings. Siblings of all ages need support and explanations, and the physician can help the parents provide them. The physician may suggest that the parents gather the family together and then give a simple explanation to all the children. The explanation should include the facts that Johnny is very ill, that everyone is doing his or her best to make the child as comfortable as possible, that the illness Johnny has could not be prevented, that it is no one's fault, and that it is necessary to figure out together how everyone can help. Later, individual children in the family may be given more information as they give evidence that they require it. If the siblings are told that death is near, they also will need help on how to conduct themselves in the presence of the dying child. The dying child needs their support, and they can give it by doing such things as making drawings for the child, bringing messages from others, and getting things he or she may need. If the dying child asks them whether he or she is going to die, they can say, "I don't know. I know it's a serious illness. Would you like me to ask Mommy and Daddy, or do you want to ask them yourself?"

When the child dies, to avoid hurt feelings, all the siblings should be told of the death at the same time if possible. A simple account of the death can be given if the children ask about it. It is better to avoid such statements as "He died in his sleep," especially when young children are present, because of the danger of engendering in them a fear of sleep.

A visit to the home by the physician is nearly always deeply appreciated by the parents and siblings of the dead child. If the physician has had a long-standing relationship with the family, he or she should ask about the funeral or memorial service and should attend the service. A physician who has provided extended care for a dying child may be remembered only for failing to attend the funeral service or convey his or her condolences.

Sometimes parents will ask whether a young sibling should attend the funeral. The physician first should decide whether the parents will probably be in control of themselves and who else will be present at the funeral who could support the child. For children younger than 5 years of age, the funeral can be a puzzling experience unless it is explained and unless a great deal of support is given by a familiar and caring adult. Attendance also depends on cultural practices. Children older than 5 years often can use the funeral rite in the same way adults do, especially if they have adults in attendance who also can explain to them their feelings and describe what is taking place. A child who does not wish to attend the funeral should not be made to feel guilty. Rather, arrangements should be made for the child to be in the company of an understanding adult during the time of the funeral. Older children should be encouraged to attend the rites and observe the rituals the adults are attending and observing because, again, these practices usually help the person to deal with the reality of death. If the older child chooses not to attend the funeral, the reason for the choice should be explored, but if the child continues to feel that he or she does not want to attend, this wish should be respected. Each person mourns in his or her own way. In no circumstance should the subject of the dead person be closed off. A wall of silence hampers the child as he or she struggles with the reality of the death and his or her feelings about death. Some of the specific ways of helping children understand the many facets of death have been described by [Wolf \(1958\)](#).

Other questions involving siblings may arise later. A younger sibling may ask to have some of the dead child's toys. The transfer can be done in a helpful way by suggesting that the dead child would have wanted his or her younger brother or sister to have his or her toys. Other decisions, such as rearranging the dead child's room or giving a sibling the dead child's room, might be deferred until most of the work of mourning has been done. Such decisions probably can be made on a rational basis then, when the mourners are less affected by their emotions.

### Requesting Autopsy Permission or Organ Donation

A difficult task for the physician is requesting autopsy permission or organ donation. Because of the difficulties, the request frequently is made in a hasty, tactless manner. The physician must be aware that many families have strong feelings against such procedures. For example, Orthodox Judaism prohibits the permanent removal of organs. Despite the physician's medical curiosity and zeal to learn, he or she must resist pressuring a family into agreeing to a procedure to which it objects. On the other hand, the physician may legitimately describe an autopsy to the parents as a postmortem internal examination that determines the cause of death and the effects of the treatment given. He or she can honestly present to them the potential benefits of an autopsy or organ donation to others. If parents ask whether the child will be cut open, the physician must answer honestly, even if the physician knows that the autopsy or donation request may then be refused. Families who refuse to agree to such procedures should not be made to feel guilty about their refusal.

## WHEN A PARENT DIES

### The Children

When a parent dies, the physician should help the surviving parent anticipate the reactions to be expected from the children. Children, particularly young children, are unable to tolerate—and therefore complete—the painful task of mourning the death of a parent. Sad feelings often are curtailed, and often the child quickly returns to everyday activities as if nothing had changed. Although the immediate manifestations of mourning in extremely young children usually are brief, it is difficult to assess the impact of a parent's death on the child's future personality development. Occasionally, a child may express hostile feelings toward the surviving parent. The child actually may be angry at and feel abandoned by the parent who died. Because such feelings usually are experienced as unacceptable, the child displaces them onto the surviving parent. The expression of hostile feelings toward the surviving parent unfortunately invites punishment when it is misunderstood. Frequently, a child, by virtue of his or her still somewhat primitive way of viewing the world, is convinced that he or she caused the parent's death, either by not being a good child or by having at one time or another wished the parent dead. When the child provokes the surviving parent, he or she may in part be seeking punishment to assuage feelings of guilt. Therefore, it is necessary to prepare a parent for these reactions as well as to attempt to correct the child's fantasies. Some families will benefit from participation in support groups for grieving children or families; recommendations for written resources for further information often are appreciated ([Emswiler and Emswiler, 2000](#)).

The child who has lost a parent is a child at psychiatric risk. After a review of the literature on bereavement in childhood, the Institute of Medicine ([Osterweis et al., 1984](#)) summarized the factors that are associated with an increased risk of psychological morbidity for children after the death of a parent or sibling:

1. Loss in a child younger than 5 years of age or during early adolescence
2. Loss of a mother for girls younger than 11 years of age and loss of a father for adolescent boys
3. Premorbid psychological difficulties in the child or lack of prior knowledge about death
4. When the relationship with the deceased had been conflictual or when the parent remarries and there is a poor relationship between the child and the stepparent
5. When the surviving parent is psychologically vulnerable and excessively dependent on the child, or the environment is unstable and inconsistent
6. When there is a lack of adequate family or community supports, or when the surviving parent is unable to access available supports
7. When the death was unanticipated or the result of suicide or homicide

Impairments in the child's capacity to form new, lasting relationships may show up later. Shame at being different may be experienced. Impaired sexual identity and conscience formation also may occur ([Bonnard, 1962](#); [Neubauer, 1960](#)). In addition, the loss of a parent during childhood may predispose a child to attempt suicide during adolescence.

The family disruption and the reactions of the surviving parent may lead to a depression in the child. The presenting symptom may be a school learning problem or a behavior difficulty. Another hazard that sometimes occurs is a morbid attachment of the surviving parent to a child of either sex, particularly an adolescent. The

adolescent in question may have great difficulty in separating from the parent or may develop along homosexual lines.

On the other hand, as development proceeds, the child may be able to continue the work of mourning on a piecemeal basis. As his or her cognitive capacity matures and reality testing is strengthened, the child may at some later date be able to express some of the feelings that he or she had earlier repressed. These feelings may include yearning and sadness, which may occur at times of special significance in the form of anniversary reactions ( Fox, 1985), as well as anger and resentment.

The physician can help most if he or she can enable the parent, who also is in a state of mourning and withdrawal, to recognize the needs of the child. The child needs to know that there is someone he or she can depend on to meet his or her needs, and to whom feelings can be expressed. In some instances, the physician may appropriately support the parent in this role by making himself or herself available to the child, if the parent agrees. The pediatrician should suggest a consultation with a child psychiatrist if there is concern about the child's behavior.

### The Surviving Parent

The death of a parent almost always disrupts a family. As much as possible, the physician should help the family to maintain its stability and to avoid making hasty decisions while the family is in a state of acute grief. The services of a relative or a homemaker may be helpful during this acute period. Some tact is required as the physician tries to steer a course that will not be experienced by the parent either as intrusive or as an abandonment.

The disruption in the family caused by the death of a parent is not confined to the period of mourning. Loss of income, reduction in the amount of time that can be spent with the children, changed roles for the surviving spouse, caretaking responsibilities for the older children in the family, and altered social relationships are some of the repercussions that continue to affect the family. The physician should remain accessible to members of the family. Sleep difficulties, psychosomatic disturbances, and school learning difficulties are some of the common signs of continuing distress that may require further psychiatric evaluation.

The theory and practice of early childhood education, like that of so many other disciplines, has a long past and short history. When education is taken in its broad sense, including everything a child is taught and learns during the first years of life, then early childhood education has existed for as long as humankind has been rearing children. However, in the narrow sense of education—nonparental instruction in knowledge, values, and skills—the education of young children is a relatively modern innovation.

We are concerned only with early childhood education in the narrow sense in this chapter. In the first section we look at some of the factors that have contributed to the rapid growth of early childhood education in modern times. In the second section we briefly review the contributions of some of the major figures in early childhood education as we know it today. In the third section we highlight the basic parameters of early childhood education. In the closing section, we look at some of the major mental health issues raised by early childhood education in the United States today.

## THE GROWTH OF EARLY CHILDHOOD EDUCATION

The growth of early childhood education in the modern era has many different roots. Darwin's theory of evolution, for example, transformed our ideas about the insane, the retarded, and children. Just as insanity and retardation came to be seen as natural phenomena, rather than as the work of the devil, children's behavior came to be viewed as reflecting their immaturity rather than their original sin. Humanitarian practices progressively replaced restriction and punishment for each of these groups.

Another factor that contributed to the growth of early childhood education was the establishment of socialist societies in countries such as China, Russia, and Israel. In these countries, the society rather than the family was to be the prime identity and allegiance of the individual. Accordingly, massive early childhood care programs were instituted, in part to enable women to join the work force, and in part to weaken the strength of family bonds. In many ways, these state-supported programs were large-scale experiments in early childhood education. Unfortunately, they were uncontrolled experiments, and we have no good way of assessing their effects.

In this country, a different type of social change eventually contributed to the growth of early childhood education, namely, the movement of farm families to the cities and factory work, as well as the waves of immigration around the turn of the century. Initially, in the United States, early childhood programs were introduced for the children of poor, two-parent working and often immigrant families. Many day schools, such as the "Home for Little Wanderers" in Boston, Massachusetts, were founded in major cities in the first two decades of this century.

Although programs for young children began as a service for working mothers, after World War I many of these programs were institutionalized and redirected to serve the children of single mothers or those of troubled families. Day care programs were thus associated with social pathology. As a consequence, day care centers acquired a social stigma. Children who were in out-of-home programs for a full day were looked on as unfortunate and underprivileged. The social stigma associated with day care is gradually being overcome, but some traces of that stigma may account, at least in part, for the continued resistance to early childhood education in some quarters.

Another contribution to the growth of early childhood education in this country was the nursery school movement. In contrast to the evolution of day care, the nursery school movement in America was directed toward children of middle-income parents. Between the two world wars, the nursery school movement flourished, and training schools for nursery school teachers, such as the Bank Street College of Education in New York, the Merrill Palmer School in Detroit, Michigan, and the Nursery Training School in Boston, Massachusetts, prepared young people to work with young children in nursery school settings.

In contrast to the day care programs, the nursery school program was a half-day affair and often involved the parents in one or another form of "guided observation." The contemporary growth of early childhood education has its roots in the nursery school movement, not day care programs. In fact, however, there is now so much overlapping that it would be hard to tell the difference between a good day care program and a good traditional nursery school program.

## MAJOR CONTRIBUTORS TO CONTEMPORARY EARLY CHILDHOOD EDUCATION

Many writers, both inside and outside the discipline of education, have contributed to the theory and practice of early childhood education. Among the most prominent of these are the contributors described in the following.

### Heinrich Pestalozzi (1746–1826)

Heinrich Pestalozzi was a Swiss educator who extended some of the ideas of the Enlightenment to early childhood education ( [Green, 1914](#)). The spirit of the Enlightenment was to look to experience, rather than authority, for true knowledge. Pestalozzi began several schools for children whom today we would call disadvantaged. None of these schools was very successful or lasted very long. This was probably more a result of Pestalozzi's limitations as an administrator than of the programs he initiated.

Pestalozzi was nonetheless a prolific writer and gave what is perhaps the first systematic approach to the education of infants and young children in his many books. In his most famous book, *Gertrude Teaches Her Children*, which takes the form of a series of letters to mothers, Pestalozzi described many exercises the mother could engage in with her child. These exercises were aimed at helping children develop their intellectual and physical abilities. These exercises were revolutionary in the sense that they took account of child development and catered to it. Up until that time young children were taught what adults thought they ought to know, namely, the catechism.

Although he was personally not successful in maintaining a school run according to his own principles, Pestalozzi did influence many parents and other educators,

who also began to look at what children needed to learn rather than at what adults wanted them to know.

### **Frederich Wilhelm Froebel (1782–1852)**

Frederich Wilhelm [Froebel \(1893\)](#) is generally regarded as the originator of early childhood education as a distinct field of pedagogy. Froebel believed that children could and should be taught outside the home as well as within it and that trained teachers should provide such education. He developed not only a curriculum for young children, but also a training school to prepare teachers to work with them.

Froebel is perhaps best known for his creation, kindergarten, (“children's garden”) where children could learn through play. Froebel recognized the educational value of certain toys and advocated toys and play as the appropriate way of instructing young children. His kindergarten included blocks, pets, and simple games. The toys Froebel introduced for educational purposes, such as a ball, he termed “gifts.” He believed that children could not only learn simple ideas such as “roundness” from playing with the ball, but also could begin to comprehend the shape of the earth and the concept of unity also implicit in the sphere.

### **Maria Montessori (1870–1952)**

The first woman in Italy to gain admittance to and graduate from medical school, Maria Montessori ( [1912/1964](#)), laid the foundations for early childhood education as we know it today. After graduating from medical school, Montessori worked with retarded children, for whom she designed some innovative learning materials. She was then invited to set up an educational program for young children in a low-income housing project. Using untrained teachers and modifications of the materials she had devised for retarded children, she created what is known today as Montessori education.

Like Pestalozzi and Froebel, Montessori began with observations of how children engage in learning on their own. From these observations she not only was able to choose materials that were uniquely suited to the intellectual needs of young children, but she was also able to describe some general principles of early childhood education. For example, Montessori believed that young children should always be exposed to the object, property, or quality before they are given the name for that object, property, or quality. Put differently, she believed that sensory learning should precede symbolic learning.

Many of Montessori's innovations have become part of accepted early childhood teaching practice. For example, like Froebel, she believed that early childhood teachers had to be specially trained, and she worked out an elaborate training program of teacher preparation. Today, Montessori-oriented teacher training is one of the more rigorous early childhood teacher training programs in this country and abroad. Montessori teachers are particularly well schooled in the use of manipulative materials with young children.

In addition to rigorous teacher training, Montessori also introduced what are now staples of most early childhood classrooms—child-sized tables and chairs, dishes, and utensils. Other curriculum innovations were form boards, sandpaper letters, button and shoe lacing boards, and much more. Montessori believed that if the environment were properly prepared with the right learning materials, then children would spontaneously move to these materials and extract the most educational benefit from them. Montessori programs have multiplied rapidly since the 1960s and are now in all of the states and many public schools.

### **John Dewey (1858–1952)**

Although trained as a philosopher, John Dewey became America's first original educator. Like Pestalozzi, Froebel, and Montessori, Dewey believed that childhood was a unique stage of life that should not be rushed. In addition, he believed that education should be practical—his brand of educational philosophy has been called *functionalism*—and should prepare children for the life they will experience outside of school. Although Dewey was not opposed to classical education at some levels, he believed that children also should learn more practical skills ( [Dewey, 1916](#)).

Dewey contributed to educational philosophy and introduced instructional innovations. Perhaps the most well known is what has come to be called the *project method*. Rather than teach subjects as separate and apart from one another, Dewey believed they could be taught in an integrated way if children were engaged in particular projects. In putting on a play, children would have to learn the lines (reading and vocabulary), build the sets (measurement and carpentry), and design and sew the costumes (history, measurement, and sewing), as well as follow instructions and work cooperatively (social skills).

Dewey's ideas and methods became a major movement in the United States that lasted until the mid-1950s and was called *progressive education*. It disappeared from the scene for many different reasons, not the least of which is because, in distorted form, it had become associated with “permissiveness” ( [Cremin, 1961](#)).

### **Sigmund Freud (1856–1939)**

Sigmund [Freud's \(1938\)](#) discoveries of infant sexuality, the stages of psychosexual development, and the Oedipus complex have had a significant impact on early education. Although most of what Freud had to say about early childhood dealt with parent–child relationships, there were some implications for out-of-home care as well. This is particularly true with respect to children's play.

Whereas writers such as Froebel and Montessori saw play as an all-important mode of learning for young children, Freud saw play as comparable to a dream. Like a dream, play has both a *manifest* and a *latent* content. Children's play can reflect inner complexes and conflicts and also be a way of working them out. A child who has just returned from the doctor, for example, may play at being doctor as a way of relieving some of the anxiety aroused by that visit. The technique of play therapy has grown out of this recognition that children's play can have symbolic meaning. It is now generally recognized that the play of young children has both *cognitive and affective* value.

### **Erik H. Erikson (1902–1994)**

Erik H. Erikson was trained as a child analyst but later departed significantly from analytic theory ( [Erikson, 1950](#)). In his writings, Erikson focused on the social dimensions of development and the evolution of such social orientations as trust and identity. Four of Erikson's eight stages of development occur in early childhood.

We are born with a number of social potentials in Erikson's theory. How these potentials are realized depends very much on the sort of experiences to which we are exposed, as well as our own unique characteristics. Each potential exists as a kind of polarity and has a particular time when the balance between the two opposing tendencies will be determined (although changes can occur at later ages as well).

To illustrate the relevance of the Eriksonian stages of early childhood education, we can look at the stage of initiative versus guilt, which has its critical time around the ages of 4 and 5. If the child is given the opportunity to explore the world and undertake projects on his or her own, the child will develop a sense of initiative that is stronger than the sense of guilt. In contrast, if the child is constantly told what to do and corrected if he or she makes mistakes, then the child will acquire a sense of guilt that is greater than his or her sense of initiative.

Erikson's theory, then, has rather direct implications for the practice of early education, as well as child rearing.

### **Jean Piaget (1896–1980)**

Although he was trained as a philosopher and biologist, Jean Piaget's greatest contributions were to developmental psychology. Piaget elaborated a theory of intellectual development that has influenced many different disciplines, including early childhood education. Although [Piaget \(1970\)](#) himself wrote about education in general terms, his work has had a major impact on the pedagogy of young children.

From a theoretical point of view, Piaget's work has emphasized the importance of development and the fact that learning cannot accelerate growth. Piaget's theoretical work has been a major factor in the current effort by early childhood educators to get schools to provide “developmentally appropriate” practice for young children ([Bredenkamp, 1987](#)). In addition, Piaget's work on the development of children's understanding conceptions, such as numbers, has led to major curriculum innovations ([Kamii, 1982](#)).

## Lev Vygotsky (1896–1934)

Although Lev Vygotsky ([Kozulin, 1990](#)) was a contemporary of Jean Piaget, his work is becoming generally known in America only today. Thanks to changes in Russian policy, his works are being made available and translated at an increasing pace. Although he worked in many different areas of psychology, he is perhaps best known for his contributions to our understanding of the relationships between language and thought.

Vygotsky argued that there were two levels of development: biological, which we share with animals and sociological, which is unique to humans. Both animals and humans, to illustrate, employ tools or implements to attain desired goals—a process Vygotsky described as mediation. However, only humans use language as a mediator; language is acquired socially and not as a biological given. Vygotsky believed that thought and language initially were a single undifferentiated activity and that they became separate only later in development. Initially language is entirely social, derived from hearing adults speak. As children develop, language becomes increasingly internalized (whispering is a step along the way) and individual rather than social.

Vygotsky, like Piaget, believed that children construct and reconstruct their ideas until they approximate those of the adult world. Nonetheless, he also contended that when adults mediate the child's learning, the child will arrive at the socialized concept earlier than if he or she has no adult model. Observing a parent use a spoon, for example, enables the child to use a spoon earlier than if he or she had never been witness to a model. The difference in time between the child's spontaneous attainment of a concept, and the time when the concept is attained with adult mediation is the "zone of proximal development." Vygotsky, like Montessori, believed that children could progress more effectively with a prepared environment and adult modeling than if left to their own spontaneous devices.

It is important to emphasize that Vygotsky was not arguing that development could be quickened with adult intervention. Perhaps his position is best understood in contrast to that of Piaget. In general, Piaget believed that children spontaneously maximize their abilities given an average family environment. Vygotsky, in contrast, argued that children without adult mediation do not maximize their abilities but can quicken their development with the aid of adult mediation. There is a zone of undeveloped capacity that can be achieved with adult intervention, but this zone is limited by the child's native capacity.

## MAJOR PARAMETERS OF EARLY CHILDHOOD EDUCATION

Every system of education presupposes a set of assumptions regarding the learner, learning process, knowledge to be acquired, and aims of education. Contemporary early childhood education in America can be described within these parameters. It must be said that this description represents the views of mainstream early childhood education and does not purport to convey the many varieties of early childhood education currently available.

The discussion of the parameters of early childhood education has implications for dynamic theories and therapy with young children. For example, any theory or therapy applied to young children must take the child's developing mental powers into account. The therapist must understand the child's level of mental ability, what the child can and cannot do cognitively. A case in point is the writings of Melanie Klein. Although her books have raised important issues and concepts, she nonetheless seems to attribute too much to the young infant in the way of cognitive processes. For example, [Klein \(1957\)](#) suggests that young infants have aggressive fantasies. Yet [Piaget's \(1951\)](#) work demonstrates that children do not really have images before the second year of life. Inasmuch as fantasy is comprised of images, the child could hardly engage in fantasy activity before he or she was capable of constructing images. From a developmental point of view, Klein is attributing too much mental ability to the young infant.

### The Learner

Young children are growing individuals first and foremost. From this point of view, all children are seen as having the same basic learning abilities, which they may nonetheless attain at different ages. For example, we expect that all children (with the exception perhaps of the extremely retarded) will eventually attain the mental abilities that [Piaget \(1950\)](#) calls *concrete operations*, which enable young children to reason in a syllogistic way and follow rules. Although most children acquire these operations at about the age of 6 or 7, bright children may acquire them at the age of 4, whereas slow children may attain them at the age of 8 or 9.

The view of children as endowed with developing abilities has many educational implications. It is important to match the child's developing mental abilities with a curriculum that is nicely suited to those potentials. Curricula have to be studied to determine their "developmental difficulty," the level of mental ability required for their comprehension. For example, instruction in phonics requires children to have attained the concrete operations described earlier. This is true because children require these abilities to grasp that one and the same letter can represent different sounds and that different letters can represent the same sound. Teaching a child phonics before he or she can grasp that one and the same thing can be two things can be frustrating and demoralizing.

### The Learning Process

Learning is always a creative activity from a developmental point of view. The child never simply copies information from the external world but always transforms it in significant ways. The Connecticut youngster who heard the Lord's Prayer as, "Our Father who art in New Haven, Harold be thy Name" is not the exception but the rule. In effect this means that we cannot really separate the learning process from the content to be learned. Every different content engages us in a unique way. There are no disembodied learning principles that operate entirely apart from the content to be learned. Learning is always content oriented.

Here again this view of the learning process differs from the view of learning held by those who educate at the primary and secondary levels. At those levels there is a strong belief in the separation of learning and content. Currently, for example, there is a great deal of interest in teaching "thinking skills" ([Baron and Sternberg, 1987](#)) and "learning strategies" ([Weinstein and Mayer, 1986](#)). Such efforts reflect the belief that the learning or thinking process can be taught and learned apart from specific contents.

The issue here is what has been called transfer of training. To be sure, the developmental approach recognizes that such transfer occurs. However, those who wish to teach thinking or learning skills assume that transfer is automatic and hence unconscious. A developmental approach, which argues for the necessity of content for the operation of learning and thinking, insists that transfer can only occur when the learner is consciously aware of content and is making the effort to generalize.

On the other hand, there is a growing recognition of the importance of individual learning styles; for example, some children learn best through the visual modality, others through the auditory ([Elkind, 1994](#)). Learning styles, in contrast to thinking skills, are individual differences that transfer from one type of learning task to another. Here again, however, the identification of learning styles means that we have to adapt our materials to the child's learning mode, not decide on our own what skills they should learn.

From a therapeutic point of view, this conception of the creative nature of learning means, for example, that the child's language always contains individual symbolic significance. In this respect, the developmental approach to learning would be in keeping with the creative role attributed to language by Jacques [Lacan \(1968\)](#).

### The Nature of Knowledge

Knowledge is always a construction from an early childhood education perspective. That is to say, reality as we know it is never simply a copy of the external world but rather is a construction or creation that bears something of ourselves and something of the external world and that cannot be reduced to either one. To be sure, we all have the same sensory apparatus, and there are constants in the external world; therefore, our individual realities are never entirely egocentric. Nevertheless, we never see the world exactly the same way everyone else does.

To this individual difference dimension we must add the developmental one. As the child matures, so too do his or her mental abilities. As a consequence, the child must construct and reconstruct reality during the process of growing up. The same holds true for our memory of past reality. The child reconstructs the past each time he or she attains a new, higher level of mental ability. Thus, memory is never a simple recall of previously stored images, but rather is an active, constructive process that transforms the information derived from earlier experience.

This way of viewing knowledge and memory implies an approach to curriculum different from that which is currently taken in our schools. The idea that knowledge is tied up with thought and action and should not be separated, as was first put forward by John [Dewey \(1916\)](#) and reiterated by Vygotsky. As mentioned, in the project method, children engage in putting on a play, building a house, and so on. In the process they learn language, math, science, social cooperation, and much more.

The project method speaks to the conviction that content is an integral part of the learning and knowing process and should not be separated from it.

From a therapeutic point of view, the idea of reality as a construction again has important implications. It suggests that realities can be different and not just right or wrong. The young child who believes that adults are all-powerful and all-knowing has a different reality from the adult, but it is not wrong from a developmental point of view. Indeed, that conception is as developmentally appropriate as the more negative perception of adults held by adolescents.

The rule that there can be different realities without these being necessarily right or wrong is as important in therapy as it is in education. A child's fear of a particular animal is very real for him or her, even though it appears baseless to us. Rather than try and disabuse the child of this fear, we need to accept it as a reality for the child and reassure the child that we will not allow the animal to do him or her any harm. On the other hand, there are certainly some beliefs that are right or wrong (e.g., the Bastille was stormed in 1789 and not in 1960), and there are some evil realities. The difficult thing is always to make the right discriminations as to when we should bring in the value judgments of right or wrong, good and evil.

## THE AIMS OF EDUCATION

The aims of early childhood education have been clearly enunciated by Jean Piaget:

The principal goal of education is to create men who are capable of doing new things . . . men who are creative, inventive and discoverers. The second goal of education is to form minds which can be critical, can verify, and not accept everything that is offered ( [Ripple and Rockcastle, 1964](#), p. 18).

According to Piaget, the legitimate aim of early childhood education is to produce self-motivated learners and critical thinkers. From a therapeutic point of view, this aim suggests that therapy be directed not solely at removing this or that problem but also at helping the child acquire an orientation and strategies that will enable him or her to deal with the later stresses of life more effectively and productively.

## ISSUES IN EARLY CHILDHOOD EDUCATION

There are many different issues currently being debated regarding the education of young children. Only a few of these can be dealt with here.

### The Effect of Early Childhood Education on the Infant

Today 57% of mothers with children under the age of 6 have jobs. In addition, more than half of the mothers with infants of less than 1 year of age are employed. This means that a large percentage of infants and young children are being cared for by relatives within the home or by paid caregivers outside the home. What effect is being cared for by nonparental figures going to have on these children? There has been a longstanding debate on this issue. For example, John Bowlby wrote:

The absolute need of infants and toddlers for the continuous care of their mothers will be borne on all those who read this book. . . . We must recognize that leaving any child under three years of age is a major operation to be undertaken with good and sufficient reasons ( [Bowlby, 1950](#), p. 16).

Many contemporary researchers do not agree, however. They find that the critical issue is not the parent as caregiver but rather the *quality* of the care the child receives. There is no evidence of lasting untoward effects when an experienced, warm adult cares for a child; one adult cares for not more than three infants; and the environment is safe, pleasant, and interesting. According to one investigator, with quality child care of the sort described in the preceding, "the major effect of day care seems to be a speeding up some of the child's social and intellectual skills during the preschool period" ( [Clarke-Stewart, 1982](#), p. 75). Likewise, the authors of a leading child development textbook conclude their review of the literature with the following statement:

There is little clear evidence that day-care is likely to cause disruption of the infant-parent attachment relationship. In fact, day-care may have positive effects for some infants, particularly when it is of high quality ( [Hetherington and Park, 1993](#), p. 43).

The real issue for contemporary working parents is to find quality, affordable childcare. With such care, there is no evidence of any immediate or lasting harm to young children. However, there is one important caveat. It does appear that children in child care settings, particularly large day care settings, are more subject to communicable diseases than children cared for at home or in the home of the caregiver.

### Does Early Childhood Education Increase a Child's Intelligence or Give Him or Her an Academic Head Start?

One of the questions usually raised in relation to early childhood education is whether it will raise the child's IQ. This question is interesting because it is rarely, if ever, raised with respect to elementary or secondary education. If neither elementary nor secondary education is expected to raise a child's IQ, why should it be expected of early childhood education? Indeed, there is no evidence that early education raises a child's IQ on any permanent basis.

It is still possible, however, that early education can give children who have it an edge over those who do not. Does this in fact occur? Certainly some high-quality age-appropriate programs for disadvantaged children seem to have demonstrated long-term positive benefits ( [Schweinhart et al., 1985](#)).

However, these results cannot be generalized to all programs and to all children. A simple analogy may help to make the dangers of such generalizations concrete. Assume a group of children who are badly undernourished and who are well below their age norms for height and weight. If these children are now placed on a full-calorie, nutritionally well-balanced diet, they will make quite noticeable progress in height and weight in a reasonably short period of time. If, however, you take a group of children who are already well nourished and at or above the norms for height and weight for their age group, a comparable regimen will have little or no effect.

Does this mean that advantaged children receive no benefits from early childhood education because it merely duplicates what they have at home? Not at all. The issue here is comparable to the one raised about home schooling. Yes, parents can and do successfully school their children at home, even through high school. This does not signify that early childhood programs are unimportant. It does mean that parents who have the time, energy, and commitment to home school can do so successfully. However, parents who do not have the time, energy, and commitment to home school do need the public education to fill that role.

Exactly the same holds true for early childhood education. If parents have the time, energy, and commitment to provide an intellectually challenging environment at home; spend regular periods of time with the child reading, talking, and engaging in other activities; and have other children in the neighborhood over on occasion, there is really no need for the child to attend a preschool. But if the parent is not ready or able to devote the time and energy to providing that kind of experience, then a good preschool experience would be enriching and rewarding for the child.

### Is Earlier Better?

The idea that earlier is better when it comes to early childhood education is widespread. It stems from the 1960s, when many writers hoped that early childhood education might be the way to break the cycle of poverty. It was hoped that if disadvantaged children could be given a head start at the preschool level, then they would be on a level playing field with advantaged children when they entered school.

The promise of early childhood education seemed unlimited at that time. Jerome Bruner wrote that "we begin with the hypothesis that any subject can be taught effectively in some intellectually honest way to any child at any stage of development" ( [Bruner, 1962](#), p. 22). It was hoped that if children were taught the basics of reading, writing, and arithmetic during the early years, then this would not only ensure them a head start but also insure them against failure later.

The idea that earlier is better was reinforced by the writing of Benjamin Bloom, who contended that "general intelligence appears to develop as much from conception to age four as it does during the fourteen years from age four to eighteen" ( [Bloom, 1964](#), pp. 207-208). Bloom went on to argue that because intelligence grows so rapidly in early childhood, it is the time to engage in serious instruction rather than play. The idea that little children are sponges ready and eager to soak up all the information we pour over them became a widespread and accepted conviction. It encouraged many parents to try to teach their infants and young children everything from reading to violin to karate.

However, is early childhood a critical period for learning basic skills? It is certainly true that infants and young children are eager and avid learners. Yet what young children need to learn is not academic subjects and skills but rather the basics of the world in which they live. Young children need to learn sights, colors, sounds, shapes, textures, and tastes. They need to discover *up* and *down*, *behind* and *on top of*. They need to discover what floats and what sinks, and encounter the many forms, sounds, and smells of different animals and plants.

Yes, infants and young children are avid learners, but they are eager to learn from their own explorations and discoveries and not from formal instruction. That is what all of the workers in early childhood education have emphasized, from Pestalozzi to Piaget. The child needs to acquire a conception of the immediate fundamental world before he or she begins to learn the derived, symbolic world of formal instruction.

#### *PROS AND CONS OF UNIVERSAL PRESCHOOL*

There is currently much discussion about making preschool education available, if not mandatory, for all young children. In some states, such as Georgia and New York, such programs are already in process. Universal preschool has long been a national policy in many countries. In France, for example, state-supported preschools for all children age 3 and older have been in operation for decades. Likewise in China, state-supported preschools are provided for children as young as 1 year of age. In both of these countries the initial impetus for supporting universal preschool was the need for quality childcare, as large numbers of young mothers entered the work force. This has changed, however. French preschools are heavily academic and early education is now regarded as part of the education system. China has not moved in this direction; their preschools are still primarily dedicated to childcare.

There is certainly a need for universal preschool in our country. Currently more than 60% of mothers with infants younger than 1 year of age are in the workforce either full or part time. Unhappily, we do not have the quality, affordable, and accessible childcare needed by these mothers and those of older preschoolers. Much of what is available is substandard because preschool teachers are poorly paid and often relatively untrained. The need for quality early childhood care is becoming even more pressing now that so many welfare mothers are joining the work force. These mothers can hardly afford to pay for high-quality childcare because they are in low-level, or entry-level jobs.

Universal preschool supported by the state makes sense for all of these reasons—particularly so, if teacher training and teacher pay are placed on a par with that for elementary and secondary schoolteachers.

The risk, with universal preschools, is what has happened in France. That is, what was originally a childcare initiative has become an educational initiative. Young French children are taught reading and math in the manner of grade school children. Many early childhood experts fear that what happened in France will happen in the United States. That is to say, developmentally appropriate early childhood programs will be transformed into academic programs. Quality early childhood education programs are academic, but in a hands-on rather than a symbolic way. Much damage can be done if the all-important distinction between hands-on learning and symbolic learning is lost, and symbolic academic learning is pushed down to the preschool level. To illustrate, children have many more reading problems in France than they do in the Scandinavian countries, where reading is introduced at a later age level.

Accordingly, universal, state-supported early childhood education is a good idea and would fill a very dire need. The real danger is that if it is not done right, if it becomes a size smaller first grade, many children will be put at risk for learning disabilities.

#### *COMPUTERS AND YOUNG CHILDREN*

Computers are here to stay, unlike many other educational innovations, such as overhead projectors and teaching machines. They are becoming an increasing part of our environment and impact all facets of our lives. Nonetheless, the personal computer is still a very complex machine that does not always work the way you want it to. There is considerable debate about whether or not young children should be exposed to computers. Some argue that such exposure takes children away from the hands-on learning so critical for young children. Others claim that computers are part of the world and that young children have a natural affinity for them, and should not be kept from using them.

This argument is academic in some ways. Many parents I have talked to tell me their children naturally gravitate to the computer when they themselves are working on them. These are the parents who are likely to buy computer programs for their young children and even give them a secondhand computer when the parents move up to a more powerful model. So, regardless of what the experts think, many young children are being exposed to computers. It is my impression that this is happening in numerous early childhood centers as well. Many early childhood programs now have one or more computers available for young children to use. That is certainly true for the Children's School and Educational Day Care Center at Tufts. Teachers have chosen what they regard as quality programs and the children are allowed to spend some time on them each day. Some children seem to be more drawn to computers than others.

In general, it seems that after the age of 3 or 4 there is little harm to exposing young children to computers so long as they do not spend too much time on them. It is important to recognize that we still do not know a lot about children and computers and that it is important to watch how they use them. I am often impressed that young children like to work at the computer in groups helping one another along with the program. It would be a mistake for a teacher to interfere and insist that the children take turns. We can learn much about computers and young children if we allow them the freedom to experiment and explore on their own.

Accordingly, computers do have a permanent place in early childhood education if we are careful about the programs we choose for young children and make sure they do not spend too much of their time at them.

#### **SUMMARY AND CONCLUSIONS**

Early childhood education is a relatively modern innovation. It had its origins in the industrial revolution, humanitarian thrust of the theory of evolution, and emergence of socialist societies and communal child rearing. In the contemporary United States, early childhood education has grown to accommodate the needs of two- and single-parent working families, as well as to provide a head start for disadvantaged children.

There are four basic principles of developmental early childhood education. The first is that the learner is an individual with growing mental abilities. A second is that learning is a creative process and necessarily involves both the subject and object or material to be learned. The third is that knowledge is always a construction and always contains something of the subject as well as the material to be known. Finally, the aim of developmental early childhood education is to produce active, self-motivated learners and critical thinkers.

There are many unresolved issues surrounding early childhood education. Among these are the questions of whether early childhood education can harm the child, improve the child's IQ, and give the child a head start.

Early childhood education is coming into its own in the United States as a part of the educational system. It is increasingly recognized that early childhood education is not a "size smaller" first grade; that young children learn differently from older children and adults; and that they require their own curriculum, teaching modes, and method of evaluation. Early childhood education is coming to be accepted on its own terms.

## 106 IMPROVING PSYCHOEDUCATIONAL OUTCOMES FOR AFRICAN-AMERICAN CHILDREN

James P. Comer, M.D., Norris M. Haynes, Ph.D., and Lynelle Thomas, M.D.

[Conclusion](#)  
[Chapter References](#)

There has been a dramatic increase in problems facing families and children in the inner cities of the United States during recent years. These social difficulties are having a significant negative impact on the school readiness and school success of African-American children and are resulting in an urgent need to improve psychoeducational outcomes for these children. Indeed, providing low-income African-American children with a successful school experience is one of the most important tasks facing the United States today. If these children remain undereducated in disproportionate numbers in this age of science and technology, all our most troublesome social problems will be exacerbated—low productivity, dependency, substance abuse, crime, children having children, and others. Across the country, in areas where such children are located in disproportionate numbers, they are often up to 2 years behind children from better-educated families. In large urban centers, school dropout rates are as high as 50% ([Children's Defense Fund, 1989](#)). Evidence indicates that these youngsters can achieve at a much higher academic level ([Comer, 1980](#); [Comer, 1988](#); [Comer, 2001](#)).

Although it is more difficult to document, some social and behavioral scientists and educators believe that many African-American young people from better-educated, middle-income families may not be achieving at the levels of their ability because of negative peer pressure, as well as insensitive schooling practices ([Ogbu, 1986](#)). If this is the case, the leadership group needed to improve opportunities for all African-Americans, which, in turn, would benefit all Americans, will not grow sufficiently rapidly or large enough.

Several causes are commonly suggested for the educational underachievement of low-income black children: school segregation, inadequate schools, disparity in instructional materials, inadequate attention to language and cultural considerations, low teacher expectations and bias, too few educational role models such as teachers, continuing insensitive schooling practices, and unemployment and its detrimental effects on families ([Boykin, 1983](#); [Clark, 1983](#); [Haynes, 1993](#); [U.S. Department of Health and Human Services, 2000](#)).

Some African-American children achieve despite these obstacles. In 1939, one of us (Comer), then a student, entered an elementary school in East Chicago, Indiana, with three other black youngsters from a low-income community. The school was racially integrated, served the highest socioeconomic group in town, and was considered one of the best. All four students were from two-parent families. All four fathers made a living wage as laborers in the local steel mills. Despite similar intellectual potential, all three of Comer's friends had difficult educational and life outcomes—one died prematurely of alcoholism, a second spent a significant part of his life in jail, and the third has been in and out of mental institutions.

The reason for the more favorable outcome for Comer was largely that his parents provided him with a preschool experience that gave him the confidence and kinds of skills necessary to elicit support in school. His parents interacted with school people in a way that encouraged support for him. Beyond home and school, a constructive social network of friends and kin, religious and other institutions, helped to make academic success possible for him.

Although another of them (Haynes) was raised in another culture, Trinidad, where racism and segregation were not part of his educational experience, but class distinctions were, he also found that his mother's understanding of the importance of positive social relationships and the existence of a supportive network of caring adults and good friends were critical in his educational and social experiences. The notion that *it takes a village to raise a child* was very much true.

A similar experience is usually found among African-Americans who have had academic success. Many, perhaps most, of today's educated, middle- and upper-income African-Americans are from low-income backgrounds ([Jaynes and Williams, 1989](#)). Most educated blacks who are more than 45 years of age, and a large percentage of the leadership group, attended racially segregated primary and secondary schools, even postsecondary schools ([Jaynes and Williams, 1989](#)). Yet many black children have not done well in racially integrated schools, even schools considered very good and serving middle- and upper-income families ([Ogbu, 1986](#)). At the same time, although unemployment is a serious problem and has probably served to increase the number of single-parent families, some black children of unemployed parents and low-income families do reasonably well in school ([Clark, 1983](#)).

How are we to explain the underachievement of American-born black youngsters from middle- and upper-income families ([Fordham, 1988](#))? This is especially curious in view of the finding that West Indian children do as well as Asian and white children. Our usual explanations for school underachievement among African-American youngsters are simplistic, adynamic, and not very useful.

In the 1960s, in part because of his own experience, Comer began to speculate that the relationship experiences of students before school and in school, and relationships between parents and school staff, affect the child's development and, in turn, the child's ability to achieve in school. This gave rise to the hypothesis that the almost exclusive focus of schools on instruction and curriculum and the comparatively little attention given to issues of relationships and development are probably at the root of the academic underachievement of many students.

Moreover, because of his own experience and his psychotherapeutic work with middle- and upper-income black children, Comer became aware of the troublesome racial identity problem that such young people face. Often without conscious intent and because of historical situations and conditions, U.S. society attributes characteristics to African-Americans or blacks such as bad, unsuccessful, having limited interest in academic learning, and the like.

Being white or a member of the majority and more powerful group in the society—even when not in a majority in a particular situation, such as school—is characterized by almost exactly opposite traits: characterized as being good, successful, highly motivated to learn, and the like. Identity as a black person, then, can be problematic ([Comer, 1972](#); [Oyserman, 1999](#)).

Slavery in a society committed to Judeo-Christian principles and democracy had to be rationalized. The argument was that blacks were inferior; thus, slavery was justified. This notion has been transmitted across time. As a result, many mainstream organizations and people are carriers of negative and stereotypical ideas and attitudes about blacks. The mass media transmits the message ([Luthar et al., 1997](#); [Watson, 2000](#)). In addition, too many teachers, health care workers, other service providers, and the general public are carriers. African-American children are aware of these stereotypes and are adversely affected by them, especially in terms of their self-evaluations and educational aspirations. Young African-American male students appear to be especially at risk.

Young people develop best when they experience positive, self-affirming relationships. The skills they can then develop provide them with a chance to function well. This, in turn, creates a sense of adequacy and belonging: These are the critical dynamics, regardless of age, sex, race, or class. We hypothesize that the effectiveness of our social institutions, especially our schools, is better based on the degree to which these self-affirmative relationships are fostered and encouraged.

Why has society largely ignored relationship issues in its efforts to improve education, particularly that of minority children? In part, it is because educational theory is influenced more by industrialization than by child development and the social and behavioral sciences. Society tends to understand teaching and learning as a mechanical process. Thus, academic learning seems to have been thought of as an entirely cognitive (mechanical) process, willfully engaged in or rejected by the individual and facilitated or limited only by the individual's ability level.

In addition, social scientists usually analyze the behavior of societies, groups, and individuals in the here and now, as if it were unrelated to their histories. The impact of powerful structural forces created by political, economic, social, geographic, and other conditions is often ignored. The effects of these forces, positive and negative, are transmitted from generation to generation—parent to child—greatly influencing child development, subsequent social and academic performance in

school, and opportunities in life ([Clark, 1983](#); [Fiscella et al., 2000](#)).

Finally, society's neglect of these effects results in part from societal guilt relative to the experience of Native Americans, Hispanics, and African-Americans in particular ([Helms and Carter, 1990](#); [Steele, 1991](#)). Even the European and Asian immigrant experience and the experience of groups isolated from the positive effects of scientific and technologic changes (and not all were positive) have not been adequately explored to help us understand individual, group, and societal functioning, teaching, and learning in school. It is necessary to consider the effects of the black experience on the functioning of the community and individuals to understand the obstacles and opportunities involved in the education of African-American children ([Anyon, 1997](#)).

We need an understanding of learning and a method of teaching that look beyond the child in school and that consider the complex interactions of children developing in families and family interactions in social networks within a larger society. This perspective must include an understanding of the force of past social and economic conditions on the present. Thus, in this chapter, we (a) discuss the relationship dynamics of children developing in families, social networks, and the school; (b) explore the relevant economic and social history of the United States and compare the differences among European and Asian immigrants and African-Americans and the corresponding psychosocial consequences; (c) present a discussion of a specialized child development program in schools as a basis for addressing the complex problems involved; and finally, (d) consider the role child and adolescent psychiatrists can play in influencing practices and policies relevant to the education of African-American young people.

## RELATIONSHIP DYNAMICS OF CHILDREN DEVELOPING IN FAMILIES, SOCIAL NETWORKS, AND THE SCHOOL

Children are born totally dependent, with biological potentials that must be developed and aggressive drives that must be channeled and sublimated into the energy of learning, work, and play. They are also born with a capacity to form relationships. When competent caretakers (usually parents) provide for them, a strong emotional attachment and bond develop between the child and the caretakers. This bond enables parents and other caretakers to help children to grow along many developmental pathways ([Bowlby, 1952](#); [Stern, 1977](#)). At least six pathways are critical for future academic learning: physical, social–interactive, psychoemotional, moral–ethical, speech–language, and intellectual–cognitive. Whereas development along the pathways takes place simultaneously and each facilitates the other, the growth of the brain is critically important. Brain growth is facilitated by child interactions with people and things in emotionally powerful environments ([Greenspan, 1997](#)).

Families are enmeshed in a social network of friends, kin, and religious and social institutions ([Erikson, 1963](#)). Social networks or groups have a history that influences their attitudes, values, and ways. However, in large, modern societies, families live in primary reference groups or subcultures as well as the larger mainstream culture. Generation after generation, mainstream parents interact with their children from birth forward and transmit attitudes, values, and ways that make it possible to participate successfully in the mainstream as children and as adults. Marginalized or nonmainstream parents often transmit attitudes, values, and ways that enable their children to function in the subculture or primary reference group but do not adequately prepare them to participate in the mainstream culture.

The school is a mainstream institution. When children's growth is adequate along critical developmental pathways in their family and social network, and the culture and expectations of the network are similar to those of the school, most children are adequately prepared to achieve in school at the level of their ability.

Development along critical pathways takes place through incidental experiences that children have with their caretakers, as well as through systematic teaching efforts on the part of the adults around them. For example, a 2-year-old child who wants to play with the ball of another child does not know that he or she cannot just take the ball. He or she may attempt to do so, and a struggle or fight may ensue. A caretaker intervenes and mediates. In the process, the caretaker spells out several options for the aggressor—do something else until Johnny is through playing with the ball, play with Johnny if there is an interest on his part, or just go away.

In this single incident, the child learns appropriate social interaction. The impulse to hit or take is controlled, and sometimes the caretaker must help the child to handle emotions or feelings related to being denied. What is right and wrong is learned. Language is involved, and thinking is involved. In the process, the caretaker is helping the child to grow along the critical developmental pathways.

The interaction most closely related to academic learning is reading. Parents who are part of the mainstream of the society usually read to their very young children. They often do so at the end of a busy day, and the child has the parent's total attention. Reading, then, is a special time and becomes a positively charged emotional experience. Children's stories often deal with the fears and anxieties they experience while attempting to cope, with few skills, in a threatening world. Thus, children want to hear the stories repeatedly. Eventually, they memorize the words and associate them with the pictures on a page. Delighted parents, and other important adults in their lives, often excitedly express their approval.

Children are programmed to seek the approval of adults. With approval, they want to read more and to master other aspects of their environment to win the recognition of important adults around them. The motivation for learning and mastery, then, grows out of early relationships with important adults. The attitude about learning and the positive learning experiences with parents and other primary caretakers at a very early age become the basis for a comparable reaction with other adults, particularly school people, later in the development of the child ([Elias et al., 1997](#)).

Children who have been living in average, expected mainstream environments approach the school experience, and the adults involved, with attitudes, values, and ways similar to those expected in school and with development at a level necessary to meet school tasks. Such children are able to interact appropriately with other students. They are able to sit still and to listen or attend to a task when it is appropriate to do so. They are able to be spontaneous and curious when it is appropriate.

Such behavior elicits a positive response from adults in the school environment and promotes positive transference between the child and school people. This permits a positive attachment and bond to take place between the child and school people, similar to, but not as strong as, the attachment and bond that took place at home between the child and the primary caretaker. The child then has the same need to please school people as to please parents at home. This enables school people to help students continue to grow along the critical developmental pathways mentioned earlier. Growth facilitates academic learning of increasing complexity.

The utility and benefits of academic learning accrue. Eventually, the child develops an inner motivation to learn and to achieve, and it is as powerful, if not more so, than the outside approval of teachers, other adults, and other external rewards such as money or gifts. Learning to read is the critical academic challenge because all other academic work requires this skill. In addition, reading success leads to the sense of confidence and competence that children need to be motivated to interact with other students and staff appropriately. Reading difficulty or failure often promotes troublesome feelings and behaviors among children, such as acting-up and acting-out behaviors that make matters worse.

The preschool and school developmental experience is often different for children growing up in families that are marginal to and outside of the mainstream of the society and often under economic, racial, or other stresses. The relationship processes in such families less often lead to school success.

Income that is not adequate to enable heads of households to meet basic family needs is a source of excessive stress. Negative societal attitudes about minorities and poor people are stressors. They contribute to the increased frequency of divorce and to never-married single-parent families, which are, in turn, a major source of poverty. Children from poor families more often grow up in neighborhoods with a disproportionate number of social problems—delinquency and crime, violence, teenage pregnancy, welfare dependency, undesirable housing, and inadequate health care ([Children's Defense Fund, 1989](#); [Zigler and Styfco, 1996](#)). Although successful families and social networks exist within such neighborhoods, extraordinary pressures interfere with the development of children at all times. Thus, all such families are under stress.

Parents often lack education themselves or bear social and psychological scars related to their social status and conditions. They often sense exclusion and feel alienated from the mainstream of society ([Mead, 1996](#)). They often carry some attitudes, values, and ways that are different from those of the mainstream. They often simply do not know mainstream expectations and ways ([Anderson, 1998](#); [Lightfoot, 1978](#)). Thus, even when they want to prepare their children to succeed in school—a mainstream institution—they are not able to do so adequately.

For example, learning to negotiate and to work things out rather than fight is expected in school. However, in many nonmainstream communities, children are expected to fight rather than to negotiate ([Anderson, 1998](#)). Many such families do not read to their children, take them on recreational and learning excursions, or otherwise give them the informal preschool learning and social skills needed to grow along the critical developmental pathways discussed earlier. By school age, such children are underdeveloped, or differently developed, along the developmental pathways most related to academic learning. They often have skills that enable them to function adequately on the playground, the halls of the housing project, and a variety of other customary places, but such skills elicit a negative staff response in

school.

The work of the Yale School Development Program suggests that children from low-income or marginalized backgrounds have the potential to achieve at high levels. The Samuel Gompers Elementary School in Detroit, Michigan has a 98% student poverty level. Yet they made the highest test scores in the state on the fourth grade Michigan Educational Progress Test in 2001. This was possible because of the collaboration in school and between the school and families that promoted the development of the children to the point that they could make significant academic gains.

However, the preparation of most school people does not help them to understand the behavior and apparent ability level of such children as underdevelopment or different development. It is viewed as “bad” and “dumb” or as evidence of inadequate learning potential. Many believe the students are willfully not trying. Most school staff members attempt to change the behavior of the children through punishment. This often leads to even more troublesome behavior and accompanying low expectations on the part of students and, in turn, to increased control efforts and continued low expectations by school staff. Some students eventually respond with severe acting-out behavior or withdrawal and apathy. This situation leads to hopelessness and despair among all in school settings ( [Edmonds, 1979](#)).

Parents who had ambivalent feelings about the school in the first place—who hoped that it would give their children a chance for greater success than they experienced, but feared that it would not—are often brought into conflict with school people, or they withdraw and avoid the school. The attachment and bonding that should occur between school staff and students do not occur, and the staff is not able to help the students invest strongly in the academic learning task. When parent–child bonding is not strong because of difficult social circumstances, inadequate bonding in school is doubly troublesome.

Before to 8 or 9 years of age, most students are able to establish the level of attachment and bonding that enables adults to influence their behavior ( [Bowlby, 1952](#)). However, around this period, the academic performance demands of the school (more abstract learning) begin to outstrip their performance preparation. Second, a child's cognitive capacity now enables him or her to understand his or her social status—at home and in the community, and in the classroom. Third, the thrust for independence is greater at this age ( [Flavell, 1985](#)). These developments limit or facilitate mainstream aspirations and reduce the ability of adults to influence positively the behavior of young people. If constructive attitudes toward learning have not been internalized by this point, it can be difficult for adults to introduce them.

Students with a weak attachment and bond to the people and the program of the school, or with extraordinary pressures to belong to troublesome social networks in and outside of school, begin to pull away ( [Anderson, 1998](#)). At this point, around third grade, one sees the academic performance gain of children from families and communities under stress begin to reach a plateau. Future brain research may well show organic changes underlying this process.

As young people confront the developmental issues of preadolescence and early adolescence, they “place” themselves in the social scheme of things. They learn to develop an understanding—correct or not—of their exclusion from, or their limited opportunities in, the mainstream of the society. Their source of self-affirmation is from their own families and social networks. In fact, when schools ask young people to achieve at a high level, they are often asking them to be different from their own parents, the people with whom they have the most important and powerful social ties.

Around 12 to 13 years of age, children develop the cognitive capacity to consider hypothetical situations—not only what is, but what could be ( [Piaget, 1970](#)). This ability, in addition to widening their world, also makes it more complex. Simultaneously, numerous confusing physiologic and physical body changes take place. Succeeding and belonging in groups—with attendant group pressures—become very important tasks at this point. In addition, in seventh grade, in many places, young people are required to change schools and to make numerous social adjustments associated with doing so.

Most young people who are developing well and who are from the societal mainstream are able to manage these challenges with the average expected difficulty. However, many capable young people go on a sharp psychosocial downhill course at this point, leading to academic underachievement, school dropout, teenage pregnancy, delinquency and crime, and other social problems ( [Luthar et al., 1997](#); [Watson, 2000](#)). Disproportionate numbers of such youngsters—for reasons we discuss later—are African-American ( [Anyon, 1997](#); [Children's Defense Fund, 1989](#)).

By midadolescence, at around ninth grade for most, social class-related and race-related expectations and occupational and career possibilities begin to influence student performance greatly. Many high-ability African-American students from low-income backgrounds begin to do less well in school, often less well than the low-ability students from middle- and upper-class backgrounds ( [Fordham, 1988](#)). In addition, by this point, many students have serious academic deficiencies and negative attitudes and beliefs about themselves that make it difficult for them to perform adequately even when they desire to do so ( [Oyserman, 1999](#)).

The situation for middle-class African-American youngsters is different but still problematic. With adequate income, such families are under less stress and are better able to prepare their children to meet the expectations of the school. Many such parents believe that their economic well-being will protect their children from negative societal attitudes and behaviors related to race. In fact, many such parents avoid any discussion of race. At the other extreme, parents express angry and hostile feelings about racial injustice in a way that conveys powerlessness. They often encourage their children to be individuals, as if raceless, and as if they will not be forced to confront and manage racial issues in their lives ( [Fordham, 1988](#)). These youngsters often receive the same message in school.

The developing young person has no way to understand the disproportionate number of problems he or she observes among African-Americans. Such persons are not prepared to manage racial antagonisms, deliberate and unintentional, in ways that minimize the negative effects on their self-esteem. With little understanding of the experience, strength, and successes of their racial group, they cannot experience the level of positive identification with the group that is needed to manage the racial antagonism in the larger society more successfully. In adolescence, some young people from better-educated, middle-income black families who are struggling to establish their identity are drawn into behaviors defined by the society as black and internalized by some as “true” black behavior—low academic achievement, troublesome social performance, and the like ( [Anderson, 1998](#); [Fordham and Ogbu, 1986](#); [Oyserman, 1999](#)).

Pop culture entertainment has made this matter worse. Many nonmainstream young people are vibrant and intelligent and have developed powerful self-affirming artistic expressions of one kind or another. Some of it has become mainstream art and entertainment and is transmitted back as such to people from all socioeconomic groups. However, these expressions and the accompanying lifestyles lead to mainstream success for only a few. Many African-American young people embrace it as “their culture” without mainstream skills, thus limiting their ability to participate in the mainstream.

Although this chapter focuses on psychoeducational outcomes for African-American children, and although the historical political and economic issues are different, the same principles of child and adolescent development and behavior hold for mostly white schools and, indeed, for all children. Whenever parenting styles are ineffective and even harmful, for whatever reason, and whenever attention to students' emotional development is insufficient compared with cognitive growth in school, there is a higher probability of problem behavior on the parts of students. Our current concern about violence in schools is directly related to inadequate attention to students' emotional development at home and at school. Schools serving African-American children are disproportionately affected because of their difficult historical, political, and economic circumstances.

## **ECONOMIC AND SOCIAL HISTORY: EUROPEAN, ASIAN, AND AFRICAN-AMERICAN EXPERIENCES COMPARED**

Since the mid-19th century, the United States has moved through four economic stages: agricultural, before 1860; late agricultural and early industrial, from 1860 to 1900; midindustrial or heavily industrial, from 1900 to 1945; late industrial and early scientific and technologic, from 1945 to 1980; and postindustrial, highly scientific and technologic, after 1980. European and Asian immigrants arrived in the United States in large numbers before 1915. Most were able to maintain a reasonable degree of cultural continuity—religion, language, and other aspects of their culture—because they lived in ethnic enclaves, resulting in a reasonable degree of social cohesion ( [Lieberson, 1980](#)).

Some immigrants had ties to financial resources in the old country. Many created local and administrative structures in their attempts to gain power and control not available to them through state and national electoral representation ( [Anyon, 1997](#)). They obtained the vote in one generation. Cultural cohesion, the vote, and economic resources, together, permitted most groups to gain political, economic, and social power in one generation at a level that permitted their families to undergo four generations of change and development that paralleled economic change and development in the country ( [Lieberson, 1980](#)).

Before 1900, heads of households could be uneducated and unskilled and could earn a living in the economy, provide for themselves and their families, and give their children the kind of experiences that enabled them to gain the moderate level of education and skill needed to succeed in the midindustrial period between 1900 and 1945 ( [Wilson, 1987](#)). Successful heads of households in this economy were able to give their children the kind of experiences that enabled them to gain high levels of education and skill needed for the last stage of the industrial era, 1945 to 1980, and, of course, a similar process permitted most heads of households to prepare their

children for the postindustrial era.

European and Asian immigrant groups experienced numerous hardships, and as a consequence many unsuccessful families from these groups are living under stressful conditions in various areas of the United States today. However, most did not experience overwhelming abuse and denial of access to political, economic, and social structures; therefore, they did not undergo significant group and family deterioration. The experience and outcome for a significant number of African-Americans, Hispanics, and Native Americans were different.

The African-American experience was characterized by cultural discontinuity ( [Franklin, 1947](#); [Frazier, 1957](#)). The sense of adequacy, worth, and direction given by culture was lost in the separation from Africa. Because the central organizing force of West African culture was tight-knit kinship and lineage groups with communal traditions, a slave culture—and ultimately, release into a society that highly valued independence and competition—was extremely traumatic ( [Hildreth et al., 2000](#)). Slavery was a system of forced dependency, inherent inferiority, and no opportunity for a better future. These are three of the most problematic conditions that can be imposed on people who are then expected to function in a competitive economic and social system ( [Berry and Blassingame, 1982](#)).

Again, because the United States is based on Judeo-Christian principles and a commitment to democracy, there was a great need to rationalize the enslavement of blacks and their exclusion from the political, economic, and social systems after the abolition of slavery. First a non-Christian religion and later racial inferiority were used. After the Bacon Rebellion in Maryland in 1676, and perhaps others, the potential of a coalition of indentured white servants, black freeman and slaves, and poor white farmers represented a threat to the white population of significant wealth. To reduce the threat, white indentured servitude was eliminated. The notion of the superiority of whites and of the inferiority of blacks was gradually written into law in surrounding areas, eventually nationwide. These doctrines flourished because of the economic, psychological, and social benefit to whites across the socioeconomic spectrum.

These conditions created negative psychosocial consequences among many, and they were transmitted from generation to generation, from parents to children, even down to the present day ( [Elkins, 1963](#)). However, many African-Americans were protected to some degree by the "Black Church," fashioned from aspects of African culture and Protestant religions in the South, and by living under better conditions of slavery. Moreover, southern rural culture tended to reinforce the church culture and to facilitate effective family functioning ( [Comer, 1972](#); [Frazier, 1962](#)).

After the abolition of slavery, blacks in large numbers were denied the vote and, in fact, denied in significant numbers right up until the 1960s, the middle of the last stage of the industrial era. In addition, blacks had no ties to capital ( [Jaynes and Williams, 1989](#)). Without the vote and capital, it was not possible for the black population to limit the level of racial antagonism or racism. Extreme violence, terrorism, and pervasive subterfuge were used to bring about these conditions. Whites often walked off better paying jobs when white employers attempted to introduce black workers, and white workers were often victimized if they agreed to work with blacks. As a result, blacks were closed out of the political, economic, and social mainstream. Most black heads of households worked at the lowest levels of the economy—sharecroppers and tenant farmers, domestics, and industrial laborers.

Without political and economic power, blacks were closed out of educational opportunities. In the eight states that had 80% of the black population, four to eight times as much money was spent on the education of a white child as on the education of a black child ( [Bose and Caliber, 1936](#)). Where the black population was disproportionate in numbers, the disparity was as great as 25 times and more ( [Bose and Caliber, 1936](#)). This situation continued into the 1940s, perhaps beyond. As late as 1964 to 1965, the combined endowment of two prestigious white women's colleges was half the endowment of Harvard. One-half of Harvard's endowment was greater than that of all black colleges put together (totaling more than 100) ( [Council for Financial Aid to Education, 1967](#)).

Racial antagonism followed the black population from the South to the North, although in a less overt form. Thus, blacks could not experience the benefits of mainstream political, economic, and social participation in the North anymore than was possible in the South. Educated blacks were limited to professional areas—teachers, physicians, nurses, and the like. As a result, the kind of information, contacts, and connections needed to make the social system work for its members was not available. Even the growing political power since the 1980s has been in the absence of economic power; thus, it is less useful in making the social system work for the entire black community ( [Anyon, 1997](#)). All of this had a negative impact on black community and family functioning. Despite these difficult conditions, the black population did reasonably well right into the 1950s ( [Wilson, 1987](#)).

As late as 1950, only 22% of all black families were headed by single parents; now the number is more than 60% ( [Lugaila, 1998](#)). Moreover, black communities were reasonably safe. Today's serious conditions among a disproportionate segment of the black population began with (a) the mass migration of undereducated people from rural to urban areas in the 1940s and (b) education's increasingly becoming the ticket of admission to living wage jobs after 1945 ( [Wilson, 1987](#)). Blacks were disproportionately undereducated, compared with other groups, and they lacked the power to gain well-paying, low-skill jobs. In addition, previous organizing cultural ties were lost with mass migration. Many families that once functioned well in the traditional church-based, extended family, rural culture of the South began to function less well under urban conditions.

In addition, families functioning well in urban areas began to reduce family size, except for religious reasons. Families not functioning well did so less often. As a result, the growth in population from 1961 to 2001—among all groups—has been among low-income families operating under the greatest stress ( [U.S. Bureau of the Census, 2000](#)). For the reasons cited, African-Americans have a disproportionate number of families operating under excessive stress.

Most industrial countries developed social and educational policies that facilitated family functioning in the 1940s and 1950s. The United States did not do so to the same extent ( [Kamerman and Kahn, 1981](#)). As a result, many minority group families—more than among groups able to undergo several generations of development and stabilization—are not able to give their children the kind of preschool experiences that will enable them to meet the expectations of the school. For the reasons described earlier, some mainstream middle-class minority youngsters are affected. Thus, too many minority group children are undereducated.

## YALE SCHOOL DEVELOPMENT PROGRAM

In 1968, a Yale Child Study Center team (directed by Comer and made up of a social worker, a psychologist, and a special education teacher) began a collaborative project with the New Haven, Connecticut school system. This team worked in two schools in the inner city of New Haven as a subsystem of the school system. The plan was to develop a successful change process within these two schools, in collaboration with the parents and school staff, in a way that could be transmitted to all New Haven schools and beyond, eventually influencing national school policies and practices ( [Comer, 1980](#)).

Work began in the Martin Luther King Elementary School, from kindergarten to fourth grade, with approximately 300 students, and in the Simeon Baldwin school, from kindergarten to sixth grade, with approximately 350 students. After 5 years, the team left Baldwin, already vastly improved but resistant to additional changes, and began to work in the Katharine Brennan School, a school with students from kindergarten to fifth grade and with a profile similar to that of the original schools. These schools were 99% black, and almost all the students were from poor families. The students ranked 32nd and 33rd of 33 city schools on standardized achievement tests. They were 19 and 18 months behind in achievement in language arts and mathematics by the fourth grade. Their attendance was among the lowest in the city, and there were serious behavior problems in both schools. Teacher turnover was common, and parent dissatisfaction with the schools was widespread.

By 1979, without a change in the socioeconomic makeup of the school communities, the children were at grade level on standardized achievement tests. The improvement process was institutionalized, and it allowed the team to leave these two schools in 1980. In 1984, the two schools, again with no change in the socioeconomic makeup, tied for the third and fourth highest levels of achievement in the city on standardized achievement tests, a year above grade level at King School and 7 months above grade level at Brennan School. King School's attendance had been first or second in the city for 5 of the previous 6 years, and Brennan School's attendance was improved and ranked first once during that period. Behavior problems were greatly decreased in both schools; teacher turnover was extremely rare, and there were no serious behavior problems ( [Comer, 1976](#); [Comer, 1980](#)).

What the team found initially in these school communities served to provide insight for the formulations described earlier. The parents and the students were largely the descendants of rural, southern African-Americans, undereducated and working at the bottom of the job market, or not working and on public assistance. Many were experiencing significant economic and social stress. The underdevelopment and different development of their children made it difficult for them to meet the expectations of the school.

The school staff was not prepared to adjust successfully. The resultant difficult interactions between home and school, among school staff and between staff and students, led to alienation, distrust, disrespect, inadequate student-staff attachment and bonding, difficult teaching conditions, and limited academic learning.

The team from the Yale Child Study Center took an ecologic and child development perspective in identifying the problems and opportunities. They realized the need

to (a) change the difficult interactions among the adults into cooperative and collaborative interactions so that they would be able to support the level of child development that would make successful academic learning possible and (b) make teaching a gratifying experience. However, the team could not mandate a change in the culture of the school—its beliefs, attitudes, values, and ways. Efforts to teach school people about child development and behavior, in the hope that they would apply their knowledge in the classroom, were unsuccessful. The team instead gradually had to develop mechanisms that permitted the staff and parents to carry out a process that allowed them to function in a way that changed the culture and climate of the school and promoted child development, teaching, and learning, as needed.

The team members used their clinical skills to help the staff work more effectively with children displaying behavior problems. With each success, the team gained staff interest and appreciation for clinical methods. Eventually, the team was able to share child development and child-rearing knowledge, skills, and sensitivity with the staff and help them to appreciate how school attitudes, beliefs, values, and practices either facilitate or limit student growth and development, teaching, and learning.

With school staff and parents, the team eventually developed a change process called the *Yale School Development Program*, which has three mechanisms, three operations, and three guidelines designed to address the problems and opportunities found in all schools, but especially in schools serving low-income minority students. The three mechanisms are the Governance and Management Team, the Mental Health Team, and the Parents' Team.

The Governance and Management Team is the most important program element. It is representative of all the adult stakeholders in the schools—parents, teachers, administrators, Mental Health Team, the nonprofessional support staff, and so forth. It carries out the three critical operations: development of a comprehensive school plan, staff development based on the plan, and systematic assessment and modification of the program. This mechanism and these operations bring the key adults together in a way that enables them to establish agreement and to coordinate and carry out a program that reduces duplication and conflict, facilitates communication, and establishes mutual trust and respect. The comprehensive school plan focuses on carrying out activities that systematically serve to improve the climate of relationships and the academic program.

The Mental Health Team brings together personnel usually found working separately in schools—social worker, psychologist, special education teacher, nurse, and the like. (As this team took on more functions, the name was changed to the School Staff Support Team.) The team works with individual children, but the focus is on prevention. Team members often gain clues from individual student problems about the kind of building-level changes that can be made that will reduce them. For example, difficult adjustments to transferring into the schools led to serious behavior problems among some students. Transfer problems were reduced by orientation sessions for new students at the classroom and building level, thus preventing immediate, sustained, and more serious problems. Problems of discontinuity in the lives of children, interfering with their ability to establish the kinds of attachments needed to trust and take chances, led to a program of keeping children with the same teacher for 2 years, with great success. A program for helping children in crisis greatly reduced disruptive acting-out behaviors. A “Discovery Room” enabled many withdrawn children, doubtful of their ability to manage in the school setting, to function adequately.

The Mental Health Team person serving on the Governance and Management Team helped that group to establish policies and practices that prevented student behavioral problems or reduced their adverse consequences. In the process, this person provided all adults in the school with knowledge about how children grow and develop and how that is related to teaching and learning. The Mental Health Team also helped staff members to interact well together and to develop a school climate that facilitated the work of all involved. Adults functioning well in a good climate, who are knowledgeable about child growth and development, can facilitate attachment and bonding, child growth, and development, leading to adequate teaching and learning.

The third mechanism was the Parents' Team. Parents were involved at three levels: as members of the Governance and Management Team, selected by other parents; as members of the parents group that put on activities with school staff in support of the school program; and as visitors and participants in school activities. A school social worker or teacher served as a liaison between the staff and the parent group and facilitated their work in the school. This approach reduced the likelihood of the development of an adversarial relationship.

During one period, parents worked as assistants in the classroom, receiving a minimum wage for 10 hours and often volunteering for 20 to 30 hours more. The presence of parents in the school working closely with school staff reduced the alienation and distrust between home and school. It facilitated the attachment and bonding between students and school staff and the program of the school. Many parents working in this way were motivated to go back to school themselves; at least seven went on to college and became professional people. The presence of a core of parents in school increased the social comfort of all parents in the school setting. Because of this and other things done to improve school operations and climate, parent turnout for an important school activity, the Christmas Program, went from 15, in a school serving a little more than 300 students, to 400 in the same building 3 years later. Similar increases in parent participation have occurred in almost every school district in which the team has worked.

However, school restructuring alone was not responsible for these outcomes. It was necessary to change the culture of the school from being punitive with low expectations to having a focus on supporting growth and development, cooperation, collaboration, and high expectations for all. The team's three working guidelines were designed to change the culture. The mechanisms and operations of the program generated and carried the new beliefs, attitudes, values, and ways, or culture.

The three guidelines were (a) a “no-fault” policy, (b) consensus decision making, and (c) an agreement that the members of the Governance and Management Team could not paralyze the principal, but also that the principal could not ignore the input of team members. In this way, time was not wasted placing blame but was used to solve problems, decision making through consensus rather than voting kept groups focused on child development principles and avoided winner–loser behavior, and leadership was based on multiple perspectives. Although the Governance and Management Team generated the desired culture, its style permeated the school because all involved carried out the work set forth in the comprehensive school plan.

When the three mechanisms, the three operations, and the three guidelines were all working appropriately, everyone experienced ownership and responsibility for the school program, and a kind of synergism developed that gave the school hope and forward momentum. It enabled student growth and development to take place; adequate teaching and learning were then possible.

The team eventually developed a program that very systematically taught low-income minority group children the same skills that mainstream children from better-educated families gain simply by growing up with their parents. The team developed units in politics and government, business and economics, health and nutrition, and spiritual and leisure time in which there was an integrated teaching of basic academic skills, social skills, and appreciation of the arts. The artistic programs enabled children to channel aggressive energy that would otherwise be harmful to themselves and others, or at least disruptive, into the energy of recreation and learning. The social skills students gained through these activities enabled them to elicit a positive response from teachers and other people in the mainstream of the society. This facilitated the needed attachment and bonding to mainstream people and programs and motivated young people to achieve. Because of the beneficial outcomes of this approach, the New Haven School System has established a social development program from elementary school through high school in which students are taught appropriate problem-solving and decision-making skills.

Initially, it was expected that the Yale School Development Program would create conditions in schools that would motivate students to learn. It was expected that the curriculum and instruction would be provided by the district and school building. Rather than a curriculum focus, there was to be an academic focus through the comprehensive school plan. The team urged the use of age-appropriate academic programs and activities, a recognition of cultural diversity, and accurate information about the nature of the African-American experience. This gave schools the opportunity to use their own creativity in implementing district required curriculum and instruction activities.

Although many schools thrived under this approach, achieving remarkable gains, some did not. The Yale School Development Program team then undertook a more active role in promoting academic development in those schools that showed only incremental or no achievement gains. A Balanced Curriculum program was developed, as well as a Teachers Helping Teachers program and an Essentials of Literacy program. All these approaches improved instruction and achievement where they were implemented appropriately. The Balanced Curriculum program integrates the many demands on schools in a way that makes it manageable for the classroom teacher. The Teachers Helping Teachers program enables the staff to share and deepen knowledge and skills. The Essentials of Literacy program has helped nonreaders in the third grade learn to read in a remarkably short time. All these approaches are being studied and integrated into systemwide school change efforts.

The Yale School Development Program expanded nationally to approximately 700 schools in 68 districts. The team soon learned that to sustain these efforts it was necessary to work systemically or on a district-wide basis. Thus, the team reduced Yale School Development Program involvement to 500 schools, and with the expectation of eventually working back to a nucleus of 600 schools, all supported by district level school officials. Although most of the students in the schools serviced by the program are African-American or from other minority ethnic backgrounds, increasing numbers of schools with majority white populations are opting to

implement the program because of its demonstrated effects in improving the psychoeducational outcomes for large numbers of African-American and culturally diverse groups of students.

The research of many investigators ([Becker and Hedges, 1992](#); [Cook et al., 1999](#); [Haynes and Comer, 1993](#); [Millsap et al., 1997](#); [Noblit et al., 1997](#); [Noblit et al., 2001](#)) has documented the program's effectiveness in improving educational and psychosocial climate of schools. The research indicates enhanced student self-esteem, motivation, learning, and achievement. The work of the Mental Health Team in focusing attention on child development principles, proactive and preventive interventions, and child and family issues from a systems perspective has served to increase parents' involvement, their sense of efficacy in helping to raise and educate their children, and, in turn resultant and significant reductions in school absenteeism and behavior problems.

The Yale School Development Program has generated a wealth of knowledge and professional expertise regarding how to help people change and improve schools. The program leaders also learned that reforming educational services is an ongoing process, one that must be nurtured and constantly reshaped to respond to larger political issues, to new service developments, and, above all, to changing child and family needs. With this in mind, the Yale School Development Program has brought together and supported activities and programs that engage scholars from within and beyond the disciplines of child psychiatry around issues that intersect with the fields of child development and public education. One such program is the Comer–Zigler Initiative. This program is a structure that combines the existing School Development Program network and organizational plan with a school-linked program model that transforms a school into a year round, multiservice center: School of the 21st Century (21C). 21C was conceptualized by Yale University professor Edward Zigler, one of the principal architects of the Head Start Program. In designing the 21C model, Zigler recognized that changes in patterns of work and family life in recent decades have meant new concerns for parents, especially a pressing need for affordable, high-quality child care.

The Comer–Zigler Initiative is a unique collaboration because it capitalizes on the natural synergy of family and children's services connected to schools. It provides a process to bring all the adults in the community to the same table, where they can plan and share information in a comprehensive way. The guiding principles of the Yale School Development Program and 21C encourage the forging of a common mission, which keeps the child's development at the heart of all planning and decision making. Just as the three Comer mechanisms, operations, and guiding principles fostered collaboration that improved a school's capacity to affect student outcomes, so may they support and facilitate these kinds of practices and collaborative connections, as well as open doors for powerful new ideas and ways of doing business.

## **ROLE OF THE CHILD AND ADOLESCENT PSYCHIATRIST**

General psychiatrists focus more on the individual person than on his or her environment. However, because children are in a state of significant dynamic development and are dependent, the people and institutions around them (their critical environment) greatly affect their behavior. With greater appreciation of the power of people and institutions, child and adolescent psychiatrists can help to promote policies and practices in organizations and institutions that promote growth and development. Child and adolescent psychiatrists have this opportunity in their work with families, the juvenile justice system, social welfare agencies, schools, and others. Schools probably offer the best opportunity to affect the most people under the best conditions.

Going to school is a normative function with no stigma attached to it. It is the final common pathway for almost all children today. It is strategically placed in the developmental pathway, early enough to compensate for potentially troublesome preschool experiences. School is the work of young people and is of long enough duration on a daily basis and over the years to influence their development significantly. Thus, the child and adolescent psychiatrist should be involved in helping people engaged in every aspect of schooling—those providing preventive and direct services, policy, and research.

Although most child and adolescent psychiatrists do not have full-time involvement in the way the Yale Child Study Center team has had, many are engaged in regular consultation, accept school referrals, and interact with school people regarding patients referred to them. Child and adolescent psychiatrists doing school consultation usually work with staff or individual students and small groups. The work is usually child and family centered. However, as the psychiatrist enables teachers and administrators to help students, the child's respect and trust develop and allow him or her to begin to help the staff look at school practices and policies that often interfere with student growth and development or aggravate existing psychological problems. Sharing such insights often leads to the child psychiatrist's involvement in building-level staff development sessions. Such involvement provides even greater opportunities.

Through such sessions, the child psychiatrist can help school staff to understand how the fears and anxieties of students, the threat that school presents to many (and the related behaviors that arise), and the staff's own tendency toward control and punishment make matters worse. The psychiatrist can help staff to understand that academic learning is more than a mechanical process in which students willfully participate or refuse—that the affective component is important and the motivation for learning grows out of relationships at home and school and between home and school. The psychiatrist can help staff members to learn how their own behaviors promote either desirable or undesirable student responses. As the child psychiatrist and his or her team work with individual children, they can share their knowledge of child development and ways to promote growth and development with teachers, administrators, and parents.

Many schools lack orientation programs for new students, conflict-resolution approaches, activities designed to promote cooperation and collaboration, and a focus on helping students to develop inner discipline, self-motivation, and personal responsibility. Social problem solving and social skills are not taught systematically in most schools. Social activities are thought of as frills rather than as opportunities to help young people who are underdeveloped or differently developed grow and develop in ways that enable them to meet the expectations of the school. The psychiatrist is in a position to help school people understand how these skills and the resultant successes, confidence, and growth in self-esteem facilitate (a) bonding and attachment to school people and the program of the school and (b) teaching and learning.

Few school people understand the real or potential conflict that exists because of the income, education, racial, and other differences between home and school. Even fewer understand how, when, and why these differences influence academic learning ([Stipek, 1997](#)). Child psychiatrists can help teachers to understand the kinds of experiences that children from poor families need to be prepared for the level of abstract learning that is more required after 8 or 9 years of age, as well as the need to appreciate the effects of the thrust for independence among young people at this age and the later effects of social and racial status "placement" or identification with their respective groups. With such understanding, practices and programs can be devised at the building level to facilitate an appreciation for learning while enabling students to make a positive identification with their own group. In some cases, there will be opportunities to influence preservice programs and schools training future teachers and others. This will help them to be better prepared to support the development of children in school once they are in practice (Knitzer, 1997).

Knowledge of how and why children learn and behave is also needed among policy makers. Decisions about the employment and use of social workers, psychologists, special education teachers, and the like depend on their understanding of child development and behavior or lack of understanding. Likewise, school size and architecture, compensatory education programs, busing, school desegregation, the management of trauma, racial identification issues, class and race relations in general, gender, and various other issues require knowledge of the behavioral and social sciences held by child and adolescent psychiatrists. When child and adolescent psychiatrists are helpful with social issues at the building level, school people at the central office level are more likely to use them to help school board members, legislators, and the media to understand school district needs, opportunities, and limitations better.

The surge in violence in recent years has resulted in significant demand for child psychiatric services in schools. Children now, more than ever before, attend schools with serious psychological problems such as posttraumatic stress disorders, severe depression, behavior disorders, and attention deficit problems, many of which result from exposure to the chronic violence in their lives. The Yale School Development Program school-involved clinical consultants and Yale Child Study Center crisis teams provide significant and valuable interventions in New Haven schools to prevent and treat violence-related psychological problems among children. The result of these vital services is a special collaborative relationship between the New Haven schools and the Yale Child Study Center in which child psychiatrists, social workers, and psychologists participate in strategic planning and program development sessions with school officials. Notable also is the police fellowship program directed by Dr. Steven Marans, in which New Haven police officers are trained in child and adolescent development and psychology to improve their skills and increase their sensitivity ([Marans, 1994](#)) (Chapter 127).

Child and adolescent psychiatrists, because of their clinical focus, are probably better prepared than are other researchers to do the kind of research that is helpful in schools. The experimental research designs favored by nonclinicians take behavior out of context in a way that limits the value of their findings. The clinician looks at dynamic interactions in context, just as school people must do. In fact, school change leaders are suggesting that teachers be trained in a way that they can engage in the clinical practice of education. The participant–observer, ethnographer, case-study approach child psychiatrists are inclined to use is much more helpful. Child psychiatrists are in a good position to understand the insights and limitations of experimental design research findings and to help school people to use them appropriately.

Any effort to understand child developmental trajectories must focus not just on the child, but also on the child's ecosystem (Zigler and Styfco, 1996). Since the 1970s, there have in fact been many innovative and sophisticated studies of child developmental pathways specific to youth outside the sociocultural mainstream (Luthar et al., 1997). Richters and Cicchetti (1993), for example, argue the need to distinguish between two broad pathways to conduct disturbances: dysfunctional pathways, which are associated with neuropsychological or social cognition deficits; and normal pathways, in which conduct problems are essentially the outcome of extrinsic, environmental factors rather than internal dysfunction. These investigators conclude that antisocial behaviors may often occur among essentially normally functioning persons, as a reflection of their adaptation to prevailing mores and norms of a counterculture subculture. Collectively, the data emphasize that conceptions of "normal" developmental trajectories can vary substantially among children and families living in poverty as opposed to those who live in more affluent, mainstream families. These empirically derived findings are supported by other researchers (Luthar et al., 1997). Yet insights from these efforts are rarely integrated into the academic literature on child development. Many textbooks continue to be written as though these new research theories and findings did not exist (Luthar et al., 1997). The analysis of these variables often emerges as either an afterthought or as nuisance variables. Many researchers may be reluctant to enter into discussions about the impact of race and socioeconomic status because of the intricacies (both practical and political) of defining and isolating the variables.

In future theoretical conceptualizations of psychosocial development among inner-city youth of ethnic minority groups, it will be useful to acknowledge from the outset not only those developmental tasks that confront all children and adolescents, but also those that are unique, significant, and inevitable in the lives of the disadvantaged (Luthar et al., 1997). Developmental psychological research must aim to (a) shed light on the factors within and across economic and ethnic groups that influence development and (b) broaden our understanding of the range of variation that is possible over the course of development. A more complete understanding of human behavior will require us to consider, in a conscious, critical way, the impact of race, gender, and other important social categories not only on study participants and clients, but also on ourselves as researchers and clinicians (Luthar et al., 1997). As we broaden and augment our theoretical conceptualizations, it will also be crucial to redress the training of mental health professionals across disciplines (Knitzer, 1996). Child psychiatrists, for example, nowadays appreciate the impact of the social, cultural, economic, and political history on child development. Indeed, knowledge and understanding of the impact of family and social network experiences on children and an appreciation of historical, sociocultural effects are easily gained. The psychoeducational outcome of African-American students and of all other students in homogeneous and complex societies will be improved as we further our understanding of how societal, institutional, family, and individual developments amalgamate to promote or limit student readiness for academic learning and teaching.

## CONCLUSION

The work of the Yale School Development Program suggests that socioeconomic conditions, race, ethnicity, and other factors are less important than the quality of the developmental experience that children receive. Schools that provide children with good developmental, teaching, and learning experiences can promote greatly improved academic and psychosocial outcomes despite significant risk factors. There is a need to demonstrate the saliency of a focus on child and youth development in school and to create large numbers of educators capable of supporting it. It is also important for institutions preparing teachers and administrators for service and leaders who craft education policies to understand and to use sound child and youth development principles. The child and adolescent psychiatrist can provide knowledge and understanding that can be useful in all these efforts. A focus on child and youth development can go a long way toward overcoming the ill effects of traumatic historical conditions.

## SCHOOL AVOIDANCE

In developed countries, education is provided for all children, and there is an expectation that they should attend school regularly to take advantage of the opportunities for learning that are offered. Penalties may be imposed if children fail to attend school without an adequate excuse ([Berg and Nursten, 1996](#)).

In the United States, attendance laws were passed early in the 19th century requiring 12 weeks at school in a year, but enforcement came only much later ([Hersov, 1990](#)). In Britain, the current system of compulsory schooling, backed by legal procedures that can be used if attendance is unsatisfactory, was introduced nearly 100 years ago. Throughout most of the 19th century, children were affected to a considerable extent by extreme poverty, crippling diseases, early death, and employment in mines, agriculture, and factories, all of which made it difficult for any sort of national system of education to be organized. There were then few schools, and those that did exist often had poor facilities and inadequate teaching. However, there were some schools that attempted to encourage regular attendance. Inducements sometimes were offered in the form of a distribution of welfare benefits. Occasionally, lists of enrolled pupils who failed to attend regularly were displayed publicly as a means of deterring absence. A century ago, laws began to be enacted that enabled schools to be set up throughout the country, that compelled all children of specified ages to attend, and that also stated how regular attendance should be enforced. Courts were empowered to act when there was lack of compliance ([Berg et al., 1988](#)).

Despite this legal framework of mandatory education, many children have always had some time off school without adequate excuse. On average, at any one time in the United Kingdom, 10% of all children are out of school. Most are away with an acceptable reason, namely, a physical illness or a family holiday, but possibly as many as a third of them are off without adequate explanation. Community surveys have indicated what social, educational, and individual factors are associated with failure to go to school ([Farrington, 1980](#); [Fogelman and Richardson, 1974](#)). Epidemiologic studies also have shown that there is a small proportion of children who remain away from school for more than half the time they should be there ([Berg et al., 1993](#); [Galloway, 1980](#)).

In general, there is no strong relationship between the sex of the child and absence from school. In this respect, there is a big difference between this problem and delinquency, which is so much more common in boys. However, there is a clear connection between absence from school and poor social circumstances, as well as lack of parental interest in the child's education ([Fogelman et al., 1980](#)). Factors in the school also have been found to be related to children's staying off ([Reynolds et al., 1980](#); [Rutter et al., 1979](#)). It also has been found that a sizable proportion of children at school show considerable dislike of it and show some reluctance to attend ([Mitchell and Shepherd, 1980](#); [Moore, 1966](#)). The simple fact of failure to attend school also has been considered to be an important indicator of antisocial conduct occurring in later life ([Robins, 1978](#)). It is important to view the problems of school phobia and truancy against the general background of school attendance.

## SCHOOL PHOBIA (SCHOOL REFUSAL)

Difficulties in going to school may be due to emotional upset. This was probably first described by Jung in 1913 ([Jung, 1961](#)). Soon afterward, Melanie Klein and Anna Freud also reported the psychotherapeutic treatment of children who had fear of going to school ([Sayers, 1991](#)). [Broadwin \(1932\)](#) reported several children who appeared afraid to go to school and stayed at home. [Partridge \(1939\)](#) also provided descriptions of children who did not go to school and who preferred to remain close to their mothers. They were generally well behaved. The term *school phobia* was later introduced ([Johnson et al., 1941](#)) essentially for neurotic difficulties in leaving mother that were manifested as fear of going to school. In Britain, an alternative term, *school refusal*, was used more generally for similar problems ([Hersov, 1960b](#)). In this chapter, to avoid confusion, the descriptive label *school phobia* is used throughout because the view is taken that *school phobia* and *school refusal* can be used interchangeably. There have been many papers and review articles on school phobia, and some of the best accounts of childhood anxiety and depression have appeared in them. It would seem that school phobia often is the presenting problem that brings disabling emotional disturbances to professional attention ([Hersov and Berg, 1980](#)).

### Definition

School phobia is easier to describe than to define. Many children are referred to clinics for treatment who stay home, apparently unable to face the prospect of having to attend school, despite normal parental efforts to help bring about their attendance and despite the absence of any evidence that the child is antisocially inclined and is deliberately attempting to avoid going there. Such children tend to show emotional upset in various ways.

Although any clear set of defining criteria would appear to exclude some children who in all other respects would be considered to be suffering from school phobia, it probably is helpful to have in mind the following features and also to be aware of the pitfalls of applying them too rigidly ([Berg et al., 1969](#)):

1. *The child remains at home with the knowledge of the parents.* This is in marked contrast with truancy, which often is considered to be characterized by staying away from home as well as from school and attempts to conceal the absence from parents ([Hersov, 1960a](#)).
2. *There is an absence of severe antisocial behavior.* This also is in marked contrast to truancy, which often is found to be associated with antisocial conduct ([Hersov, 1960a](#)).
3. *Parents make reasonable attempts to secure their child's attendance at school.* This distinguishes the problem from condoned absence ([Kahn and Nursten, 1962](#)), in which irresponsible parents allow the child to stay away from school.
4. *There is emotional upset at the prospect of having to go to school.* This may be confined to the situation of leaving home or going to school, or may be part of a more general disorder characterized by anxiety and depression ([Atkinson et al., 1985](#); [DeAldaz et al., 1987](#)).

Problems associated with use of these criteria should be mentioned ([Bools et al., 1990](#)). Staying home during school hours, with parents knowing about it, often occurs when other features of school phobia are not evident ([Belsen, 1975](#)). Parents who are at work when the child should be at school obviously are less able to influence the situation. Sometimes parents, concerned about their child's getting into trouble wandering about, reluctantly accept that they are better off staying home. Mothers weighed down with family commitments in poor social circumstances may appear too easily prepared to accept the child's complaints of illness, and this can lead to unwarranted absence, with the child remaining at home. Occasionally, there is the situation of a child who is manifestly afraid to go to school, who hides in the

vicinity of home or takes refuge with a friend or relative. However, in general, staying home in the knowledge of parents is a necessary, if not a sufficient, criterion for considering that school phobia exists. To this extent, the term *home-bound school absence* (Waller and Eisenberg, 1980) is appropriate. Considering the second criterion of antisocial behavior, confusion may arise because some apparently school phobic children manifest aggressiveness and resistiveness at home toward members of the family. However, they do not show other antisocial tendencies, such as lying, stealing, destructiveness, or wandering from home, and characteristically appear rather timid with other children away from home. Regarding the third criterion, concerning parental attitudes, it can be difficult to distinguish the irresponsible permissiveness of the parent who encourages or condones absence from school and the oversolicitous attitudes of the typical school phobic child's parents who give way to their offspring's demands to avoid having to go to school because of fears of putting too much pressure on the child or because of their own difficulties in separation engendered by overclose emotional attachments (Eisenberg, 1958). The fourth criterion of emotional upset in the child also presents some difficulties when the reaction is confined almost entirely to the situation of having to attend school, is expressed as refusal and determined resistance without obvious fearfulness, or is mainly in the form of vague physical symptoms without any discoverable cause. This last situation has been referred to as the *masquerade syndrome* (Waller and Eisenberg, 1980).

It is possible that the syndrome of school phobia is an artifact created by the obvious need to treat children who are not fulfilling their legal obligations to go to school and at the same time have an emotional or affective psychiatric disorder. Severe separation anxiety can occur without refusal to go to school (Last et al., 1987), and school phobia can occur without separation anxiety, or indeed much evidence of anxiety or depression other than in the immediate situation of school attendance (Bools et al., 1990; Smith, 1970). It will require further epidemiologic surveys to clarify this issue.

### Clinical Features

Many cases of school phobia manifest the interplay of two tendencies: avoidance behavior in relation to school and active seeking of situations providing comfort and security (Perugi et al., 1988). Unlike children displaying the common fears of childhood, such as those of insects, loud noises, or the dark, whose apprehension increases when the phobic stimulus is present, once in school, children with school phobia quite often appear to behave normally. The fear in their case appears to dissipate very rapidly, only to recur the next day at the prospect of having to go to school. So many reviews of school phobia are available (Hersov, 1990) that it is unnecessary to give yet another account of the protean manifestations of this condition; just some of the main features are outlined.

### Background Characteristics

Boys and girls are approximately equally affected. The condition is most frequent in the early teenage years, although it can occur anytime a child is enrolled in school. No social class bias is apparent. Intelligence and educational achievement are in no way different from what would otherwise be expected. Children without brothers and sisters do not suffer from school phobia more than children with siblings, but there may be a tendency for younger children in the family to be affected (Berg et al., 1972). Correspondingly, parents tend to be older than otherwise would be the case.

### Onset and Course

There usually is a gradual onset, with increasing upset on school mornings, although a sudden occurrence of the problem is by no means infrequent. Absence from school because of illness or holidays may precipitate school phobia, and there seems to be a relationship with change of school, particularly to the more demanding educational settings a child moves to with increasing age. Stressful events at home, at school, or in the peer group outside school may be related to onset. Often, however, the problem comes on out of the blue (Gittelman-Klein and Klein, 1980). Some school days may be particularly avoided because of lessons or activities the child finds stressful, but in general it is most difficult for a child to get to school after the weekend at home. The distinction between problems of leaving home and of getting to school is not an easy one to make, so often both tendencies appear to be of equal importance and inextricably intermingled. Nevertheless, some workers in the field do make this distinction (Last, 1993). Efforts on the part of the child to overcome the problem vary enormously. At one extreme, the child gets ready for school and may even leave home, but cannot progress any further. At the other, there is total unwillingness even to contemplate return to school, refusal to get ready, staying in bed, and threats of self-harm or of running away. Emotional upset is manifested by obvious fearfulness, as well as by physical complaints that appear to be due to anxiety, such as anorexia, pallor, headaches, abdominal pain, diarrhea, and frequency of micturition. Depressive features, such as misery, tearfulness, and lack of enjoyment, often are found but are less persistent than anxiety (Berney et al., 1981). Manifestations of anxiety and depression overlap in many instances (Bernstein and Garfinkel, 1986). Although some school phobic children who show a very circumscribed difficulty in getting to school behave normally at home and with their friends, most affected youngsters are severely socially impaired by the condition. They appear concerned about being seen to be off school and often go out little or not at all; they cut themselves off from social contacts and become increasingly anxious and depressed. The problem can continue indefinitely if little or nothing is done about it. However, if efforts are made to restore regular school attendance by a combined effort of family, school, and professional workers involved with the problem, they often are successful, particularly in children younger than 11 years of age (Rodriguez et al., 1959) and in the more circumscribed school attendance difficulties (Kennedy, 1965). Otherwise, return to school and improvement in more general neurotic and affective disturbances are less likely to be satisfactorily achieved (Berg, 1970; Berg and Fielding, 1978).

### Associated Psychiatric Disorders

School phobia has been characterized by symptoms of emotional disturbance, including physical complaints that can be seen as manifestations of anxiety, for a long time (Berg et al., 1969). With more recent developments in categorizing psychiatric disorders affecting children using the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and *International Classification of Diseases* (ICD) systems of classification, importance has been given to the kinds of disturbance that are part of the problem of school phobia, while playing down the particular disabilities that are associated, namely the difficulties in relation to school attendance. Also, repeated revisions of these classifications have made it difficult to compare studies that use different versions, including ICD-9, ICD-10, DSM-III, DSM-III-R, and DSM-IV. Nevertheless, some kinds of disorder have been consistently present throughout these changes (Werry, 1996). School phobia is commonly associated with separation anxiety disorder, but other anxiety and mood disorders also are found, alone or in various combinations, including specific phobias, generalized anxiety disorder, depression, adjustment reactions, and, rarely, the more severe psychiatric disorders, such as schizophrenia and bipolar manic-depressive disorder. In a study of children who met the DSM-III criteria for separation anxiety disorder (Last et al., 1987), approximately three-fourths were having difficulty going to school. Additional diagnoses were made in 90% of the entire sample: Half of them had overanxious disorder, and a third, major depressive disorder. An investigation of approximately 50 school phobic children 9 to 14 years of age showed that approximately one-half had depression as assessed on well defined criteria (Kolvin et al., 1984). Separation anxiety, more or less corresponding to DSM-III separation anxiety disorder, was found in only approximately one-seventh of a group of Japanese school phobic children (Hoshino et al., 1987), a third of a sample of British school phobic students (Smith, 1970), and four-fifths of cases studied in New York (Gittelman-Klein and Klein, 1980). It is difficult to imagine that cultural factors are entirely responsible for discrepancies of these magnitudes. Referral practices determining the characteristics of samples of cases studied, differences in diagnostic criteria, and possibly unusually severe educational pressures, in the case of Japan, may have played a part (Chiland and Young, 1990).

In ICD-10, (World Health Organization, 1992) Separation Anxiety Disorder of Childhood (F93.0) is often used. Phobic Anxiety Disorder of Childhood (F93.1) is another category that is used. Social Anxiety disorder of Childhood (F93.2) also will be appropriate sometimes. Categories not limited to children are useful in some instances: Agoraphobia Without Panic Disorder (F40.00), some other Anxiety Disorders (F41), Reactions to Severe Stress and Adjustment Disorders (F43), Somatoform Disorders (F45), and Mild Depressive Episodes (F32.0) are likely to be found in some school phobic children. In DSM-IV (American Psychiatric Association, 1994), the category in the section of Other Disorders of Infancy, Childhood or Adolescence: Separation Anxiety Disorder (309.21), is particularly relevant. Of the DSM-IV disorders not confined to young people, Specific Phobia (300.29), Social Phobia (300.23), Agoraphobia Without History of Panic Disorder (300.22), Generalized Anxiety Disorder (300.02), Avoidant Personality Disorder (301.82), Posttraumatic Stress Disorder (309.81), Somatoform Disorders (300.81, 300.11), and Depressive Disorders (296 etc.) all have a place. Other categories of disorders also occasionally may be appropriate. School phobia has also been found to occur in the general population when no associated classifiable psychiatric disorder exists (Bools et al., 1990).

### Occurrence

The incidence of school phobia among referrals to child and adolescent psychiatric clinics has been reported as 11% (Chazan, 1962), 8% (Kahn and Nursten, 1962), and 4% (Smith, 1970). It thus forms a small, but not inconsiderable, part of the work of these services. In the cross-sectional Isle of Wight epidemiologic survey of children 10 to 11 years of age in the general population, the prevalence of school phobia was less than 3% of all psychiatric disorders (Rutter et al., 1970). A follow-up study at age 14 years produced substantially more cases of school phobia in the Isle of Wight, but no precise prevalence figures were given (Rutter et al., 1976). The severity of the manifestations of anxiety and depression that characterize school phobia, coupled with the severe social impairment that also is typical of the condition and the urgent need to do something about it that the legal requirement to attend school engenders, would provide obvious reasons for most cases coming to professional attention. However, there is some evidence that a considerable number of school phobic children are not identified as such and are dealt with more generally as school attendance problems (Galloway, 1985). A nonclinical sample of 100 severe school attendance problems (Bools et al., 1990) contained a

considerable proportion of children with school phobia, but only some of them had a classifiable ICD-9 emotional disorder. A study of 80 13- to 15-year-old children who failed to attend school for more than 40% of the time over several months ([Berg et al., 1993](#)) identified school phobia without an identifiable psychiatric disorder as well as school phobia accompanied by a DSM-III-R anxiety/mood disorder; 15 children in the sample had one of the latter disturbances. Few had had any contact with psychiatric services.

## Dependency

A child's attachment to and reliance on parental figures is referred to as *dependency* ([Bandura and Walters, 1963](#)). School phobic children often have been described as overdependent on their parents and as being overprotected by them ([Kahn and Nursten, 1962](#)). A self-administered questionnaire, completed by mothers, was developed to measure dependency: the Self-Administered Dependency Questionnaire (SADQ) ([Berg, 1974](#)). Compared with children in the general population, young adolescents with school phobia were found to be more likely to require assistance in washing, dressing, and carrying out other domestic tasks. There therefore was some evidence for undue reliance on parents. In the case of school phobic girls, they were less willing than control subjects to travel around unaccompanied. The SADQ includes a preference rating, and it appeared that mothers of school phobic children were more likely to encourage dependency in their children than would be expected ([Berg and McGuire, 1974](#)). However, an investigation of family life variables failed to show that families containing a school phobic child are deviant in the way they live their lives, looking at contact with relatives and friends, leisure and work activities, and how household tasks are apportioned ([Berg et al., 1981](#)). Some deficiency in self-reliance in the child's makeup therefore would appear to be a feature of children who get school phobia.

## Agoraphobia

The essentially adult disorder of agoraphobia is characterized by difficulties going out, traveling, and entering places from which escape is difficult, such as trains, buses, elevators, and crowded shops. There is a tendency to rely on the company of friends and relatives in going around because their presence seems to reduce anxiety. Agoraphobia has been thought of as a complication of panic disorder, which consists of severe and regular anxiety attacks. However, because agoraphobia often occurs without panic disorder, the suggestion has been made that some predisposition exists as shown by previous school phobia or a dependent personality ([Gelder, 1989](#)). A small proportion of adults who have agoraphobia have had the condition from before the end of the period of compulsory education ([Marks, 1969](#)). Transposing the features of adult agoraphobia to childhood and imagining how it would affect children, the result is very much what is observed with some children with school phobia who will not travel alone, who cannot go into school assembly, who are fearful of crowded playgrounds, and who rely excessively on their parents for comfort and security. Follow-up studies, in which adult psychiatric patients were asked if they had suffered from school phobia when they were young, showed an increased incidence compared with what would be expected in the case of affective and anxiety disorders in general, not just agoraphobia ([Berg et al., 1974](#); [Tyrer and Tyrer, 1974](#)). It also was found that children of agoraphobic women were more likely to have school phobia ([Berg, 1976](#)).

## Chronic Fatigue Syndrome

The so-called chronic fatigue syndrome, as it affects children, appears to have much in common with the masquerade syndrome described by [Waller and Eisenberg \(1980\)](#), where there is "home-based school absence" and physical symptoms without any apparent organic cause. In itself, staying home with little or no physical exercise can lead to a state of persistent fatigue and debility ([Wright and Beverley, 1998](#)). This suggests that those who advocate active rehabilitation and prompt return to school, in essence treating the problem as school phobia, have the correct approach ([Marcovitch, 1997](#)).

## Outcome

A number of follow-up studies of school phobic children have been carried out ([Gittelman-Klein and Klein, 1980](#)). In one of them ([Berg and Jackson, 1985](#)), 160 young adolescents with school phobia were reviewed on average 10 years after treatment in an inpatient psychiatric unit, when they were a mean 24 years of age. It was found that a third of them had required further treatment for psychiatric illness, mostly anxiety and depression. Five percent of the group had been readmitted to hospital because of severe affective disorders. Half were well on discharge after their treatment for school phobia, and they remained essentially free from further problems. The remainder had persistent but fluctuating symptoms and social impairment. More psychiatric illness had occurred than would have been expected. Similar findings were reported from a follow-up of 35 younger Swedish school phobic children with separation anxiety disorder (DSM-III), after 30 years of age, compared with other psychiatric patients and general population control subjects. Outpatient psychiatric treatment had been given in more of them and more of them had lived longer with their parents, as well as having produced less children themselves ([Flakierska-Praquin et al., 1997](#)).

## Management

So much has been written about the treatment of school phobia ([Berg, 1980, 1985b](#); [Hersov, 1990](#)) that it is necessary to include only a brief outline here. The principal aim is to bring about an early return to school ([Hersov, 1980](#)) because many of the symptoms of anxiety and depression that continue while the child is at home rapidly resolve once regular school attendance is restored. Management of associated psychiatric disorders is dealt with elsewhere in the book, so is not given much attention in this chapter.

### *Parental Counseling*

Regular contact with parents is important, on their own or with the affected child and other members of the family, when appropriate. It may be difficult to persuade parents of the need to bring about an early return to school. The usual reasons are either that they have been told by teachers, doctors, or others that the child is too ill to go and must be treated first, or they believe there is some physical illness as yet undiagnosed that should be identified and dealt with before the child can be expected to return. Less commonly, parents have a fixed view that something is wrong at school and that the child should not go back until that is put right. The process of counseling is to help disabuse parents and secure their cooperation. When there is the question of undiagnosed physical illness, the condition is called the *masquerade syndrome* ([Waller and Eisenberg, 1980](#)); persuading parents to accept that the problem is school phobia can take a little time. By rearranging hours of work, it may be that both parents can be there when it is time to go to school, so as to provide the child with more firm support. It may be necessary to accompany the child to school. It sometimes is only when the child realizes that the parents are at last determined to restore normal school attendance that resistance begins to crumble and progress is made. Counseling techniques along behavior modification lines can be used with parents to reduce their overprotectiveness and bolster their resolve, so that the child gets consistent cues and parent responses that help restore normal attendance ([Yule et al., 1980](#)).

### *Assisting the Child*

It is important to try to get the child's cooperation in going back to school. Regular individual counseling sessions may be helpful in achieving this. Initially there may be frank hostility, with the child refusing to cooperate in any way, but the situation usually improves with time, and it may help for the child to have some say in when and how return to school is brought about.

### *Behavioral Methods*

There is some evidence that a behavioral approach to ensure return to school and help parents and teachers respond appropriately to the problem of school phobia can be successful ([Blagg and Yule, 1984](#); [Yule et al., 1980](#)). A cognitive-behavioral approach used in a randomly assigned study indicated that school attendance improved significantly and emotional upset was reduced ([King et al., 1998](#)). However, an equally well designed and even more substantial investigation of cognitive-behavioral treatment failed to show that it was any more effective than traditional educational and supportive methods of management ([Last et al., 1998](#)).

### *Medication*

Some anxiolytic medication may be helpful in the initial stages of reintroducing a child to school ([Elliott, 1999](#)). There is no evidence that tricyclic antidepressant medication adds anything therapeutically to the clinical and psychological methods of management mentioned previously ([Berney et al., 1981](#); [Klein et al., 1992](#)). In their review of the use of antidepressant medication in school phobic children, [Murphy and Wolkind \(1996\)](#) take the view that it is not to be recommended because safer psychological treatment is available.

### *Placements*

Change of school often is suggested as a means of overcoming school phobia. It rarely is successful because the same problems arise at the new school, and neither

teachers nor other children have known the affected child under more normal circumstances. Sometimes special educational centers are available with transport provided, which can admit the child for a few weeks or months on a daily basis. The use of such units is recommended only when all attempts to get the child to normal school have failed. Special units normally have few children and a high staff-to-student ratio. Children with school phobia often find such centers acceptable and attend regularly without too much difficulty. From time to time, outpatient treatment, either alone or combined with a day placement, has no success, and admission to a residential center is required. Such centers often are part of psychiatric services and may be run on a weekly basis so that the child can be at home on weekends. There often are difficulties in getting the child to accept admission, but once this is accomplished, symptoms of emotional upset soon improve, and a planned return to school from home is arranged. Unit staff can be helpful in bringing this about. One or 2 days a week at the child's own school while he or she is still in the unit can be a useful stepping stone. The hospital admission has the added advantage of enabling associated psychiatric difficulties to be treated ( [Berg and Fielding, 1978](#)) by such methods as family therapy, social skills training, psychotherapy, and behavior modification, as appropriate. Bringing about separation from the family by admission does appear to have a beneficial effect in itself and starts the process of rehabilitation because the child usually attends the unit school and mixes with other children. Only rarely is admission to a boarding school, as a definitive solution to the problem, necessary. However, this may be the only answer when home circumstances warrant it (e.g., when there is mental or physical illness affecting a parent).

## TRUANCY

### Definition

Staying away from school without good reason with attempts to conceal the absence from parents is probably the most satisfactory definition of truancy ( [Fogelman et al., 1980](#)), although the term often is used more loosely to cover any unwarranted failure to go to school ( [Robins, 1978](#)).

### Prevalence and Etiology

Teachers' estimates of truancy often are preferred to those of parents or children, for obvious reasons. In one survey carried out in Glasgow, teachers judged that 3% of boys and girls were truanting at any one time ( [Institute for the Study and Treatment of Delinquency, 1974](#)). In the British National Child Development Study, teachers estimated that 8% of children had truanted in the previous year ( [Fogelman et al., 1980](#)). There probably are more boys than girls among truants ( [Fogelman et al., 1980](#)). Truancy predominantly affects poorer homes, where adverse social factors are evident, including large families, overcrowding, and multiple family problems ( [Farrington, 1980](#); [Hersov, 1960](#)). Some schools seem to foster truancy more than others ( [Reynolds et al., 1980](#); [Rutter et al., 1979](#)), possibly because of their more authoritarian regimes. There is a well established relationship between truancy and poor educational achievement ( [Douglas and Ross, 1965](#); [Fogelman and Richardson, 1974](#); [Gittelman-Klein and Klein, 1980](#)). There is a definite association between truancy and delinquency, even in girls ( [Berg et al., 1985](#)). The British Cambridge Study of Delinquent Development found truancy and delinquency to have similar backgrounds characterized by social adversity ( [Farrington, 1980](#)).

### Conduct Disorder

Psychiatric disorders characterized by antisocial behavior are common ( [Quay, 1986](#)) but tend to be confused with hyperactivity and attention deficit disorders, which frequently coexist ( [Taylor et al., 1986](#); [Trites and LaPrade, 1983](#)). In ICD-10 ( [World Health Organization, 1988](#)), truancy is given as one of the antisocial behaviors that occur in conduct disorders, but a recommendation is made that it should have persisted for 6 months before a child is considered as having a conduct disorder on the strength of it. Two main varieties are described: unsocialized conduct disorder, in which there is a pervasive impairment of relationships with other children, and socialized conduct disorder, in which there is not. Conduct disorders long have been thought of as the basis of truancy ( [Hersov, 1960a](#)). Suggestions that children who truant from school often fail to show the features of conduct disorders emerged from a general population survey of persistent absentees from school in Sheffield, England ( [Galloway, 1985](#)), and in a clinical study of 100 children who persistently failed to attend school without adequate reason ( [Bools et al., 1990](#)) who had been dealt with as disciplinary problems. It was found that approximately one-half of the group were typical truants, with a sex ratio of 3 boys to 1 girl. A cluster analysis indicated a group of 11 children nearly all of whom had both truancy and a severe conduct disorder, but there also was another group of 68, 44 of whom were categorized as truants but who usually had no conduct disorder.

### Clinical Features

Severity and persistence of truancy vary enormously. On the one hand, a child may take odd days off school because of some transient problem, and on the other, there may be persistent absence extending over weeks or months. Absence from school may be a solitary activity, or it may be in the company of others. The day may be spent wandering around, or the child may come home while the parents are at work ( [Belsen, 1975](#)). Efforts are made to pretend that normal school attendance is continuing, and accusations of staying off school frequently are met with denials. As would be expected based on previous discussion in this chapter, educational backwardness usually is associated with truancy, and when there is an associated conduct disorder, the situation is complicated by aggressiveness, destructiveness, poor personal relationships, wandering from home, dishonesty, and other antisocial activities, with or without delinquency. The family situation is, likewise, usually unsatisfactory in various ways, with severe social adversity creating stress in many instances. The child and adolescent psychiatrist is likely to encounter young teenagers who truant and who come into hospital having taken an overdose ( [Hawton, 1982](#)).

In Britain, disruptive pupils, many of whom truant, sometimes are permanently excluded from school when their conduct is particularly unacceptable. A recent survey by the Youth Justice Board found that the level and frequency of criminal behavior substantially increased after such pupils were expelled from school.

### Outcome

Severe and persistent truancy is an important forerunner of antisocial conduct occurring in adult life ( [Robins, 1978](#)). This may take the form of criminal behavior with convictions in the courts ( [Farrington et al., 1989](#); [Huissy and Howell, 1985](#); [Loeber and Dishion, 1983](#)). The importance of truancy as a predictor of antisocial tendencies in adult life is well established, but it should not be forgotten that many truants develop normally without manifestations of deviant behavior in later life.

### Management

Truancy normally is dealt with as a social, legal, or educational problem by social work, law enforcement, and school agencies. The severity and duration of the problem and its associated difficulties, particularly the occurrence of delinquent acts, often determine the ways in which it is handled ( [Turner, 1974](#)). Similar types of problems may go to juvenile court or be referred for psychiatric treatment ( [Gath et al., 1972](#)), so there appears to be an element of chance about which agency is left to manage the problem.

Some schools are more assiduous than others about checking up on and finding ways of preventing school attendance problems, by keeping in close touch with parents, providing education in keeping with the needs of their pupils, and motivating children to keep coming to school ( [Boyson, 1974](#); [Jones, 1980](#)). Special day units sometimes are available, which have a high teacher-to-pupil ratio and offer a limited education, which truants sometimes find more acceptable than normal school ( [Galloway, 1980](#); [Sproule, 1974](#)).

In Britain, there are education welfare officers, employed by local education authorities, who have the task of enforcing school attendance ( [Clark, 1976](#)). They keep an eye on school registers and visit homes where they suspect a child may be away from school without good reason. Parents or children may be taken to court if unwarranted absence from school continues. A series of randomly controlled trials carried out by juvenile court magistrates showed the value of courts supervising children who were persistently out of school without a satisfactory excuse in reducing unwarranted absence ( [Berg et al., 1988](#)). Occasionally, children who continue to truant are taken into care or sent to residential schools when efforts to provide a solution to truancy have failed.

Confronted with the problem of truancy, the clinician often must deal with associated conduct problems, educational backwardness, and family disadvantage. Close liaison between home, school, and the professional agencies involved is essential in restoring and maintaining normal school attendance. Particular difficulties may be helped by clinical procedures. Thus, poor peer group relationships may respond to social skills training. Social work counseling along behavioral lines may be helpful in motivating parents to keep in regular touch with school and take the child to school when appropriate. Very little has been written about the efficacy of routine clinical methods in truancy ( [Berg, 1985a](#)). If the analogous problem of absconding from residential institutions is anything to judge by ( [Clarke, 1980](#)), then close supervision, surveillance, and preventative activity by home and school will be the most useful approaches. Occasionally, children who come to clinics with problems of truancy have satisfactory homes, no educational backwardness, and few associated conduct problems. Clinical techniques such as counseling and behavior modification procedures, including the use of reinforcement, may be worth trying. Further work on the evaluation of different treatment approaches in truancy

is urgently needed.

[Chapter References](#)

Adoption involves the child psychiatrist primarily in terms of clinical consultation and treatment of the child–adoptive parent family unit. This chapter focuses on extrafamilial adoption, which currently comprises close to one-half of adoptions. The other half of adoptions, intrafamilial adoption, is comprised of adoption by step-parents after divorce, adoption by fathers of their out-of-wedlock children, and adoption of family members by uncles, aunts, and grandparents. The major psychodynamic issues affecting children who experience intrafamilial adoption are quite different from those affecting children who are adopted extrafamilially and are not treated in this chapter.

## ADOPTION AND SOCIAL CHANGE

Spanish immigrants brought to this country adoption modeled on the Roman tradition, in which adoption primarily benefitted the adopter ( [Huard, 1956](#); [Presser, 1971](#)). The purpose of adoption soon changed to that of providing homes for children in need of parents. Adoption, like divorce, was an occasional event until well into the 1800s. If one wished to adopt or divorce, a petition was made to one's state legislature ( [Witmer et al., 1963](#)). In 1851, Massachusetts was the first of the states to provide a general adoption law ( [Whitmore, 1876](#)).

Until the middle of the 20th century, adoption by deed without involvement of public agencies or the courts was the rule. In Texas until 1931, a child could be adopted by filing a written statement of adoption with the county clerk ( [Jacobs and Goebel, 1952](#); [Texas Revised Civil Statutes, 1925](#)). If the natural parents were living, a written transfer of parental authority accompanied the statement of adoption. After World War II, as adoption became part of the child welfare system, the system of agency adoption with screening and preparation of parents and counseling with birth parents was established ( [Kadushin, 1976](#)).

The number of children that young single women have given up for adoption has diminished because of increased use of contraception and wider availability of abortion, but probably most of all because these mothers choose to raise their children. Adoption of healthy infants appears to be increasingly the domain of independent adoption arranged by individuals and their attorneys ( [Wells and Reshotko, 1986](#)). Nonrelatives adopt probably 50,000 children yearly. Roughly 40% involve public agencies, and about 30% involve private agencies and independent adoptions ( [Berry et al., 1996](#)). International adoptions have stayed at about 10,000 per year for a number of years ( [Altstein et al., 1994](#)). Transracial adoptions within the United States of Native American children by white couples have been very few since the passage in 1978 of the Indian Child Welfare Act. Adoption of African-American children by white couples has varied according to changing federal legislation ( [Grotevant and Kohler, 1999](#)). Children who come from the foster care system and those with special physical and emotional needs are generally placed by public agencies. More than 50% of all adoptions via public agencies involve children designated as having special needs ( [Rosenthal and Groze, 1994](#)), which includes children who: (a) are over 10 years of age; (b) have serious physical, intellectual, or emotional problems; or (c) are members of a large sibling group. The most commonly occurring special needs are emotional disturbance and mental retardation ( [Rosenthal, 1993](#)). Recent developments in this area are presented in some detail because of the importance of the child welfare system to adoption and because consultation is often requested of child psychiatrists by public agencies.

## The Child Welfare System and Adoption

Some changes have taken place regarding the stability of foster placements, and foster parents being allowed to adopt children in their care. The changes have resulted in large part because of increased public awareness of the problems facing children in care. [Maas and Engler \(1959\)](#) published their study of over 4,000 children in foster care in 1959. Their data indicated that more than half of the children would remain in foster care for most of their childhood. A 1973 study of children in foster care in Massachusetts indicated that 60% had been in foster care between 4 and 8 years, with the average being over 5 years ( [Gruber, 1973](#)). The Columbia University longitudinal study of children in foster care in New York City showed that two-thirds of the 36% of children who remained in foster care had lost contact with their biological parents at the end of 4 years ( [Fanshell, 1976](#)). In 1983 a class action suit was brought against the entire foster care system of Jackson County, Missouri, which encompasses Kansas City. Twenty-nine percent of the children had been placed in four or more homes within a span of less than 5 years. The longer a child remained in care, the more likely he or she was to experience movement from home to home ( [Mushlin et al., 1986](#)). A federal court ordered specific improvements in foster care policies and practices ( [G.L. v. Zumwalt, 1983](#)). That decision relied on a doctrine that children in public care have a "right to freedom from harm" ( [New York State Association for Retarded Children v. Rockefeller, 1973](#)).

Various schemes have been devised for stimulating permanency planning and activity in order either to return the foster child to the parental home or make the child available for adoption ( [Bush and Goldman, 1982](#); [Festinger, 1975](#); [Seltzer and Bloksberg, 1987](#); [Ten Broeck and Barth, 1986](#); [Wiltse, 1985](#)). The 1980 Adoption Assistance and Child Welfare Act (PL 96-272) stipulated federal requirements for a reporting and tracking system for children in foster care ( [Hartley, 1984](#)).

## The Foster Parent: More Rights and the Ability to Adopt

Traditionally foster parents have not been considered to have a legally recognizable interest in their foster child. When foster parents have attempted to contest removal of the child by the welfare agency or have attempted to adopt the child against agency wishes, courts have almost uniformly upheld the sanctity of the placement contract between foster parents and the agency along with the rights of the biological parents ( [Katz, 1971](#)). In the 1977 case of *Smith v. Organization of Foster Families*, the Supreme Court recognized that for a child

who has been placed in foster care as an infant, has never known his natural parents, and has remained continuously for several years in the care of the same foster parents, it is natural that the foster family should hold the same place in the emotional life of a foster child, and fulfill the same socializing functions as a natural family. For this reason, we cannot dismiss the foster family as a mere collection of unrelated individuals (pp. 844–845).

The Court, however, judged the procedures utilized by the State of New York to be constitutionally adequate for the protection of the foster care parent–foster child relationship. Any rights that foster parents accrue can benefit the foster children in their care because of the enhanced stability of the foster placement ( [Derdeyn, 1986](#); [Derdeyn et al., 1978](#)).

Studies of children's experience in foster care and adverse publicity regarding various aspects of the public child care system have led to some significant changes with regard to foster parents' becoming adoptive parents ( [Coyne and Brown, 1986](#)). In the past child welfare agencies selected adoptive and foster parents according to quite different standards. Now the requirements for foster and adoptive parents vary little, and adoption by foster parents has become commonplace ( [Derdeyn, 1990](#)).

### Openness Versus Privacy in Adoption

Adoption policy until the last three decades has required that the biological parents, whether terminating rights voluntarily or by legal force, disappear completely from the child's life ( [Wrobel et al., 1998](#)). In recent years, because of pressure from some adopted persons and advocacy on the part of some professionals, there is interest in and more adoptions taking place under conditions of "open" adoption ( [Avery, 1998](#); [Baran and Pannor 1990](#); [Belbas, 1987](#); [Berry, 1993](#); [Chapman et al., 1987](#); [Demick and Wapner, 1988](#); [Sachdev, 1991](#); [Triseliotis, 1987](#); [Watson, 1988](#)). This means that the birth parent meets the adoptive family and has some arrangement regarding sharing information or visiting after adoption. In a related phenomenon, an English study ( [Ryburn, 1996](#)) discovered postadoption contact after termination of parental rights between children and their birth relatives to be over 50%.

Some states have passed laws to open the sealed adoption record for adoptees wishing to make contact with birth parents. The birth parent is notified and is given the option to consent or to refuse the adoptee's request. If one birth parent has died or a birth parent does not consent, the adopted person may petition the court to open the birth record. The court then acts on the basis of weighing the interest of all the parties ( [Auth and Zaret, 1986](#); [Weidell, 1984](#)).

In the areas of joint custody and grandparent visitation, the courts and society are increasingly accepting of diminished family boundaries. In these instances, however, it is adults and not the children of divorce who have been motivated for change and effected that change by political means ( [Derdeyn, 1985](#); [Derdeyn and Scott, 1984](#)). The desire for change in adoption is different from that in divorce, in that it is the adoptees themselves who are feeling the need to make changes in the structure of adoption to diminish the secrecy and mystery, and to provide knowledge of and contact with biological parents. Some years ago, [Triseliotis \(1973\)](#) suggested that people searching for biological parents might have unsatisfactory relationships with adoptive parents and poor self-images, whereas [Sorosky and associates \(1975\)](#) determined that their interview study established that was not the case. Today the desire to make some sort of contact with biological parents is widely accepted as a normal phenomenon devoid of implications of psychopathology or maladjustment ( [Anderson, 1988](#); [Aumend and Barrett, 1984](#); [Campbell et al., 1991](#)). Clinical experience as well as some reports in the literature ( [Moran, 1994](#); [Sorosky et al., 1974](#)) indicate that making contact with birth parents is generally found to be arduous but ultimately relieving emotionally for the adoptee and birth mother, and challenging for adoptive parents ( [Silverman et al., 1994](#)). It is becoming apparent that many women who relinquished a child have a desire to establish contact and gain some emotional relief from doing so ( [Field, 1992](#)). A group of clinicians have determined a need for and have developed adoption triad—adoptee, adoptive parents, and birth parent(s)-support groups ( [Valley et al., 1999](#)). A suggestion has been made of a relationship linking dissimilarity between adoptee and adoptive parents and the drive to search for birth parents. The drive to search would arise out of the more problematic identification with dissimilar parents ( [Hollingsworth, 1998](#)).

A survey regarding 1,396 newly adopted children in California indicated that most of the adoptions were open, and that children in open adoption had better behavior scores than children without access to birth parents ( [Berry, 1991](#)). One investigator found that adoptive mothers who had prenatal contact with the child's mother reported a significant positive effect on their attitudes toward both the biological mother and adopted child ( [Lee and Twaite, 1997](#)). Two-thirds of these adoptive parents had met one or both of the birth parents. A study of 12 high-risk adopted children and their families determined that cooperation between the children's adoptive and birth family members appeared to positively affect social and emotional outcomes for these children ( [Grotevant et al., 1999](#)). Agencies, typically protective of confidentiality, had 40% of their adoptions open, whereas 80% of the independent adoptions were open ( [Berry, 1991](#)). Regardless of whether adoption was open or closed, families adopting through private agencies have been found to feel best prepared and satisfied ( [Berry et al., 1996](#)). A 4-year follow-up study of a sample of 764 adoptions showed a marked drop in contacts in open adoptions over that span of time, and indicated no effect of openness on child adjustment ( [Berry et al., 1998](#)).

### ADOPTION OUTCOME

Reports of the incidence of adoption in children referred for outpatient treatment have established that adopted children are overrepresented compared to their proportion in the population, which is usually estimated to be 3.5% ( [Schwam and Tuskan, 1979](#)), and that they tend to be referred for externalizing, acting-out behaviors ( [Finley, 1999](#); [Goodman et al., 1963](#); [Humphrey and Ounsted, 1963, 1964](#); [Menlove, 1965](#); [Offord et al., 1969](#); [Schechter, 1960](#); [Schechter et al., 1964](#); [Simon and Senturia, 1966](#)). A study of 2,148 international adoptees found that early neglect, abuse, and the number of changes of care taking environment increased the risk of later maladjustment ( [Verhulst et al., 1992](#)). Recent studies have continued to find an overrepresentation of adopted children and adolescents in outpatient clinics ( [Kotsopoulos et al., 1988](#)) and on inpatient wards. A study of 3,698 adolescents, 145 of whom were adopted, corroborates the overrepresentation of young adoptees in clinical settings. The adoptees did have more problems than the controls, but were also referred more readily for lesser problems ( [Warren, 1992](#)).

Adopted children are often classified for investigative purposes according to the following factors: adoption at birth; adoption at an older age after satisfactory early-life care; and adoption at an older age after adverse early-life care. Problems in childhood and adolescence tend to increase with age at adoption and having experienced adverse care ( [Howe, 1997](#)). Some children adopted from orphanages in foreign countries have experienced the deprivations of limited caretaker contact, yet adapted surprisingly well, and their parents were satisfied with the adoption ( [Groze and Ileana, 1996](#)). Developmentally vulnerable is the term often applied to children with multiple developmental challenges: having been born to drug abusing mothers, having histories of low birth weight, failure to thrive, neurological problems, and so on. The drug-exposed children tend to become indistinguishable from non-drug-exposed children ( [Barth and Needell, 1996](#)), and children with other developmental vulnerabilities tend to do well and have satisfied adoptive parents ( [Hoopes et al., 1987](#)).

A 1985 study of inpatient adolescents found a great overrepresentation (over 21%) of adopted children, but no difference in diagnosis from the control group ( [Senior and Himadi, 1985](#)). Senior and Himadi cite a number of studies of adopted inpatients. Although one of the studies found a slight underrepresentation ( [Humphrey and Ounsted, 1963](#)), the rest showed a significant overrepresentation: 9.4% of girls and 9.3% of boys ( [Work and Anderson, 1971](#)), 7% of boys and 11% of girls ( [Kellman-Pringle, 1961](#)), and 4.3% of both boys and girls ( [Kirk et al., 1966](#)). A review of over 5,000 patients registering for their first psychiatric hospitalization found a moderate overrepresentation of adoptees on the children's service and an underrepresentation on the adult service ( [Brinich and Brinich, 1982](#)). [Rogeness and colleagues \(1988\)](#) found 8.7% of 763 consecutive admissions to a children's psychiatric hospital to be adopted. [Dickson and colleagues \(1990\)](#) found 11.7% of their inpatient population to be adopted.

[Kim and associates \(1988\)](#) found an overrepresentation of adoptees in their hospitalized children and an underrepresentation of adopted children referred to the regional juvenile court. These authors postulated that the relatively high socioeconomic status of adoptive parents was instrumental in their adoptive children's entering the psychiatric rather than the criminal justice network. A 1975 study of adopted children before the juvenile court found the children's parents to be extremely rejecting of them and the courts to be particularly harsh with them, compared to a group of neglected children also referred by the court to the psychiatric clinic. The authors ascribed the difference in the court's dispositions in the two groups to the parents of neglected children contending for their custody and the parents of the adopted children failing to defend them or even requesting placement in correctional facilities ( [Lewis et al., 1975](#)). A more recent study of 3,280 juvenile delinquents did not find significant differences between adopted and nonadopted children in terms of their dispositions ( [Kim et al., 1992](#)).

Studies carried out with nonclinical school populations also found some differences for the adopted group. [Brodzinsky and colleagues \(1984\)](#) studied 260 adopted and nonadopted children by means of maternal and teacher ratings. Adopted children were found to be higher in psychological and school-related problems and lower in social competence and school achievement than were nonadopted children. [Lindholm and Toulaitos \(1980\)](#) compared 41 adopted and 2,991 nonadopted children of a suburban school district by means of teacher ratings on a behavior problem checklist. Adopted children evidenced more conduct and personality problems. The Ontario Child Health Study, a community survey of 3,294 children, 104 of whom were adopted, found that adopted boys had a significantly increased risk of psychiatric disorder versus nonadopted boys ( [Lipman et al., 1992, 1993](#)). A recent comprehensive review of adoption as a risk factor for development pointed out that

the increased involvement of adopted children in mental health treatment may be because of their parents' and other adults' predisposition to seek treatment, and because of disturbance related to early-life maltreatment ([Haugaard, 1998](#)). The issue of adoption and psychopathology might best be stated: Adopted children exhibit more psychopathology than nonadopted ones but not as much as their adoptive parents think they do ([Sullivan et al., 1995](#)).

### Transracial Adoption

The literature indicates that the adjustment of these children is indistinguishable from that of white children ([Feigleman and Silverman, 1984](#); [McRoy et al., 1982](#); [Shireman and Johnson, 1986](#); [Silverman and Feigleman, 1981](#); [Tizard, 1991](#)). An 18-year follow-up study of Asian, black, and white children adopted by white couples showed better adjustment of Asian and black children than of white ones ([Brooks and Barth, 1999](#)). A comparison of early adopted Korean-American adoptees with biological children of their adoptive parents showed lower social competence in the adopted children and higher internalization in biological children, but very little difference in adjustment overall ([Kim et al., 1999](#)).

Although adopted children and the adoptive family receive a disproportionate share of clinicians' attention, it is also evident from the literature that most adoptions go very well indeed. [Kadushin \(1967\)](#) reviewed a number of follow-up studies regarding children adopted in infancy ([Brenner, 1951](#); [Davis and Douck, 1955](#); [Edwards, 1954](#); [Fairweather, 1952](#); [Fradkin and Krugman, 1956](#); [Morrison, 1950](#); [Nieden, 1951](#); [Theis, 1924](#); [Witmer et al., 1963](#)) and found "success" rates of 78% to 86%. The younger the age of adoptive placement, the better the outcome ([Humphrey and Ounsted, 1963](#); [Kotsopoulos et al., 1993](#); [Offord et al., 1969](#)).

### BENEFITS OF ADOPTION

Adoption is very desirable and constructive for those children who are in need of it. Although the fact and the mystery of being relinquished by parents is an important issue for every adopted person, it is the early life experiences that are surely the most problematic for children who are later adopted. Studies of children who moved from foster to adoptive families have found that immediate and long-term problems were greater when the move was made between 6 and 12 months than when it was made before 6 months ([Yarrow and Goodwin, 1973](#); [Yarrow and Klein, 1980](#)). The deleterious effect of early experience was mitigated by high quality of care in the adoptive home.

The value of adoption to children is made particularly evident by studies that include children who have fates other than adoption. A group of children who spent their first 2 to 7 years in an institution was followed for a number of years. The children who were adopted were noted to be overly friendly with strangers and attention seeking, and to cause moderate to severe problems in the school situation. The children who were in foster care or who returned to their families, however, fared much worse ([Tizard and Rees, 1975](#)). [Bohman and Sigvardsson \(1980\)](#) identified 624 Swedish children who were candidates for adoption as infants. At 11 years of age they evidenced greater maladjustment than classmates, whether they had been adopted, placed in foster care, or remained with their biological mother. At age 15, adjustment of the adopted children differed only slightly from that of their classmates, whereas children living in foster homes or with their biological mothers had a high degree of social maladjustment and/or scholastic underachievement. The military enlistment process at age 18 confirmed the findings at age 15. The adopted boys were indistinguishable from age-matched controls. Boys who remained with their mothers or were raised in foster homes scored lower in intelligence and psychological tests and were more frequently exempted from military service for social or psychiatric reasons than the adoptees ([Bohman and Sigvardsson, 1990](#)). [Dumaret \(1985\)](#) followed the progeny of 28 French mothers: 35 children were abandoned and adopted early in life by well-to-do families, 46 were raised by their biological mothers and/or her relatives, and 21 were raised in institutions or foster homes. In primary and secondary schools the percentage of school failure for the adopted group was 17%; for the biological family-raised group, 67%; and for the institutional or foster care group, 100%. (All the institutional or fostered children had been excluded from the normal secondary school curriculum.) Teachers' ratings of behavior showed both the adopted and family-raised groups of children to be more problematic than their classmates.

### HEREDITY AND ENVIRONMENT

The developing field of behavioral genetics has shed much light on issues of nature and nurture through studies comparing siblings, partially related siblings, twins raised together and apart, and biologic parents and their adopted-away offspring. Although quantifying the role of genetics, these studies are also quite remarkable for quantifying the effects of environmental influences. Two general forms of environmental influence, shared and unshared environment, have been shown to contribute to developmental processes and outcomes in the context of genetic influence. Shared environment refers to the environment common to siblings raised together. Nonshared environment refers to influences and experiences unique to an individual within a family of siblings. It may include perinatal factors, traumatic experiences, extrafamilial experiences, illnesses, different parental expectations and reinforcement, or even common factors experienced differently by different children ([Pike and Plomin, 1996](#); [Rowe, 1987](#)). Behavioral genetics gives us a unique window into the interaction of genes and environment in adoption.

### Intelligence and Cognitive Abilities

An early study by [Skodak and Skeels \(1949\)](#) suggested a substantial influence of early environment in raising the average IQ of a group of adoptive children. The brighter children had brighter biological mothers, however, indicating that heredity played a role in individual differences, although the environment raised the IQs of the group of adopted children as a whole.

Subsequent studies have indicated that individual differences in IQ are substantially influenced by genetic differences among individuals, but that family environment also has a significant impact ([Scarr and Weinberg, 1983](#)). A Texas study involved 300 families who were adopted immediately after birth from a home for unwed mothers ([Horn, 1983](#)). Psychometric testing was carried out with the biological mother, the child, and both adoptive parents. The adopted children were more influenced by their biological mothers than by the intellectual milieu of the adoptive family. Other research suggests the environmental influence of middle- to upper-class families on the IQ of adopted children may be a temporary one limited to childhood ([Rowe, 1997](#)).

Environmental factors play an important role in childhood, but by late adolescence genetic influences best predict intelligence ([Lynn, 1994](#); [Scarr and Weinberg, 1983](#)). [Alarcon and colleagues \(1998\)](#) assessed data from the Colorado Adoption Project and found that heritability accounts for around half of the correlations among cognitive abilities at age 12. Plomin also has suggested that genetic influences account for approximately half of the variance in general cognitive ability ([Plomin, 1999](#)). Reviewing the environmental influence on intelligence, Kaufman has compared it to the environmental influence on weight, where lifestyle plays an important role in the context of a genetic predisposition ([Kaufman, 1999](#)).

### Behavior Disorders

Studies in this area are notable for findings of both significant hereditary predisposition and significant environmental effects of the adoptive home. [Cadoret and Crowe \(1983\)](#) found a marked increase in antisocial behaviors in adolescence when the adoptee had both a genetic factor and an adverse environmental factor such as psychiatric problems, antisocial behaviors, or drinking problems in the adoptive home. Biological parents who were alcoholic or antisocial tended to have adopted-away offspring who were antisocial in adulthood. Two environmental factors significantly increased adoptee antisocial personality: placement in a home where there was an alcohol problem or antisocial behavior, and placement in a lower socioeconomic home for a child whose biological parents had exhibited criminality or delinquency ([Cadoret et al., 1990](#)). [Roth and Finley \(1998\)](#) reviewed the literature on the development of antisocial behavior and concluded that biological parent antisocial behavior, adoptive parent antisocial behavior, and low adoptive family socioeconomic status all predict antisocial behavior in adoptive children, although the association appears to be strongest with the biological parent status. [O'Conner and coworkers \(1998\)](#) investigated antisocial behavior and depressive symptoms over a 3-year period in a population of siblings and twins, finding a strong role for both genetic and nonshared environmental influences on the stability of these symptoms. Shared environment influenced antisocial behavior but not depressive symptoms. Additionally, genetic factors appeared to vary over the 3-year period, suggesting that the nature and impact of genetic factors on behavior may change through the developmental process. [Gjone and Stevenson \(1997\)](#) showed a genetic influence on the covariance between emotionality and attention problems and emotionality and aggressive behavior. The importance of nonshared influences on antisocial behavior and depressive symptoms is underscored by findings that suggest almost 60% of the variance in antisocial behavior and almost 40% of the variance in depressive symptoms is because of conflictual and negative parenting behavior directed toward an individual ([Reiss, 1995](#)).

### Depression

Most investigations into the development of depressive symptoms show that heredity causes between 33% and 50% of the variance between individuals, with nonshared environment being the dominant environmental factor ([Eley et al., 1998](#)). Eley found that in childhood, nonshared environmental factors have the greatest impact on the development of depressive symptoms, followed by shared environment, and finally genetic factors. There is evidence to suggest that the effects of heredity may increase with age, but favorable environmental factors may delay or alter the manifestation of hereditary influences ([Muhs and Schepank, 1995](#)). [Pike](#)

[and Plomin identified maternal negativity to be particularly salient in the development of depressive symptoms \(1996\)](#).

## **Adoption and the Interaction of Heredity and Environment**

Genes and environment have an interrelated impact on the development of adopted children. The parenting practices of adoptive parents (adoptive environment) are affected by the behavior of their adopted children, which itself may be significantly modulated by genetic factors. Thus, genetic influences on the child may also act to modify the environment in which the child lives. The impact of a child's genes on the environment has been demonstrated to begin in infancy through both cognitive and temperamental factors ([Saudino and Plomin, 1997](#)), and there is also evidence for genetic influence on the environment through antisocial and hostile behavior ([Ge et al., 1996](#); [Roth and Finley, 1998](#)). The relationship between negative parenting, generally seen as an environmental influence, and antisocial or depressive symptoms may be primarily because of genetic factors (Niederhiser et al., 1999).

Behavioral genetics has shown that genetic factors play a significant role in child and adolescent development, and that these factors influence the cognitive and personality traits of adopted children. As significant as these influences are, environmental influences, especially nonshared environment, play a vital role as well. Genetic influences, with the possible exception of some cognitive abilities, do not lock individuals into a particular developmental trajectory. Rather, there is a complicated and diverse interaction between genetic and environmental factors affecting development.

## **ADOPTIVE CHILDHOOD: CHALLENGES AND DIFFERENCES**

It is a testament to the complexities of the human mind that the fact of adoption makes the difference that it does. One could surmise that on the face of it, adoption should not make much difference to a child adopted early in life, for the child can have no perspective on the identity of the care taking adults. Later, however, when the child is told of adoption, he or she must deal with the incomprehensible questions of who the other parents are and why they left him or her. Although the practice of telling children early of their adoption is almost universal, the benefits and liabilities remain unclear ([MacIntyre and Donovan, 1990](#)). [Brodzinsky and colleagues \(1981, 1984, 1995\)](#) have established that "being told" about adoption leads to a process of understanding on the basis of outside information provided and inside cognitive development. As in most areas of significant communications between parent and child, the parent's comfort regarding adoption is of utmost importance. The parent who can talk easily of adoption is likely to be able to observe the child's response and gauge what is communicated by the child's response at a given time.

### **Adoptees' Images of Biological Parents and Self**

Children tend to "solve" the narcissistic injury and unfathomable mystery of having been given up for adoption by assuming that they were unlovable, dirty, too angry, or otherwise bad or unrewarding to their biological parents.

One adopted boy talked about how at the orphanage the children were not cared for and were fed slop. When his parents brought him home at 3 months, he vomited white stuff that he had been fed at the orphanage. At the orphanage they only cared for themselves and were just trying to get rid of all the little kids, which is what his real mother wanted to do also.

Nickman points out the complex of losses adoption entails: the knowledge of having been relinquished, with its deleterious effect on self-esteem; lack of knowledge regarding one's birth parents; and the multitude of stigmatizing experiences society visits on adopted children.

The core issue for the child is "not having been kept by one's parents . . . the fact that the child did not come into the world as a wanted person, into the arms of a man and woman who together could eagerly and lovingly assume his care." ([Nickman, 1985](#), p. 376). Nickman advocates a continuing dialog regarding adoption between the child and adoptive parents to grieve the various losses and counter the tendency of adoptees to experience themselves as devalued.

Some children deal with the injury and mystery by attributing the cause or blame to the biological parents. They assume their parents were bad, alcoholic, or mentally ill; their fathers were criminal and their mothers were prostitutes. This process of blaming their parents still does not leave the child unscathed, because the identification with "bad" parents can be quite strong.

### **Anxious Attachment**

Many adopted children readily assume that abandonment or other loss could well happen again. This is probably enhanced by unconscious rage at having been abandoned previously, in that the parents may retaliate against the anger by "again" abandoning the child. For example, an adopted 13-year-old boy reported that his parents had gone for a few days to Israel. He immediately commented in what appeared to be a casual fashion that if something happened to them, he would have to be adopted again, and he sure would hate that.

### **Identity Issues in Adolescence**

Knowledge about and experiences with one's parents and extended family contribute greatly to the establishment of a sense of identity. [Erikson's \(1959\)](#) definition of the sense of ego identity as "the accrued confidence that one's ability to maintain inner sameness and continuity is matched by the sameness and continuity of one's meaning for others" (p. 89) suggests the liabilities adoption might bring with it. [Wellisch \(1952\)](#) and [Sants \(1964\)](#) has written of the adolescent experiencing "genealogical bewilderment."

### **Searching**

Adolescents are curious about their own and their family's history. Adoptive children have a double handicap in this regard, in that they find it difficult to locate their own personal history within that of their family, and they are likely to experience their curiosity about their origins and early life as conflictual within themselves and difficult for their adoptive parents.

Many adult adoptees continually search faces for resemblance and wonder if a person talked with or observed might be a relative. [Sants \(1964\)](#) described adoptees developing a fear of committing incest, and this also has been an issue in the author's clinical experience with adoptees.

[Schechter and Bertocci \(1990\)](#) reject the frequently mentioned "curiosity," and explain its use as relegating the search to a simple cognitive issue and as an attempt to avoid any impression of pathology. Underlying the relatively conscious and commonplace motivations—dissatisfaction with the adoptive family, finding someone who looks and is like the adoptee, seeking genealogic or medical information, finding an way to feel "connected"—is a powerful need to be the driver instead of the passenger in life's drama.

All studies of reunions indicate positive experiences by the adoptees. Relatively few develop intense connections with their biological parent, in spite of that being an important initial motivation for their search. The sense of relief, completeness, and renewed readiness for life that people with a completed search almost universally experience is an internal event of great developmental importance. The wrong is righted; the lost parent (child) is found; and control is gained over the chaos, confusion, and helplessness with which life began.

## **ADOPTIVE PARENTHOOD: CHALLENGES AND DIFFERENCES**

### **A Reciprocal Relationship between Parent and Child**

Under the best of circumstances, there are challenges to the development of a reciprocal relationship between parent and child. There are differences of "fit" between parent and child in terms of responsiveness, activity level, and other characteristics. Because of marked genetic differences, the fit of parent and child may be especially problematic in adoption. At the least, the child is days old on arrival at the adoptive home, or the child may be years old. The child's relationships may have been disrupted several times before; therefore, the child brings ambivalent attitudes to the relationship with the new parents. Differences in intelligence between the adoptive parents and adopted child may create problems. The legal course of adoption, where the adoption is not finalized for many months, with the parents being essentially on probation for that period of time, also can impede the relationship's development. The rights of biological parents continue to be a threat, in that courts

may belatedly remove a child from adoptive parents ([Kermani and Weiss, 1995](#)). Other issues of importance that can cause attenuation of the parents' attachment are societal ambivalence regarding adoption and grandparents' disapproval of the adoption ([Blum, 1983](#)).

### **Infertility and Situations Where Pregnancy Is Medically or Genetically Contraindicated**

Infertility has not usually been suspected by either of the adults, requiring a painful alteration of self-concept of the prospective adoptive parent. Medical problems of the woman and genetic liabilities of either spouse may lead to a choice not to conceive.

### **The Fate of the Biological Child**

Adoptive parents must acknowledge emotionally that the adopted child is a replacement of the child that they cannot have ([Solnit and Stark, 1961](#)). If the parents are not able to adequately grieve the wished-for biological child, the extent and nature of their attachment to the adopted child may be affected. In addition, there may be a parental analogy to the child's confusion about having two sets of parents: The parent may maintain a fantasy about a dual identity of the child—the natural and adopted child. Insufficient emotional acceptance for the adoption alternative may be accompanied by an idealized image of the natural child who might have been. In addition, the adopted child may be the target of some anger because of the child's not affirming the parental biological role and reminding the parent of what is not possible.

### **The Absence of Pregnancy**

Most couples experience many months of preparation for parenthood throughout the pregnancy. The myriad manifestations of pregnancy serve as a focus to stimulate both parents to come to grips with some of the changes occurring in the marital relationship. The birth of the new child is increasingly anticipated, and the pending loss of freedom and of being able to attend to one's own and each other's needs unavoidably will be faced because of various aspects of the pregnancy process. In adoption, these processes tend to be attenuated because there is no pregnancy, and often because it cannot be predicted when a child will become available for adoption.

### **The Adoptive Parents as Rescuer**

There is a particular danger to the parent-child relationship if the parent views adoption as a rescue. When there is frustration of rescue fantasies in the course of the conflict inherent in child raising, a very angry response from the adoptive parents often results. Problems in this area may be closely connected to the issue of failure to work through the loss of the child one cannot have. When the child has had significant deprivation in the past and exhibits the characteristic sequelae of emotional withdrawal, indiscriminate friendliness, or provocative behavior, however, even the most capable adoptive parent is likely to feel rejected.

### **Entitlement or Ownership of the Child**

Adoptive parents sometimes feel that their right to be the parents of the child is tenuous. This attitude may, in major part, be the result of insufficient resolution of the losses and issues inherent in the developmental process of adoptive parenthood. As a result, the adoptive parents may fail to take on the full role of parenthood in terms of confidently providing the guidance and control that enhance feelings of security and self-confidence in younger children. A recent study suggests that adoptive parenthood is associated with enhanced paternal and diminished maternal interaction with the adopted child ([Holditch-Davis et al., 1999](#)).

### **The Adoptee as Alien Child**

For the biological mother, her child is, or was, part of her. For the adoptive mother, the child was part of someone else. This may relate at the mildest level to difficulties of attachment and of the parents' feeling entitled to the child. But there may also be implications for strongly negative parental attitudes. When there are difficulties in adoption, one quite often observes that the parent has trouble accepting the adoptive child's instinctual expressions in a variety of areas—soiling, sexual curiosity, aggression, and, very frequently, eating ([Brinich, 1980](#)). The child's instinctual side is the target of strong and quick prohibitions and expressions of negative expectations. There may be a rather disconnected pair of internal representations, one acceptable and one not. Referral tends to revolve about behaviors in the instinctual sphere.

## **CLINICAL ISSUES**

Parents who bring their adopted children to psychiatric facilities often have a high degree of concern regarding the child's behavior, typically sexual behavior in girls and aggressive behavior in boys. The degree of parental concern is often notably disproportional to the actual behavior the child is exhibiting. An example of such over concern is a 2-year-old referred for "stealing." A source of this concern relates to the parents' fantasies of the behavior and personalities of the people whose union produced the child and whose imagined weakness, immorality, or instability also led to the child's adoption. And again, in the adoptive parents' minds there may be a too-readily available transition from "our good child" to "their bad child" ([Brinich, 1980](#), p. 126), although parental ambivalence is certainly not unique to adoption ([Brinich, 1995](#)). Another aspect of importance is guilt for having someone else's child. The adoptive parents' fantasies regarding the biological parents plus their guilt and fear that they might not deserve the child may predispose them to be overly concerned about the child's behavior. These phenomena may predispose adoptive parents to develop an inaccurate parental portrait of the child ([Ferholt, 1996](#)) because of the adoptive parents attributing known or imagined aspects of the biologic parent(s) to their adopted child. They may tend to look to the child for excessive reassurance to assuage their own anxiety about the child becoming antisocial and their guilt about having someone else's child. Open adoption may mitigate this situation through the adoptive parents' enhanced knowledge of or acquaintance with the biological parents. Alternatively, in some instances such knowledge may elicit more negative parental expectations than the adoptive parents' negative fantasies ([Riggins-Caspers, 1999](#)).

[Johnson and Szurek \(1952\)](#) described how parental concerns might lead to their acting in ways that may influence the child to engage in the behavior that the parents consciously least desire. Because of the parents' anxieties regarding such matters, there is a tendency to express unnecessary prohibitions about sexual and aggressive behavior. Parents may express unfounded but vocal allegations of drug use, ask their adolescent daughter whether she kissed her date or "went further," or otherwise express what the child eventually views as an expectation that he or she is going to do some of these things. As Johnson and Szurek state it, "Such constant checking, or such warning, means to the child that there is an alternate image of him in the parent's mind." The transmission to the child of an alternate, antisocial image on the part of the adoptive parents may have a peculiarly powerful effect on the adopted child. The child's having two sets of parents makes it more difficult to fuse the intrapsychic good and bad parents' images of infantile object relations into a workable, realistic identification. To use [Erikson's \(1968\)](#) terminology, the child may be particularly vulnerable to the development of a negative identity because of the unhappy combination of the child's fantasy that he or she could be "someone else" and living in another home and the adoptive parents' unfortunate expression of their negative expectations to the child.

Sources of the adoptive child's hostility to the adoptive parents have the usual developmental determinants as well as one unique to the adoptive situation: rage at having been abandoned. This can readily be displaced from the biological parents to the adoptive parents. The child's rejection of the adoptive parents may serve as an illusory reversal of the painful actuality of history, by way of identifying with the rejecting biological parents. Often all that is immediately evident is provocative behavior. Generally this antagonistic, aggressive behavior serves as a defense against feeling vulnerable and is one of the major reasons that adopted and foster children are referred for therapy in the first place. One author describes such an adopted child's desire that someone see through her aggressive shield and reach out to her "scared and longing core" ([Cohen, 1996](#), p. 292). In the treatment situation, the therapist and any treating institution may become the objects of the adolescent's rejection. At breaks occasioned by the therapist's vacation or other activities, children often play out compensatory displays of strength ([Sherrick, 1983](#)), and adolescents tend to leave therapy or run away from the institution.

Another illusory reversal related to repair of narcissistic injury that is often exhibited by adopted children is the telling of incredible stories. [Sherrick \(1983\)](#) suggests this is a form of "fantasy lying" as described by [Fenichel \(1945\)](#), p. 529). Such stories relate to such things as possessing superior wealth and expensive automobiles and having great mental or physical attributes. These types of fantasies are surprisingly powerful and persistent. The children may be of normal physical and intellectual ability, manifest minimal signs of emotional disturbance, and be the object of considerable teasing by peers because of what is perceived as bragging. Yet the behavior continues unabated. This phenomenon is also quite resistant to psychotherapy, where interpretations of the meaning are often drowned out by a continuation or elaboration of the theme. [Wilkinsen and Hough \(1996\)](#) call attention to the therapist's impulse to dismiss these productions as untrue as a reenactment of the role of the denying, neglectful parent, and emphasize the difficulty in formulating interventions regarding this behavior. Responses on the part of the therapist that are restricted to reflecting the wish to be wealthy, powerful, or famous are much more likely to be heard than are interpretations of what these stories are geared to accomplish in terms of repair of self-esteem. It is the impression of the writer that in many instances these fantasies are most responsive to improvements of

self-esteem related to the development of an attachment to the therapist and improvement in other relationships that result from the therapist's work with parents or residential school staff. The ideal situation for resolving these or other problems, of course, is when such children are in good adoptive homes and the therapist can work with the child and adoptive parents (Samuels, 1995). One might look on these stories as adoption self-narratives constructed in isolation by the adopted child (Lichtenstein et al., 1996), in contrast to the adoptive self-narratives developed in conjunction with helpful adults; these overshoot their mark.

Brinich suggests that the core problem for some adopted children is to create a self-representation as a "wanted" child. He also points out some practical limitations of therapy:

All the psychoanalytic investigation and assistance in the world cannot undo the fact that the adopted child has been rejected or abandoned. This is one reason why adopted children present a particularly difficult therapeutic challenge ( Brinich, 1980, p. 126).

When things do not go well in adoption, there is often a combination of some of the issues discussed in the preceding. Parents may have insufficiently worked through giving up the biological child and accepting adoption and the adopted child, and feel insufficient entitlement to and ownership of the child. Their over concern about problematic behavior has had a paradoxical effect whereby the child has started to identify with the parents' apparent expectations and started to act accordingly. The parents' lack of feelings of entitlement undermines their confidence; therefore, their efforts to direct and set limits are ineffective. Parental frustration leads to increasing hostility on their part, which triggers the child's separation anxiety. The child typically deals with the separation anxiety in a counterphobic manner in terms of provocative behavior ( Stein and Derdeyn, 1980), which is, of course likely to make things worse.

In one study of a hospital population, it was found that adopted adolescents had significantly more runaway episodes and terminated hospitalization via a runaway prior to the planned discharge more often than did the nonadopted adolescent population ( Fullerton et al., 1986). The authors postulated that increasing anxiety about attachment might play a role, as well as "taking charge" of leaving the hospital in lieu of being discharged. These authors suggested that particular attention should be paid to the adolescent's dependency conflicts and defensive needs for inappropriate pseudoautonomous actions. In other studies of inpatient adolescents, a trend was noted for these children to be discharged to placements out of the parental home ( Senior and Himadi, 1985), and it was concluded that the parent-child relationships of hospitalized adopted adolescents were more problematic than those of hospitalized nonadopted adolescents ( Weiss, 1984).

### Adoption Disruption

Adoption disruption refers to adoptions that end with the return of the child to the adoption agency either before or after formal legalization. A number of issues have been identified as contributing to the likelihood of disruption: limited ability of the child to attach to the new family or let go of the birth family; the parents' expectations of a less difficult child; unresolved infertility issues; gaps in information and child history; and inadequate support for the adoptive parents ( Schmidt et al., 1988). Previous adoption, older age at adoption, adoption by a nonfoster parent, the number of child problems, and the higher level of education of the adoptive mother predict a significant portion of disruptions ( Barth et al., 1988; Berry and Barth, 1990). Of the issues identified, the population with the greatest number of adoption disruptions is children with special needs ( Barth et al., 1988; Groze and Ileana, 1996; Rosenthal et al., 1988). When adoption disruption does occur, the emotional aftermath is often intensely negative for both the child and adoptive parents. Not only the child but also the adoptive families are in great need of some form of postdisruption support ( Deykin, 1984; Elbow and Knight, 1987; Valentine et al., 1987).

### COMMENT

There is a consensus among therapists that there are unique challenges to being an adoptive parent and an adopted child. It is important for a therapist to be familiar with the challenges and differences in adoptive families, so as to make the family feel accepted and empowered to take a helpful parental role regarding their child (Nickman and Lewis, 1994).

Many interacting forces shape the unique experience of adoption. The adoptive parents' fantasies, fears, and perceived lack of entitlement to the child can detrimentally influence their parenting abilities. The adopted child's often powerful need to master early abandonment may lead to maladaptive behaviors that feed the adoptive parents' fears and fantasies regarding the biologic parents' past and the child's future. The therapist familiar with the challenges of adoption can take an empathic stance with the adoptive parents and the adoptive child that can contain their anxieties and conflicts and pave the way toward a better resolution of their individual and shared experience.

Adoption continues to change, and will continue to offer children who need homes the opportunity to be raised by people who desire to have a child and who have generally made difficult conscious decisions and gone to efforts that most biological parents do not even approach on their route to parenthood. This chapter of necessity focuses on differences and difficulties pertaining to adoption; however, the great majority of adoptions go well.

Changes within the contemporary family are reshaping the experience of growing up in the United States. The steep rise in recent decades of the incidence of divorce is foremost among the changes that are profoundly influencing the lives of children and their parents. The number of children from divorced families more than doubled between 1960 and 1980 ([Spanier and Glick, 1981](#)). There have been a million children from divorced families each year since 1972 (A.J. Norton, U.S. Bureau of the Census, personal communication, 1998). By the 1990s, demographers informed us that one-fourth of all adults between the ages of 18 and 44 years had experienced their parents' divorce (Statistical Abstract of the U.S. Bureau of the Census, 1997). A newer study reveals that Americans are spending more of their adult lives outside the institutions of marriage and parenthood, and children are experiencing three or more different family structures and living arrangements while growing up ([Teachman et al., 2000](#)).

Although many children weather the stress of marital discord and family rupture without psychopathologic sequelae, many falter along the way. As a result, the high divorce rate has also had a notable effect on the makeup of clinical populations. Children of divorce are greatly overrepresented in outpatient psychiatric, family agency, and private practice populations relative to their presence within the general population ( [Furstenberg et al., 1983](#); [Gardner, 1976](#); [Kalter, 1977](#)). Parental divorce and parental loss significantly predict mental health referrals for school-age children ( [Felner et al., 1975](#)). A national survey of adolescents whose parents had separated and divorced by the time the children were 7 years old found that 30% of these children had received psychotherapy by the time they reached adolescence, compared with 10% of adolescents in intact families ([Zill, 1983](#)); by young adulthood, 40% had received psychological help. The representation of children from divorced families is even higher among inpatient populations. Although national figures are unavailable, many inpatient psychiatric facilities for adolescents report informally that 75% to 100% of their patients are from nonintact families. Overall, national data show that young people from single-parent families or stepfamilies have a two to three times greater likelihood of experiencing emotional or behavioral problems, and a higher incidence of learning problems, than children and adolescents living with both biological parents ( [Zill and Schoenborn, 1990](#)).

The divorce literature, which scarcely existed before the 1970s, has proliferated as growing numbers of investigators in psychiatry, psychology, and sociology have examined the processes involved in family separation and marital dissolution. As a result, we have begun to acquire knowledge in many critical areas: the nature of the divorce process, the responses of children and adolescents by age and gender, the impact of divorce and parental conflict on parent–child relationships, factors in good and poor outcome in the short- and long-term perspectives, patterns of custody and visitation, the role of the father, the roots and dimensions of interparental conflict, and some of the issues that children and adults confront in remarriage. More recently, as findings from longitudinal studies have become available, we have been able to shed light on divorce-specific anxieties that emerge belatedly in the lives of children of divorce, when they enter young adulthood and well into their 30s and 40s ([Wallerstein et al., 2000](#)).

By and large, however, professional interest has not been directed toward issues of treatment. With the exception of mediation programs and court- and school-based groups that have been developed in scattered areas of the United States, and a few pilot and demonstration projects (some clinical, others primarily educational), there has been a paucity of preventive or clinical services specifically designed to respond to the stressful changes in divorcing families or to the special needs of children and adolescents whose family structure has been temporarily or more lastingly weakened by marital distress and breakdown. Most families struggling with divorce have relied perforce on the traditional mental health services available in the community.

In the 1980s, an increasing number of courts offered lectures on parenting to divorcing, and some also offered groups for children that customarily meet for several sessions to discuss the children's feelings. By and large, the effectiveness of the parent education lectures and of the children's groups has not been evaluated in terms of psychological change in adults or children or changes in the parent–child relationships. Not surprisingly, the interest of the court has been first and foremost in diminishing the amount of litigation over custody and visitation. It seems evident, however, that the groups for children can offset the child's loneliness at the time of the breakup, and it may relieve the child's suffering to be with peers who are undergoing the same difficult changes in their lives.

Additionally, much of the interest in exploring the theoretical issues inherent in the family forms that are being created (e.g., joint-custody families; single-parent families in which one parent, usually the father, continues to visit; remarried or redivorced families) has centered around reassessing the role of the father in child development ([Cath et al., 1982](#); [Hanson and Bozett, 1985](#); [Lamb et al., 1997](#)). Although it is widely acknowledged that the psychological theory that underlies established clinical interventions with children (whether in psychoanalysis, family systems theory, or child development) was developed primarily within the paradigm of the intact two-parent family, there has been little theoretical exploration of how changes in family structure can or should modify the goals or approach of the clinician, either in work with parents, who find themselves cast in unfamiliar roles, or with the child, whose primary identification figures are often shifting and unclear.

## NATURE OF DIVORCE: DIVORCE AS A PROCESS

Divorce is a process of social and psychological change in the individual and in family relationships that can extend over many years. It has no true counterpart in other crises of adult life. Although it was initially considered analogous to bereavement in the central significance of loss as the critical component of the adult experience, we have come to recognize that, in divorce, grief is only one of many powerful affects; rage, sexual jealousy, and unrequited love share equal power and significance ([Wallerstein and Kelly, 1980](#)). Divorce is not a time-limited event for the adults or the children involved, in part because a complex undulation of changes including remarriages and redivorces and love affairs leads up to and, in turn, is set into motion by the marital rupture. These changes often occupy a significant portion of the adult's postdivorce life. They typically occupy a significant portion of the youngster's childhood and adolescence and, as we are learning, of his or her own young adulthood.

Divorce can be broadly conceptualized as progressing through three successive phases ( [Wallerstein and Blakeslee, 1989](#) ). The ambiance of the first, acute phase of dramatic and highly emotional responses is established by the fact that divorce in a family with children is rarely a mutual decision. Separation often occurs amid escalating spousal conflict, which can include physical violence between the parents. During this acute phase, in extreme cases, one or both parents may experience depression with suicidal ideation and may regress considerably in behavior. Similarly, one or both parents may experience ego-syntonic rage, which can reach paranoid dimensions. There is, in many of these people, a temporary weakening of ego control over aggressive and sexual impulses, accompanied by lapses in customary judgment. This acute phase may be relatively brief, or it may extend over several years. Sometimes, the divorcing couple remains fixated in this acute phase for years, reenacting the separation drama again and again, in the vain hope of modifying the events or the ending but never obtaining relief from the narcissistic injury that was initially sustained. These reenactments may take place in the courts, or they may be played out in the many other arenas available when

there are children from the broken marriage. In most instances, the acute phase is followed by a transitional phase in which the parents begin to disengage from each other's lives and move into new relationships and new work and home settings. The physical, social, and emotional environments of the family during this time may be in continual flux. This intermediate period may be relatively brief, or it, too, may last for several years. Finally, with the onset of the third phase comes the establishment of the relatively stable postdivorce single-parent or remarried-parent household, each of which has its own associated strains and gratifications.

Ongoing stresses confront many postdivorce families. Some of these stresses are rooted in convergent economic and social issues that communities have been reluctant to address, particularly those that affect the serious economic disadvantaging of women and children after divorce ( [Weitzman, 1985](#)). Other reports describe the many complex psychological issues that adults face in reconstructing their postdivorce lives and how their tasks are affected by the number of years invested in the marriage, the age of the adult at the divorce, and the discrepant opportunities that are available to divorced men and women in the sexual, social, and economic marketplaces ( [Wallerstein and Blakeslee, 1989](#)). Moreover, observations on remarriage have called attention to the many psychological differences between first and subsequent marriages and the complex challenges that a second marriage, with children, poses to all the participants ( [Pasley and Ihinger-Tallman, 1987](#); [Wallerstein and Blakeslee, 1989](#)). These concerns have been reinforced by reports from demographers that the incidence of divorce in remarried families with children from a previous marriage is even higher than the divorce rate in first marriages ( [Pasley and Ihinger-Tallman, 1987](#)).

## EFFECTS OF DIVORCE ON THE PARENT-CHILD RELATIONSHIP

### Diminished Parenting

[Hess and Camara \(1979\)](#) point out that "for children, the threat of divorce lies in the disruption of relationships with the parents." This applies both to the availability of the parent and to the quality of the postdivorce relationship itself. Hetherington and her associates observe disorganization, deterioration of discipline, rising angers, and lowered expectations for appropriate social behavior by their children on the part of custodial mothers ( [Hetherington et al., 1978](#); [Hetherington et al., 1982](#)). Others ( [Santrock et al., 1982](#)) note the more conflicted postdivorce relationship of children with an opposite-sex custodial parent. The impairment of relationships between parent and child may appear early in the separation and divorce process, or may remain latent, emerging only in young adulthood. Mother-child relationships that have previously weathered the storms of adolescence have been noted to deteriorate in young adulthood. This finding parallels Wallerstein's observed "sleeper effect" in young women from divorced families ( [Wallerstein, 1991](#)).

[Wallerstein \(1985a\)](#) suggests that a diminished capacity to be an effective parent is an expectable short-term consequence of divorce, and it has the dangerous potential of becoming chronic when the custodial parent or joint custody parents fail to reconstitute or becomes involved in new relationships that overshadow or replace the relationship with the child. This diminished capacity is most evident in the parent's decreased ability to separate the child's needs and reactions from those of the adult. Wallerstein proposes that the fantasy underlying the sometimes astonishing changes in the parent's relationship with the child is a conscious or unconscious wish to abandon the child coincident with the breakup of the marriage. As a fantasy, this impulse to leave the child behind may remain unacted on, or it may unconsciously spur sudden flight or unexpected rejection by a parent of a child who had previously been cared for properly. Whatever the conscious or unconscious roots of the disrupted parent-child relationship may be, the consequence is that the child's fears of abandonment at the time of the breakup are powerfully reinforced by a parent's changed attitudes and behavior. Often, these fears lead to a hypervigilant tracking of the parent's responses and an intense anxiety that can dominate the child's inner life and can intrude on his or her capacity to accomplish normative developmental tasks.

[Wallerstein \(1985a\)](#) also proposes that a contrapuntal theme to the temporary rejection of the child at the time of the marital breakup is an intensified need of the parent for the child. This dependence on the child by one or both parents is often at the core of parental conflict and prolonged litigation over custody and visitation. In extreme cases, the dismantling of customary supports within the marriage, combined with the humiliation of the narcissistic injury inflicted by the divorce and the painful persistence of attachment to the divorcing partner, may result in severe ego regressions in parents whose previous functioning, separately or together, may have been at least adequate. Feeling suddenly bereft and in need of help, such parents turn to their children for help in warding off the threatened depression.

In many divorcing families, the temporary dependence of the adult on the child is a transient phenomenon that has no lasting deleterious effects and may indeed be of benefit to a child suddenly elevated to unaccustomed importance. However, as [Wallerstein \(1985b\)](#) points out, turning to a young son or daughter as a peer, or worse, as to a parent, may overwhelm the child with responsibility and may place the child at serious risk if the intense dependence continues. These overburdened children—out of worry, guilt, compassion, or, indeed, out of their conviction that it is their assigned task to keep the parent alive—may devote themselves entirely to maintaining the psychic functioning and physical needs of the ailing parent and may relinquish their responsiveness to their own needs over many years.

There is by now convincing evidence that witnessing violence between the parents has very serious lasting effects on the psychological development of children, on their conscience formation, and especially on their future relationships with the opposite sex. The violence, which may arouse erotic excitement, especially for the daughters, may lead them in adulthood to seek out men who abuse them. As reported in [Wallerstein et al. \(2000\)](#), the young women are often governed by the fantasy that they can rescue the loving man who is hidden inside the abuser. This can, of course, have tragic consequences for the young woman.

### Children in High-Conflict Divorce

The struggle for and through the children embodies the intense conflicts that often accompany the failing marriage. Although competition for a child's affection may occur in an intact, even well-functioning family, disruption of the family system and its resulting angers bring the parents' competitiveness into sharpened focus. It is not uncommon for angry, sometimes distraught parents to cast their children in a great many roles during postmarital battles, ranging from that of audience, whose presence appears to be a necessary backdrop for the parental fighting, to that of fully positioned battle allies. The children often range in their participation from astonished, frightened observers to denunciatory Greek chorus or, in some instances, ardent champions of one parent against the other.

Many of the anger-driven parent-child relationships that emerge at the time of the marital breakup are new alliances that diverge from the pattern that existed within the intact marriage. The child's conscious behavior may be powered by loyalty to the disrupted marriage or by the quixotic impulse to defend or rescue the parent who has been identified by the child (sometimes erroneously) as the victim. Not atypically, a child may take up the cause of the absent parent, representing his or her interests in the events of the custodial household. A child's active involvement in the marital battle is additionally fueled by the rise in physical violence between the parents that often erupts at the separation, even though it had never been a feature of the marriage ( [Wallerstein and Kelly, 1980](#)).

Such alignments occur most often between a late latency or early adolescent child and the parent who has vehemently opposed the divorce. The adult's participation is almost always rooted in an entrenched sense of moral outrage at having been betrayed and cruelly exploited during the marriage. The avowed agenda of these alignments is likely to be the restoration of the failed marriage; the unspoken agenda is almost always revenge.

These anger-driven alliances serve a range of psychological purposes for both parent and child. The loneliness of the divorce period is reduced significantly by the new partnership. The child's own gnawing fear of being abandoned is alleviated by becoming the needy parent's trusted companion. Directing their anger outward against the absent parent serves as a powerful antidote to the intolerable pain of rejection and helplessness that the allied child and parent experience, nor is it accidental that many children join cause with a parent with whom their relationship during the marriage had been tenuous or emotionally impoverished and take up an angry campaign against the parent they once had cherished. Additionally, for the child, the new alignment provides an opportunity to resolve any existing ambivalence of feeling toward the parents by creating a clear repository of virtue in one and villainy in the other. These alignments have triggered court fights and have resulted at times in the removal of the child from the mother's custody. These court cases have been rooted in the writing of a psychiatrist Richard A. Gardner, who has characterized them as evidence of *parent alienation syndrome*, alleging that the mother is the primary initiator of these alignments, and removal of the child in severe cases is the treatment of choice. Gardner's influence has been challenged by the absence of supporting research for the diagnosis of parental alienation or its recommended treatment and the absence of this condition from accepted classification of psychiatric illnesses ( [Gardner, 1992](#)).

Evidence indicates that such active alignments generally do not survive the adolescence of the young ally. Nevertheless, many young people come to adulthood complaining that their responses to the "villainous" parent had been governed by perceptions that they did not truly share. They regret deeply that they were not given the opportunity to form their own judgments, and their anger at having been cheated out of a true relationship with both parents is often intense. Some also express profound and pervasive guilt at having participated in lying or even more serious misbehavior directed at hurting their parent ( [Wallerstein and Blakeslee, 1989](#)).

One of the most significant findings in family research concerns the serious hazard posed to the psychological health and development of children by continued exposure to high conflict between the parents, whether in the context of an intact marriage or as part of ongoing postdivorce antagonism ( [Emery, 1982](#)). In one California study of 1,124 divorcing families, one-fourth were characterized by high levels of conflict at an average of 3½ years after separation ( [Maccoby and Mnookin, 1992](#)). There is increasing interest in the plight and fate of children in such families and the impact of witnessing abuse and violence between the parents,

especially if it is prolonged. The psychological effects and disturbances in parent–child attachments observed are not unlike those reported in families where the child has been the target of abuse directly. As yet, it is not clear whether this detrimental impact is mediated by the influence of the conflict on critical aspects of the parent–child relationship or whether it largely represents the intense reactions of the children who directly witness or overhear the fighting. Nor is it known whether children's reactions are primarily governed by the stimulation of seeing the parents fight, by the anxiety engendered from parents who appear to be out of control, by the fear that one or both parents—and perhaps the children as well—may be severely harmed, by complex issues of identification, or by some combination of all these factors. The persistence of high conflict for many years, even after the parental divorce, may be particularly psychotoxic to children in that it appears to lack any remedy.

The link between parental conflict and the subsequent psychological adjustment of children represents one of the most fertile areas for increased theoretical understanding and new models of psychotherapeutic intervention. [Johnston and Campbell \(1988\)](#) and [Johnston and Roseby \(1997\)](#) address the serious effects these lasting impasses create in some families after divorce and report severe reactions among the children, including impairment in reality testing. Adding to this concern is the report from a longitudinal study that, at 10 and 15 years after the divorce, many young people remember with great clarity incidents of physical conflict between their parents and describe having been continually haunted by those memories during their waking and dream lives throughout the postdivorce decade and well into their young adulthood. Many of these children from homes where there was physical and verbal abuse between parents during the intact marriage became involved, at entry into young adulthood, in abusive relationships of their own, although they had been separated by at least a decade from the trauma of witnessing their parents' quarrels ([Wallerstein and Blakeslee, 1989](#)).

At the cutting edge of research in this area is the work of Johnston and Roseby on the developmental impact of high-conflict divorce and of separations in the context of violent relationships. Children caught in such circumstances show problems in psychological separation and individuation and disturbances of gender and sexual identity ([Johnston and Roseby, 1997](#); Roseby and Wallerstein, in press).

## EFFECTS OF DIVORCE ON CHILDREN

### Initial Reactions

Children and adolescents experience parental separation and its immediate aftermath as an immensely stressful period in their lives. Indeed, for middle-class children in the United States, their parents' divorce is likely to be the central stress of their growing-up years. The family rupture evokes an acute sense of shock, intense anxiety, and profound sorrow. Many children can feel relatively content and even well parented within families in which one or both parents are unhappy. A surprising number (one-third in one study) did not know that their parents' marriage was troubled ([Wallerstein and Kelly, 1980](#)). Few youngsters experience relief with the divorce decision; those who do are usually older and have witnessed open conflict between their parents. Children's initial responses are typically governed neither by an understanding of the issues leading to the divorce nor by the fact that divorce has a high incidence in their community. To children, their own parents' divorce signifies the collapse of the structure that was responsible for providing them basic nurturance and protection, even when the family was performing poorly in this role.

The initial pain experienced by children and adolescents in response to a marital separation is compounded by their fantasies of the catastrophes they fear the divorce will bring in its wake. Children suffer with a pervasive sense of vulnerability as they experience the family's breaking apart. They grieve over the loss of the intact family, including the hopes and dreams attached to it, and over the absence of the noncustodial parent. Often, they must also confront the additional losses of familiar friends, neighborhood, and school. Children worry about their distressed parents. They are concerned about who will take care of the parent who has left and whether the custodial parent will be able to manage alone. They experience intense anger toward one or both parents for disrupting the family. Some of their anger is reactive and defends them against their own feelings of powerlessness, their concern about being lost in the shuffle, and the fear that their needs will be disregarded as the parents give priority to their own wishes and needs. They often feel a painfully divided loyalty, as if they were being forced to choose between their parents, even when this question has not been put before them. They may suffer with imagined guilt over having caused the divorce. This is especially likely among young children, or when the parents have fought over child-related issues. Young children sometimes decide heroically that it is up to them to mend the broken marriage.

The responses of children, particularly their sense of loneliness and social isolation, are also strongly influenced by the social context of the divorce. Children all too often must face the tensions and sorrows of divorce with little outside help. Fewer than 10% of children in one widely reported study ([Wallerstein and Kelly, 1980](#)) had any support at the time of the crisis from adults, other than relatives, who could have helped them, such as teachers, pediatricians, clergy, or family friends. Only 25% felt that grandparents came to their aid emotionally. Many children are poorly prepared by their parents for the impending upheaval, some not at all. Thus, it is a striking feature of divorce that when it occurs—unlike in bereavement or other stressful events that can occur in childhood—customary support systems, either through adult ignorance or diffidence, fall away.

### Developmental Factors

Developmental factors are critical in the responses of children and adolescents at the time of the marital rupture. Despite significant individual differences in children, in their families, and in parent–child relationships, it appears that children's dominant concerns, their capacity to perceive and understand family events, their central psychological preoccupations and conflicts, their available repertoire of defenses and coping strategies, and the dominant patterning of their relationships and expectations, all primarily reflect their age and developmental stage at the time of the parental separation.

A major finding in divorce research has been these common patterns of response within age-related groups ([Wallerstein and Kelly, 1980](#)). The groups reported to share significant perceptions, responses, underlying fantasies, and behaviors are as follows: (a) preschool age, 3 to 5 years; (b) young school or early latency age, 6½ to 8 years; (c) later latency age, 8 to 11 years; and (d) adolescent age, 12 to 18 years. The responses of young adolescents have also been differentiated from those in middle and late adolescence ([Springer and Wallerstein, 1983](#)). It may be that the similarities observed within children's age groups represent their commonly shared responses to acute stress generally, not simply to marital rupture. Until recently, no systematic research has addressed the short- or long-term effects of divorce on infants and toddlers less than 3 years of age. The newest work in this area is a longitudinal study in progress by [Solomon \(1992\)](#), who examines the effects of overnight visitation on the parent–child attachments of 100 children ages 12 to 18 months at the time of the family rupture. This is an important subgroup to understand, because many divorces occur within the first 2 years of marriage.

Observations about preschool children derived from longitudinal studies in two widely divergent regions, northern California and Virginia, are remarkably similar ([Hetherington et al., 1982](#); [Wallerstein and Kelly, 1980](#)). Preschool children are likely to regress after one parent's departure from the home. The regression usually occurs in the most recent developmental achievement of the child. Intensified fears are frequent and are evoked by routine separations from the custodial parent during the day and at bedtime. Sleep disturbances are common. The preoccupying fantasy of many of these youngsters is fear of abandonment by both parents. Yearning for the departed parent is intense. Preschool children are likely to become irritable and demanding and to behave aggressively with parents, younger siblings, and peers.

Children 5 to 8 years old grieve openly for the departed parent. Many share the terrifying fantasy of replacement: "Will my daddy get a new dog, a new mommy, a new little boy?" Little girls weave elaborate Madame Butterfly fantasies, asserting that the departed father will someday return to them, that he loves them "the best." Many very young children cannot believe that the divorce is permanent. In their preoccupation with their fantasies, there is often a precipitous decline in their schoolwork ([Wallerstein and Kelly, 1980](#)).

For those 8½ to 12 years old, the central response often seems to be fierce anger at one or both parents. These children grieve over the loss of their intact world and suffer anxiety, loneliness, and a humiliating sense of their own powerlessness. They often see one parent as "good" and the other as "bad," and in this latency age, they appear especially vulnerable to the blandishments of a parent to participate in the marital battles. They also have a high potential for assuming an empathic and engrossing role in the care of a needy parent. School performance and peer relationships may consequently suffer ([Wallerstein and Kelly, 1980](#)).

Adolescents are also vulnerable to the impact of their parents' divorce. The incidence of acute depression, accompanied by suicidal preoccupation and acting out, is frequent enough to be alarming. Anger can be intense. Several instances have been reported of direct violent attacks on custodial parents by young adolescents who had not previously shown such behaviors ([Springer and Wallerstein, 1983](#)). Preoccupied with issues of morality, adolescents may sit in judgment on their parents' conduct around the divorce, and they may identify with one parent and do battle against the other. They are often anxious about their own future entry into adulthood, fearful that they may experience marital failure like their parents. Nevertheless, as researchers have pointed out, many adolescents show an impressive capacity to grow in maturity and independence as they respond to the family crisis and their parents' need for help ([Weiss, 1979](#)). The presence or absence of perceived fairness and integrity in their parents' postdivorce dealings with each other is not lost on them; yet they are capable of considerable compassion for their parents' weaknesses

and struggles, even as they continue to grapple with their own.

## Gender Differences

Although it had been widely accepted by researchers that boys are more vulnerable than girls in both initial and long-term responses to divorce, this finding has been called into question by a critical analysis of the methods employed in a range of studies ( [Zaslow, 1988](#); [Zaslow, 1989](#)). The picture is confusing, in part because the comparative developmental course of boys and girls in intact families, from infancy to young adulthood, is far from being clearly understood. The current state of our knowledge of divorce populations links gender differences to the different developmental stages. Thus, major differences between preschool boys and girls at approximately 4 years after the separation have been observed on a wide range of cognitive, social, and developmental measures ( [Hetherington et al., 1982](#)). Although traditional sex-role typing in girls does not appear to be disrupted by divorce, boys score lower on male preference and higher on female preference on the sex-role preference tests at this same time. The boys also spend more time playing with girls and with younger children. They show affective narrowness and a constriction in fantasy and play and are more socially isolated than their female peers.

Gender differences were observed as well in the California Children of Divorce Study ( [Wallerstein and Kelly, 1980](#)). Although boys and girls did not differ in their overall psychological adjustment at the time of the marital breakup, 18 months later, the boys' psychological adjustment had deteriorated, whereas that of the girls had improved, making for a significant gap between the two groups ( [Springer and Wallerstein, 1983](#)). [Guidubaldi and Perry \(1985\)](#), in a national survey of elementary school-age children 6 years after their parents' divorce, found that boys, but not girls, tested significantly below a matched control group from intact families in academic achievement and social relationships. Other evidence suggests that, in general, marital turmoil has a greater impact on boys than on girls, both in divorced families and in intact, discordant families ( [Block et al., 1981](#); [Emery, 1982](#); [Rutter, 1970](#)). In fact, a report of two national, longitudinal studies of divorce effects on children in Great Britain and the United States suggests that, at least for boys, negative symptoms that are usually considered divorce sequelae are actually apparent before the marital split ( [Cherlin et al., 1991](#)).

A critical question is how much of the reported differential response between the sexes, if it does exist, is mediated by being in custody of the mother. One small study from the late 1970s found that children of latency age who were in the custody of the same-sex parent showed greater sociability and independence than did those boys and girls in the custody of the opposite-sex parent ( [Santrock and Warshak, 1979](#)).

Finally, increasing evidence indicates that adolescent girls in divorced and remarried families confront particular difficulties. Kalter describes special problems that girls from divorced families face in their relationships with their mothers, especially the difficulties of separating at adolescence ( [Kalter et al., 1985](#)). The 10-year study of Wallerstein and Blakeslee ( [Wallerstein and Blakeslee, 1989](#) ) also reported that young women from divorced families often have a turbulent adolescence and a conflict-ridden entry into young adulthood. Many young women at the 10-year mark were caught up in a web of short-lived sexual relationships, some with much older men. They described themselves as fearful of commitment, anticipating infidelity and betrayal. Many of the young women who encountered difficulties in late adolescence had done well during the early years after the divorce, when they were preschool and latency children. It may be that boys, especially oedipal boys and those of and latency age who are in the custody of their mothers, have a more difficult time immediately after the divorce, whereas girls in the custody of their mothers find adolescence and entry into young adulthood particularly hazardous. Clearly, gender differences need to be explored further for the various age groups and within different family structures.

## Long-Term Outcomes in Children

Mounting evidence indicates that the effects of divorce in a general population extend well beyond the previous expectation of a several-year, but limited, aftermath to the marital rupture. Wallerstein's research over a 25-year period ( [Wallerstein et al., 2000](#) ) represents the most extended longitudinal study of children and adults after divorce. Their findings show ongoing as well as delayed effects that come to the fore during the years from midadolescence to young adulthood, as relationships with the opposite sex move to center stage. The ongoing effects associated with good or poor adjustment are likely to reflect the quality of life and the parent-child relationships within the postdivorce or remarried family. The delayed (often long-delayed) effects are more likely to reflect concerns associated with the possibility of repeating the failure of relationship between a man and a woman that the child observed during the marriage, as well as with the parents' subsequent failures in coparenting or new love relationships that the child may have observed. When the postdivorce relationship that the parents develop with each other is more satisfactory, and when the parent individually is able to reconstruct his or her life successfully, the child's memories of the first poor marital relationship are less likely to be disturbing but remain of central significance in their search for lasting love and commitment.

Observations over the 25-year postdivorce period have led Wallerstein to propose that the inner developmental course of children of divorce is significantly altered by the parents' failed marriage and its frequently troubled, long-lasting aftermath ( [Wallerstein and Blakeslee, 1989](#) ; [Wallerstein et al., 2000](#) ). There is no question that children of divorce face more difficulties in their relationships. They not only fear failure but also feel poorly prepared for the complex interactions of adult intimacy. Many state that they have never seen a man and a woman "on the same beam." Amato also finds that the greatest impact of divorce occurs in adulthood in troubled relationships between the sexes ( [Amato, 1996](#) ; [Amato, 2000](#) ). He has called attention to the lack of social skills of these persons. However, there is reason to assume that the problem is much deeper than the educational issue of needing social skills. Wallerstein suggests that they lack the requisite internal images to construct a lasting relationship, and their internalized images include those of failure to resolve conflict and flight when frustrations within the relationship begin to mount.

Men, particularly in adulthood, feel helpless about their capacity to influence the woman's behavior or feelings. Additionally, many fear that disaster will strike at any time and will take away what they have. Their fears of loss increase when things are going well in their lives. They live with chronic anxieties that they attribute to their parents' divorce when they were children and their remaining sense that the family rupture occurred when they did not expect it ( [Wallerstein et al., 2000](#) ). This is true whether the child falls into a more resilient group with better outcomes or into a more vulnerable group with poorer outcomes. The reports from the children over the many years of the follow-up suggest that the internal developmental tasks of establishing intimacy and trust in their own relationships with the opposite sex are felt to be persistently burdened to a greater or a lesser degree by the template of a failed man-woman relationship that these children carry within them. Additionally, the fears of disappointment, betrayal, and abandonment that are legacies of the failed parental marriage are often reinforced by extended periods of diminished parenting during the postdivorce period. When many find as well that the bond with the father does not survive transplantation into the alien, rocky soil of arranged visitation, this adds to their sense of the unreliability of relationships.

Other delayed effects of divorce may not emerge until many years later. There is evidence that, at adolescence, the need for the father increases in both boys and girls, and feeling rejected by the father at this critical development time may pose special hazards. For the young adult, relationships with both parents appear burdened by divorce-specific issues surrounding the normative events of separation from home and family, which are emotionally much more complicated if the custodial parent will be left alone. In brief, children of divorce face many tasks in addition to the usual ones of growing up. These tasks are formidable and may require more help than children in intact families in our society typically receive ( [Wallerstein, 1983](#) ). What seems very clear is that, over the years of their growing up, children of divorce find it necessary to work hard and consciously on the mastery of their experiences. It may be for this as well as other reasons that they continue to think of themselves as "children of divorce," as if that were their fixed identity ( [Wallerstein and Blakeslee, 1989](#) ).

## Factors in Outcome

The initial responses of children do not predict long-term consequences for psychosocial adjustment, either for those who did well at the time of the divorce or for those who fared poorly. Nor do preliminary findings at the 15-year mark of the California Children of Divorce Study indicate that even 10-year outcomes have remained stable ( [Wallerstein and Blakeslee, 1989](#) ). There appears to be considerable shifting in individual adjustment as the young people, now in their third decade of life, either seek psychotherapy for themselves after several relationship failures or succeed in building gratifying heterosexual relationships and marriages. No single theme appeared among the children in this study who were functioning well immediately after the separation and divorce, or over the years that followed, nor was there a single thread associated with poor outcome. Many of the children who seemed to be functioning appropriately at the 10-year mark were well parented or had had considerable help along the way from a parent or grandparent. Only a few were helped by both parents. Visiting frequency or patterns of visiting were unrelated to outcome, but whether or not the child felt rejected by the father remained a critical factor. Some were fortunate enough to find adult mentors, and those who did showed particular promise in scholarship or athletics. Many had taken a great deal of responsibility for their own upbringing.

Although in remarried families the stepparent can, on occasion, play a critical role in the child's development, the extent to which this occurs is doubtful. In the cited 10-year study, few stepparents took on a central role in the child's life. Moreover, in many remarried families, the children felt excluded from the orbit of the remarriage. The latest national figures provide no clear support for the protective or mitigating influence of remarriage for children of divorce, although when divorce had occurred early in the child's life, parental remarriage seemed to offer some benefit to the child ( [Zill et al., 1993](#) ).

In the Wallerstein study, the amount of stress noted in the postdivorce family was considerable. One of two children experienced a second parental divorce. One of two continued to live with intense anger between their parents that did not subside over the years. Three of five felt rejected by one or both parents. There were additional economic stresses, and one-fourth of the youngsters experienced a significant drop in their standard of living, which they did not recoup during the postdivorce decade.

In effect, in investigating the long-term adjustment of the child of divorce, we confront a rich mix of individual issues in the resiliency and vulnerability of child and parent, the individual talents and staying power of the child, the nature of the relationship between the child and each parent, the extent to which the postdivorce coparenting relationship is relatively free of continued conflict that involves the child, and the encouragement and support available to the child from whatever other sources are available within or outside the family.

## DISPUTED CUSTODY AND VISITATION

The most tragic children of divorce are those aptly described as “the children of Armageddon” ( [Watson, 1969](#)), who are caught in the entrenched legal battles of their parents. No national figures are available on the numbers of families involved in full-scale legal battles over custody and visitation, but based on an early estimate, it is likely that 10% to 15% of families with children struggle in the courts over many years, and that one-third of divorcing families return to court for modification of the initial orders ( [Freed and Foster, 1974](#)). In the study by Maccoby and Mnookin, researchers estimated that 10% of families encountered “substantial” legal conflict over custody and visitation, whereas 15% experienced “intense” legal conflict ( [Maccoby and Mnookin, 1992](#)). Thus, although most families make custody and visitation arrangements without recourse to the courts, many relying on the advice of their attorneys, even private arrangements are very much influenced by court decisions, which cast a long shadow over all postdivorce arrangements, including those that were never in dispute ( [Mnookin and Kornhauser, 1979](#)).

The causes of continued legal contest between divorcing spouses are complex and multidetermined. Fortunately, studies have begun to shed light on the interlocking issues that maintain the conflict at high intensity over many years. [Johnston and Campbell \(1988\)](#) suggest a triad of factors that contribute to the impasse in the family: those that reflect psychopathology in the individual, those that derive from the marital relationship and the changed interaction between the partners, and those factors in the social surround that support the continued litigation and contribute to the increasing stress of the parties involved. In the individual, a history of repeated un mourned losses is not uncommon and may go hand in hand with a pathologic dependence on the constant presence of the child. The severe narcissistic injury of the divorce may trigger a rage against the divorcing spouse that continues to bind the partners to each other through conflict over the children. The same psychodynamics may underlie child stealing.

There is growing recognition among mental health professionals that the adversarial system of the courts is not only poorly suited to resolving family conflict but also may intensify it by further dividing the hapless parents and adding to the stress on the family. Concern with “family values” has become almost a code word to reflect the widespread worry about the high incidence of divorce. Political and religious groups in several states have tried to pass legislation that would narrow the exit from marriage with a range of restrictions but mostly by a return to “fault divorce” in which one person is held culpable for the deterioration of the marriage and is punished by withholding the children or by imposing greater financial burdens. These efforts have largely been unsuccessful. As [Gardner \(1982\)](#) notes, “the adversarial system is ill suited to deal optimally with custody conflicts, is psychologically detrimental to children, and is therefore antithetical to good psychiatric practice.” The [Group for the Advancement of Psychiatry \(1980\)](#) recognizes the impact of the entire family's interrelationships during the postdivorce years and strongly advocates that all family members should be examined before a court decision on custody or visitation is made. Practitioners have increasingly refused to appear as an expert witness for one side in a custody or visitation dispute and have insisted on meeting with both parents before rendering a recommendation to the court.

Much progress has been made in understanding the tormented and driven behavior of parents whose fight for the child is mostly determined by the unbearable narcissistic injury of the divorce and the dependence on the child to offset their sense of abandonment and to keep severe depression at bay. The work of Janet Johnston, Vivien Roseby, and their colleague has been at the forefront of the progress that has been made ( [Johnston, 1994](#); Johnston, in press; Johnston and Campbell, 1998; [Johnston and Roseby, 1997](#); [Roseby, 1993](#); [Roseby and Johnston, 1995](#)). In two seminal books, Johnston and Campbell and Johnston and Roseby propose a complex model for understanding the impasses that baffle judges and attorneys that shows how the internal dynamics of one or both parents are soon reinforced by the ways that the couple continue to hurt each other and by the presence of the Greek chorus of attorneys and mental health professionals who are caught up in mischievous countertransferences and, of course, family members on each side ( [Johnston and Campbell, 1988](#); [Johnston and Roseby, 1997](#)). Conflicts that are reinforced in this way can go on seemingly forever, with little perceptible dimming of the anger that led to the dispute. Children caught in these battles are tragic casualties whose interest are soon lost sight of by everyone, including the courts, which are caught up in adjudicating the rights of the parents.

## Mediation

Mediation has attracted considerable interest in recent years as the intervention of choice for disputing families ( [Coogler, 1978](#); [Haynes, 1981](#)). Reports from a study of mediation in four court systems (Hartford, Denver, Minneapolis, and Los Angeles) indicate that families agreeing to make use of the mediation services in the courts are generally pleased with the process and outcome. Many families, however, reject mediation even when it is made available without charge. Many issues continue to hinder the full realization of mediation's early promise. Research shows that severely conflicted parents are unable to make use of the mediation process successfully ( [Kressal et al., 1989](#)), and long-term studies do not distinguish outcome in children whose parents mediated their differences from those whose parents relied on traditional negotiation between the respective attorneys ( [Emery and Dillon, 1996](#)). Still unresolved is the issue of whether mediation falls within the domain of the attorney or the mental health professional or whether they should work in concert with the disputing family. A critical issue is that the mediator's role may leave the child's interests without adequate protection, because mediators, by and large, lack training in child development or psychopathology and are unable, except from a common sense vantage point, to assess how the mediated agreement will influence the child. Furthermore, the mediation process makes the assumption that the child's interests will be protected by the parents, an assumption often unwarranted at divorce, especially in the case of intensely conflicted parents. Finally, whereas the judge is charged with protecting the best interests of the child, the mediator in most settings does not share this responsibility.

In 1981, California enacted mandatory mediation for divorcing families who are disputing custody or visitation. Reports from different jurisdictions within that state show a high settlement rate, ranging from 55% to 85% of the disputing families in the different counties, who then refrain from taking their case to court. There is still much to be learned about the nature of these agreements and their impact on the psychological adjustment of the children or their parents. Overall, however, the courts have considered mediation services to be of great benefit, and the availability of mediation services has increased rapidly within courts throughout the United States.

## Custody

The changing roles of men and women are mirrored in the courts and in legislation regarding custody and visitation. Early in the 1980s, the courts relied extensively on the concept of “the psychological parent,” assuming that, except in unusual circumstances or for older children, the mother would fulfill this role. Our society has now moved away from the expectation that single-parent custody, combined with reasonable visitation with the noncustodial parent, is the legacy of divorce. Attention has increasingly focused on the contribution of the father as parent and as a potential primary parent ( [Cath et al., 1982](#); [Jacobs, 1982](#); [Ricci 1980](#)). Custodial arrangements have changed since the mid-1980s ( [Maccoby and Mnookin, 1992](#)). We still lack sufficient information about the extent of this change in the direction of joint custody. It is important, however, that during the 1980s more than one-half of the states enacted legislation that permits joint custody. In several instances, the public policy has leaned toward a presumptive preference for joint custody. In California, in 1988, legislation went against the presumption of joint custody; while acknowledging the importance of both parents for the child, it emphasized the necessity of matching the custody arrangement to the needs of the individual family. Clearly, community attitudes and social policy are in flux.

Joint custody remains a variously defined arrangement, differing not only among states but also even among local jurisdictions. Joint *legal* custody typically refers to an equally shared responsibility between parents for major decisions regarding their children's lives and well-being. Joint *physical* custody indicates that the child actually resides for substantial periods in each parent's home, although the proportion of time spent and the schedule of transitions between households may vary widely.

Joint physical custody can be properly regarded as a new family form. The motivation for its choice varies widely. Some parents select joint custody out of commitment to the child's continuing relationship with both parents; others, however, select this custody form out of the demands of the workplace; and still others select joint custody because neither parent truly wishes to take responsibility for the child. Obviously, the experience of the child will vary with the parents' motivation and emotional investment.

Researchers have raised the question of how important the custody arrangement by itself is to the psychological adjustment of the child. [Kline et al. \(1989\)](#), in a sample of 93 white middle- and upper-class divorcing families, compared the psychological adjustment of those 38% of the children who were living in joint custody with that of the remaining group who were in sole custody. She and her colleagues found that neither the custody arrangement itself nor the frequency of access and visitation with the father influenced the child's psychological adjustment. The factors affecting the child's psychological and social adjustment, regardless of custody arrangement, were the prior psychological functioning of the parents and the degree of postdivorce hostility and conflict between the parents.

One study of intensely conflicted families, in which the court had ordered joint custody over the considerable reluctance of one or even both parents, showed that children in involuntary custody situations seemed seriously deteriorated in their psychological and social adjustment, school performance, and peer involvement, as observed over a several-year period. Both boys and girls seemed to suffer when frequent access to both parents was imposed on families locked in ongoing disputes ([Johnston et al., 1989](#)). This work addressed the very serious issue that has been raised in many jurisdictions regarding whether the courts should award joint custody in the face of one parent's strong opposition. Findings from this study are very much in accord with the clinical opinions that practitioners have held over many years.

Evidence from numerous studies indicates that many children prefer joint custody to sole custody, and many children benefit from this arrangement ( [McKinnon and Wallerstein, 1986](#); [Steinmann, 1981](#)). Our knowledge at present indicates that, when it is entered into voluntarily by both parents with dedication and conviction, joint physical custody can be regarded as a viable family form. Under appropriate circumstances, it serves well, especially in the transition from divorce to remarriage. Joint custody does demand special effort and commitment from the parents, the ability of the formerly married partners to remain in close touch with each other's lives, and considerable flexibility from both child and parents ( [Wallerstein and Blakeslee, 1989](#)). There is an insufficiency of research in this entire domain, especially on the long-term effects of joint custody. We especially await findings from the study of infants and young children to shed light on how the frequency of going back and forth from one home to another affects bonding and development.

Several studies, most notably that of [Maccoby and Mnookin \(1992\)](#), show that whatever the court order, many children change their residence from one person to another during the postdivorce years. Joint physical custody is particularly likely to become a situation in which the mother is the primary parent who tends to medical and dental appointment, clothing, and other important aspects of the child's life. Dornbush find that adolescents who are in trouble are more likely to gravitate or be sent to live with their father during the postdivorce years.

## **PUBLIC POLICY AND DIVORCE RESEARCH**

Although policy makers, legislators, and judges have increasingly sought support from the findings of behavioral science and guidance from the mental health professions, the accumulation of psychological knowledge has not kept up with the rapid evolution of family law. Knowledge about children and parent-child relationships in the postdivorce family is still fragmentary and is insufficient to support many of the legislative changes in family policy that have found powerful adherents. The subtleties of psychological thinking and shadings of individual difference that are so critical to the perspective of the behavioral scientist translate poorly into the arenas of court and legislature. The several years of follow-up required to assess the impact of changed circumstances on altered family structure are ill-suited to the pressured agendas of the political and judicial process. Despite the widespread acknowledgment given to the important interface between family law and mental health, the major task of building cooperation and mutual understanding on a firm basis of empirical knowledge and shared values still lies ahead.

## **INTERVENTIONS**

It is evident that many families need professional advice and guidance in negotiating their way through the complex and tangled pathway of divorce and the postdivorce years. Moreover, it is important not only to provide the services that they need but also to find ways to reach both adults and children at the appropriate times, namely, at the marital rupture and at critical turning points along the arduous road that lies ahead. Essentially, divorcing families confront two sets of divorce-related issues that fall within the domain of the clinician: those associated with the acute crisis engendered by the marital breakup and those associated with rebuilding the family, and subsequent families, that will provide a "holding environment" for children and adults during the postdivorce years. These two sets of issues translate into a series of immediate and long-term psychological and social tasks for adults and children ( [Wallerstein, 1983](#); [Wallerstein and Blakeslee, 1989](#)). They translate as well into two separate preventive and clinical agendas: one addressed primarily to the amelioration of the psychological disequilibria of the separation crisis and its immediate aftermath and a second addressed to building or restoring family structure and parent-child relationships within the postdivorce or remarried family ([Wallerstein, 1990a](#)).

A third, clinical agenda is addressed to children who show a relatively consolidated psychological disturbance. Although children in this group present clinical issues that are relatively familiar, the therapist's relationships with the parents and other significant adults will differ sharply from those with most intact families. Thus, for example, in the divorced family the issue of who bears primary financial responsibility for the child's therapy is often in dispute. The treatment itself, whatever its course, has a high potential for being caught within the continuing angers between the parents, and the therapist is likely to be identified by one or both as allied with "the other side." Furthermore, there is the thorny issue, which needs to be resolved on a case-by-case basis, of which adults should be included in the therapist's relationship with the family. When and under what circumstances should a biological father who has had little contact with the child be seen? When should a stepparent be dealt with as the primary parent? When and how should live-in lovers be included? These multiple relationships need to be carefully assessed by the clinician not only for their bearing on the child but also because of their importance in constructing a network that will support the child's treatment.

Another critical issue that will influence treatment process and goals is that the development of many children is hindered by the continuing failure of their families to provide sufficient nurturance and protection to sustain the youngsters' developmental progress. As a consequence, in addition to addressing issues of neurotic conflict, the clinician may need to take a more supportive role. These supportive parameters, which so many of the children need, have implications not only for process but also for the duration of treatment.

### **Tasks of Divorce**

The reorganization and readjustments required of the child of divorce, namely, the psychological tasks that need to be addressed, represent a major addition to the expectable tasks of childhood and adolescence in our society. In effect, the child of divorce faces a special set of challenges and carries an added burden, which may indeed require professional help at different points along the developmental course. The individual child's resolution of these tasks is profoundly influenced by the family ambiance and by the extent to which the parents have made progress in resolving the many issues to which divorce gives rise. Nevertheless, it is the child who must carry the burden of mastery and resolution on the way to successfully achieved adulthood; there is no necessarily determining relationship between the resolution and adjustment achieved by either of the parents and the outcome for any particular child in the family. There is, in fact, a widening difference in outcome among siblings as they approach young adulthood ( [Corbin, 1988](#)).

These readjustments are likely to stretch over the growing-up years and through adolescence. They are the coping tasks that are shaped by psychological threats to the child's psychic integrity and development. These tasks have been conceptualized as a hierarchical series, which follows a particular time sequence beginning with the critical events of parental separation and culminating at late adolescence and young adulthood. They represent the agenda for the child as well as for the therapy.

Six psychological tasks have been formulated by [Wallerstein \(1983\)](#). They fall into an unfolding sequence with varying time spans attached for the accomplishment of each. Task 1, *acknowledging the reality of the marital rupture*, and task 2, *disengaging from parental conflict and distress and resuming customary pursuits*, need to be addressed immediately at the time of the decisive separation, and they are optimally resolved within the first year. The child's successful mastery of these two immediate tasks is tied to the maintenance of his or her appropriate academic pace and overall developmental agenda, after the initial dip at the time of crisis. However, the child's successful mastery of divorce-engendered stress is only partially related to the early period after the marital rupture. Task 3, *the resolution of losses* (including the loss of the presence of one parent in the home), task 4, *resolving anger and self-blame*, and task 5, *accepting the permanence of the divorce*, will be worked and reworked by the child over many years. They, along with the final task 6, *achieving realistic hope regarding relationships*, will become salient at adolescence and entry into adulthood.

### **Some Treatment Considerations**

Various treatment modalities have been employed with this population to facilitate adjustment, including family therapy, individual psychoanalytically oriented therapy for the child, parent guidance, supportive group therapy for parents, and supportive group therapy for children. Cognitive-behavioral approaches have been used, primarily in groups for children within school settings. In working with all these modalities, it is important to keep in mind that treatment of the adult *qua* adult does not necessarily trickle down to help the child. Our own work of many years shows that parent-child relationships need to be addressed directly within the treatment and

cannot be counted on to extend from the treatment of the parent as the primary patient to the child ( [Wallerstein and Blakeslee, 1989](#) ). The conjoint treatment of divorced parents and their children may place children in jeopardy. It is not uncommon for the child in a divorced family to be punished severely by disputing parents for statements that may have been acceptable within the framework of an intact family. The child's greater vulnerability in these families needs to be understood by the clinician.

The psychological assessment of both child and parent takes on special importance in work with a divorce population. A significant measure of responsibility for the selection of the treatment goals falls on the clinician. In the ordinary course of child psychotherapy, parents present their concerns, which provide the starting point for the therapeutic alliance. By contrast, divorcing families, especially those coming to a preventive program, bring multiple and conflicting overt and covert agendas, each of which may cancel out the other. These agendas range from the wish to reconcile the marriage to fantasies of Medea-like revenge, from the need to hear that the children are untroubled to well-founded serious concerns about their welfare. Nowhere is the difference between an intact family, however conflict ridden, and a disrupted family more evident than in the difficulty in arriving at a common treatment agenda.

An additional consideration in the clinician's greater responsibility for the agenda of the intervention is that often parents are unaware of what may be the grave psychological condition of the children. Time and again, we have observed children in serious trouble, even in dire emergencies, whose normally attentive parents seem oblivious to the danger, caught up as they are in their own concerns. This is true not only of threats to psychological health of the child but also of a decline in the physical health of the child as well. Both need to come under the special scrutiny of the psychiatrist.

A considerable likelihood exists that children in these families will have witnessed severe verbal abuse or physical violence between the parents. Often, the effects of such experiences will not show up initially in the child's symptoms. They may well be associated, however, with serious superego lacunae, deficits in object relations and identity, and skewed expectations regarding relationships between men and women, which, although they may not become manifest during childhood, may, if left untreated, come to the fore at subsequent developmental stages. The therapist is well advised to make appropriate inquiries about parental conflict in the child's history that may not be readily forthcoming and to attempt to engage the child in an exploration of his or her reactions to what may have been searing incidents.

Finally, treatment of children and parents in the separating and divorced family often depletes the therapist's emotional resources. The final scenes of the failed marriage are played out in the consulting room not only in the painful context of the verbal interactions but also, just as importantly, in the transference reactions of the client caught up in the crisis and in the subsequent countertransference responses of the clinician. There is an extraordinary lack of psychological distance between therapist and client as identifications move back and forth across the therapeutic interface. The most common countertransference is for the clinician to experience anxiety about the stability of his or her own intimate relationships ( [Wallerstein, 1990b](#) ).

### **Future Directions in Interventions**

There are indications of mounting community concern about the changes in the family in our society and their impact on children, particularly the initial and long-term effects of divorce. Whether this concern will translate into adequately funded preventive and clinical programs, we cannot predict. Thus far, mediation and court-based programs have traditionally excluded children, whereas school-based programs have typically excluded parents. Nevertheless, the possibility is greater that the next decade will see a proliferation of new and integrated educational and preventive programs that will address families at the time of the separation crisis. Such programs should ideally reach out to parents within a general divorcing population and provide them with guidance in regard to the many decisions that they face and with specific advice about how to restore parenting and how to help their children during the crisis and its often extended aftermath.

One such demonstration project has been developed in northern California at the Judith Wallerstein Center for the Family in Transition, funded by private foundations. The outreach includes a letter sent to every family filing for divorce within the county. Children and adolescents are assessed individually and receive intensive counseling over an initial 3-month period, returning for brief follow-ups at the 1- and 2-year marks ( [Wallerstein, 1990a](#) ). This model has been copied in several clinics within the United States and Canada. There has also been some recent interest in modifying the model to meet the demands of the private sector. The work of Johnston and her associates offers another important template for working with families in high-conflict situations.

Precisely because divorce draws a large segment of the general population, it provides an unprecedented opportunity for developing and testing models of prevention in mental health. Because the subgroups at greater risk can often be identified at the time of the separation, among both parents and children, the clinician is provided with the opportunity to offer a range of intervention programs early in the process. One such subgroup that may well receive increased attention consists of those high-conflict families who fall through the net of the mediation services provided by the court. It is possible that the courts will recognize the grave psychopathology among these children and their parents and will develop referral networks within the private sector. The high incidence of allegations of physical and sexual abuse in divorcing families may also encourage the development of clinical services through a referral network attached to the courts.

Among the hopeful signs is the new willingness of public, private, and parochial schools to recognize the link between the learning and behavioral problems of many children and the weakening in the family structure. School systems are increasingly willing to permit or even welcome groups for children within the school setting, especially in the elementary schools.

Finally, there is burgeoning recognition of the needs of children of divorce that emerge with new intensity at young adulthood. Group programs are being developed that primarily attract adults in their 20s and 30s who find their shared experience a useful supplement to individual psychotherapy.

Overall, however, our society has been reluctant to undertake measures related to helping families deal with change. The mental health professions have not taken a leadership role, and children continue to lack a powerful voice raised on their behalf. Still critically needed are research that will address the large lacunae in our knowledge and programs in prevention and intensive clinical interventions that can push our knowledge far beyond its current compass. Both the research agenda and the intervention agenda appear to lengthen and to unfold before us as we come closer to understanding the psychodynamics of these new family forms.

# 110 LEGAL CONSIDERATIONS IN THE PSYCHIATRIC HOSPITALIZATION OF CHILDREN AND ADOLESCENTS

Stephen Wizner, J.D.

---

[The Parham Decision](#)  
[State Legislation](#)  
[The Responsibility of the Psychiatrist](#)  
[The Medical Decision to Hospitalize a Child or Adolescent](#)  
[Chapter References](#)

The mode and procedure of medical diagnostic procedures is not the business of judges. What is best for a child is an individual medical decision that must be left to the judgment of physicians in each case (1).

No area of medical practice affords a physician as broad and far-reaching discretion in the exercise of professional judgment as does psychiatric hospitalization of children and adolescents. Unlike the circumstances under which adults are admitted to psychiatric hospitals or wards—as voluntary patients, under short-term emergency procedures, or after a judicial hearing replete with due process protections and specific commitment criteria—children and adolescents, as a rule, may be confined at the request of a parent or guardian. In most states, only the admitting physician (and, in many cases, a managed care organization) stands between a parent's desire to hospitalize a child, for whatever reason, and the child's interest in not being improperly or unnecessarily institutionalized. Even in those states that afford objecting minors some judicial review of their involuntary confinement, review procedures and substantive commitment standards tend to be less formal and precise than those applicable to adults.

In addition to the lack of procedural formality and precise commitment criteria, the “mental illness” that brings most minors to psychiatric hospitals in the United States is manifested by behavioral problems rather than by cognitive or affective disorders. The typical minor whose psychiatric hospitalization is sought by parent or guardian is given a diagnosis of conduct disorder, personality disorder, adjustment reaction, or transient or situational disturbance. Only a relatively small proportion of hospitalized youngsters, less than one-third, are hospitalized for severe or acute mental illness, such as psychotic, organic, or serious affective disorders (2).

The reasons that some seriously disturbed minors who are hospitalized are diagnosed as having conduct disorders or a situational disturbance may reflect a reluctance to label a child as having a serious mental illness prematurely and the difficulty in diagnosing a child or adolescent without a significant history of psychiatric disturbance. Nevertheless, the fact is that most minors who are hospitalized are hospitalized because of conduct or personality disorders and do not have a serious mental illness.

In her 1988 study of psychiatric hospital admission rates of juveniles, psychologist Lois Weithorn reported that in 1980 there were 81,532 psychiatric hospital admissions of persons younger than 18 years of age, of which 49,910, or 61%, were to private hospitals (3). The fact that large numbers of minors without serious psychiatric disorders are confined in mental hospitals is attributable to several factors, not least of which is the absence of clear procedural protections and precise commitment standards. Since managed care has become more prevalent, fewer children and adolescents receive inpatient treatment (4), but the medical and profit-maximizing judgment of the managed care industry still is not an adequate substitute for legal rights.

During the 1970s, the practice of parental volunteering of minors into psychiatric hospitals was the subject of scholarly criticism (5) and judicial disapproval (6) as a violation of the constitutional right of juveniles not to be confined in institutions without due process of law. These academic critics and lower court judges concluded that parental discretion, subject only to psychiatric ratification or acquiescence, was insufficient to protect the liberty interests of minors.

## THE PARHAM DECISION

In 1979, in the case of *Parham v. J.R. and J.L.*, the United States Supreme Court upheld the practice of parental volunteering of minors into mental institutions, stipulating only that a physician at the admitting facility be “free to evaluate independently the child's mental and emotional condition and need for treatment” and that this physician “has the authority to refuse to admit any child who does not satisfy the medical standards for admission” (7).

The Court used the opportunity presented by the *Parham* case to constitutionalize a presumption that parents act in their children's best interests and therefore ought to be able to decide, free of state interference, that their children require psychiatric hospitalization. The Court sought to justify the state's failure to institute procedural safeguards by hypothesizing benign, and even beneficent, reasons the state might have for refusing to provide procedural protections for institutionalized children. The Justices speculated that a cumbersome or intrusive procedure might dissuade parents from taking advantage of state-provided health opportunities, to the detriment of their children and the public. Also, the Court inferred that the state could have an interest in ensuring that psychiatrists and other staff spend their time treating patients, rather than preparing for and appearing in court. Nevertheless, balancing the interests of the parents and the state against the “risk of error” from the child's perspective, the Court concluded that “some kind of inquiry should be made by a ‘neutral factfinder’ to determine whether the statutory requirements for admission are satisfied.” That “neutral factfinder” is the physician who approves the parent's decision to hospitalize the child.

The Justices were unwilling to accept the notion that children's rights might be violated by apparently well-meaning parents and predicted that the focus of an evidentiary hearing was likely to be an examination of the parents' motives rather than evaluation of the child's need for hospitalization.

The Court expressed concern about the possible antitherapeutic consequences of such a hearing, theorizing that it would exacerbate tension between parents and children and make the child's subsequent return home more difficult. Finally, the Court observed that the adversary system is not the best mechanism for discovering truth when psychiatric decisions are at stake.

Under the Supreme Court's ruling, the kind of inquiry that must occur is to be conducted by a staff physician at the admitting facility. The review of the admission decision should focus on “what is best for the child.” “Informal, traditional medical investigative techniques” are satisfactory. There must be an interview with the child; mere review of records is not sufficient. Finally, periodic review is required, although the Court did not specify how frequently review must occur, nor whether it may be less formal than the preadmission screening.

On only one remedial point did the Supreme Court agree with the trial court. The danger to children who are state wards of becoming “lost in the shuffle” after being admitted to the hospital might necessitate some formal postcommitment review procedures.

The facts of the *Parham* case, which the lower court had found to be “representative” of the class of children volunteered into state mental hospitals, would appear to cast doubt on the presumption that parents (and guardians) always act in the best interests of their children. At the request of his mother, J.L. had been admitted to a state mental hospital in 1970 at the age of 6 years. His diagnosis was “hyperkinetic reaction of childhood.” He was still there 5 years later when the case was filed because his parents would not take him home and, in fact, had voluntarily terminated their parental rights the year before. Hospital staff had recommended that J.L. be placed in a foster home, but that recommendation had not been carried out.

J.R., the other named plaintiff, had been declared a neglected child and removed from his parents' custody at the age of 3 months. He had been placed by state authorities in a succession of seven different foster homes and was eventually volunteered by social workers into a state mental hospital at the age of 7 years. His diagnosis was “unsocialized, aggressive reaction of childhood.” More than 5 years later, when the lawsuit was filed, he remained in the hospital, solely because state authorities had failed to implement a hospital recommendation that he be placed in a foster home.

In the words of Justice Brennan in a dissenting opinion, “In these circumstances, I respectfully suggest, it ignores reality to assume blindly that parents act in their children's best interests when making commitment decisions and when waiving their children's due process rights” (8).

## STATE LEGISLATION

Although the Supreme Court in *Parham* expressly rejected the views of academic critics, civil rights lawyers, and lower court judges, it left the door open for states to provide additional protections for minors beyond the minimum that it found to be constitutionally sufficient. Virtually every state currently has legislation that applies to the admission to (and discharge from) psychiatric facilities. Because of the significant variation in standards and procedures contained in the various state statutes, it is essential for the physician contemplating psychiatric hospitalization of a child or adolescent to be familiar with the law in his or her own state ( 9). Statutes change frequently, so although the following discussion provides guidelines for understanding the law in a given state, it cannot substitute for thorough research into the current applicable statutory scheme for a physician's own state.

In many states, a minor's admission to a psychiatric hospital is governed by statutes different from those used in an adult's admission to a psychiatric hospital. The statute relating to the admission of minors may be in a different part of a state's code altogether and may not even be referred to in the code relating to admission of adults (10). This is not true in all states; Iowa, for example, addresses the admission of minors and adults in the same statute ( 11). In general, however, a physician should be careful to ensure that he or she has identified the applicable statutes.

Once the proper set of statutes is identified, the physician should determine what kind of psychiatric admission is required. There are two primary types of admission to psychiatric hospitals: voluntary and involuntary. In cases involving minors, however, these terms may be misleading. Often, if a parent consents to the minor's admission, even if the minor is opposed to the admission, the admission is considered voluntary and governed by voluntary admission statutes ( 12). Even if the terminology of "voluntary" admissions is not used, separate statutes may govern parental admission of minors and involuntary admission of minors ( 13).

A psychiatrist's approach to admission also may depend on the age of the minor in question because the weight given to the minor's opinion about admission sometimes depends on the minor's age. For example, Virginia requires no hearings or court reviews for admission of a minor younger than 14 years of age if the minor's parent consents to admission, regardless of whether the minor consents ( 14), but does require judicial approval for admission of an objecting minor 14 years of age or older, even if the parent consents to the minor's admission ( 15). [The minor's age may continue to be relevant even after admission: For example, Illinois (16) permits minors 12 years of age or older to request postadmission judicial review, whereas Louisiana grants the right to all minors, regardless of age, to request a postadmission judicial hearing ( 17), although only those minors 16 years of age and older may institute certain formal objection procedures ( 18). And, of course, a person's age determines whether he or she is considered a minor at all. For example, in Connecticut ( 19), a person 16 years of age or older is covered by the adult voluntary and commitment statutes, whereas in New Mexico (20), a child is anyone younger than 18 years.]

After determining whether the admission is legally voluntary or legally involuntary, the psychiatrist should determine the standards for admission as outlined by the relevant statute. The specificity of these standards varies. Some state statutes merely enact into law the vague admonition of the Supreme Court that "some kind of inquiry" be made at the time of admission, and periodically thereafter, by a hospital physician to ensure that hospitalization is appropriate. For example, the Arizona statute permits hospitalization of a minor on application of a parent, guardian, or custodian, after a determination by the medical director of the admitting facility that the "child needs an inpatient evaluation or will benefit from care and treatment of a mental disorder or other personality disorder or emotional condition in the agency" and that "the evaluation or treatment goals can[not] be accomplished in a less restrictive setting" ( 21). Some states, like Idaho (22), do not require any type of review before the voluntary admission of a minor, beyond that conducted by the admitting physician. In contrast, some states make such hearings mandatory. Florida ( 23), for example, mandates that a person 17 years of age or younger may be admitted to a psychiatric facility only after a hearing to verify the voluntariness of his or her consent.

State laws also differ in the form of judicial review provided and the procedural protections afforded to minors in the case of involuntary admissions. For example, Connecticut (24) provides for an evidentiary hearing, with representation by court-appointed counsel, an independent psychiatric evaluation, and the right to present evidence and cross-examine witnesses. New Mexico (25) also gives the child the right to be represented by counsel, present evidence, and cross-examine witnesses, as well as giving the child the right to a complete record of the proceedings and the right to "an expeditious appeal of an adverse ruling."

States that provide judicial hearings to minors also differ with respect to the substantive criteria to be applied at such hearings. Connecticut ( 26), for example, requires a judicial finding that "the child suffers from a mental disorder, is in need of hospitalization for treatment, and such treatment is available, and such hospitalization is the least restrictive available alternative." For involuntary commitment of minors, New Mexico ( 27) requires a judicial finding

- (1) that as a result of mental disorder or developmental disability the minor needs the treatment or habilitation services proposed;
- (2) that as a result of mental disorder or developmental disability the child is likely to benefit from the treatment or habilitation services proposed;
- (3) that the proposed involuntary placement is consistent with the treatment or habilitation needs of the minor; and
- (4) that the proposed involuntary placement is consistent with the least drastic means principle.

Iowa (28) takes a somewhat different approach; it classifies an admission of a minor on the application of a parent or guardian as voluntary, but requires that "[t]he juvenile court shall order hospitalization of a minor, over the minor's objections, only after a hearing in which it is shown...that: (1) The minor needs and will substantially benefit from treatment. (2) No other setting which involves less restriction of the minor's liberties is feasible for the purposes of treatment," without further definition or specificity.

In contrast, although Virginia allows any minor younger than 14 years of age to be admitted as a voluntary patient if the minor's parent has requested the minor's admission, Virginia has extensive requirements for involuntary commitment of a minor. Specifically, it requires that for a minor to be involuntarily committed, the court must find that

1. Because of mental illness, the minor (i) presents a serious danger to himself or others to the extent that severe or irremediable injury is likely to result, as evidenced by recent acts or threats, or (ii) is experiencing a serious deterioration of his ability to care for himself in a developmentally age-appropriate manner, as evidenced by delusory thinking or by a significant impairment of functioning in hydration, nutrition, self-protection, or self-control;
2. The minor is in need of compulsory treatment for a mental illness and is reasonably likely to benefit from the proposed treatment; and
3. If inpatient treatment is ordered, such treatment is the least restrictive alternative that meets the minor's needs.

If the parents or guardians do not agree to the child's hospitalization, the requirements are even stricter: In that case, "the court shall order inpatient treatment only if it finds, in addition to the criteria specified in this section, that such treatment is necessary to protect the minor's life, health, or normal development and that issuance of a removal order or protective order is authorized ..." ( 29).

As this brief overview shows, statutory schemes for the admission of minors to psychiatric facilities vary widely from state to state, and may change over time even within a state. Psychiatrists should determine the current relevant statute in their respective states, paying attention to issues such as the applicability of the statute to minors; the distinctions drawn between involuntary and voluntary commitments; the age distinctions drawn by the statute; and the procedural and substantive protections provided to minors by the statute.

## THE RESPONSIBILITY OF THE PSYCHIATRIST

It is unlikely that either the Supreme Court decision in *Parham* or the wide variety of state legislation governing the admission of children and adolescents to psychiatric institutions will make a difference in most cases of parental hospitalization of children for psychiatric treatment. In many, if not most cases, the decision to hospitalize a child is made by responsible parents and competent psychiatrists, and only when there is no other way to provide necessary treatment. In such cases, whether a minor has a right to a hearing or exercises his or her right to a hearing, and regardless of the standards for commitment, the decision to hospitalize is likely to be the same.

However, there will remain a significant number of cases in which children and adolescents face unnecessary, or unnecessarily prolonged, confinement in mental institutions. State statutes will protect some of them. But there will continue to be young people, particularly in those states that have chosen not to enact detailed child commitment statutes, whose right to liberty must be protected, if at all, not by lawyers or courts but by the medical profession.

The psychiatrist called on to make the decision whether to institutionalize must not allow himself or herself to be party to using the process of commitment to remove unruly or unwanted children from unpleasant situations. Particularly in light of the long stays of some children for lack of a home to which to return or a more

appropriate placement, the admitting psychiatrist should see that discharge planning begins at the time of admission rather than at the time the child is ready for release.

Finally, the psychiatrist should realistically view the dangers inherent in forced hospitalization by taking the long view of treating a child's problems. More than determining whether the child can benefit from a stay in a hospital, the psychiatrist should ask how this period of institutionalization will likely affect the child's life over a period of years. What kind and quality of treatment will the child actually get? Will the family or state agency use this as a way to abdicate responsibility for the child? Will hospitalization improve the child's lot, taking into account the entire living situation, including the home to which the child may return? If a seemingly therapeutic short stay in a hospital stretches into an unnecessarily long period of time, will the benefits of the originally prescribed treatment be undone?

Although it may be true, as Chief Justice Burger asserted in *Parham*, that "in the typical case" the decision to hospitalize a child is made cautiously, by competent, caring parents in consultation with well trained and qualified psychiatrists, even the Chief Justice would have to concede that there are instances, such as those presented in the *Parham* case, involving uninformed and expedient decision making by parents and other caretakers; conflicts of interest between children and their parents; abandonment of troublesome or intellectually limited children; use of mental institutions as asylums or as a form of incarceration; confinement of children and adolescents in understaffed, overly restrictive, depressing state institutions; and hospitalization of youngsters who could receive appropriate treatment in nonhospital, community-based programs.

In 1969, the Joint Commission on the Mental Health of Children reported that most state mental hospitals for children and adolescents provided little or inappropriate treatment because of shortages of professional staff, untrained aides, lack of educational and recreational programs, and outmoded facilities, and it concluded that, for these thousands of hospitalized youngsters, "instead of being helped, the vast majority are the worse for the experience" ( 30). More than a decade later, the Children's Defense Fund surveyed mental health facilities for children and adolescents and reported disturbingly similar findings ( 31).

Shortly after the Supreme Court's decision in the *Parham* case, Edward Futterman, a child psychiatrist, drafted a partial "dissenting opinion":

While children do need protection from their own rebelliousness, they also need protection from arbitrary and capricious decision-making by parents and caretakers. While children do need protection from decision-making beyond their developmental capabilities, they also need protection from abandonment and from the use of the hospital as a form of incarceration. While parental responsibility, family autonomy and cooperation by families in the care of their children need to be respected, children need protection when their own interests are in conflict with parental wishes. While children need to be protected in their access to necessary treatment, they need protection from the imposition of overly restrictive treatment approaches when less restrictive alternatives are available (32).

Parents' decisions to hospitalize their children may bear little relation to the severity of the child's mental condition or to the optimal therapeutic approach. Parents simply may not want to or not be able to continue living with a difficult child. Parental unwillingness to live with a difficult child may result in placement in a mental hospital because parents know of no other alternative, either because of a failure to devote sufficient effort to looking for appropriate services or inability to afford whatever appears to be available, or a combination of both (33).

Even if less restrictive alternatives exist, a youngster may be accepted for inpatient treatment by a psychiatric hospital because hospital staff are not required to investigate the availability of alternatives, may lack the time or competence to assist parents in identifying and making arrangements for nonhospital treatment, or may have a financial interest in accepting a child into their program.

Parents who have volunteered their child into a mental hospital may undercut the child's treatment by failing to cooperate in family therapy. Parents may be inconsistent or hostile in their attitudes toward their child's treatment and improvement and reluctant or unwilling to have their child return home, even when hospital staff conclude that the child should be discharged ( 34).

In addition to parent-child conflicts of interest and parental ignorance of less restrictive treatment alternatives, there are other causes of inappropriate hospitalization of children and adolescents. Admission usually is based on a short interview with the child, together with additional information supplied by the parent, guardian, or referring agency. Diagnosis is difficult, and diagnostic labels are vague. "Adjustment reaction" and "transient situational disturbance" are ambiguous and encompass a broad range of "normal" as well as "sick" behavior. Youngsters can spend extended periods of time in mental hospitals despite early findings of "no mental illness."

Often there is third-party pressure on the child, the parents, and the hospital. Judges, police, probation officers, social workers, and school personnel may recommend or insist on psychiatric hospitalization, either for evaluation or treatment. All of these individuals may be acting from motives that, however well-intentioned, do not provide adequate protection against erroneous and unnecessary hospitalization.

Children and young adolescents may experience painful and traumatic psychological effects from being "locked up" in mental hospitals. Disruption in the continuity of relationships with adults is harmful for both young children and older adolescents. The committed child lives in a restrictive environment characterized by frequent staff turnovers and three different "shifts" of staff each day, making it difficult, if not impossible to develop new, stable relationships. The committed child is denied the opportunity to explore the world. Instead, he or she confronts an environment that places a premium on institutional efficiency and encourages compliant and passive behavior (35).

Because of the adverse effects of institutionalization on a child's cognitive, emotional, and social development, mental health professionals caution against hospitalization of a child, even in a superior facility, except when clearly necessary: "[N]o matter how good a treatment program for children in the state hospital is, hospitalization of an emotionally disturbed child is not the best answer . . . [The] basic experiences which a child needs in order to grow into an emotionally healthy, happy and productive adult . . . cannot be found in a hospital" ( 36).

Confinement in a mental hospital creates a special stigma not present in the placement of children in general hospitals or residential schools. The personal and social consequences of being labeled "mentally ill" are well documented in the professional literature ( 37). The label becomes "a double-edged blade . . . caus[ing] [the individual] to demean himself and to magnify social ostracism" ( 38).

The problem of stigmatization is magnified for children, who are more impressionable than adults, who are more likely to accept as true society's judgment that they are "crazy," and whose peer group is less tolerant of those who are "different."

For the child who requires psychiatric hospitalization, stigmatization is an unfortunate "side effect." But when a child is confined unnecessarily, the profound and long-term harm that results cannot be justified. A system that provides few procedural protections at the time of admission and no assurance that discharge will occur when therapeutically appropriate cannot protect children from the severe deprivation of liberty and other suffering caused by unnecessary, or unnecessarily prolonged, confinement in mental hospitals.

## THE MEDICAL DECISION TO HOSPITALIZE A CHILD OR ADOLESCENT

There exist differing professional standards, and differences in professional practice, regarding the conditions and circumstances that warrant psychiatric hospitalization of children and adolescents. Other than in the relatively uncommon, clear cases involving suicidally depressed or dangerously psychotic juveniles, most minors whose hospitalization is sought by parents or other legal guardians manifest symptoms of conduct or personality disorders, adjustment reactions, or situational disturbances. Adults carrying such diagnoses would not be considered appropriate for involuntary commitment because, as a rule, such persons do not pose an imminent risk of physical harm to themselves or others and are not wholly incapable of caring for themselves as a result of mental illness.

The National Association of Private Psychiatric Hospitals, the American Psychiatric Association (APA), and the American Academy of Child and Adolescent Psychiatry each have issued standards for psychiatric hospitalization of children and adolescents ( 39). Notwithstanding their clinical language, the National Association guidelines are sufficiently general and behaviorally based that they could be used to justify the involuntary hospitalization of a wide range of acting-out and nonconforming, as well as mentally ill and emotionally disturbed, youths. These guidelines include "self-defeating" or "self-destructive" behavior, inability "to attend to age-appropriate responsibilities," and "pronounced affective and/or behavioral disturbance" as reasons for psychiatric hospitalizations. An example of self-defeating or self-destructive behavior that might require "immediate acute-care hospitalization [as] the only reasonable intervention" is "sexual promiscuity," although the standards provide no definition of the type of sexual behavior to which that term ought objectively to apply ( 40). Behavior demonstrating "inability to function" that might justify hospitalization under these guidelines could be refusal to communicate with parents, angry outbursts, or participation in disapproved social activities, rather than

doing homework, having a job, participating in socially approved extracurricular activities, and spending time with one's family. Not only do the National Association guidelines emphasize behavioral disturbances, they lack a clear definition of the "mental disorders" that justify hospitalization.

The APA standards provide a more "medical" definition of the type and severity of "mental disorder" that would justify the emergency or long-term psychiatric hospitalization of a minor: "'Mental disorder' means a substantial disorder of the child's cognitive, volitional, or emotional processes that grossly impairs judgment or capacity to recognize reality or to control behavior" (41). Under the APA guidelines, involuntary civil commitment of a minor would require a judicial finding "by clear and convincing evidence, that (a) the child has a mental disorder and that (b) the child is in need of treatment or care available at the institution for which certification is sought and that no less structured means are likely to be as effective in providing such treatment or care" (42).

The American Academy of Child and Adolescent Psychiatry standards are even more precise and medically based and assume that inpatient treatment should be used only in situations where outpatient psychotherapy or other community-based treatment programs have been shown to be inadequate (43), and the youth is suffering from a severe problem that is primarily attributable to a "psychiatric disease" (44). Specific criteria justifying hospitalization under the American Academy standards include (a) "acute disabling symptoms of mental illness such as impaired reality testing, disordered or bizarre behavior, psychotic organic brain symptoms"; (b) "acute danger to property or self or others ...attributable to primary psychiatric disease"; and (c) "severely impaired social or family or educational or vocational or developmental functioning" (45).

Whatever standards or guidelines are followed, the admitting physician who is called on to make the decision whether to hospitalize a child or adolescent must exercise clinical judgment. He or she must determine whether the youngster suffers from a severe or acute disabling mental disorder that requires psychiatric treatment, whether he or she requires hospitalization to receive the treatment, whether such treatment is actually available in the hospital, whether he or she could obtain the treatment in a less restrictive setting or on an outpatient basis, and whether the potential benefits of involuntary psychiatric hospitalization outweigh the restriction of liberty, separation from family and friends, stigmatization, and other harms associated with institutionalization. In addition, the physician must carefully monitor the course of the treatment to ensure that the hospitalized juvenile does not spend any more time in confinement than is necessary to carry out the treatment plan, which should, in any event, be designed to help him or her return and adjust to life in the community as quickly as possible.

# 111 THE MENTAL HEALTH PROFESSIONAL IN THE JUVENILE JUSTICE SYSTEM

Stephen Wizner, J.D.

---

[History of the Juvenile Court](#)  
[Practice in the Juvenile Court](#)  
[The Mental Health Professional in the Juvenile Court](#)  
[Evaluation and Treatment in the Juvenile Justice System](#)  
[Chapter References](#)

Mental health professionals occupy a special place in the juvenile justice system. Because of the rehabilitative and therapeutic goals of the juvenile court and its expressed commitment to individualized, nonpunitive dispositions for children and adolescents who are brought before it, mental health professionals are frequently called on to evaluate juveniles, recommend treatment or other rehabilitative programs, and provide consultation and expert testimony.

Juvenile court judges, probation officers, and attorneys defer to and rely on the opinions and recommendations of mental health professionals. Therefore, it is important for the clinician who would provide services in the juvenile court to be familiar with its history, jurisdiction, and procedure, as well as its limitations.

## HISTORY OF THE JUVENILE COURT

Jane Addams and other turn-of-the-century social reformers brought the juvenile court into being in order to rescue misbehaving children from the harshness and rigidity of the adult criminal justice system (1). In contrast to the criminal justice system, designed to apprehend, prosecute, and punish offenders for the protection of society, the goals of the child-saving movement were the identification, evaluation, and treatment of maladjusted youths for their own benefit, and ultimately society's.

Beginning in Chicago in 1899 and eventually spreading throughout the country, the juvenile court (in some states called the family court) was envisioned as a humane, informal, treatment-oriented social agency that would "save" delinquent children from what the reformers saw as the failure of many immigrant and other impoverished parents to cope with the adverse effects on their children of an increasingly urban and industrial environment.

Initially, the jurisdiction of the juvenile court was broad, encompassing both criminal and noncriminal misbehavior. Children who had committed no crimes but who were alleged to be truant, disobedient, engaging in undesirable behavior, associating with unacceptable companions, or otherwise beyond the control of their parents ("ungovernable") were brought before the juvenile court, together with those who were charged with criminal offenses, in order that they might receive the treatment, discipline, and care they required. These so-called "status offenders" were treated the same as youths who were charged with criminal offenses, although in many jurisdictions they were given a different label, such as "persons in need of supervision."

The juvenile justice reformers believed that juvenile misbehavior, criminal or otherwise, was not a law enforcement problem but a social-psychological problem of children and their families, requiring state interference with and assumption of the parental function of child rearing. It was possible, they believed, and therefore proper, to discipline, educate, and reform the errant and neglected children of the urban poor through the intervention of kindly judges, supportive probation officers, and well-meaning social workers and volunteers. If necessary, children were to be removed from their families and placed in rural reform or "training" schools where they would be subject to long hours of physical labor and strict discipline.

There were theoretical flaws and practical problems in the child-saver's program for curing juvenile delinquency. The coercive nature of involuntary court-imposed "therapy," however benevolently intended, must have seemed punitive from the child's perspective, because it was imposed as a consequence of the child's having engaged in disapproved conduct. The "treatment" provided—judicial admonition, probation supervision, counseling, and confinement in reform schools—was frequently both excessively intrusive and ineffective. Moreover, the theory was based on a simplistic and sentimental view of the nature of children and their psychological development and a naive and romantic faith in the extent to which youthful rebelliousness and antisocial behavior were amenable to treatment of the type offered by the juvenile court.

From the outset, juvenile courts lacked the resources even to attempt to carry out their program. Insufficient funds were appropriated by legislatures to enable juvenile courts to provide individualized justice or implement costly treatment plans for the majority of juveniles who appeared before them. There were not enough qualified mental health professionals available to the court to perform the evaluation, referral, and treatment services that were required. As with many social reform movements, rhetoric outpaced reality.

In addition, the court's treatment-oriented approach was thought to provide insufficient protection for the community from certain juveniles who committed serious crimes or were repeat offenders. Thus, as early as 1903, only 4 years after the first juvenile court was established in Chicago, that court transferred 14 children to the adult criminal system (2). By the 1970s every state, the District of Columbia, and the federal government had laws authorizing or requiring the criminal prosecution in adult courts of certain minors found to be "not amenable to treatment" (3).

Critics have pointed to the unbridled discretion, rehabilitative pretensions, and punitive realities of the juvenile court. They have called for restriction of juvenile court jurisdiction, limitation of the discretion of juvenile court judges, diversion of petty (or first) offenders to nonjudicial alternatives, procedural safeguards, and improved facilities, resources, and treatment (4).

The rising tide of criticism of the juvenile court culminated in the 1960s and thereafter in legislative reforms and judicial decisions that mandated procedural protection for juveniles and narrowed the court's jurisdiction. The New York Family Court Act of 1962 (4a) introduced due process into that state's family courts. A major innovation of the act was its provision for "law guardians," independent lawyers who were appointed to represent juveniles who came before the court. In 1966, the United States Supreme Court decided the landmark case of *Kent v. United States*, holding that the transfer, or "waiver," of a juvenile to an adult criminal court was "an invitation to procedural arbitrariness," and a decision "of such tremendous consequences" that it ought not be made without a hearing that provided "the essentials of due process and fair treatment" (5).

In 1967, in *In re Gault*, the Supreme Court expanded on its decision in *Kent* and ordered the provision of due process protection to all juveniles in delinquency proceedings, characterizing the existing informal juvenile court procedure as "a kangaroo court" (6).

Finally, in 1977 the United States Congress enacted legislation requiring states seeking federal financial assistance for juvenile delinquency programs to cease confining status offenders—children charged with noncriminal misbehavior—in secure detention or correctional facilities intended for juvenile delinquents (7).

The combined effect of the introduction of due process protections into juvenile delinquency proceedings, due process restrictions on the transfer of serious offenders to adult courts, and the effective removal of status offenders from the court's delinquency jurisdiction, together with an apparent increase in the incidence of serious juvenile crime, have left the juvenile court with a clientele that is more violent, more disturbed, and less amenable to superficial therapeutic interventions than that envisioned by Jane Addams and her fellow child-savers. In the words of one juvenile court prosecutor:

[The juvenile court is] a very depressing, horrible place. It's completely not in the real world....How does this court think it's going to rehabilitate a fifteen-year-old who's lived in an entirely different society....The Family Court was made for the little newsboy who broke somebody's window with a stone. That's when the laws were made. Not for the fifteen-year-old who's into drugs and killing (8).

## PRACTICE IN THE JUVENILE COURT

Mental health professionals are called on by the juvenile court to perform evaluations, make treatment and program recommendations, and provide consultation and

expert testimony (9). It is important that the clinician who chooses to work in the juvenile court be familiar with its procedures and specialized terminology.

A juvenile delinquency case normally begins with an arrest, referred to as an “apprehension.” The juvenile is either released to the custody of his or her parent or held in a “detention center,” the equivalent of an adult jail for pretrial detainees. If the child is to be detained, he or she is provided a “detention hearing” before a judge. The standard for detention is customarily whether detention is necessary for the protection of the community or is otherwise in the child’s best interests. “Preventive detention,” the practice of incarcerating juveniles prior to trial in order to prevent them from committing further delinquent acts during the pretrial period, was upheld as constitutional by the United States Supreme Court in a 1984 decision, *Schall v. Martin*, on the ground that “juveniles, unlike adults, are always in some form of custody” (10).

Whether or not a juvenile has been taken into custody, the child and his or her parents will normally be summoned to an intake interview with a court probation officer. At that stage, a decision is made whether to proceed “nonjudicially” by diverting the child to a community resource for services or to advance the case to the next stage of the process. This normally requires that the youngster “admit” (confess) to the charges and agree to participate in the treatment or program recommended by the probation officer.

In some jurisdictions the child is brought before a judge, either before, after, or instead of the intake meeting with the probation officer, in order to “admit” (plead guilty) or “deny” (plead not guilty) the allegations contained in a “petition” (indictment or complaint) alleging that the child has committed specified acts that if committed by an adult would constitute a crime. The court official—probation officer or prosecutor (in some jurisdictions euphemistically referred to by some title such as “court advocate”)—who signs the petition, or the state, is called the “petitioner,” and the child the “respondent.” At that hearing, analogous to an adult arraignment, the judge informs the juvenile and his or her parents of their rights, including the right to counsel. If the family cannot afford to hire an attorney, the court appoints a public defender or private attorney paid by the court to represent the child.

If the juvenile is an older, repeat offender and is charged with a serious criminal offense, the probation officer or prosecutor may seek to have the case “waived” (transferred) to an adult criminal court on the ground that the respondent is “not amenable to treatment” as a juvenile. A hearing is then held by the court to determine whether the types of “dispositions” (sentences) available in the juvenile court are likely to be of benefit to the juvenile and sufficient for the protection of the community.

The juvenile delinquency proceeding itself is in two stages. First, there is an “adjudicatory hearing” (trial). If the child is found guilty, there is said to have been a “finding” or “adjudication” (conviction). Second, if there has been an adjudication, the case proceeds to the “dispositional” (sentencing) phase. Prior to disposition, a probation officer conducts a predisposition investigation and prepares a dispositional recommendation. At the disposition hearing the judge considers the recommendations of the probation officer, the child’s attorney, and any other relevant information and imposes a “disposition” (sentence), which may be supervised or unsupervised probation, including probationary conditions such as a curfew, school attendance, counseling, or psychotherapy; community service; or a residential program in a private residential school or treatment center or in a state “training school” (the equivalent of an adult correctional institution).

## THE MENTAL HEALTH PROFESSIONAL IN THE JUVENILE COURT

The rehabilitative ideal continues to inspire the rhetoric and guide the practice in the juvenile court. Individualized justice and nonpunitive, treatment-oriented dispositions intended to help juvenile offenders and, in so doing, to protect society are the articulated goals, if not the reality, of the juvenile court. Forensic child clinicians are regularly called on by the court to perform mental health evaluations and family assessments, recommend and refer juveniles to treatment, consult with court staff and the child’s advocate, and provide expert testimony.

Unlike the adult criminal justice system, where mental health professionals most frequently are called on to offer expert opinions on issues of competency, insanity, and diminished capacity, in the juvenile justice system the principal mental health issue is “amenability to treatment.” At preadjudicatory and postadjudicatory stages of a juvenile delinquency proceeding, the need for treatment, appropriate type of treatment, and likelihood of benefit from treatment are central concerns.

At intake the probation officer must decide whether to handle (“adjust”) the case “nonjudicially” by releasing the juvenile or diverting him or her to a community agency or file a petition and seek an adjudication of delinquency and court-imposed disposition. At this stage “disposition bargaining,” analogous to adult plea-bargaining, is common. The juvenile’s advocate or the juvenile may attempt to avoid the risk of incarceration or other restrictive disposition by admitting to some or all of the facts in exchange for some less intrusive form of community-based treatment.

If the probation officer is persuaded that the juvenile is amenable to treatment by a community agency, and the juvenile admits some or all of the facts alleged as the basis for the arrest and agrees to accept the referral to the community agency and cooperate in the proposed treatment, the juvenile will not be required to stand trial before a juvenile court judge and face the possibility of an adjudication and court-imposed disposition.

At the intake stage both the probation officer and the juvenile’s advocate may seek an expert clinical opinion regarding the respondent’s amenability to treatment as an alternative to incarceration or other court-imposed disposition.

The next point in the process at which amenability to treatment may be evaluated is the so-called “waiver hearing” at which a judge decides whether to transfer a juvenile to the adult court for criminal prosecution. Often, a juvenile considered for transfer will be an older, repeat offender, charged with a serious crime. The mental health professional asked to evaluate such a youngster’s amenability to treatment will need to consider the youth’s prior experience with juvenile court dispositions, whether there are appropriate dispositional alternatives available to the juvenile court that have not been tried, and the relative superiority of dispositional alternatives available in the criminal justice system to address the juvenile’s problems.

If the juvenile is not diverted or transferred from the juvenile court and he or she is adjudicated a juvenile delinquent, the mental health professional may be called on at the dispositional stage to assess the youngster’s amenability to treatment by performing a mental health evaluation and recommending a particular type of therapeutic or rehabilitative disposition.

The most common disposition is probation, involving periodic meetings with a juvenile court probation officer, and special conditions of probation, which may include psychotherapy. If the juvenile is determined not to be amenable to treatment in the community, then he or she may be incarcerated in a training school or “placed” in a residential treatment program. The court is frequently guided by the recommendations of mental health professionals in deciding which of these dispositions to impose.

Assessment of the need for and amenability to treatment and recommendation of appropriate dispositions is the principal function of the mental health professional in the juvenile court. This function can be carried out in different roles. The forensic child clinician may serve as an adjunct to the court, providing consultation (or testimony) for the judge, probation staff, or prosecutor. The clinician also may assist the defense. In either role, the clinician may be able to provide expert assistance in diagnosing mental health problems and their relationship to the particular behavior at issue, in supporting or rebutting claims that individual juveniles are or are not amenable to treatment, recommending treatment or other rehabilitative programs, and evaluating previous efforts to treat or rehabilitate an individual juvenile.

## EVALUATION AND TREATMENT IN THE JUVENILE JUSTICE SYSTEM

The term *treatment* is used broadly in the juvenile justice system. A child or adolescent may be considered to be in need of or amenable to treatment not only because of a psychiatric condition but also, and more often, because of behavioral problems that may not be treatable by psychotherapy alone, or at all. Consequently:

a thorough assessment of a juvenile’s amenability to treatment should usually include an evaluation not only of personality functioning, but also of cognitive, educational, vocational, and social needs in the context of the various systems (e.g., family, school, neighborhood) of which he or she is a part (11).

It is important for the clinician to appreciate that the juvenile court’s rhetorical commitment to individualized treatment and the rehabilitative ideal tends to mask a law enforcement function. As a practical matter, the juvenile court is concerned with community protection, notwithstanding its child-saving rhetoric. Judges, probation officers, and prosecutors want to know not only whether a child or adolescent suffers from a mental health problem for which he or she should receive treatment but also whether that problem is the cause of the misconduct and whether the proposed treatment is likely to prevent the juvenile from recidivating. Therefore, mental

health professionals must take care that they are not co-opted into a system that may misuse their expertise and induce them to exceed the bounds of their professional competence.

It is often not possible for the clinician to establish a clear connection between a juvenile's mental or emotional problems and the specific offense charged, or predict the efficacy of a treatment plan in preventing recidivism. Indeed, research on the effectiveness of "correctional treatment" shows that most interventions appear to have little positive effect on recidivism and many appear to exacerbate the problem ( 12). Nevertheless, the clinician should offer the court his or her expert opinion and clinical judgment about the child's treatment needs and leave it to the court to determine whether the recommendations, if followed, will strike the proper legal balance between promoting the best interests of the child and protecting the community from the child.

## CURRENT SITUATION

All physicians feel the burden of malpractice insurance, and many will be sued at some time in their careers. Child psychiatrists are not sued as often as physicians who rely heavily on technology; however, their involvement in the hospitalization and medication of severely disturbed patients makes it likely that the profession will be a target for litigation.

Since 1980, the overall size of malpractice awards has risen by 12.7% per year, nearly double that of the yearly increase in the cost of living and more than double the average yearly rise in medical costs. This startling increase is the result of vigorous and ingenious legal advocacy ( [Rosenberg, 1988](#)). Although they are more difficult to win, medical malpractice claims produce higher awards than the usual civil liability suit. Currently, the national average, in the United States, for recovery in medical malpractice suits is 46%, compared with 57% in civil liability actions. The average monetary award in psychiatric malpractice suits is \$340,000, compared with about \$1,100,000 in all medical malpractice.

Traditionally, emotional injury was not compensable, largely because authorities feared opening the floodgate to dubious, unassessable suits. However, the courts have begun to regard emotional injury more favorably, particularly if the defendant's breach has been wanton, outrageous, or extreme. Moreover, the proposed limitation of monetary awards for "pain and suffering" has been struck down in several states as unconstitutional, and awards have been made in some jurisdictions for "hedonic damages" (i.e., for posttraumatic impairment in the capacity to enjoy life).

The potentially lucrative nature of malpractice litigation crowds the legal field and makes it intensely competitive. Able lawyers are current with the medical literature, brandish the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* in the courtroom, and grill clinicians on the meaning of such terms as "reliability" and "validity." The clinician would be wise to understand the basis of malpractice law and to take steps to limit liability. Conversely, despite the increasing regulation and legal scrutiny of medicine, it is imperative that the profession avoids defensive psychiatry with its interminable tests and therapeutic homeopathy: paradoxically, excessive caution could put the clinician at risk of an action for negligence ( [Simon, 1987](#)).

## ELEMENTS OF MALPRACTICE LAW

The term *malpractice* refers to an *act or omission* by a professional in the course of his or her *professional duty* that *causes or aggravates an injury* to a patient or client and is *the consequence of a failure to exercise a reasonable degree of prudence, diligence, knowledge, or skill*. In other words, to be held liable for malpractice, one must do something one should not or fail to do something one should, and the act or omission must represent a level of care that is demonstrably less prudent, less diligent, less informed, or less skillful than would be provided by the average practitioner of the same training, in the same circumstances. Furthermore, the substandard act or omission must cause the patient a demonstrable injury that is of a compensable nature.

To substantiate malpractice, the plaintiff must establish the following four points, by a preponderance of the evidence:

1. A relationship existed between the clinician and the patient such that the clinician owed a *duty of reasonable care* to the patient.
2. When judged by the standard of the average, prudent practitioner, the clinician *breached the duty of care*.
3. The patient sustained *compensable injury or harm*.
4. The said injury or harm was a *direct result* of the clinician's failure to exercise a reasonable standard of care; or, in other words, the clinician's dereliction was the *proximate cause* of the patient's injury.

### Duty of Care

#### CONTRACTUAL RELATIONSHIP

The clinician owes a duty of reasonable care toward a patient when a professional relationship exists between them. This relationship is formed when a clinician explicitly or implicitly agrees to provide care to a patient. The clinician thus enters into a contract that binds him or her to provide a reasonable level of care in return for a valuable consideration (the fee). Unless the clinician has unwisely promised a cure, he or she is not bound to provide more than a reasonable level of care.

The doctor-patient relationship cannot be imposed on a competent patient, nor can a doctor be forced to care for a patient. The most controversial situations arise when it is argued that a relationship has been implied by the physician's actions or words. For example, the discussion of a patient's condition by telephone before transfer to a different hospital has been held to imply a contractual relationship ( [O'Neill v. Montefiore Hospital, 1960](#)). Payment is not necessary; gratuitous services attract a duty. The clinician should be careful about giving casual advice at cocktail parties and the like, lest it be construed that a contractual relationship has been formed.

Conversely, a physician cannot be forced to treat patients who are unable to pay for services or to use a treatment that he or she is not competent to implement. The physician also has a legal (if not an ethical) right to refuse to give aid in an emergency. Good Samaritan laws have been enacted to protect from liability those physicians who do render emergency aid, unless they have been grossly negligent (e.g., abandoning a live patient who is still hemorrhaging).

After the termination of the contract, the physician owes no further obligation to the patient other than that of confidentiality. Physicians who terminate contracts unilaterally and without reasonable cause are at risk of actions for *abandonment*. The physician must give the patient due notice of termination and must ensure that necessary arrangements are made for alternative care. If the patient resists termination, failure to refer to another physician may be construed as negligence.

Clinicians may examine people on behalf of a third party, such as a government agency, to whom they owe a contractual duty. However, if the examination causes the examinee harm, for example, by failure to detect suicidality or the possibility of child abuse, the liability risk is ambiguous. Some courts have held that the clinician's duty is to the employer; others have held that, if the person being examined reasonably relied on the examination for diagnosis, a duty may be owed. The physician is

advised to inform the examinee that the purpose of the examination is not therapeutic.

#### VICARIOUS LIABILITY

In accordance with the doctrine of *respondeat superior*, a physician is legally responsible for the negligent actions of employees or supervisees. Thus, a psychiatrist may be held liable for the negligent or outrageous actions of interns, residents, or nurses in an inpatient service or office.

#### FIDUCIARY RELATIONSHIP

The clinician's obligations toward the patient go beyond the duty to provide reasonable care. The relationship between psychiatrist and patient is analogous to that between guardian and ward. The patient has a right to expect the physician to show good faith, that is, to act in the patient's best interest. This, the physician's *fiduciary duty* is especially onerous in psychiatry, because emotionally disturbed people share their most private experiences with their mental health clinicians and are thus very vulnerable. Improper sexual contact, invasion of privacy, breach of confidentiality, outrageous manipulation of the patient's emotions, and the exploitation of patients for financial gain are all examples of *double agency* and *breaches of fiduciary trust*. These *intentional torts* are discussed later in this chapter.

#### CONFIDENTIALITY AND PRIVILEGE

By ethical code and law, the physician is precluded from divulging private matters revealed by the patient in the context of the doctor–patient relationship. *Privilege* is the patient's right to bar the physician from disclosing confidential matters in a court of law. In most jurisdictions, testimonial privilege derives from statute. Physicians should consult their local statutes to understand the extent of this privilege and its exceptions. Confusion may occur when a clinician receives a *subpoena* to appear in court (with or without records). *A subpoena merely requires the clinician to appear in court. It does not compel him or her to testify about confidential matters unless the patient has specifically authorized the clinician to do so, or has waived privilege, or unless the clinician is ordered to do so by the judge.* Although the states vary somewhat in the exceptions allowed to the rule of privilege, the following are the most usual:

1. *Waiver of privilege.* The clinician should seek specific written authorization from the patient before disclosing confidential material in court or to other parties (e.g., other mental health agencies).
2. *The psychiatric evidence exclusion.* If a patient offers his or her mental health as evidence in litigation, he or she waives privilege concerning the specific issue in evidence. Similarly, if the patient pleads insanity as a criminal defense, the psychiatric examination conducted to evaluate that matter is not privileged (*Bremer v. State, 1973*).
3. *Evaluation for a reason other than psychiatric treatment.* For example, the psychiatric evaluation of a disputant in a child custody case is not privileged if the evaluation was conducted as part of the case. A similar exclusion applies to evaluations for the purpose of civil commitment.
4. *Duty to protect endangered third parties.* The *Tarasoff* exclusion applies when the community is endangered. It is discussed later in this chapter.

#### Standard of Care

In accordance with the contract inherent in the doctor–patient relationship, the physician is bound to provide a reasonable level of care. In other words, the physician contracts to provide reasonable, prudent, diligent, knowledgeable, and skillful medical care. Unless the clinician has unwisely promised a cure, the contract does not call for exceptional care, only a level of expertise equivalent to that exercised under similar circumstances by the average practitioner in the same field of medicine. *The clinician is not liable for an error of judgment unless the error represented a substandard level of care.*

The considerable variation among clinicians in methods of treatment has made standards difficult to establish, particularly in regard to psychotherapy. Conversely, the standard is tighter with regard to precautions against suicide or violence or the monitoring of medication.

#### Breach of the Duty of Care

Malpractice suits are founded in the legal theories of intentional and negligent torts. An *intentional tort* involves deliberate intent on the part of the wrongdoer or wrongful conduct that the wrongdoer ought to have known was unacceptable (in which case it is known as a *quasiintentional tort*). Examples of intentional torts are assault, battery, false imprisonment, fraudulent commitment, defamation, invasion of privacy, sexual exploitation, and the intentional infliction of emotional distress. Expert testimony is not required to substantiate an intentional tort, and malpractice insurance may not cover it. A *negligent tort* involves an unintentional error that reflects a failure by the clinician to exercise a reasonable standard of medical care. Expert testimony is required for proof of negligence.

The standard of care traditionally required that the clinician be judged by the professional standard in the locality. However, the emergence of national standards has caused the courts to move in this direction, with allowance for the paucity of resources in some areas. The standard of care is linked to the standard of professional practice at the time of the alleged breach of duty; clinicians are expected to stay abreast of developments. If a clinician practices medicine in a specialty area for which he or she is not trained, the clinician is likely to be held to the standard applying to that specialty.

#### Harm, Injury, or Damage

*Harm* may be physical or psychological. As previously described, the courts have been reluctant to award damages for psychological injury, unless the wrongdoer's actions have been wanton or outrageous. Physical harm or damage resulting from negligence can vary: for example, side effects of medication (e.g., tardive dyskinesia), physical injury incurred when a patient is improperly restrained, or homicide or suicide occurring when a patient is negligently released from a hospital. All these situations are discussed later in this chapter.

#### Proximate Cause

The plaintiff must substantiate that the defendant's wrongful act or omission directly caused or aggravated the patient's injury. In other words, it must be proven that, but for the wrongful conduct, the damage would not have occurred or would not have been aggravated or that a direct, uninterrupted link or foreseeable chain of events exists between the wrongful conduct and the injury or its aggravation. The legal concept of *cause* is analogous to the psychiatric concept of *precipitation* or *aggravation*.

If Dr. A misdiagnoses B's illness, B must prove that, if not misdiagnosed, he would have received treatment that would have alleviated his condition. If Dr. A is held negligent in prescribing treatment X rather than treatment Y, B must still prove that, more probably than not, treatment Y would have been successful.

#### Damages

If the defendant is found liable, the judge or jury may award damages. Damages are designed to be *compensatory*, that is, to recompense the victim for medical expenses, pain, suffering, loss of enjoyment of life, impairment of capacity, and future loss of earnings and to restore the plaintiff to his or her original position, so far as money is able to do so. If the defendant's behavior has been egregiously outrageous, malicious, or wanton, *punitive* damages may be imposed over and above compensatory damages. Psychiatric evidence may be required to inform the jury about the impact of an injury on the plaintiff's capacity to enjoy life. Injury to a parent or child may give rise to an action for loss of consortium, that is, loss of the care, comfort, and society of a spouse, parent, or child.

### CIRCUMSTANCES IN WHICH MALPRACTICE IS MOST LIKELY TO OCCUR

Child psychiatrists are most at risk of liability in particular circumstances. This section describes the most perilous situations and their attendant risks.

#### Hospitalization

Hospitalization and medication, which are often combined, present certain situations in which the clinician is at risk of liability.

## ADMISSION

### *Negligent Failure to Admit*

The physician may fail to admit a suicidal or violent patient who subsequently harms himself or herself or others. Such an error may be actionable if the physician had failed to evaluate the patient adequately, for example, by assessing mental status or by reviewing the patient's past history for dangerous behavior. The assessment of suicide or violence risk is discussed later in this chapter.

### Wrongful Commitment, False Imprisonment, and Fraud

A physician who causes a patient to be admitted to a psychiatric hospital without proper evaluation may be sued for *negligent diagnosis* or *false imprisonment*. A falsely imprisoned plaintiff may recover damages for *loss of dignity* and *emotional distress*. Ignorance of the Mental Health Act is no defense; failure to comply with statutory requirements could be actionable. For example, in [Johnson v. Greer \(1973\)](#), a patient recovered damages after being forcibly detained in hospital for several days beyond the 24 hours permitted on an emergency warrant. Malice, spite, ulterior motive, bad faith, or fraud during involuntary hospitalization could also result in damages for false imprisonment or *malicious prosecution*, as was the case in [Pendleton v. Burkhalter \(1968\)](#). Parents or guardians may admit unemancipated minors against their will, and health care providers should be able to rely on parental consent ( [R.J.D. v. Vaughn Clinic, 1990](#)). However, the psychiatric justification for admission should be carefully documented.

## NEGLIGENT DIAGNOSIS

The failure to distinguish organic disease from psychiatric disorder, to differentiate functional psychosis from other psychiatric disorder, or to discriminate among the major psychoses could be actionable if it resulted from inadequate or inept diagnostic investigation and if it caused harm to the patient.

## PATIENT MANAGEMENT

### *Failure to Protect or Control a Suicidal, Violent, or Sexually Aggressive Patient*

Hospitals assume a duty of care toward patients with a potential for suicide or violence. The psychiatrist must carefully assess the potential for danger and must ensure that the hospital staff takes adequate precautions to protect a suicidal or violent patient from doing harm to himself or herself or to others. Past medical records should be scrutinized concerning suicide potential, and referring agents and parents should be questioned. In accordance with the imminence of the risk, housing in a secure unit, confinement to a room, close observation, a search of clothing and personal effects, and removal of all dangerous objects (e.g., belts, mirrors), may be required. If the patient is medicated, staff members should check that medication is actually swallowed. It is essential that the degree and nature of risk be communicated to all staff who care for the patient. The importance of good medical record keeping cannot be overstressed. Timely, clear, legible, pertinent, thorough, dated, timed, and signed records are the key to communication and the best proof that the hospital and staff have exercised reasonable care. In [Abille v. United States \(1980\)](#), after a psychiatrist transferred a patient from a suicidal status to a less dangerous status, the patient committed suicide. The finding of negligence against the defendant hinged on the psychiatrist's failure to keep detailed records that explained his decision to transfer the patient, even though it was conceded that, under the circumstances, the decision may have been reasonable.

What if the patient refuses to cooperate with the admitting psychiatrist, who consequently does not elicit and diagnose an imminent suicide risk? In [Skar v. City of Lincoln, Nebraska \(1979\)](#), a recalcitrant patient injured himself in a suicide attempt. The court found for the defendant and held that the patient had a duty to cooperate with his physician as far as he was able. However, it is essential in such a case that the psychiatrist record the questions put to the patient and the patient's responses or failure to respond.

The prevalence of sexual abuse and its relationship to psychiatric disorder mean that many minors admitted to psychiatric hospitals are at risk of precocious sexual activity and unwanted pregnancy. Known perpetrators should be closely observed and housed in single rooms, if necessary. Actions may be brought against hospitals and physicians who fail to take reasonable precautions to protect other patients from sexual assault, sexual coercion, or illicit sexual activity. Similar strictures apply to a failure to take reasonable precautions to protect others from physically violent patients. However, the closeness of the observation possible decreases if the therapeutic environment is less restrictive, for example, in a residential treatment center.

### *Negligent Release or Discharge of a Suicidal or Violent Patient*

A patient may harm himself or herself or others while on pass in the grounds of the hospital, on leave with relatives or friends, after discharge, or after absconding from hospital. Was the tragedy foreseeable by a reasonably prudent psychiatrist? This is the question that the courts seek to answer. In doing so, they are aware that the safety of the public must be balanced against the need to rehabilitate patients, that reasonable, calculated risks must often be taken, and that *bona fide* errors of clinical judgment are unavoidable ( [Higgins v. State, 1965](#)).

Increasing pressure by managed-care organizations, Medicaid agencies, and insurers has raised the specter of premature discharge against medical advice forced by withdrawal of funding. The clinician should be aware that legal responsibility for any harm that consequently befalls the patient or community will be placed on his or her shoulders. Hospitals and private clinicians who collaborate with health maintenance organizations would be wise to draw the line. If premature discharge is forced against medical advice, the clinician should protest vigorously in the medical record and should appeal by letter before allowing it. The risk may be so great that the hospital should bear the cost of continued hospitalization.

### *Failure to Protect Endangered Third Parties*

If a patient absconds from the hospital and one has reason to suspect that a third person or persons are placed in jeopardy thereby, it is the psychiatrist's duty to take whatever steps are required to protect the community. This duty, which emanates from the *Tarasoff* decision, is discussed in more detail later.

### *Wrongful Injury, Assault, and Battery*

A patient injured by staff members who use excessive force to subdue him or her may have a claim against the hospital for battery or wrongful injury. Wrongful injury may also be claimed when one patient is harmed by another whom the staff could not control; however, the plaintiff would have to establish that the hospital was derelict in its duty to control the violent patient.

Seclusion and restraint present serious liability risks. They may be legitimate management techniques when the risk of harm is imminent and there are no alternatives; but they should not be used to compensate for understaffing. Physical control should be time limited, and the patient should be examined by a physician if the maximum permissible time (e.g., 1 hour) requires extension. Seclusion and restraint should never be ordered "as needed." Quality assurance tracking is required to ensure that the use of physical controls does not become excessive.

If the person causing the harm is a hospital employee, the hospital may be liable, particularly if it were known that the employee had a propensity for violence or sexual misbehavior ( [Samuels v. Southern Baptist Hospital, 1992](#)). The hospital may also be liable for the misbehavior of physicians, agency nurses, or others who work in hospital but who are not employed by it. State institutions may claim *sovereign immunity*, which precludes litigants from suing governmental institutions; however, most jurisdictions have greatly limited or abolished this doctrine.

## IMPROPER TREATMENT

Treatment may be administered against the patient's will in an emergency or if the patient has been adjudicated incompetent. In other circumstances, a mature minor and his or her legal guardian, or the legal guardian alone (in the case of immature minors), must give informed consent to treatment. This matter is discussed in more detail later in this chapter. Erroneous choice of treatment, the use of an unapproved treatment, and failure to monitor side effects are also discussed later in this

chapter. The hospital will be liable for failure to provide adequate staffing, equipment, and support to manage the problems associated with the procedures it offers.

## RECORD KEEPING

### *Improper Release of Information from Medical Records*

The comments made in this section are relevant to both hospital and outpatient practice. Traditionally, privilege has applied to all private communications between patient and doctor, including the medical record. However, in recent times, the confidentiality of the medical record has been “polluted” (i.e., invaded by a number of bodies). Third-party insurers, for example, have access to patients' records to ensure that medical costs are legitimate. Nevertheless, the unauthorized disclosure of confidential information from a patient's record could be actionable on the ground of breach of confidentiality. Medical records should be kept in a locked place in the ward or medical records department to bar access to unauthorized people. The patient or legal guardian must give written consent for the transfer of information to legitimate professionals or agencies (e.g., other involved clinicians, attorneys, hospitals, schools, social welfare departments, and insurance companies).

If a subpoena is served without the written consent of the patient or guardian, the clinician has three alternatives: to seek the patient's consent; to have a motion filed by an attorney to quash the subpoena; or to refuse to testify unless ordered by the judge to do so. If the clinician persists in refusing to testify despite the judge's instruction to do so, he or she may be held in contempt of court ([in re Lifschutz, 1970](#)).

### *Defamation*

*Defamation* involves communication by one party about a second party to a third party that damages the reputation of the second party. Defamation is most likely to occur in child psychiatry when carelessly written medical records are released to third parties. For example, the patient may have been described in the record as a “psychopath” or “malingerer,” labels that could be extremely damaging in the hands of employers or creditors. Clinicians who gossip about patients over coffee or in elevators put themselves at risk of liability on the grounds of defamation or breach of confidentiality.

Defenses against defamation include *substantial truth* and *conditional privilege*. For example, if Dr. A refers patient B to Dr. C, and Dr. C reports to Dr. A that B has antisocial personality disorder, Drs. A and C have a duty and interest to receive and report such matters. In other words, conditional privilege applies. No such privilege applies to those who have no such duty and interest. Testimony given in court or provided to the court in documents such as medical reports or medical records attract *absolute privilege* insofar as they refer to the broadly defined matter at issue. *Malice*, if proven, destroys conditional privilege. Malice is substantiated by the author's evident self-interest, excessive distribution of the defamatory material, reckless disregard of the truth, or the vituperative style of the documents involved in the case.

### *Liability for Failure to Communicate Records*

The courts have generally refused to find that patients have a property or constitutional right to their records. However, records may be made available on request for legitimate reasons such as litigation. Some states have enacted legislation to allow patients to have access to their mental health records. However, “personal notes” may be excised (e.g., confidential information, information potentially injurious to the recipient, and the therapist's speculations), thus limiting access to the official record only.

## Medication

The points in the medication of a patient at which negligence is most likely to occur are as follows:

1. The diagnosis of the psychiatric disorder
2. The adoption of an appropriate rationale for drug therapy
3. The choice of a particular drug to treat the patient's psychiatric disorder
4. Inquiry concerning a past history of excessive therapeutic response, severe side effects, or allergic reaction to the drug in question or to related drugs
5. The search for coexistent medical conditions that would contraindicate the medication in question or would indicate the need for caution in its use
6. Obtaining informed consent
7. The administration of an appropriate dose of the drug in question, by an approved route
8. The prescription of drugs in combination, or the addition of a drug or drugs to an existing medication regimen
9. The choice of a drug not approved by the U.S. Food and Drug Administration or the use of a drug in a way, or for a purpose, that deviates from that recommended in the package insert or *Physician's Desk Reference*
10. Monitoring the therapeutic effect and side effects of the medication
11. Ceasing the medication after a therapeutic effect has been achieved or maintaining long-term medication at the lowest effective dosage

## DIAGNOSIS

The physician must distinguish organic disease from functional disorders and, within the latter, must differentiate the major psychoses from each other and from other Axis I and II conditions. The physician who admits patients to a psychiatric hospital must be alert for signs that could indicate a toxic condition. In [Hirschberg v. State \(1997\)](#), for example, a patient who had taken an overdose of salicylates died after having been hospitalized without adequate physical examination, special investigations, or proper precautions. The hospital was found liable.

The physician who fails to diagnose the patient accurately (e.g., by missing psychosis when it is present or by confusing bipolar disorder with schizophrenia) may find treatment on a false premise and thus may be open to a liability suit. However, there have been few actions on these grounds. Lawyers have been reluctant to pursue such cases in view of the reputedly widely varying expert opinion concerning the most appropriate treatment for different psychiatric conditions. As child psychiatry becomes more empirically based, it is likely that such actions will increase in frequency.

## DECISION TO MEDICATE

### *Failure to Medicate When It Is Appropriate to Do So*

In [Osheroff v. Chestnut Lodge et al. \(1987\)](#), suit was brought against a private hospital for negligent failure to disclose all treatment alternatives. The plaintiff, who suffered from mixed affective and personality disorder, had been treated for several months with individual psychotherapy. After transfer to a different hospital, he responded to antidepressant medication within a few weeks. Several eminent psychiatrists testified for the plaintiff that antidepressant medication was the treatment of choice, and the plaintiff had had insufficient opportunity to consider it as a treatment alternative. The suit was settled out of court in favor of the plaintiff. It is likely that this case, which became an ideologic battlefield, foreshadows future similar actions.

### *Inappropriate Rationale for Treatment*

Psychotropic drugs are sometimes prescribed to control inmates in correctional or mental retardation institutions. These situations warrant close scrutiny; the physician may have been induced to medicate the patient by the urgings of harassed staff, rather than by the medical needs of the patient, a practice that has been specifically criticized in at least one class action suit ([Nelson v. Heyne, 1972/1974](#)) and one malpractice case ([Clites v. State of Iowa, 1982](#)).

### *Choice of an Inappropriate or Unapproved Drug*

This kind of error occurs when the physician orders a drug that is inadequate to treat the patient's disorder (e.g., a benzodiazepine for major depressive disorder) or when the physician prescribes a drug for which there are less risky alternatives (e.g., a neuroleptic for anxiety disorder). A different problem arises when the clinician prescribes a drug not approved by the Food and Drug Administration. Undoubtedly, the risk of malpractice is greater if approved guidelines have not been followed. The clinician should reserve unapproved drugs for cases in which conventional treatment has failed. In addition, he or she should document a risk-to-benefit analysis,

seek expert consultation, and obtain specific informed consent before prescribing the unapproved drug.

#### *Failure to Obtain a Medication History*

The patient's past medication history should be ascertained by interview, by review of medical records, and by telephone contact, if required, with other clinicians. The physician may be held liable for excessive side effects, allergic reactions, idiosyncratic responses, or drug interactions, if these had been foreseeable.

#### *Failure to Detect Contraindicative Conditions*

The physician may fail to check for conditions or disorders that would render the patient vulnerable to severe side effects. For example, preexisting subthyroidism may be overlooked when lithium is prescribed. Each class of psychotropic drug requires a standard workup involving medical history, physical examination, review of past medical records, and special investigations. If a contraindicative condition is uncovered but the medication is still considered potentially justified, a risk-to-benefit analysis should be documented, expert consultation should be obtained, and specific informed consent should be recorded. Hospitals should mandate, as policy, standard diagnostic workups for all psychotropic drugs.

#### *Failure to Obtain Informed Consent*

The doctrine of informed consent is founded on the constitutional right of the individual to control what is done to his or her own body ([Schloendorff v. Society of New York Hospital, 1914](#)). A patient cannot give informed consent unless he or she has (a) *sufficient information* on which to base a decision, (b) *mental competency* to make a rational decision, and (c) freedom to exercise *voluntary choice*.

The physician must therefore disclose sufficient information to enable the patient to weigh all material pros and cons. How much is that? The earlier "professional" standard ([Natanson v. Kline, 1960](#); [Aiken v. Clarey, 1965](#)) referred to *what a reasonable medical practitioner would disclose* under similar circumstances. Following two 1972 cases, [Canterbury v. Spence](#) and [Cobbs v. Grant](#), some jurisdictions may have adopted the "patient" standard, that is, *as much information as a reasonable patient would require* to make a rational decision under similar circumstances. [Canterbury](#) and other cases suggest that the physician should discuss the following matters with the patient:

1. The nature of the condition that requires treatment
2. The nature, purpose, and benefits of the proposed treatment, and the probability that it will succeed
3. The risks and consequences of the proposed treatment
4. Alternatives to the proposed treatment (including no treatment) and their attendant risks and consequences
5. The prognosis with and without the proposed treatment

The courts have held that *not all risks need be disclosed—only the material ones*. Unfortunately, there are no clear guidelines concerning what is "material," except to suggest that, even if the likelihood be slight, the more serious the risk, the greater the probability that it should be discussed. *A risk is material when a reasonable person would be likely to attach significance to the risk or cluster of risks*. Risk is linked not only to the procedure but also to the physician and his or her competence to perform the procedure (e.g., if the physician has alcoholism or suffers from human immunodeficiency virus infection). The plaintiff must prove that nondisclosure of material risk caused the injury of which he or she complains. Some courts require that the plaintiff prove that a reasonable person would have refused the procedure had the risks been disclosed.

*Therapeutic privilege* countervails the clinician's duty to disclose. The physician is obliged to protect a vulnerable patient from the emotional trauma that could be sustained if upsetting risks were prematurely revealed. However, therapeutic privilege should never be invoked merely because the clinician fears that, if apprised of the facts, the patient would reject a desirable treatment. If the clinician proposes to limit disclosure on the ground of therapeutic privilege, clear documentation and expert consultation are required concerning the patient's exceptional sensitivity.

Disclosure is not required for an emergency in which the harm from failure to treat is imminent and outweighs the potential danger of the treatment. However, if possible, a relative's consent should be obtained.

Patients beyond the age of majority are presumed competent to make decisions about their own treatment. Competence may also be extended to emancipated minors. When should an unemancipated minor be regarded as sufficiently mature to participate in health care decisions? A series of landmark decisions (e.g., [Planned Parenthood of Central Missouri v. Danforth, 1976](#); [Bellotti v. Baird, 1976](#)) extended to minors the right to make health decisions concerning abortion, and some states have enacted legislation with regard to mature minors and contraception, venereal disease, substance abuse, and emergency psychiatric care. The present situation is very confused ([Wadlington, 1983](#)), and the practitioner should ascertain the law on the matter in his or her own state. However, although it may not be legally required, the desirability of promoting a treatment alliance suggests that it is judicious to promote the understanding and cooperation of all minors mature enough to comprehend. For patients more than 13 years of age, it would be prudent to obtain formal assent. Other than in emergencies, when minors are treated, parental consent is also required. However, according to [Annas \(1975\)](#), no court in recent years has found a physician liable for treating a consenting minor who is more than 15 years of age in the absence of parental consent, provided the treatment was given in good faith.

The third element of informed consent, *voluntariness*, is easily compromised. True voluntary consent requires that the patient be free of coercion. However, even a mature minor can be susceptible to threat, cajolment, bribery, or false inducement by parents, physicians, or hospital staff. The inmates of correctional institutions and psychiatric hospitals are particularly vulnerable to therapeutic coercion.

## IMPLEMENTATION OF TREATMENT

### *Forcible Administration*

The involuntary commitment of a patient to a psychiatric hospital does not permit involuntary medication, except in narrowly defined circumstances. Forcible medication can place the practitioner at risk of an action for the intentional tort of battery. The legal doctrine most pertinent to this issue, *the right to refuse treatment*, has been most clearly articulated in two convoluted cases, [Rennie v. Kleir \(1978/1979/1981/1982\)](#) and [Rogers v. Okin \(1979\)](#). In [Rennie](#), a New Jersey case, it was determined that the mentally ill had a sufficient liberty interest to require due process before treatment was forcibly administered, but due process was satisfied by an in-hospital review. In considering this case, the United States Supreme Court deferred to the professionalization standard articulated in [Youngberg v. Romeo \(1982\)](#), in effect declining to uphold a constitutional right to refuse treatment.

[Rogers v. Okin \(1979\)](#), a Massachusetts case, evolved into [Rogers v. Commissioner of Mental Health \(1983\)](#) and was reviewed by the United States Supreme Court as [Mills v. Rogers \(1982\)](#). The Massachusetts Supreme Court held that involuntarily committed patients should be presumed competent to refuse treatment except in emergencies. An "emergency" was defined as a situation fraught with the need to prevent violence or associated with the likelihood that the patient's health would significantly deteriorate without treatment. In nonemergency situations, forcible treatment may be administered only after a judicial hearing in which the court approves a "substituted judgment" treatment plan. "Substituted judgment" requires the court to determine what the patient would have decided if he or she were competent.

The failure of the Supreme Court to clarify this matter means that each state must make its own determination of the boundaries of the right to refuse treatment. The legal situation with regard to children is unclear. The right to refuse treatment apparently extends to the legal guardians of minors and to emancipated minors. What of the mature minor? Arguably, except in emergencies, the clinician should seek the consent of both mature minor and parent before starting treatment. If the mature minor refuses treatment, and the treatment is regarded vital, a judicial determination of competence should be requested.

### *Inappropriate Dosage or Route of Administration*

The *Physician's Desk Reference* includes the information found in all official drug package inserts, together with manufacturers' information concerning drug products that have no insert. In [Mulder v. Parke Davis & Co. \(1970\)](#), the court held that a departure from *Physician's Desk Reference* guidelines represented a *prima facie* case of negligence unless the clinician could provide adequate reason for having done so. To protect themselves from liability claims, drug manufacturers publish information concerning all reported adverse reactions, however rare, and are conservative in the dosages they recommend. In some circumstances, it may be good clinical practice to regard the risk of particular adverse reactions as insignificant or to exceed the recommended dosage. However, before doing so, it would be

advisable for the clinician to document a risk-to-benefit analysis, seek a consultation, and locate references in the literature that would support the proposed medication regimen.

An intravenous or intramuscular route of administration carries an increased risk of excessive or adverse response. This is particularly likely if the patient is predisposed to side effects as a result of hepatic, renal, cardiac, or brain dysfunction. The clinician should be cautious if such conditions are detected. Parenteral administration should generally be reserved for emergencies or long-term depot treatment.

### *Polypharmacy*

Psychotropic cocktails increase the risk of adverse reactions. They are most likely to be prescribed when psychotic patients are slow to respond or in general hospitals and residential centers that have inadequate structure or psychiatric nursing care. Conversely, as [Simon \(1987\)](#) points out, drug combinations (e.g., of an antidepressant with a neuroleptic) are sometimes more efficacious than one drug alone. Nevertheless, the clinician should record a risk-to-benefit analysis before prescribing multiple psychotropic agents.

### *Failure to Monitor Treatment*

The case of [Clites v. State of Iowa \(1982\)](#) illustrates negligent failure to monitor psychotropic medication, in addition to other errors. The plaintiff, a mentally retarded patient, was admitted to a state residential facility at the age of 11 years. Between the ages of 17 and 22 years, he was treated with various psychotropic drug combinations, until tardive dyskinesia was noticed. The appellate court held that the hospital had failed to document behavior sufficiently aggressive or self-abusive to warrant neuroleptic treatment, that the medication appeared to be designed primarily for the staff's convenience, that the practice of prescribing polypharmacy was substandard, that the treatment had not been monitored adequately by a physician, that "drug holidays" should have been employed, that the staff had been too slow in recognizing the patient's dyskinesia, and that informed consent had not been sought from the patient's parents. Damages of more than \$750,000 were affirmed.

Adequate monitoring of drug effects requires baseline and regular mental status examinations, physical examinations, vital signs, and laboratory testing, in accordance with the pharmacology of the drug and its potential side effects. "Drug holidays" should be considered if long-term medication is required. Physicians run a serious risk if they write "as-needed" orders for potent drugs, if they telephone prescriptions into a pharmacy without examining their patients, or if they provide multiple repeat refills.

### *Suicide*

An action for wrongful death may be brought against the physician who prescribed a drug that was subsequently used to procure a suicide. The precautions that could prevent such a tragedy are discussed later in this chapter. When the risk of suicide is significant, less lethal drugs should be prescribed, in small amounts. Blood levels should be regularly determined, to ensure that the patient is not hoarding the medication.

### **Psychotherapy**

Psychiatrists are most at risk of liability when they terminate the treatment of patients without adequate safeguards, when they are unavailable and either no covering physician is provided or the covering physician has not been given sufficient information, or when adequate steps are not taken to protect endangered third parties. A therapist runs the risk of being held to have committed an intentional tort when he or she recklessly inflicts emotional distress on, has improper sexual contact with, breaches the confidentiality of, or defames a patient.

Unless the physician has behaved outrageously or recklessly, or unless the patient has committed suicide, it is difficult to prove harm as a result of negligent psychotherapy, because mental injury is hard to substantiate when the plaintiff was already emotionally disturbed before the alleged negligence. It can also be awkward to establish what is a reasonable standard of care, because there are so many schools of psychotherapy. Thus, most successful actions have alleged either negligence leading to suicide or outrageous conduct.

### **ABANDONMENT**

The physician has the duty to provide continued care, as long as needed, until the doctor-patient relationship is terminated. This relationship may be severed by mutual consent or by the patient. However, unilateral termination of care by the clinician, if abrupt or premature, may put him or her at risk of breach of contract should harm (e.g., suicide) befall the patient. Failure to provide a telephone number for a disturbed patient to call, failure to provide adequate substitute care during absences, or failure to convey adequate precautionary information to substitute physicians may all be construed as abandonment if the patient is found to have suffered harm as a consequence. The absolute duty to provide continued care does not apply to a consultant who has been asked by a primary physician to render an opinion, that is, unless it has been agreed that the consultant will treat the patient.

When is the therapist warranted in unilaterally terminating the relationship? Lack of cooperation or threatening behavior may justify termination; failure to pay the bill does not ([Smith, 1986](#)). If the clinician does decide to terminate the relationship, the following safeguards are required ([Simon, 1987](#)):

1. The reason for the termination should be discussed with the patient. The clinician should give at least 1 month's notice of termination, to allow the patient to locate another therapist.
2. The patient should be provided with the names and telephone numbers of alternative therapists or agencies.
3. The clinician should mail to the patient a certified letter (return receipt requested) reflecting this discussion and containing the reasons for termination. The letter should also convey the names and telephone numbers of alternative clinicians or agencies.

These problems are most likely to occur in highly ambivalent adolescent patients with personality disorder whose suicide risk is aggravated by loss, separation, or rejection.

### **FAILURE TO PROTECT ENDANGERED THIRD PARTIES**

This matter is discussed at this point, rather than under hospitalization, because it is with outpatients that the most problematic situations arise. The facts of the original case, [Tarasoff v. Regents of the University of California \(1974, 1976\)](#), illustrate the problems of deciding what to do when, during outpatient treatment, a patient threatens to harm a third person.

In the course of psychotherapy with a psychologist at a university health center, Prosenjit Poddar mentioned that he had fantasies of killing Tatiana Tarasoff, a young woman with whom he was infatuated. The therapist also learned from Poddar's roommate that Poddar had obtained a gun. After the patient unilaterally terminated treatment, the psychologist consulted a psychiatrist at the center who had previously evaluated Poddar. The clinicians decided to contact the campus police and informed them that Poddar met criteria for involuntary hospitalization on the ground of dangerousness. The campus police detained and questioned Poddar, concluded that he was not dangerous, and released him when he promised to stay away from Tatiana. Two months later, Poddar stabbed Tatiana to death. Tatiana's parents brought suit against the University of California; they alleged that the university was negligent in not hospitalizing Poddar and in not safeguarding the public by warning the Tarasoff family.

The trial court dismissed the suit on the ground that there was no duty to warn. The case was appealed on two occasions, known as [Tarasoff I \(1974\)](#) and [Tarasoff II \(1976\)](#). In [Tarasoff I](#), the California Supreme Court found that the defendants were not liable for failing to confine Poddar, but a treating clinician bears a *duty to warn threatened persons of foreseeable danger arising from a patient's condition*. Damages were awarded to the Tarasoffs.

Concerned by the serious implications for confidentiality of this judgment, the American Psychiatric Association pressed the appellate court to reopen the case. In [Tarasoff II](#), the issue of failure to warn was debated. The court decided that there was a *duty to protect* rather than a duty to warn: *if there is a serious danger of violence, the clinician must take reasonable care to protect the foreseeable victim*. The court failed to define what constituted "reasonable care" and how dangerous the patient must be before precautions should be taken.

*Tarasoff* spawned other cases. In [McIntosh v. Milano \(1979\)](#), a New Jersey case, the *Tarasoff* standards were applied even though the patient had never actually been heard to utter threats against his victim. The psychiatrist was described as having a broadly based obligation to protect the welfare of the community. In [Lipari v. Sears, Roebuck & Co. \(1980\)](#), the Nebraska court held that the duty to protect applies even when the potential victim is unknown or unidentifiable. It was not made clear how the duty to protect unknown third persons should be discharged, other than by detaining the patient or informing the police. In [Peck v. The Counseling Service of Addison County, Inc. \(1985\)](#), the Vermont court held that a community mental health clinic was liable for the destruction of a barn by a fire-setting patient, thereby extending the *Tarasoff* doctrine to nonmedical therapists and to property damage as well as personal harm.

Conversely, in [Thompson v. County of Alameda \(1980\)](#) and [Brady v. Hopper \(1983\)](#), the California and Colorado courts reaffirmed the *Tarasoff* decision by holding that the duty to protect was precipitated only by a *specific threat to an identifiable third person*, a decision upheld subsequently in other states.

In [Bellah v. Greenson \(1978\)](#) and [Cole v. Taylor \(1981\)](#) the California and Iowa courts, respectively, held that (a) the *Tarasoff* duty to breach confidentiality and to warn others did not apply when the patient threatened suicide, and (b) a psychiatrist was not liable to pay damages to a patient who killed her husband when the psychiatrist had allegedly failed to control the patient or to warn the victim. However, in a Pennsylvania case, [Hopewell v. Adebimpe \(1981\)](#), a psychiatrist who informed a third party considered to be endangered was found liable for breach of confidentiality. In those states that have a statute concerning privilege in the doctor-patient relationship, the requirement to maintain confidentiality may take precedence over the *Tarasoff* doctrine. The clinician should ascertain the situation in his or her own state.

In [Jablonski v. United States \(1983\)](#) and [Davis v. Lhim \(1983\)](#), the findings of negligence were based on such dubious evidence that it has been suggested that a doctrine of *strict liability* was applied ([Smith, 1986](#); [Simon, 1987](#)). In other words, if a patient causes harm, the clinician must be culpable. Such broad interpretations of the *Tarasoff* doctrine appear to be founded on the myth that mental health clinicians are reliable predictors of violence, that they have the means of preventing violence in patients not under their direct control, and that "warnings" or other unspecified precautions (short of hospitalization) would protect the community. In fact, in [Lundgren v. Fultz \(1984\)](#), the Minnesota court regarded warnings as problematic because they add to the stigma of mental illness while doing little to protect the community.

What, then, should a clinician do if a patient threatens violence? The following steps are recommended. First, undertake and document a violence risk-resource analysis. If the risk is serious, take precautions to protect endangered parties. Second, if the patient is already hospitalized voluntarily, consider whether civil commitment is required. Take precautions against elopement, consider limiting visitation and leave, and do not discharge the patient unless you are convinced that the risk of violence has diminished. Ask for a consultation if you are in doubt. Third, if a potentially violent hospitalized patient elopes or fails to return from leave, seek consultation from a colleague and from the hospital's attorney. If the risk of harm is significant, inform the local police and the police department of the area where the patient lives, by telephone and certified letter. If certain people (e.g., family, friends, or acquaintances) could be in danger, warn them by telephone, through the police, and by certified letter. Fourth, if you warn a third party by telephone or letter, take care to divulge only as much as necessary to let them know they are at risk. For example:

In the course of my professional duties, it has come to my attention that John Smith has feelings of anger toward you and that he has made threats to harm you. On (date), John Smith eloped from this hospital and is at large in the community. I have informed the police at \_\_\_\_\_.

Fifth, if the patient is an outpatient, attempt to deal with the problem in therapy. Seek consultation from a colleague, and consult your attorney. If you regard the risk of violence as serious, consider hospitalizing the patient on a voluntary basis or after an emergency commitment. Consider whether close observation at home is preferable to hospitalization. Document the rationale for your final decision. Finally, if the risk is serious but hospitalization is not feasible, inform the police and the endangered third party by telephone and certified letter. Let the patient know that it is your professional and legal duty to do so. Try to enlist the patient's cooperation by allying yourself with his or her ego controls. For example, if possible, let the patient be present when you telephone the police and the third party and allow him or her to read the contents of the letters sent to the endangered third party and the police.

In summary, the *Tarasoff* decision has created many problems for clinicians and the courts. The doctrine assumes that clinicians are reliable predictors of violence and that the threshold of risk that should precipitate reasonable precautions is clear, and that reasonable precautions are available and effective. The courts in different states have varied from requiring that a specific threat have been made against a foreseeable victim, to applying the doctrine when no specific threat has been made and the victim was unknown to the patient, to including property damage as well as personal injury, to holding that the doctrine of confidentiality takes precedence and eliminates *Tarasoff* obligations. Thus, contrary trends are operating in different jurisdictions, extending, limiting, or preempting the *Tarasoff* duty. [Simon's \(1987\)](#) recommendations can be summarized as follows:

1. In outpatient cases, the courts have generally held that, unless there is a foreseeable victim, the clinician's control over the patient is insufficient to create a duty to protect. The danger of harm must be substantial (i.e., involve bodily harm or death), and the evidence must be specific (i.e., involve threats or acts of violence towards a third person) for the *Tarasoff* duty to apply.
2. In inpatient cases, if harm results after release or elopement, liability may be created by the duty to control, regardless of whether or not a victim was foreseeable. Continued dangerousness necessitates continued close observation.

If the situation is unclear in the home state, the clinician would be well advised to act as though the broadest interpretation of the doctrine applies. However, as [Simon \(1987\)](#) points out, one should not allow concern about *Tarasoff* liability to interfere with sound clinical practice. Instead, the clinician should make reasonable efforts to control potentially violent patients before resorting to warnings; and if warnings are required, they should be incorporated into treatment, whenever possible.

#### IMPLANTATION OF ILLUSORY MEMORIES OF ABUSE

In some cases, a third party, usually the parent of a patient, sues a psychotherapist for implanting in the patient illusory memories of sexual abuse. For example, in [Ramon v. Isabella](#), the father of a patient who had remembered sexual abuse during therapy brought suit against a psychotherapist on the grounds of slander, negligent and intentional infliction of emotional distress, and economic loss.

The question of the extent to which a therapist owes a duty of care to someone other than the patient continues to exercise jurists. These cases raise legal and scientific questions that are the subject of much debate. Is it possible for a person to remember childhood abuse after a gap during which he or she had no memory of it? Should the statute of limitations be tolled in such cases? What is the scientific validity of the concepts of repression and dissociation? Do they satisfy the criteria for scientific evidence cited in [Daubert v. Merrill Dow Pharmaceuticals, Inc?](#) Would the imposition of a duty of care to third parties prevent patients from obtaining the treatment they need? The most egregious cases involve therapists who persuade their allegedly abused patients to seek retribution and who subsequently commit the cardinal error of appearing as expert witnesses on behalf of their patients.

In a variant of this genre, the patient sues the therapist for failing to recognize that dissociative identity disorder is confabulatory or for accepting uncritically the patient's recovered memories of abuse. For an extended discussion of these issues, see elsewhere ([Partlett and Nurcombe, 1998](#); [Simon and Gutheil, 1997](#).)

#### SEXUAL EXPLOITATION AND THE TORT OF OUTRAGE

Expert testimony is not required to substantiate the impropriety of sexually molesting a patient. As an intentional tort, *res ipsa loquitur* ("the thing speaks for itself"), and the burden of proof shifts to the defendant. In [Roy v. Hartogs \(1976\)](#), the court held that public policy protected patients from such malicious abuses of authority, power, and fiduciary trust. The perpetrator faces criminal sanctions for rape or aggravated assault, as well as civil actions for malpractice or battery (unconsented touching). He or she may be insured against the costs of such an action. Liability for improper sexual relations may extend beyond the patient to others involved, such as the spouses of patients so harmed. Residual transference has persuaded courts that cessation of treatment does not open the door to a sexual relationship. Indeed, *negligent management of the transference* is often adopted as the theory behind the action for damages.

The tort of *outrage* refers to the intentional infliction of severe emotional distress on a patient, as a result of reckless and intolerable behavior. For example, in [Abraham v. Zaslav \(1970\)](#), damages were awarded to a woman who had sustained bruising and renal failure after exposure to "rage-reduction therapy," an intrusive intervention involving several hours of physical restraint, poking, tickling, and verbal insult. Patients have a right to expect that clinicians will adhere to established methods of treatment. If exceptional methods are proposed, full informed consent is required, supportive consultation from a colleague would be advisable, and

adequate reference to the scientific literature should be made.

### Teaching, Research, and Publication

The torts of *invasion of privacy*, *breach of confidentiality*, and *defamation* are the liability risks most commonly incurred by teachers, researchers, and writers. The doctrine of informed consent is discussed earlier in this chapter.

These torts stem from the ethical, contractual, and (in some jurisdictions) statutory obligation of the clinician not to disclose private information that should be kept within the doctor–patient relationship. In invasion of privacy, the plaintiff alleges that details from his or her private life have been publicized. This may occur, for example, if a clinician publishes an article in which the identity of the subject is insufficiently disguised. It has been held that a patient undergoing psychotherapy cannot give proper informed consent to the publication of a book concerning the treatment ( [Jane Doe v. Joan Doe and Peter Poe, 1977](#) ).

A patient has the right to bar nonessential onlookers when he or she is being examined or treated or when his or her case is discussed. The teacher should seek informed consent before exposing patients to case conferences or discussing cases for teaching purposes. The use of videotapes for teaching necessitates written informed consent, the continuation of which should be requested on a yearly basis.

### LIABILITY UNDER NEW COST-CONTAINMENT SYSTEMS

The current national preoccupation with cost containment by means of managed care and capitation puts the clinician at risk, particularly in the care of suicidal or dangerous patients. In [Wickliffe v. State of California \(1986\)](#), a Medi-Cal reviewer allowed only 4 extra days of inpatient treatment after an arterial graft, rather than the 8 days requested by a vascular surgeon. The patient was duly discharged after 4 days, and complications cost her the leg. The patient sued the physician, the hospital, and the state of California. The court determined that the state, through Medi-Cal, owed the patient a duty of care in that it was bound by statute to evaluate the medical necessity of length of stay and level of care. However, in this case, no breach of duty was found. The surgeon was found liable for having acceded without appeal to the Medi-Cal determination. Conversely, in [Wilson v. Blue Cross of California \(1990\)](#), a suicidal patient was prematurely discharged from hospital, over his psychiatrist's protest. After the patient's death, an appeal court found the insurer liable in that the managed-care firm contracted by the insurer to conduct a utilization review had made a "medically insensitive" decision. However, in this case, the patient's insurance contract had contained no provision for managed care, and vexatious questions remain unanswered. Managed-care reviewers often preface their denials of further hospitalization by saying that the physician or hospital is at liberty to continue to treat the patient gratuitously; and, in many cases, the patient should be kept safe pending appeal. Physicians who receive financial incentives for diverting patients from specialized care should reveal this to their patients. Any economic constraints that could modify a physician's medical judgment should be disclosed.

The failure to regulate managed-care regulators is certain to generate future liability actions that will help to clarify some of the questions. However, managed care and capitation will continue. Physicians and hospitals should define their standards and should not be pressed to sink below them.

### Assessment of Violence and Suicide Risk

It is generally accepted that clinicians have little expertise in the long-term prediction of violence or suicide ( [Monahan, 1981](#) ). However, most of the research in this area comes from prison populations or from the long-term follow-up of involuntary psychiatric patients. There has been no research concerning the prediction of imminent risk, and such research will never be done. Faced with an uncontrollable, potentially self-destructive or assaultive patient in an emergency room, no clinician would be willing to assign the subject randomly to a no-treatment control group. Thus, although the accuracy of clinical predictions of imminent dangerousness is unknown, such predictions must and will be made. The following risk–resource analyses present a method of taking into account the factors that increase or mitigate risk.

#### VIOLENCE

A risk–resource analysis should be conducted whenever a patient presents a risk of violence. Such an assessment is most likely to be required in the following circumstances: when the risk of violence is raised during outpatient evaluation or treatment; when a potentially violent patient presents for admission to hospital; and when the leave or discharge from hospital of a potentially violent patient is being considered, or when such a patient elopes.

The factors to be considered can be grouped into the following areas: (a) demographic factors, (b) the violent threat, (c) past history, (d) psychological factors, (e) the social environment, and (f) the therapeutic alliance. Do not merely sum the positive and negative items; their weighting and combination differ in different cases.

#### Demographic Factors

*Late adolescent, male patients from disadvantaged ethnic groups with a cultural tradition of masculine defensiveness are at greater risk of violence.*

#### Violent Threat

Has the patient *directly expressed a violent threat* or threats toward another, by word or message? Does the potential victim have a *provocative relationship* with the patient that could provoke hostility? Does the patient have a *plan* for harming the victim, and does he or she have *access to lethal weapons*?

#### Past History

Is there a *past history of violent threats or actions*? Does the patient have a *history of being victimized* in early life by child abuse? Has the patient a *history of serious head injury, epilepsy, or neurologic impairment*? Does the patient have a *history of alcohol or drug abuse*?

#### Psychological Factors

Is the patient prone to cope with anxiety or hostility by *externalizing* or *projecting* it in the form of *impulsive, explosive actions, suspicious vigilance, or frank persecutory delusions*? Is there evidence of *command hallucinations* that instruct the patient to take violent action or that *threaten violence* to the patient or his or her family? Are the patient's *inner controls* against violent actions subjectively or objectively reduced? Is there a *strong inner urge to be violent*? Is the patient's *intelligence below average*? Is there evidence of *impairment of the sensorium*? Is the patient subject to *alcohol or substance abuse*?

#### Social Environment

Are the patient's *family or caretakers able and willing to control* the patient? Is there evidence of family psychopathology in the form of *rejection, neglect, physical or sexual abuse, or family violence*? Is *parental mental or physical health* impaired?

#### Therapeutic Alliance

Has the patient *lost or terminated a therapeutic relationship*? Is he or she *competent and motivated* to enter into one?

#### Resources

Factors that may protect against violence or enhance self-control are as follows: *younger, female, white, religious, middle-class* patients are at less risk. If there has been a threat of violence, a *threat without plan or identified victim*, in a patient *without access to lethal means*, is of relatively lower concern, particularly if the patient has *obsessional traits, low subjective urge, and above average intelligence*. A *secure family* without major psychopathology or mental or physical ill health is protective, as is a *positive relationship with a therapist*; or the *motivation and competence* to enter into one.

### Hypothetical High-Risk Case

The patient is an intoxicated 17-year-old, male, Hispanic youth from an impoverished family living in an urban ghetto. He was brought to the emergency room by police because he was acting belligerently in a local bar. During the interview, he threatens to kill his allegedly unfaithful fiancée and her lover by stabbing them to death. He has a history of several episodes of juvenile violence and is known to be a user of alcohol and street drugs. He has access to knives and other weapons. At the interview, he is highly emotionally aroused, threatening, hostile, and suspicious. He says that he is directed by an inner voice to take vengeance for the insult to his honor. His family is chaotic and afraid of him. He has no therapist and, at the interview, no desire to seek help.

### SUICIDE

A suicide risk–resource analysis is required when the clinician must decide whether the risk of suicide is *imminent* and *serious*. This decision is most often required in the following situations: when the possibility of suicide is raised in the course of ambulatory or inpatient treatment, when a new patient presents for voluntary or involuntary hospitalization, or when leave or the discharge of a potentially suicidal patient is being considered. In these circumstances, it is important for the clinician to record the pros and cons on which the clinical decision is based.

The factors to be considered incorporate 25 items in six sections. These items cannot be equally weighted because their relative valence and combination differ according to the particular circumstances and characteristics of each case. As with a violence risk–resource analysis, one should not merely sum the risks and resources, but rather consider their weight and combination in each case. The factors to be considered can be classified under six headings: (a) demographic factors, (b) the suicide attempt, (c) physical factors, (d) psychological factors, (e) the social environment, and (f) the therapeutic alliance.

### DEMOGRAPHIC FACTORS

*Older white men* are at greater risk.

### Suicide Attempt

Pay close attention to the suicide attempt, if one has occurred. *Lethal means* involve hanging, gassing, jumping from a height, drowning, knife or gunshot wound, using a motor vehicle for suicidal purposes, self-poisoning, major overdose, or other concerted attempts at self-destruction. Remember that, to a child who is ignorant of pharmacology, 10 aspirins may represent a lethal dose.

Greater risk attaches to suicide attempts that were *planned* and *concealed*, although *impulsiveness* (e.g., drinking and driving wildly after an upset) can also be very dangerous. The intent of the patient should be explored from suicide notes, prior conversations with family and friends, and the patient's recollection of the attempt. Did the patient truly *wish to die, sacrifice himself or herself, expunge shame, exit permanently from an intolerable existence, find peace, or be reunited with a lost loved one*? Was the suicide attempt a response to *command hallucinations*? Conversely, did the suicide attempt represent a communication of the *need for help* or a *desire to punish someone*? Is the patient *able to grasp the finality of death*? Does he or she fantasize that *resurrection* is possible?

### Past History

A history of a *previous attempt or attempts* adds to the risk of future suicide. The *means and intent of previous attempts* may also predict the seriousness of future attempts. Some patients have given up on the future as a result of *chronic illness or handicap*. *Alcohol and drug abuse* increase the risk potential of other factors because the intoxicated adolescent may take desperate risks or express suicidal impulses that would otherwise be controlled. Is the patient *intoxicated* at the time of the examination? Is he or she *likely to resort to drugs or alcohol* if you do not hospitalize him or her?

### Psychological Factors

Does the mental status examination reveal or confirm the presence of *depressive affect, despair, hopelessness*, or the *vegetative signs* associated with *melancholia*? Is there evidence of *psychosis* with mental disorganization, abnormal perception, or delusional thinking? Can you detect evidence of *command hallucinations*, which instruct the patient to kill or injure himself or herself or to take serious risks (e.g., to fly from the roof of a building)? Is there evidence of *mental confusion, obtundation, or delirium* suggestive of an organic confusion or acute psychotic condition? Does the patient's history indicate *poor internal controls* with impulsiveness or explosive behavior when under stress? Is the patient preoccupied with *suicidal ideation* or with the *desirability of death*?

### Social Environment

The resources and deficiencies of the family or caretakers are very relevant to the determination of suicide risk. Are the family members able to provide a *safe environment*? Are the parents able to cooperate with each other? Are they willing or competent to remove, or secure, all potentially lethal agents of suicide (e.g., prescription drugs, poisons, weapons)? Are they prepared or able to watch the patient closely and to be emotionally available to him or her in times of stress? Conversely, is there evidence of *parental rejection, neglect, physical or sexual abuse, mental illness, severe personality disorder, substance abuse, or physical illness or handicap* of a severity that would render the caretakers unable to provide adequate security and emotional sustenance to an acutely disturbed child?

Has there been a recent *loss or the severance of an important relationship*, such as the death of a close relative or beloved family pet, loss of contact with a noncustodial parent, or the departure of a close older sibling or special friend? Such an event may represent the "last straw" to an isolated, troubled child. One should pay special attention to *peer relations*. Particularly vulnerable is the isolated, alienated, persecuted, or rejected youngster or the patient who has withdrawn from contact with peers. *Has a love relationship been threatened or severed*? Does the patient feel intolerably *guilty* or *ashamed* before his or her family or peers, as a result of some action or dereliction? *Shame toward the family* is a particularly powerful emotion in Asian patients.

Is there a *family history of suicide*? A positive family history may reflect a genetically transmitted psychiatric disorder that increases suicide risk or a family tradition of committing or attempting suicide in stressful circumstances. Suicidal parents may unwittingly act as *suicide models*.

### Therapeutic Alliance

It is crucial to determine whether the patient has, or has lost, an adequate *therapeutic relationship*. Is the patient capable of forming an alliance? Do you believe the patient if he or she promises to cooperate? Has he or she been reliable in the past? Is he or she prepared to sign a "suicide contract"? Although such contracts have no legal status, they are a useful clinical index of the patient's cooperativeness.

### Resources

To some extent, the reverse of the risk factors can operate as mitigating factors. For example, a suicide attempt associated with the *desire to communicate a need for help* indicates that the patient is still potentially available to other people. A *competent family*, free of serious mental, physical, or personality disorder, is the most powerful protective factor. A *network of caring friends* who can be mobilized is also protective. The *capacity for internal control*, accentuated for example in obsessional patients, may impede direct suicidal action and may be activated if the patient has, or wants, a therapeutic relationship. Finally, an *existing adequate therapeutic alliance* and the *competence or motivation to seek one* are mitigating factors.

### Circumstances of Extreme Risk

The following stereotype describes an extreme case. The patient is a 17-year-old white male adolescent who was discovered making his second suicide attempt by hanging, while intoxicated, in a remote part of the woods near his home. His family is chaotic. The father has psychosis and alcoholism, and his mother is chronically physically ill. One sibling has died by suicide and one by accidental gunshot wound. The patient's suicide was planned, and he intended to do away with himself. He has no friends, is persecuted at school, and was recently greatly upset by the death of a beloved grandmother. Mental status examination reveals severe depression with agitation, despair, and vegetative signs. He is preoccupied with the idea of dying and joining his grandmother. At times, he hears the voice of his grandmother

begging him to join her. He has had no recent mental health contact, and rejects the offer of therapy.

### *Circumstances of Less Risk*

The patient is a 14-year-old girl who swallowed 10 aspirin tablets in the bathroom at home after an argument with her mother about permission to go out with a boyfriend on a week night. She told her mother about the overdose an hour after it occurred, and the mother brought her to the emergency room at once. The parents have been separated for 3 years, but both of them remain close to the patient, and neither suffers from serious mental, personality, or substance use disorder. The parents and child are in good physical health. The patient reveals no psychotic or melancholic symptoms. She says that she did not really want to die, but she was angry with her mother for not listening to her and for restricting her too much. She accepts the need for therapy, promises not to attempt suicide without calling you, and agrees to return for an outpatient appointment on the following day.

## CONCLUSIONS

Clinical practice is fraught with error, and error can have serious consequences. Confronted by the catalogue of litigation in this chapter, even the insouciant may quail. However, defensive psychiatry is no answer, because overly timid treatment can also put the clinician at risk of negligent malpractice. What, then, is the best way to avoid litigation?

The best precaution is to practice careful medicine while fully apprising the patient and family of the diagnosis, the treatment plan, and the progress of therapy. Many malpractice suits arise from a neglect of this simple principle. Hospitals provide many opportunities for failed communication, particularly when the attending physician delegates to other members of the team the responsibility for keeping parents informed of their children's progress. A good therapeutic alliance is the key to good medicine and the avoidance of lawsuits. Used for this purpose, informed consent can be transformed from an empty legalism into the foundation of a true collaboration.

*If it wasn't written down, it didn't happen.* The clinician should keep a good record of the rationale for treatment. Progress notes should be timely, regular, dated, and signed. Whenever a course of action is problematic, a risk-to-benefit analysis should be undertaken and documented, and a consultation obtained. If you disagree with the diagnosis, investigations, or treatment plan, in the record, note that you disagree and insert your amended diagnosis and plan. If you merely sign off on a trainee's notes, you could be concurring with erroneous observations, diagnosis, or treatment. One of the most common errors is to raise a diagnostic question but not follow through by investigating it or, having ordered investigations, to lose sight of the results.

Note any discrepancies between the nurses', the therapist's, and the physician's progress notes. If there is such a discrepancy, try to account for it. Do not allow a nursing progress note concerning suicide risk to go unremarked.

If you detect an error in your notes, do not erase it. Draw a line through the error, write "error," and date and sign your correction in the margin. Do not criticize or argue with other professionals or agencies in your notes, and avoid gratuitous or extravagant commentary (e.g., "This child has had an appalling home life").

Before a particular treatment is commenced, be careful to check that the patient harbors no conditions and is taking no drugs that would contraindicate it, and inquire about previous allergic or idiosyncratic reactions to drugs. Avoid polypharmacy. Monitor the progress of medication regularly. In patients taking long-term medication, "drug holidays" should be considered. Unless there are good reasons for departing from them, follow recommended guidelines for dosage and administration. Avoid prescribing medication "as needed" and automatic refills, and be careful of telephone requests for repeat prescriptions. If the suicide risk is serious, only small amounts of a potentially lethal drug should be prescribed. Hospitals should check that potentially suicidal patients are not cheating, concealing, and hoarding medication.

When a patient is admitted to the hospital, the degree of risk of suicide or violence should be assessed, and each degree of risk should be linked to a set of nursing precautions that are automatically activated when the clinician indicates the degree of risk. Every attempt should be made to obtain past records and to scan them for risk factors.

If you are unavailable in case of emergency during treatment, the name of a fully informed substitute physician should be provided to the patient. Do not terminate treatment unilaterally without preparing the patient, giving adequate notice, and providing him or her with the names of other clinicians or agencies who could help.

In outpatient practice, the duty to protect is precipitated when the patient makes a specific threat to harm a specified victim. When possible, incorporate the protection in therapy. Psychotherapy, hospitalization, and medication may be both more protective and more therapeutic than warning the foreseeable victim or alerting the police.

Do not record psychodynamic speculations in the clinical record; those unconscious incestuous strivings may come back to haunt you. You may consider keeping your psychotherapy *process notes* separate from the official record of therapy *progress notes*.

Be vigilant to avoid unauthorized disclosure of confidential information to external agencies, do not gossip about patients, and do not publish articles about patients without adequately disguising their identity. Obtain the parents' consent before releasing reports to external agencies. Blanket consent forms, obtained during the rush of admission, may not hold water, legally.

In conclusion, remember that the law has no wish to penalize physicians for honest errors. Its purpose is to protect patients from being harmed by reckless, careless, or incompetent clinical practice, and if they have been so harmed, to compensate them for injury. In most successful suits for negligent malpractice, the errors are glaring. Attention to the safeguards described in this chapter will protect clinicians from litigation while allowing them to practice nondefensive psychiatry.

## SELECTED READINGS

This chapter relies heavily on [Smith's 1986 \*Medical Malpractice: Psychiatric Care\*](#), which elaborates the legal principles of malpractice litigation and gives numerous case precedents, and on [Simon's 1987 \*Clinical Psychiatry and the Law\*](#), which contains a detailed examination of malpractice liability from the clinician's viewpoint. [Gutheil's 1980](#) article, "Paranoia and Progress Notes: A Guide to Forensically Informed Psychiatric Recordkeeping," is required reading for all psychiatric residents. Gutheil and Appelbaum's 2000 *Clinical Handbook of Psychiatry and the Law* contains an elegant analysis of the doctrine of informed consent within its chapter on malpractice.

[The Child Psychiatrist in Court](#)  
[Chapter References](#)

Although child psychiatrists still are sued less frequently than physicians in most other specialties, in the past several years there have been an unusual number of very compelling suits against psychiatrists who were treating children.

The most frequent source of legal suits against psychiatrists (adult and child) remains drug reactions such as tardive dyskinesia ( 1). The issues in these cases tend to revolve around two questions: (a) Was the drug properly prescribed? In these cases, this usually means that the issue is whether the patient's illness was sufficiently severe to justify administering a drug with such serious side effects; and (b) Did the patient or the family understand the risks and consent to them ( 2)?

A second issue involving the prescription of medication arises in the context of a diagnosis of attention deficit/hyperactivity disorder (ADHD) and the use of methylphenidate (Ritalin) or other drugs to treat it. Although there have been reports in the press or a large number of preschoolers being treated for ADHD and professional differences of opinion about how the drugs should be used, somewhat surprisingly, there have been no malpractice cases arising from prescription of the drug. A very clear problem, however, could arise if the child psychiatrist (or other physician) assumed that the symptoms reported by parents or teachers were ADHD and did not investigate properly for other causes of the behavior, including brain tumors or other medical and nonmedical causes. If a medical condition is not diagnosed because a facile conclusion led to a finding of ADHD, liability for misdiagnosis would be hard to escape.

In this area of child psychiatry, the issue also arises of the child's or parent's right to refuse these drugs. In many instances, the child's diagnosis results from his or her disruptive behavior in the classroom and the psychiatrist sees the child as a referral from the school, not because the parent thinks the child needs to be treated. Even if the parent accepts the diagnosis (many do not), there may be many reasons, some of them quite valid, for why these parents refuse to permit their child to take these medications. Some parents, such as Christian Scientists, may reject any medications; others may question the long-term effects of giving their child these particular medications. Although private schools have a great deal more control over the conditions of admission and retention of their students than do public schools, it is unlikely that a private school could require medication if the parent found any licensed physician who agreed that the medication was not in the child's best interests. It is absolutely certain that no public school could require it ( 3). On the other hand, if there is a school nurse or other system for giving students any medications during the school day, a school nurse or principal cannot refuse to give Ritalin or similar drugs because they disapprove ( 4).

Physicians of all specialties, among others, are mandated to report child abuse to state authorities. In most cases, even if the diagnosis is incorrect, as long as it was made in good faith, the physician is statutorily protected from suit by the child or the family. In the past few years, however, courts in several states have held that diagnoses of child abuse must be made with the skill, care, and knowledge that would be required in any other diagnosis. If a child is negligently diagnosed as a victim of abuse and the parents are prosecuted, the child psychiatrist may be held to be liable to the parents. Courts are increasingly willing to find that the therapist owes a duty of care to the parent (not just to the child patient) when an accusation or report is made and that the techniques used to make the diagnosis of abuse must be those generally accepted in the profession ( 5).

Another area in which numerous malpractice suits against psychiatrists have succeeded is liability claims based on the patient's violent behavior, directed toward himself or others. In adult psychiatry, there is a clear duty to warn a person whom the psychiatrist believes may be in danger, as well as a duty to take reasonable steps to prevent the violence by committing the patient to a hospital or taking other such action ( 6).

In dealing with children as patients, a psychiatrist has every right to conclude that the standard of disclosure to parents of a possible threat by the child is very low. Virtually any concern about suicidality or any danger to others (particularly to the parents themselves) does not have to be proven credible before the psychiatrist discloses it to the child's parent or custodian ( 7). In fact, failure to disclose to the parent the possibility that a minor might be suicidal is sufficient, after the young person commits suicide, to impose liability on the psychiatrist ( 8).

In one recent and horrifying case, a supervising psychoanalyst knew that a child psychiatry resident at least had serious thoughts of being a pedophile. Moreover, the analyst suspected that the resident had probably engaged in such acts at some time. He did not report this to anyone at the hospital where the resident was in training. As might have been foreseen, the resident sexually molested a young boy in his care. The patient sued not only the hospital for the resident's acts but sued the supervisor as well. The analyst defended himself on grounds of confidentiality, but the court held that he had had a duty to speak up to keep the resident away from children ( 9). Physician-patient (or psychiatrist-patient) privilege never applies to situations with a potential for child abuse or confession of recent abuse of a child ( 10).

In the absence of any threats to self or others, however, what an adolescent patient says in confidence to a mental health professional is usually entitled to the same degree of confidentiality that an adult patient would expect ( 11).

## CHILDREN AND ADOLESCENTS AND CONSENT TO TREATMENT

At common law, a minor child, which meant anyone younger than 21, not 18 years, was effectively a chattel of his or her father. A father had the right to sue a physician who treated a child without his permission, even if the treatment was appropriate and had a good result, because such intervention transgressed on the father's right to control the child.

This still is the rule in a nonacute situation involving a young child. If for example, a 3-year-old is visiting his grandmother and she takes him to a plastic surgeon for repair of a birthmark his parents had decided to leave alone, the plastic surgeon would be at substantial risk if he operated without consent of the parents ( 12).

On the other hand, since at least the early 1950s, adolescents in our society have become increasingly independent, and courts have recognized and accepted this independence. It has been at least 40 years since a parent successfully sued a physician in this country for treating a minor 15 years of age or older without parental consent ( 13). It should be remembered, however, that, except in emergency situations, a parent is not liable for the cost of medical care for a minor unless the parent consented to having that care provided ( 14).

### Consent in Emergencies

In an emergency, a child of any age may be treated without parental consent if the parents cannot be located immediately ( 15). For this purpose, an "emergency" is any condition requiring prompt treatment, and not only a condition that may lead to the child's death or disability if untreated. For example, a small child who has an

earache or a cut foot and is brought to an emergency room by a teenage baby sitter would constitute an “emergency” for this purpose.

### Special Consent Statutes

Because physicians were concerned about treating adolescents without parental consent, beginning in the early 1950s state legislatures began enacting statutes permitting teenagers to consent to their own treatment for venereal disease (VD). It was perfectly evident to legislators as well as to physicians that, if parental consent to treatment were required, teenagers simply would not go for treatment, and the epidemic of VD in this population would get worse. All states have enacted VD treatment statutes (16); most, in fact, forbid the physician to tell the parent that the young person has been treated, and some specify that the parents may not be billed for the care (on the theory that, if the parent receives a bill, he or she will find out the purpose of the visits) (17). The next public health concern involving adolescents was drug and alcohol abuse. Most, if not all, states now have specific statutes covering consent to treatment for these problems. These disease-specific statutes do not have an age limit—a 9-year-old with a drinking problem is given the same right to confidential treatment as a 17-year-old with the same difficulty.

### General Consent Statutes

Many states also enacted statutes that provide that a minor of a given age—usually 16 years, but some statutes provide for consent as early as 14 years—may consent to any and all medical treatment as if she or he were an adult. Some of these statutes specifically prohibit consent to abortion or organ donation without parental consent, but a physician in a state with such a statute may, in keeping with any limitations the statute imposes, treat a teenager without discussing the situation with parents (18).

### Emancipation

For at least 200 years, courts in the Anglo-American system have recognized the concept of an “emancipated minor.” This means one who is living on his or her own (in the earlier days of the law, it was on *his* own), is self-supporting, and is not subject to parental control. The old concepts of emancipation included minors in the military (of which there were numerous when the age of majority was 21 years) (19) or married minors. The concept has evolved nowadays to include college students younger than 18 years of age, even when parents are completely responsible for paying the bills, or unmarried minor mothers (20), and in some states a pregnant minor is considered completely emancipated. A runaway also is considered an emancipated minor, no matter how young he or she may be.

### The Mature Minor Rule

In addition to the exceptions to requirements of parental consent discussed previously, courts in this country have bowed to modern reality, and decisions all over the country apply what has come to be known as the *mature minor rule* (21). The legal principle now applied is that if a young person (of 14 or 15 years of age) understands the nature of a proposed treatment and its risks and can give the same degree of informed consent as an adult patient, and if the treatment does not involve very serious risks, the young person may give a valid consent. The age and maturity of the patient must be considered, but the nature of the illness and the risks of therapy also are relevant. A 14-year-old might be perfectly capable of consenting to treatment of a sprained ankle; no oncologist would consider treating the same patient for leukemia without his or her parents' knowledge.

In almost all cases, the issue of treatment without parental knowledge arises in the context of ambulatory care. Most hospitals refuse to admit minors for nonemergency treatment unless the parent, who almost always is the person with insurance (on which children are carried as dependents), signs financial responsibility and insurance forms.

Thus, as we can see, in terms of consent to general medical care, courts are granting much more autonomy to increasingly younger adolescents. Preadolescents, however, do not have a right to consent (22).

## REFUSAL OF TREATMENT

If a minor has the right to consent to treatment, it is likely that he or she has the right to refuse treatment. It is therefore always a good idea, if dealing with an adolescent of 14 years or older, to obtain the patient's consent, as well as that of his or her parents, to a procedure. In any purely elective situation (such as cosmetic surgery) where a parent wishes an adolescent to be treated but the patient refuses, a prudent physician would decline to treat the patient. In any situation where a minor can be treated at his or her own request and without knowledge of the parents, it is likely that the minor has the right to refuse, at least if the problem is not life threatening.

Because a younger child does not have the right to consent, he or she also does not have the right to refuse.

It is clear that a pregnant teenager has the right to refuse an abortion that her parents wish her to have (23). In situations such as requests for court orders for treatment of a minor over parental religious objection, judges usually consult adolescent patients about their views on the matter before treatment is ordered, particularly if the patient's lack of cooperation could affect the outcome of the intervention (24). These cases, however, usually do not involve life-threatening problems. Only one case can be located in which a court allowed an adolescent to refuse life-saving treatment (25). A 16-year-old girl, who was the daughter of Jehovah's Witnesses, refused on religious grounds to have blood transfusions for leukemia. Her physicians and the hospital in which she was a patient asked the court for guidance on the legality of a minor's refusal of life-saving treatment. The judge ruled, and his ruling was upheld on appeal, that once he had determined that her religious views were her own and that she was not being coerced by her parents, her knowledgeable refusal should be respected to the same extent that it would be if she were an adult. It is unlikely that any judge would give such credence to the views of a minor younger than 16 years of age; it also is not at all clear that courts in other states will follow the same reasoning and allow any minor to decide to die where successful treatment of the problem is available.

### Freedom of Religion and Refusal of Treatment

A parent's failure to provide “adequate” medical care for a child is a criminal offense under all states' child neglect and abuse laws (26). Court intervention is an option in circumstances in which physicians and hospital administrators wish to invoke it. Until recently, court orders to treat were virtually automatic, and in almost all cases, that is still the case. Where, however, parental objection to treatment is based on a risk assessment of complex therapy or newly developed surgical intervention, courts appear to be willing to consider parental reservations. For example, if a court order for chemotherapy is sought by physicians and the parents' reason for refusing the treatment is that their child is, by all accounts, terminally ill and they wish to let her “die in peace,” it is unlikely that a court would order administration of the drugs. When a treating physician asks for court-ordered treatment, orders still are virtually automatic, but increasingly, when requests are initiated by welfare agencies, police, or school personnel under circumstances in which the physician taking care of the child agrees with the parents' decision, parents do seem universally to prevail. For example, in the *Babies Doe* cases involving handicapped newborns, when the physicians agreed with the parents that surgery on the infants was undesirable and state or federal governmental entities tried to intervene to ask the courts to order treatment, in every instance the parents and treating physicians prevailed (27).

Although it now is clear that a competent adult has the right to refuse life-saving treatment for himself or herself for religious or other reasons, in all states parents whose refusal to allow necessary treatment of their child is based on religious conviction still are found to be “neglectful,” even though their right to religious freedom is protected by the First Amendment (28).

All courts have held that a Jehovah's Witness whose child's condition requires blood transfusions has no right to forbid them on the ground of religious conviction (29).

## THE MINOR IN THE MENTAL HEALTH SYSTEM

### The Minor in the Outpatient Psychiatric System

Because minor treatment statutes and the mature minor rule apply to all forms of care provided by physicians, one must assume, although there are no cases on the point, that the same legal rules apply to an adolescent who goes to see a psychiatrist as apply to a visit to a gynecologist. If the psychiatrist wishes to treat the teenager, it is difficult to see how a parent could object. Because private psychotherapy is, however, extremely expensive, the issue is most likely to be raised when

the teenager goes to a mental health center or community counseling service. Where the community facility is one in which a qualified psychiatrist is on staff and other mental health professionals, such as psychologists, nurse clinicians, or psychiatric social workers, provide therapy as a team effort with physicians, there is little question that the minor has the right to seek treatment. There are, however, many so-called mental health facilities where no physicians are involved or available. In particular, many drug treatment centers provide therapists who are drug addicts themselves, and no medical backup is available. This may be a viable method of providing drug treatment or other specialized therapies, but it is not at all clear that the legal right of a minor to seek medical care necessarily applies to such facilities.

The intent of legislatures and courts who broadened the adolescent's right to seek medical care was to get young people to physicians, not to well-meaning but nonmedical counselors whose training may be questionable.

The issue of refusal of outpatient mental health treatment that the parent wishes the adolescent to have but the adolescent does not want is a legally fascinating one, but for very practical reasons not a real issue. If a parent takes a young person to a psychiatrist and the patient does not want to cooperate, all he or she has to do is refuse to talk to the psychiatrist. It is physically possible to hold someone down and administer medical care if one must do so; it is not possible to engage in psychotherapy with someone who refuses to talk.

## COMMITMENT OF THE MINOR PATIENT

Adult mental patients have certain legal protections against unjustified or malicious commitments to mental hospitals that minors do not necessarily have. An adult may voluntarily go to a mental hospital and may also leave it if he or she wishes to, unless the hospital concludes that the patient is so ill that involuntary commitment is necessary. In that case, the patient has a right to a judicial hearing. Commitment as an involuntary patient, if one is an adult, may occur only after a judicial hearing at which one is, among other things, entitled to counsel. The standard of commitment of an adult is that he or she is dangerous to self or others or is gravely mentally disabled, meaning that the person is too mentally ill to provide himself or herself with the basic necessities of life ( 30).

Minors, however, fall into an entirely different category. Many states allow "voluntary" commitment of minors by their parents, which means that although the young person cannot leave the hospital, he or she is considered a "voluntary" patient and has no right to a hearing at which a judge can rule on the merits of the commitment. If all families were healthy and happy, that might be a reasonable solution to the problem, but in any number of instances, minors have been "dumped" into mental hospitals by their parent, when the parent is probably the one who needed treatment ( 31).

Nowadays it seems that frightened parents, probably in good faith in most instances, are having teenagers in record numbers admitted to for-profit drug and alcohol hospitals and treatment centers in instances in which there may not be very clear indications that inpatient treatment is required and, if recent media reports are correct, where the quality of care and the training of therapists is open to very serious question ( 32). At least two states' courts have held that, because these facilities are not considered "mental hospitals," a minor admitted by parents has none of the due process rights or access to the legal system that would accrue to him or her if admitted to a psychiatric hospital ( 33).

Beginning in the 1960s, after a fair number of young people literally were committed to mental hospitals by parents who were upset with antiwar protests, long hair, and general hippiness, most states did enact statutes providing for judicial intervention in the commitment process when minors were patients. In other states, courts ruled that these minor patients had the right to some constitutional protections. In North Carolina, for example, it was held in a 1975 case that a 15-year-old boy who had been committed by his mother had a right to a hearing within 72 hours of admission, although the young person still could be signed in by a parent in an emergency ( 34). This decision was fairly typical of those in most other states' courts during this period.

Many of the states' new statutes provided that a child younger than 13 or 14 years of age could be admitted by parents without judicial intervention. Most, however, specified that minors over that age might continue to be admitted by their parents, but once in the hospital, the patients had a right to prompt hearings with the assistance of counsel if they wished to object to their admissions. Many statutes also provided that teenagers could admit themselves to mental hospitals as voluntary patients. If they did so, however, they had the same right as adult patients to discharge themselves unless the hospitals were willing to ask courts for orders of involuntary commitment ( 35).

On June 20, 1979, however, the Supreme Court ruled ( 36) that if a state legislature did not choose to enact procedural rights for minor mental patients, minors' federal constitutional rights were not violated if their parents admitted them to a mental hospital over their objection.

Thus, the rights of children and adolescents committed to mental hospitals are, at this time, exclusively derived from state law, and no federal constitutional protections are given them.

## THE CHILD PSYCHIATRIST IN COURT

A physician may appear in court as a witness for one party or the other, as a treating physician, or as an expert witness. A treating physician may be subpoenaed to testify about facts within his or her knowledge relevant to the case; however, expert opinion testimony may never be compelled from an unwilling witness ( 37). The expert, who may never have seen the patient but who has reviewed the medical records, usually testifies about his or her *opinion* of the situation—views on child placement, whether medical care met the requisite standard or was negligent, or the like.

In an increasing number of cases involving children, judges feel the need of objective expert medical advice and may use their discretion to appoint a physician to be an independent witness. The purpose of such an appointment may be to examine a party to the action or the children in a family, or, in most cases, to serve as a true advisor to the judge, providing assistance based on information already in evidence in the court and giving the judge professional analyses of that evidence. In any case in which a physician is a court-appointed witness asked to examine a party, his or her testimony about that examination is not covered by physician-patient privilege because he or she is not a "treating physician" for purposes of privilege statutes. His or her role as a court-appointed expert is to investigate, as "an arm of the court," those matters on which professional expertise is requested, and not to represent the interests of any party ( 38). If one is the treating physician of either parent or child involved in a custody case, physician-patient privilege is considered much less important than are the best interests of the child, so the physician usually will be obliged to testify. However, disclosure of confidential psychiatric information without being ordered to do so by a court may subject the psychiatrist to a successful malpractice suit. No information should be disclosed, particularly to the adverse party or his or her attorney, without consent of the patient or the patient's parent who has asked the psychiatrist to treat the child. If testimony is needed, a judge can order it to be given, and until that time arrives, no information should be disclosed without the patient's consent ( 39).

Another sort of issue is presented in some cases involving subtle forms of child abuse. Children's protective agencies usually are not staffed by particularly well educated workers, and even if they are, in all jurisdictions they are overworked and understaffed. Abuse that is primarily emotional in nature or, although physical, does not leave clear marks, fractures, or other undeniable signs on the child may, when reported, not impress the caseworker enough to result in any action. One sort of situation in which most child protective services workers are uncomfortable is in a case of Munchausen's syndrome by proxy, in which a parent is deliberately making a child ill in some way. (Actually, this is the wrong name for this situation. Munchausen's syndrome refers to a factitious illness; these children may be made critically ill.) Typically, the child with mysterious symptoms is admitted to the hospital, and it eventually becomes obvious to the caregivers that the child becomes worse when one or both parents are present and recovers when the parent or parents go away. Close observation short of witnessing the act may convince everyone at the hospital that the parent is harming the child, but the child protective services worker says "prove it" and refuses to go forward with court proceedings in the absence of objective evidence. Obtaining such evidence may, in rare cases, demand a hidden video camera, taping the child's room and all activities therein.

Although such taping raises clear-cut moral dilemmas about invasion of privacy, it is, when used as a last resort, legal. First, no such spying operation on a parent should be carried out in a hospital unless the suspected activity is or may be causing serious harm to the child. (If the child has been admitted to the hospital in the first place, however, the child usually is sufficiently ill that there is no question about the gravity of the situation.) Second, all other means of obtaining evidence should have been exhausted, and, third, the child protective services authorities should have been told of the suspicion and refused to act without the evidence provided by a tape. If all those factors are present, the important factor to remember is that the privacy rights involved are those of the patient (the child), not the patient's parent. Whatever privacy rights a young child may or may not have, they obviously are subservient to his or her rights to be protected from life-threatening or disabling abuse. From the constitutional perspective, the provisions of the Bill of Rights (such as protections from searches and seizures) apply only to state agencies and would not, therefore, be relevant to evidence gathered by a private hospital. Even where a public hospital is involved, however, a warrant to videotape would be granted on a showing of probable cause to believe that abuse is occurring within the hospital.

In many of these cases, before the evidence is gathered or, if gathered, before it is turned over to child protective services authorities, the pediatrician may ask a child

psychiatrist to interview the parent. The issue then becomes whether the parent should be told the purpose of the interview. It would seem that in general the parent does have a right to know that the interview is not intended to be directly therapeutic for the child and therefore she or he should be told that the interview is to assist in establishing whether the parent is making the child ill.

Because state statutes on evidentiary matters and state constitutions' provisions on such issues as videotaping vary widely, under no circumstances should a physician or a hospital engage in this sort of evidence gathering without advice from the hospital's local attorney. If a child may die if unprotected, a judge will be available to help with these situations.

## 114 TESTIFYING IN COURT: A TRIAL LAWYER'S PERSPECTIVE

David N. Rosen, LL.B.

---

[One: Telling a Story in Direct Examination](#)  
[Part Two: The Use and Management of Aggression in Cross-Examination](#)  
[Coping with Aggression in Cross-Examination](#)  
[Special Problems of Child Psychiatrists](#)  
[Chapter References](#)

What does it mean for a child psychiatrist to be an “expert witness?” On one hand, the phrase conjures images of a scientific demonstration by a chemist or fingerprint analyst. This conception is unlikely to seem appropriate because psychiatry does not lend itself to the seemingly unassailable conclusions of “hard” science. Alternatively, an invitation to testify may feel like being propositioned to be a hired gun and to do “junk science,” appealing only to those who enjoy fighting or being on display. In fact, a child psychiatrist who testifies in court can be both effective and true to his or her understanding of the reality of the case. In order to do this, the prospective expert witness should think about the structure of a trial. Trials create a framework within which the expert’s story will be told and evaluated, which creates a specific set of opportunities and hazards for an expert witness. This chapter discusses that framework and proposes that a child psychiatrist can be an effective witness by approaching testifying as an application or extension of his or her professional skills and activities. It is useful to consider separately direct examination and cross-examination, because these are very different activities and require the use of very different metaphors to understand and master. For direct examination, the first topic discussed in this chapter, a child psychiatrist must think about how to construct the most compelling story; whereas for cross-examination, he or she must cope with and learn to use the aggression inherent in the confrontation with the cross-examiner.

### PART ONE: TELLING A STORY IN DIRECT EXAMINATION

A trial is not a direct reflection of reality. It is a reconstruction of reality. It might more accurately be called a *construction* of a reality of its own, because it has its own purpose and structure, created by the law. Even a straightforward-seeming criminal case does not address a question as simple as “Did A kill B?” The question is, rather, “Has the state proven beyond a reasonable doubt that A murdered B and, if so, was it murder in the first degree, or perhaps manslaughter?” Changing the question from “what happened?” to “what has been proven?” and introducing legal categories that may have little connection to how anyone perceived events as they were occurring inevitably makes a trial different from, and more complex than, simply a search for truth. Additional complexity is added as the questions the trial seeks to address become forward looking, as in a custody case, where the issue is, “where will it be in the child’s best interest to live in the future?” In such a case there can be no pretense that the trial is simply finding a preexisting reality; however, in all cases the trial is a competition between versions or stories of what happened or will happen or should happen, a competition that is familiar to psychiatrists. Psychotherapy prominently includes formulating reconstructions of reality that ring true or are useful to the patient. Inevitably, such formulations are based on incomplete, perhaps fragmentary, evidence, but if they hang together and capture something important in the information the patient has been conveying, they can be persuasive and compelling; therefore, it is in a trial, where the adversaries present competing stories, or versions, to the fact-finder, who must choose between them based on necessarily limited information.

As there may be formidable barriers to hearing a patient’s story clearly and coherently, much about the structure of a trial makes it difficult to present a coherent narrative. One of the most striking features of most trials to any observer, and perhaps the most salient for a child psychiatrist contemplating testifying as an expert witness, is their fragmented, disjointed quality. Although trials make great subjects for stories and are often gripping drama, they are constantly subject to a variety of centrifugal forces that make them prone at any point to become incoherent. It is useful to identify the reasons trials are so much in need of the coherent unity effective expert testimony can provide because the expert’s role in direct testimony is above all to counteract that incoherence and provide order and a narrative thread to the case he or she is called to support.

Why are trials always in danger of becoming incoherent? First, because the adversary system entails by definition the clash of views. There are, at least, two sides to every story, and presentation of both sides almost invariably makes the narrative harder to follow. Moreover, in the adversary system, at every point confusion is likely to be in someone’s interest. Ordinarily, when one side is presenting part of its case, it is in the other side’s interest to disrupt the coherence of the presentation. As a result, one side is often doing what it can to interrupt the flow of the other side’s presentation—and the rules of procedure offer many opportunities to do so, from objections to cross-examination to legal claims.

In addition to being under constant threat from the very nature of the adversary system, coherence of narrative is also jeopardized by features of the rules of procedure and evidence. For example, trials proceed by questions and answers, which tends to give testimony a staccato, as opposed to lyrical, quality. The lawyer and the witness are performing a duet, and if either gets out of step the narrative will quickly become choppy, entirely apart from interruptions by an adversary claiming that questions are improper or answers are nonresponsive or contain inadmissible material. Indeed, the basic rule that evidence must be presented through witnesses, each of whom is limited in the scope of his or her testimony, makes it harder to sustain a narrative thread. The story is told in pieces that come from different witnesses; and in real life the contributions of each witness cannot be shaped entirely by needs of dramatic effect. The areas about which any given witness may testify are not always adjacent to each other in the logical sequence in which one side’s narrative unfolds. For example, in a trial for sexual abuse of a child, a teacher may be able to identify some relevant physical evidence such as the child’s clothing, testify extensively about the child’s behavior and condition at different times, and also testify about some contacts with the suspected abuser. The teacher’s testimony about all these subjects will almost invariably be presented at once, rather than at different times according to the demands of dramatic narrative.

Of course it is also the case that cross-examination of each witness follows the direct testimony of that witness, rather than, for example, beginning only after all witnesses have completed their direct testimony. Each witness, therefore, presents testimony that zigzags according to the competing dictates of the adversaries. Additionally, the scheduling difficulties and delay for which the legal system is justly notorious result in trials that are frequently interrupted, sometimes for long stretches, and in which witnesses cannot always testify in the sequence that would make for the most coherent narrative. Doctors in particular are often called “out of turn” to accommodate their schedules but, as a result, find themselves talking about evidence the court should logically have heard already but in fact has not. Finally, and most fundamentally, the story of a trial is told through witnesses, each of whom contributes only a part of the story. A case is built by weaving together the threads of the testimony of different witnesses or, to use another common metaphor, as a mosaic in which each exhibit and witness’s testimony adds elements that together form a coherent pattern. In every case, the task is to show that the elements form a coherent whole, and the danger is that they will simply be a jumble.

The trial lawyer’s response to this problem is to develop and emphasize a theme for the case. It is a truism of trial advocacy that every successful case has a theme, a narrative structure on which the advocate tries to hang all the information the fact-finder receives. A theme provides clarity to a form of presentation that otherwise can easily dissolve into incoherence. A theme is the essence of one side’s case boiled down to a clear, simple, attractive statement. In a murder case the prosecution’s theme might be that the defendant was a violent, possessive husband who killed his wife in a jealous rage, whereas the defense’s theme might be that a biased and sloppy police force fixated on the defendant and failed to perform the thorough investigation necessary to find the real killer—even more concisely: jealous rage versus rush to judgment. A theme is no less important in a civil case, such as a child custody dispute. One parent’s theme might be, “The child belongs with me because I was the one who raised her,” whereas the other parent’s theme might be, “The child belongs with the parent who is more stable and supportive now and promises to remain so in the future.” Although some might find this simplification frustratingly incomplete or even simple-minded, trial lawyers consider it distillation rather than distortion. The right theme captures the essence of one side’s view of the truth, and it is often true that a case that cannot be summarized in a brief, clear, forceful way is not a very good case.

The child psychiatrist who is going to testify in court needs to understand how his or her testimony fits into the themes each side is presenting. If he or she is allied in some way with one side, as is common, he or she will want not only to understand but also help shape the theme of that side’s case. Like an actor in a play, a child psychiatrist witness must understand his or her role in the drama of the trial. The psychiatrist can help the lawyer and the patient/client by collaborating on identifying and formulating the essential theme of the entire presentation because, unlike an actor, the child psychiatrist’s lines are limited not only by what is plausible but also but by what is actually true. In a child custody case, for example, the psychiatrist ordinarily gives an opinion about the ultimate issue in the case—what custody arrangement is in the best interest of the child. Before testifying, the psychiatrist should try to formulate the basis for her opinion as concisely as possible, ordinarily in

a single, simple sentence. Two examples were given in the preceding.

Others might be, "Honoring the child's expressed desire to be with one parent is critical to giving the child a needed sense of autonomy" or, "The child's most critical need is not to be separated from his or her half-sibling" or, "That parent is dangerously unstable." These examples may or may not even count as good bases for a custody decision to some readers, but by virtue of being clear and simple themes, they will have force in a trial. Once having chosen a theme, a trial lawyer will look for opportunities to repeat it and point to evidence that supports it throughout the trial. In an important way, the trial will become about the theme, or competing themes, and the psychiatrist's role will be to testify about which theme is closer to the evidence and—what is more challenging—to critique one of the themes as shallow or irrelevant, at least to some extent.

A child psychiatrist may protest that boiling the results of many hours of observation and years of training and experience into a phrase or a sentence trivializes any contribution he or she might make by substituting a slogan for an opinion. A trial lawyer would reply that simplicity is necessary because of the diffused and fractured nature of trials and also because the audience is either a lay jury or a judge who, whatever his or her experience with similar cases, is not a child psychiatrist. It is common also for experts to make a virtue of the necessity of simplicity in the courtroom. Boiling down opinions to their simplest and most direct expression can be a useful analytical as well as rhetorical device, and an expert who can summarize his or her most important point in a brief, direct sentence may find his or her ideas sharpened and improved as a result.

Having said this much about the virtues of simplicity and focus is not to say that there is no place for complexity; On the contrary, the issue is not whether complexity and nuance have a place in a trial and the expert's testimony, but rather how to formulate and present complexity. Here the expert's model, like the trial lawyer's, should be the story. Fact-finders, like any audience, have tolerance, indeed an appetite, for complexity so long as it is presented within a narrative framework that holds it together.

The expert witness is privileged by the rules of evidence to tell a more complete and coherent story than other witnesses are allowed to tell. Experts can testify not only to their conclusions but also, reasonably enough, to the basis for those conclusions. When explaining the basis for their conclusions, therefore, experts can draw on and restate other evidence. Consequently, they have a unique opportunity to draw the evidence together into a unified narrative. Moreover, in testifying about the basis for their conclusions, expert witnesses are not even limited to information that is admissible evidence. The rule is that they may rely on any information, even hearsay or other inadmissible evidence, so long as the expert affirms that the information is the type of material ordinarily relied on by experts in the field. Thus, the expert may testify about information he was given by a child's teacher even though the teacher does not himself come to court to verify the information. (It is important surely to take any reasonable steps to verify such information, particularly because it is a likely area for cross-examination.) The expert has an opportunity, then, to synthesize a lot of information and communicate and discuss that information on the witness stand.

Robert Coles, a child psychiatrist, has written of "the call of stories." His view is that the clinician does well to eschew theoretical formulations of patients' psychodynamics, or at least keep them in their place, and focus primarily on the narratives, the stories, the patients will tell about themselves to those who want to listen. He argues, and demonstrates, that "a good deal of the time our patients' comments tell their own story, one that can be interpreted by us in ordinary language with no loss of psychological nuance and subtlety" (Coles, 1989, p. 27). This perspective is readily adaptable to trials, and expert testimony in particular. A child psychiatrist could present her conclusions by following a theoretical schema or reporting first test results, then the findings of a clinical examination, then conclusions, and so on. Ordinarily, however, a more compelling and persuasive method of presentation is to start wherever possible with a framework of the patient's story and to relate the details of findings and conclusions to the framework of a story that illustrates the expert's theme. Clinical observations and findings can be reported using this approach as illustrations of the themes of the story. Thus, the expert might begin testimony about her findings and conclusions as follows:

**Q:** Doctor, did you reach any conclusions concerning what custody arrangement would be in the best interests of the child?

**A:** Yes, I did.

**Q:** What conclusions did you reach?

**A:** My ultimate conclusion was that it would be in the best interest of the child for her mother to have custody of her.

**Q:** What is the basis for your conclusion?

**A:** [Introducing the theme] To put it as simply as possible, I found that this child's mother is the most important person in the world for her, and she needs to live with her mother to feel secure and protected.

**Q:** Can you explain what led you to this conclusion?

At this point the expert can try as best as he or she can to narrate the child's story and illustrate the theme in a nontechnical way. Rather than proceeding deductively by announcing the principle that the adult with whom the child has formed the closest bonds or who is appropriately designated the "psychological parent" should have custody, the story can properly revolve around the child's relationship with that adult. From the specifics of the child's life and relationship with that adult, the expert can then move convincingly to the observation that the child's experience of depending on and needing a sustained central relationship with the particular adult is just what the expert would expect. In fact, the expert can continue, everything we know about the way children develop is consistent with what this child's needs appeared to be from looking closely at her life story. This form of narration ordinarily will feel more "right" and persuasive to either a jury or a judge than one that begins with the generalizations of theory and then moves to apply theory to the particular case at hand.

Psychiatrists are well trained to be expert witnesses because they are students of people and their life stories. By focusing on the fundamental point they are going to make in their testimony and how that point relates to the theme of the trial, and then allowing themselves to tell the story, with all its individual richness, that supports that theme, they can make a presentation on direct examination that feels right and consistent with their professional role and is at the same time highly effective in the courtroom.

## **PART TWO: THE USE AND MANAGEMENT OF AGGRESSION IN CROSS-EXAMINATION**

What awaits a child psychiatrist who is to testify in court? The experience, particularly cross-examination, inevitably seems somewhat surreal: Anticipating a serious and consequential discussion about clinical issues, the psychiatrist instead may find himself or herself being hectorated by an inquisitor who evidently has no interest in either the truth or the best interests of the child whose welfare is ostensibly the purpose of the proceeding. Equally disconcerting, the cross-examiner's questions may proceed from the assumption that the psychiatrist is dishonest or biased, leaving the psychiatrist feeling like a murder suspect protesting her innocence to a cynical police detective.

An important part of the difficulty many psychiatrists experience testifying in court is that they use the wrong model to understand it. A psychiatrist may imagine that testifying in court is more or less like giving an invited lecture. Using this model (or laboring under this misapprehension), the psychiatrist will be likely to regard cross-examination as uninformed, distracting, and impertinent. Exchanges like the following will ensue:

**Q:** How much time did you spend reviewing the report of the family relations officer before you formed your opinion regarding custody?

**A:** I am afraid you didn't understand my earlier testimony. The report of the family relations officer has very little significance for me because I performed my own independent evaluation and spoke with all the people the family relations officer spoke to. In fact, I deliberately did not study that report because I did not want my own views to be biased by another professional's opinion.

**Q:** So the answer to my question is "none." Is that right?

**A:** You aren't taking into account the reason I didn't examine the report at that time.

**Q:** Is the answer to my question, "none?"

**A:** Yes.

**Q:** Thank you.

The witness would have done much better to respond as follows:

**Q:** How much time did you spend reviewing the report of the family relations officer before you formed your opinion regarding custody?

**A:** None; I read the report after I formed my opinion.

Or, simply,

**A:** None.

Somewhat similar results may occur when a psychiatrist-witness regards cross-examination as a debate or an argument. He or she will invite being viewed as biased, belligerent, or both and will have missed the opportunity to be an effective witness. For example:

**Q:**How much time did you spend reviewing the report of the family relations officer before you formed your opinion regarding custody?

**A:**None at all, which is probably fortunate, since when I ultimately did review it I found it very misleading.

**Q:**Was it misleading when it said the child has lived with her father for the past 6 months?

**A:**No, the part I was referring to is ...

**Q:**[Interrupting] Please answer my question, Doctor. The answer to my question is, "No?"

**A:**Yes, but ...

**Q:**Thank you. Now, was the report misleading when it said the child is doing well in school?

And so on. Again, the witness would have done better simply to answer the question and trust that subsequent redirect examination by the lawyer who originally had called her to testify would give her the opportunity to correct any misimpressions left by the cross-examination.

A more useful reference point is another form of dialog with its own peculiar set of rules: the psychoanalytic session. Thinking about the similarities and differences between cross-examination of a witness and a psychoanalytic session is a helpful way to understand and therefore cope with the demands cross-examination places on a child psychiatrist testifying in court.

The lawyer's job, like the analyst's, is to lead a subject to the most difficult and painful topics and peel away layers of rationalization or dissimulation to reveal a truth within. That is, not only are both psychoanalysis and cross-examination investigations, but also they both begin with the assumption that people's testimony should not be taken at face value, nor should their honesty be presumed. Thus, cross-examination has been described, in a phrase Freud might have used about psychoanalysis, as the greatest engine ever invented for the discovery of truth.

On the other hand, although psychoanalysis depends on the patient free associating—saying whatever comes into his or her head without censoring any thoughts—the witness is entirely constrained in cross-examination and must answer precisely the question put by the cross-examiner. To a psychiatrist witness, used to a more discursive approach to the truth, this constraint can make cross-examination feel like the course in oral expression Holden Caulfield took in *The Catcher in the Rye* (1964), where each boy had to make a spontaneous speech in class:

And if the boy digresses at all, you're supposed to yell 'Digression!' at him as fast as you can. It just about drove me crazy.... What I think is, you're supposed to leave somebody alone if he's at least being interesting and he's getting all excited about something.

That is not what cross-examiners think. What cross-examiners think is that their job is not so much to *discover* the truth as it is to *demonstrate* the truth, as they have been hired to see it, so that the judge or jury may discover it. Accordingly, the first rule of cross-examination is, never ask a question to which you do not know the answer. What this precept means in practice is that virtually all questions on cross-examination are closed-ended, and witnesses are very often merely foils whose role on cross-examination is simply to admit facts the examiner wants the judge or jury to hear in the sequence the examiner has selected. For example, consider the following sequence:

**Q:**Doctor, how much time did you spend observing the mother and child interacting together?

**A:**One hour.

**Q:**And you have based your recommendation regarding custody primarily on your opinion about the relationship between the child and mother, isn't that right?

**A:**Yes.

**Q:**And that one hour was in your office, is that right?

**A:**Yes.

**Q:**And of course how people behave in your office when you are watching them may differ from how they behave at home when they are not being observed, isn't that right?

**A:**Yes.

**Q:**For example, the mother certainly may have been trying to impress you during that single one-hour session that you observed her with the child, isn't that right?

**A:**Yes.

**Q:**And that might affect her behavior, isn't that right?

**A:**I suppose so.

**Q:**So your only direct observation of the mother and child relating to each other was for a single hour, outside the home, under circumstances where the mother might be acting differently from the way she would before she came to your office and after she left it, isn't that right?

**A:**Yes.

And so on. Anticipating all of this, the psychiatrist may wish to respond by taking control of the conversation, for example, as follows:

**Q:**How much time did you spend observing the child and her mother together?

**A:**I don't think that is what is important in making an evaluation concerning child custody in this case.

She is not allowed to do so, however. If she does, the lawyer is entitled to say, "Please answer my question, Doctor," or even, "Are you willing to answer my question, Doctor?"

The psychiatrist cannot expose himself or herself to this line of questioning without damaging his or her credibility. The psychiatrist is not entitled to ignore the constraining rules of cross-examination and will score no points by attempting to do so. If the psychiatrist persists in trying to step outside the rules of cross-examination, she will be perceived, accurately, as breaking them.

Both court testimony and a psychoanalytic session are dialogs of a sort, but both are asymmetrical in important respects, in which the witness is analogous to the patient and the lawyer to the psychoanalyst. For example, they are asymmetrical with respect to disclosure. The central function of the witness or patient is to disclose information, freely and fully. On the other hand, the examiner and analyst need disclose nothing. This asymmetry can be frustrating in both settings; unlike an ordinary conversation, openness and candor in these settings cannot be expected to be reciprocated. Therefore, the witness, like patients, is vulnerable to feelings of powerlessness and loss of control.

These feelings may be intensified by the rule (or meta-rule) illustrated by the cross-examination excerpt in the preceding, but applicable to both settings, that the witness or patient cannot make the examiner or analyst step outside of his or her role. Thus, a patient who demands of an orthodox psychoanalyst, "What do *you* think?" about this or that may get for a reply only, "What do you think I think about it?" or silence. Likewise, a witness who demands of a cross-examiner, for example, "Don't you really think the child should stay with the parent who has been most involved with her up until now?" cannot expect to disarm the lawyer and get a straight, honest answer. Instead, the lawyer may reply, "Are you suggesting by that question, Doctor, that in your opinion the *character* of the parent is irrelevant to the best interest of the child?" The lawyer is *supposed* to respond only in whatever way he or she thinks is best calculated to advance a client's claim in the litigation, and this imperative typically will lead the lawyer to view a witness's appeal to step outside the game of the adversary system as simply another move in the game, calling for a countermove on the examiner's part.

These constraints on the witness suggest another, more fundamental asymmetry in cross-examination, which also has its counterpart in the psychoanalytic relationship. This is asymmetry with regard to aggression. Cross-examination is a weapon in the lawyer's arsenal within the adversary system. The lawyer uses it either to attack the witness or, perhaps, to turn the witness into a weapon directed at the adversary. But the witness is not supposed to be an adversary; the expert witness especially is supposed to be a representative in court of the commitment to truth. Thus, the cross-examiner properly regards the conversation, that is, the examination, as a form of warfare, but the witness cannot take this stance. The witness is required to treat the examination as a search for truth.

In this respect, the witness is analogous to the psychiatrist, not the patient, in the psychoanalytic relationship. Although the lawyer is permitted to give more or less free rein to his or her aggression, the witness is required, no matter what accusations are leveled or what hostility expressed, not to retaliate in kind but to be the anchor of reason and respond to hostility and aggression with understanding and without permitting himself or herself to be provoked to anger.

To understand why it is so important for the witness to preserve this asymmetry—not to respond in kind to the lawyer's aggression—consider that the expert witness, like the patient, is more knowledgeable about the subject matter of her testimony than the lawyer cross-examining her or the judge or jury evaluating her testimony. As the analyst, who has never met the patient's family and friends, evaluates the patient's narrative in part through careful attention to the patient's affect and with the aid

of generous amounts of intuition rather than logical deduction or reference to externally acquired information, therefore the judge or jury evaluating the psychiatrist cannot be expected to learn as much as the psychiatrist knows about psychiatry. They do not perform a kind of peer review of the psychiatrist's testimony. Judges and particularly juries are lay people, not experts in any of the fields about which they may hear testimony. Indeed, people with special expertise in the area in which an expert will testify frequently are excluded as jurors, in order to prevent them from using their knowledge in a way that is not open to scrutiny and control by the court. Of course, one must ask on what basis, then, are judges and juries supposed to evaluate the conflicting testimony of experts?

The answer is that fact-finders in court, and particularly juries, evaluate an expert's conclusions based primarily on their assessment of how the expert has handled the tension between the aggression of the cross-examiner and the witness's obligation to speak for scientific truth. That is, although judges or juries may well follow the substance of an expert's testimony carefully and attempt to evaluate it as a peer might, that is not the main thing they do, indeed not the main thing they are supposed to do. What courts and juries are designed to do is to evaluate the credibility of witnesses. And what this boils down to above all is evaluation of the witness's commitment to the value of truth when confronted with the aggression of the adversary system.

### **Coping with Aggression in Cross-Examination**

The way this process works in practice is that, to be persuasive, witnesses must accept and use the asymmetry of cross-examination. Like a psychiatrist with a belligerent patient, the witness must be careful not to be provoked by the aggression of the cross-examiner (and in this way the psychiatrist witness is not switching roles but may call on familiar skills). Because the cross-examiner is aggressive, the witness succeeds by being gentle; the jury understands that, as aggression and an adversary stance are companions, so their opposites, gentleness and fidelity to truth, also go together. Thus, the cross-examiner marks it a success when he or she succeeds in getting under the skin of the witness, or making the witness *blow up*. The successful witness, on the other hand, is one who *deflates* the cross-examiner.

Some examples of common lines of cross-examination show features of the adversary system in action and illustrate how the witness's use and management of the aggression inherent in the adversary system is the key to being an effective expert witness. Let us begin by imagining a case in which the psychiatrist who has treated a child for emotional problems arising from a physical injury is called to testify in a case seeking damages for the injury. Cross-examination begins as follows:

**Q:**You have seen the plaintiff as a patient for almost a year. Is that right?

**A:**Yes.

**Q:**In that time have you sent her family bills?

**A:**Yes.

**Q:**Have they paid the bills?

**A:**No.

**Q:**How do you expect to get paid?

**A:**They have agreed to pay me as they are able to do so.

**Q:**In fact, you expect to get paid out of the proceeds of this lawsuit don't you?

**A:**Well, yes.

**Q:**So you have a stake in the outcome of this lawsuit don't you?

**A:**I am being honest in my testimony.

**Q:**Isn't that for the jury to decide, Doctor?

**A:**Yes.

**Q:**My question was not: Are you being honest? It was: Don't you have a stake in the outcome of this lawsuit?

**A:**Well, not really.

**Q:**Don't you stand to get paid nearly \$5,000 if the plaintiffs win this lawsuit and little or nothing if they lose?

**A:**Yes.

**Q:**But \$5,000 is not a stake in this lawsuit, is that your testimony?

What is a witness to do about this sort of questioning? Clearly, the answer is not to say, for example, "Well, \$5,000 is not very much to me," or, "I wouldn't change my testimony for a million dollars." The first is condescending, the second defensive. This is the sort of questioning against which the best inoculation is not the witness's protestations of innocence but rather her *demonstration* of lack of bias in her answers. The psychiatrist could answer as follows:

**Q:**How do you expect to get paid?

**A:**I suspect I will either get paid out of the proceeds of this lawsuit or not at all.

By anticipating the lawyer's point in her answer, the witness has taken much of the sting out of it. And when the lawyer asks the inevitable question, "So you have a stake in the outcome of this lawsuit, don't you?" the better answer is simply, "To that extent I do, yes." By refusing to be put on the defensive—that is, refusing to resist a point that the examiner is going to make anyhow—the witness defuses the examiner's aggression. The point is *not* the witness's expectations regarding payment but whether the witness appears to be more concerned with accuracy than with preventing the examiner from scoring debating points.

Now consider an attack purportedly on the witness's expert knowledge, which again when looked at in action actually depends for its effectiveness not on the substance of the witness's answers but on how adversarial the witness is:

**Q:**Doctor, you diagnosed the patient as having posttraumatic stress disorder. What are the diagnostic criteria for posttraumatic stress disorder?

**A:**In my report I mention four basic diagnostic criteria.

**Q:**Can you name the criteria without looking at your report?

**A:**Well, (a) there must be a stressor, (b) the patient must reexperience the trauma, (c) there is a withdrawal from social engagement, and I am afraid that's all I can recall.

**Q:**You are not really an expert in the area of posttraumatic stress disorder, are you, Doctor?

**A:**Well, just because I don't remember all the criteria, that doesn't mean I'm not an expert. I have written in the area of schizophrenia and I couldn't recite all the diagnostic criteria for schizophrenia.

**Q:**But you have not written in the area of posttraumatic stress disorder, have you?

**A:**(Doesn't matter.)

The point about this line of questioning is that knowledge of the four diagnostic criteria may be elementary information or it may be arcane, but the jury does not know which it is, and even if they did know, they probably would not care. Their concern is with how the witness handles the questions, not with how high he or she scores on a pop quiz. The witness can defuse this line of questioning by refusing to take it as a challenge and at the same time staying within her role by not appearing to claim to judge the materiality of the question. For example:

**Q:**Can you name the four basic criteria without looking at your notes?

**A:**I don't think so.

By using a matter-of-fact, noncombative tone the witness has communicated all he or she needs to: This information is not something he or she needs to have memorized in order to feel capable of reaching whatever conclusions have been reached. Moreover, the witness is not acting like an adversary; implicitly, therefore, he or she is interested in the truth, not simply in winning. (If the psychiatrist can in fact name the criteria, the best answer is "Yes, I can." This answer is better than actually listing the criteria because it is not showing off and accordingly does not imply any agenda other than the accurate transmission of information.)

Likewise, to the inevitable question, "You are not really an expert in the area of posttraumatic stress disorder, are you?" a better answer is, "Posttraumatic stress disorder is among the psychiatric disorders that I treat, but it is not an area of special expertise," or (if true), "No, I believe I am an expert in the area of posttraumatic stress disorder."

### **Special Problems of Child Psychiatrists**

However, all this is not to say that the testimony of a child psychiatrist must be or appear to be without feelings. On the contrary, to be persuasive a child psychiatrist

must, like any expert, communicate commitment to the *field* and its values. In addition, as a child psychiatrist, the witness, unlike most expert witnesses, may properly, indeed must, communicate a form of partiality to the *welfare of the child* who is the subject of the court proceeding. Nevertheless, this is quite a different matter, indeed the reverse, of being adversarial or combative on one's own behalf or in order to score points. Consider the following exchange, from a child custody case before a judge without a jury:

**Q:**Doctor, if the mother is permitted to move far away with the child, it will be harder for the child to see her father, won't it?  
**A:**Not if the father moves too.  
**Q:**But don't you think if the mother wants to move away from the father now, she would just try to move again if he followed her?  
**A:**Not necessarily.  
**Q:**But you certainly aren't claiming that won't happen. Are you?  
**A:**I don't think it's likely.  
**Q:**But you really don't know one way or the other. Do you?  
**A:**Of course not; no one can know for sure at this point.  
**Q:**But if the court orders the mother not to move, then we would know for sure that the father will be nearby. Wouldn't we?

Here the psychiatrist, probably giving in to her frustration with the father, his lawyer, the legal system, or some combination of them, was unable in her answer to the first question to resist the impulse to be clever. Giving in to that impulse invariably gives the cross-examiner the opportunity to score points. If the witness had held her tongue, she would have had an opportunity to make her point not by being clever but simply by manifesting her commitment to the child's well being:

**Q:**Doctor, if the mother is permitted to move far away with the child, it will be harder for the child to see her father, won't it?  
**A:**It certainly may.  
**Q:**There is no "may" about it, is there, Doctor?  
**A:**Oh, I think it is far from certain that the mother's moving will necessarily have that effect. If the mother is permitted to move, she may feel more secure and be more open to the father's visitation; or, the father may even decide that being close to this child is so important that he will consider moving also.

The witness has in effect earned the right to give this answer by not jumping into combat with the examiner earlier. As a result, the effect of her testimony is fundamentally different from the effect of the first sequence.

Psychiatrists, particularly child psychiatrists, face a variety of other special problems as witnesses. The first of these is the plethora of experts who may be involved in a case. A child custody case may have testimony from psychiatrists retained by each of the parents, a court-appointed psychiatrist and/or one retained by counsel for the child, a court-employed family relations officer, and welfare department employees. To all these voices, frequently discordant, add those of counsel for the parents and the children, and the result can be that the competing opinions tend to cancel each other out, leaving the judge free to act on his or her impulses.

Moreover, confusion of roles is common in child custody cases ([Goldstein et al., 1986](#)). The child psychiatrist ordinarily is asked to testify concerning what custody arrangement is in the best interests of the child, the very same issue the judge ultimately will decide. (By contrast, an expert's testimony in a criminal case may establish that the bullet that struck the victim came from the defendant's gun, but that testimony is only one link in a chain needed to establish the defendant's guilt of a given crime.) As a result, it can be hard to distinguish the judge's role from the psychiatrist's. The psychiatrist may feel, and be treated by the parties, as if he or she is adjudicating competing claims. The psychiatrist accordingly may be subjected to criticism for not according one of the parties due process before deciding against that party, for example, by meeting with one side more than the other. The judge may also treat the child psychiatrist as the adjudicator and simply rubber-stamp his or her recommendation, particularly a psychiatrist retained by the court itself or by counsel for the child. More troubling from the point of view of the psychiatrist witness, the judge, like the parties, may evaluate the psychiatrist's work and testimony like a sort of court of appeals, asking not what is in the best interests of the child but whether the psychiatrist has been fair to all the parties. The psychiatrist, of course, is not trying to be fair to all the parties: At most, he or she is trying to determine what outcome will be in the best interests of the child. However, because the psychiatrist is confused with a judge, he or she is liable to be criticized for not taking into account the interests of the disappointed parent.

Moreover, the judge, particularly in child custody cases, very frequently has had so much experience deciding such cases that he or she is convinced that the opinion of a child psychiatrist is superfluous. That is, the judge, not to mention the lawyers and other professionals, confuses his or her role with the psychiatrist's because, after all, in a way it is everyone's job to determine the best interests of the child. This confusion is exacerbated by the fact that many people, including many judges, do not believe child psychiatry has much special expertise to offer. Child psychiatrists thus encounter triple skepticism—as witnesses, expert witnesses, and specialists in a field that is viewed with suspicion (as, say, surgery is not).

To be an effective witness under these circumstances, the child psychiatrist, even more than other expert witnesses, must not be inflamed by the aggression of cross-examination. The best defense of her expertise a child psychiatrist can offer as a witness is a demonstration of his or her therapeutic approach in the process of testifying. That is, the psychiatrist should let the court see how he or she operates as a therapist, not by practicing psychiatry in the courtroom but by showing a caring, gentle thoughtfulness rather than combativeness.

It is just this tone that makes for an effective witness: Any witness is more persuasive if he or she appears to treat the trial as a truth-seeking activity rather than as an arena. However, for a psychiatrist a gentle, noncombative tone serves the additional function of illustrating the maturity and thoughtfulness that a court will recognize as characteristics of a good therapist. For example, consider the following exchange:

**Q:**Doctor, did you perform any formal psychological testing on your patient?  
**A:**Certainly not. Psychological testing would have been a waste of time in this case.  
**Q:**Isn't psychological testing recognized as an important diagnostic tool?  
**A:**But I wasn't doing the kind of diagnosis that calls for psychological testing. I was investigating the question of custody, not doing a full-scale work-up of a psychiatric patient.  
**Q:**Wasn't this case just as important as a full-scale work-up of a psychiatric patient?  
**A:**As I just explained, it's not a question of importance, it's a question of whether psychological testing is going to be of any significant value in this context, and in my opinion it clearly isn't. What I did do was to talk at length with all the parties involved and observe the child interacting with each of her parents, and I think that was much more valuable than psychological testing could possibly be in this context.

Among the problems with this approach to testifying on cross-examination is that the witness does not sound like someone who is a gifted listener. A judge already somewhat skeptical of psychiatrists is unlikely to trust this witness. A better approach to the same line of questioning would be:

**Q:**Doctor, did you perform any formal psychological testing on your patient?  
**A:**No, I didn't.  
**Q:**Isn't psychological testing recognized as an important diagnostic tool?  
**A:**Yes, it is.  
**Q:**But you did not use that tool here, did you?  
**A:**No, I didn't.

The witness is being used as a foil in this sequence, and instead of fighting that role, simply allows the lawyer to make points, patient and secure enough not to need to correct every misimpression right away. Such a witness will get an opportunity to say what he or she wants to say, either on direct examination or perhaps even, as in the following example, on cross-examination:

**Q:**So inasmuch as you did not do any psychological testing, you did not really do a thorough evaluation, did you?  
**A:**No, I think my evaluation was thorough.  
**Q:**But it would have been more thorough had you done psychological testing, wouldn't it?  
**A:**No, the important issue that emerged in my evaluation was Mary's need to stay with her mother and her fears of losing the security her mother represents. And psychological testing would not really have added to my understanding of that issue.  
**Q:**But it might have added to your understanding of other issues, isn't that right?  
**A:**Yes, that is certainly true.

When and if the psychiatrist does get an opportunity like this one to say to the cross-examiner what he or she thinks is important about the case, the judge will be ready to listen, much more readily than if the psychiatrist mistakenly believed that his or her job was to say what was necessary to say no matter what. (And if the psychiatrist does not get to say it on cross-examination, the other lawyers or even the judge will give him or her an opportunity when the cross-examination concludes.)

In short, the judge will be most likely to notice the psychiatrist's virtues as a therapist if some of them are shown as a witness. Ultimately, the psychiatrist's professional skills—an ability to listen attentively and thoughtfully, care about the well-being of patients, and resist the urge to respond to aggression with aggression—will enable him or her to be a persuasive witness in court.

In this chapter, we explore the role of the child expert in court-contested child custody and placement conflicts. A *child expert* is a person who, by training and experience, has acquired and uses that body of knowledge referred to as clinical child development. No one discipline or profession is the exclusive source of such knowledge and its applications; the professions of pediatrics, child psychiatry, child psychoanalysis, social work, and clinical child psychology all require a mastery of the theoretical and practice aspects of this body of knowledge as defined by state and national standards of academic and supervised training. We assume that the knowledge used by child experts in the clinical evaluation, expert opinion, and recommendations conveyed to the court about what will serve the child's best interests is based on (a) the child's need for appropriate physical nurture and safety and (b) the child's need for a continuity of affectionate care by a limited number of adults who want to take care of the child on a permanent basis.

The child expert may be called upon to perform a clinical evaluation as part of a legal proceeding by agreement of the adult parties, by order of the court, or at the behest of one of the disputing parties. The legal conflict may stem from a custody or visitation dispute between divorcing parents or as part of a placement dispute between the child's parents and the state stemming from issues of neglect, abuse, or abandonment.

Divorce cases (issues of custody and visitation) are usually heard in family court, whereas placement cases are most often heard in juvenile court; guardianship and occasionally custody issues are determined in probate court. The most frequent request for clinical evaluations involves a legal decision about the child's custody and may include termination of parental rights. Although the principles of child development knowledge being applied are the same in evaluations regarding custody assignments and in state placement evaluations, the issues are considered separately in this chapter.

## DIVORCE

After a rapid increase between 1960 and 1980, family disruption in our society is believed to have stabilized such that about half of couples married after 1970 will divorce at some point. Half of all children are likely to experience the divorce of their parents and go on to spend an average of 5 years in a single-parent household ([Glick and Lin, 1986](#)). In 1999, the proportion of children younger than 18 years of age who lived with two parents was 68%, a decline from 1980, when 77% lived with two parents, and from 1970, when 85% lived with two parents ([U.S. Bureau of the Census, 2000](#)). Approximately 72% of divorced women and 80% of divorced men will remarry. The divorce rate for second marriages is greater than in first marriages. One of every 10 children will experience two or more divorces of the custodial parent before he or she becomes 16 years old ([Furstenberg, 1988](#)). In 1994, and in each following year into the foreseeable future, more than 1 million American children are likely to be reared in families disrupted by separation and impending divorce ([Maccoby and Mnookin, 1994](#)).

Many societal factors have contributed to the increased acceptance of divorce in our society. No-fault divorce represents a judicial shift from the "tender years" doctrine, favoring mothers, to a "best interests of the child" standard. The best interests standard not only places the child's needs at the center of custody decision making, but also it satisfies the requirements of our society for freedom from gender bias with respect to custody decisions. In the present divorce climate, dispute resolution through cooperation and mediation is preferred to litigation ([Levy, 1998](#)). Programs to assist divorcing parents in dispute resolution typically offer parents information on the legal process for determining the following: custody, visitation, and child support; the effects of divorce and separation on adults; and the effects of divorce and separation on children and how parents can help children to cope with this difficult transition ([Pruett and Pruett, 1999](#); [Schepard, 1993](#)).

Present knowledge about the impact of divorce on children suggests that it creates an immediate or short-term stressful challenge that may adversely effect the long-term development of the involved children. [Wallerstein and Corbin \(1991\)](#) note that "children of divorce are greatly overrepresented in outpatient psychiatric, family agency, and private practice populations relative to their presence within the general population." Confirming this view, [Maccoby \(1992\)](#) comments on the Hetherington study and states, "A central finding is that the children in intact families were doing better at each assessment period than those living with divorced mothers who had either remained single or remarried. This finding is consistent with a considerable body of literature pointing to the disruptive effects of divorce (and/or the familial conditions that precede divorce) on children's functioning." There is no way to predict which children will be more vulnerable. Many clinicians believe that the single most corrosive element in the child's experience when parents divorce results from emotions of unabated and intractable conflict. However, these inferences must remain tentative because there is no way at present of knowing whether these findings are associated with the divorce or are the influences of a child-disturbing marriage.

Nevertheless, many children and their reconfigured families will be able, over time, to achieve a progressive development and to restore an adequate sense of continuity and security. The parents' ability to resolve visitation and custody issues cooperatively either independently or with assistance (by family relations services of the court, mediation efforts, or voluntary mental health consultation) can be responsive to the child's needs for a sound unique relationship with each parent. Such effective collaboration after the divorce provides the conditions that enable parents *de facto* or *de jure* to create voluntary joint custody. The parents' ability, willingness, and motivation to cooperate enable the child to feel wanted and to trust and count on the parents to continue to provide nurture and guidance.

## ROLE OF THE MENTAL HEALTH EXPERT

Most divorcing parents make their own custody arrangements. Statistical data on the percentage of divorces in which contested custody issues arise are estimated to be 5% to 8%. In their California study, [Maccoby and Mnookin \(1994\)](#) found that only 1.5% of families actually relied on the judge to decide the custody or visitation issue; another 2.2% went to trial but were able to settle during the trial. In the same study, 75% of families experienced negligible or mild conflict, whereas 25% experienced substantial or intense conflict.

When a mental health expert is consulted by divorcing parents on a voluntary basis, the usual rules of confidentiality apply. Some therapists make formal signed agreements with potentially litigious parents to emphasize the therapist's willingness to assist the parents to come to an agreement on a voluntary basis. Conversely, clinicians may not be willing to serve as experts in court if they already are committed to voluntary, confidential therapy. Usually, a verbal understanding is sufficient. No agreement can completely shield the process from the possibility of a later subpoena by one of the parents. Most often in voluntary situations, the child is not seen; rather, the emphasis is on assisting the parents to maintain their relationship to their child in an affectionate and appropriately authoritative manner as the true experts on what the child needs.

When divorcing parents cannot agree about the custody and visitation arrangements for their child, the state temporarily becomes the parent in its *parens patriae* function. Once the parents cede their decision-making prerogative to the state and the court assumes the decision-making role, the atmosphere is likely to be charged with anger and conflict. In such instances, the parents' disagreements are usually heightened, and there is a greater risk that psychological war will lead to emotional wounds, to feelings of betrayal and bitter rage that too often remain unhealed even after the judge has made a decision about custody or visitation. It is in connection with such cases that the child expert may be called on to render an evaluation and recommendation that can be used in the court proceeding.

## WHAT THE CLINICAL CHILD EXPERT SHOULD KEEP IN MIND ABOUT LEGAL CONSIDERATIONS

The child expert is frequently called on in conflicted cases by one or both attorneys representing the parents. When the child has separate counsel, the child's lawyer may initiate or be involved in the designation of the child's clinical evaluation. Regardless of who hires the expert witness, the contribution of the child expert is as an advocate for the child's needs, that is, for the "best interests of the child." The child expert translates this legal standard into clinical terms, meaning what is best or least harmful to the child, given her or his age, developmental level, special needs, and relationship with each parent. The child expert's recommendation to the court is based on a clinical evaluation of the child's development and attachments and on what can best facilitate the child's developmental progress.

From the legal side, the best interests standard is given lip service in most states, especially as the court's adversarial process forces into view the competing interests of the adults. In reality, concerns of fairness to adults and personal value biases of the individual judge or the society often prevail. In this sense, all involved will verbalize their concern for the child's best interests, but only a few will transcend their identification with the contending adults in a manner that makes the child's interests and needs paramount.

Lawyers and judges complain about the vagueness and indeterminacy of the best interests standard. Although some experts advocate more rules and less discretion in custody decisions as a deterrent to litigation, the law as practiced requires a highly individualized determination of what is in the best interests of, or least detrimental to, each particular child ([Mnookin, 1975](#)).

Although the mental health practitioner is likely to be looked to by the court to assist in providing insight into the individual child's needs and the competing caretakers' capacities to meet the child's needs, increasingly the claims of these experts are being subject to question. [Homer and Guyer \(1991\)](#) believe "...by whatever processes of reasoning they use, clinicians predictably fail the most fundamental requirement of basic scientific inquiry, which is to achieve convincing demonstrations of interjudge reliabilities of perception and inference when the latter are applied to the same body of facts." We assume that experts disagree because their knowledge is not and cannot be precise. We respect the diversity of lifestyles and believe the community is best protected, not by experts, but by those who administer the rule of law, as imperfect as it is, to guide us in ensuring parents and children of their constitutional rights.

## DEVELOPMENTAL PRINCIPLES

[Goldstein et al. \(1996\)](#) define the central principle in custody and placement decisions, "the least detrimental available alternative," as "...that child placement and procedure for child placement which maximizes, in accord with the child's sense of time, the child's opportunity for being wanted and for maintaining a continuous, unconditional and permanent basis...relationship with at least one adult who is or will become the child's psychological parent." The authors further explicate the child's sense of time as varying with the urgency of his or her instinctual and emotional needs; for example, separation from a central nurturing person is less tolerable to an infant or young child or a child with particular vulnerability or identified special need than to an older or sturdier child. The child needs to be wanted by at least one adult who offers safety, affection, and appropriate stimulation. The child's developmental needs are best met when there is opportunity to experience such an attachment to an adult in a continuing unconditional and permanent relationship. These principles offer the clinician a conceptual guide and frame of reference but are not meant to be formulaic.

The restoration of emotional security for those few children who are the subject of continued litigated custody disputes in postdivorce conflict often requires the difficult acknowledgment that, for the time being, the child's future is best safeguarded in the hands of one primary, custodial parent. The least detrimental alternative in extreme cases when parents are addicted to fighting and cannot tolerate the contact required by visitation is to support and protect the child's relationship with the custodial parent. Despite the flaws and limitations in the child's relationship with the custodial parent, even in extreme situations the child can do reasonably well if the relationship and identification with at least one parent are ensured and if the child's best interest is given preference over equity for the contending parents. Intervention by the court or other experts can risk undermining the custodial parent's security, sense of control, and effectiveness and can often result in less cooperation between the parents ([Nordbaus, 1991](#)).

Noncustodial parents and those who consult with them would be well advised to emphasize how the noncustodial parent can persuade and make worthwhile voluntary agreements regarding visitation and other arrangements that will promote improved relationships of both parents in the service of the child's progressive development. For example, support by the noncustodial parent, not limited to money but including availability for child care, for doing errands, and for helping the custodial parent with various demands he or she confronts in maintaining the child's home, can be very useful if presented as a voluntary, nonthreatening option.

## CLINICAL EVALUATION

When the evaluation is for court purposes, what is the overall task of the child expert, and how is the task accomplished? The clinical evaluation in custody or placement issues, although similar to the psychiatric evaluation, is different in its goals. The purpose of a child psychiatric evaluation is to arrive at a psychodynamic formulation of the child's presenting problems, a diagnosis, and a treatment plan recommendation. Ordinarily, it is conducted on a voluntary and confidential basis. In a custody evaluation, the question is posed by the court. Usually, a custody conflict requiring a court-ordered evaluation signifies that the parents are unable to cooperate voluntarily in planning for custody and visitation arrangements. The questions are as follows: With whom should the child live? Which parent should have legal decision-making authority regarding education, medical decisions, religion, financial support, vacations, and so forth? How can the opportunities for the child to maintain a useful and sound relationship with both parents be optimized?

Intractable postdivorce conflict usually has a noxious and long-term negative impact on children ([Emery, 1982](#)). It is crucial that throughout the evaluation process the child expert support whatever capacity the parents have or can recover to resolve their own disputes, to diminish conflict, and to place themselves in the child's shoes in guiding themselves to be the best parents they can be for their child. Even experienced experts may find themselves unwittingly drawn into the family dispute because all adults, no matter how well trained, drift toward an identification with one of the conflicting adults. At times, the evaluator may experience a resurgence of her or his own childhood family struggles, especially if divorce is a significant experience in his or her own past.

The first practical step is to clarify as much as possible the court's questions. In complex cases (particularly foster care placement cases), it is advisable to obtain a copy of the motion for evaluation. The evaluator can request that the court furnish the exact questions to be addressed in the evaluation. This phase of the process is significant, because it initiates the attempt at a dialogue between the professionals in the two intersecting fields. The legal side usually values winning, establishing fault, being explicit, and meting out "justice"; mental health and developmental experts traditionally value helping and promoting understanding while tolerating ambiguity and ambivalence. During this phase, it may be necessary for the clinician to explicate the nature and limits of his or her expertise to the court.

Some clinicians will agree to be retained by one side or the other in a case. There are several reasons to insist that the court order the evaluation. It enables the expert to state effectively that he or she serves as an expert on behalf of the child and strives to be neutral with respect to the adult because the child's interests are paramount. Court-ordered evaluations discourage multiple evaluations, which constitute an undesirable intrusion and burden for the child. When the evaluation is ordered by the court, the report of the evaluation is sent to the court. Each court has its own policy with respect to making the report available to the lawyers in the case. Lawyers sometimes request that the consultant furnish them with the report even when this would be improper. When one is in doubt about any aspect of the legal proprieties, the court clerk is usually the appropriate person to consult.

Financial arrangements need to be attended to carefully. Many clinicians require a retainer fee before embarking on the evaluation because they have learned that, in adversarial settings, the child expert's bill may be overlooked or may be deliberately left unpaid by disgruntled parents even when a court order obliges them to pay the costs. Whatever the fee arrangements, they should be clarified at the outset, including the charges for expenses entailed in reviewing case materials, preparing the report, and testifying in court.

Outside materials should not be used without signed permission of those involved or through approval by the court. In divorce cases, the child's pediatric and school records should be obtained, because they provide essential information including the child's educational family, developmental, and health history. It is optimal if teachers or day care providers can write a paragraph about the child's school experience to supplement checklist forms that are used by many experts. If the child is or has been in counseling or psychotherapy, a brief report with the informed consent of the parents should be requested to include the presenting complaint, diagnosis, and progress or termination summary. If such an intrusion into the confidentiality of an ongoing treatment would significantly disturb the treatment, the question should be raised whether the additional information is warranted, considering the burden it would place on the child's or adult's treatment. All such reports should be in the form of written documents that can potentially be reviewed by anyone in the court proceeding. Verbal reports, that is, hearsay, do not carry the same weight in court. Drug and alcohol treatment, psychiatric hospitalization, and criminal records concerning the adults are pertinent for review.

Clinicians should be familiar with the guidelines developed by their professional disciplines. These include the following: "Practice Parameters for Child Custody

Evaluation" (*Journal of American Academy Child Adolescent Psychiatry*, October, 1997); "Guidelines for Child Custody Evaluations in Divorce Proceedings" (*American Psychologist*, July, 1994) and "Guidelines for Psychological Evaluations in Child Protection Matters" (*American Psychologist*, August, 1999).

## CLINICAL INTERVIEW

In preparing for the report and court testimony, the child expert evaluates the child's developmental and emotional level of functioning and describes what the child's needs are and whether there are special needs to be taken into account. The central issue is the child's relationship with the competing caregivers. As Anna [Freud \(1971\)](#) points out in her 1968 comment on the *Painter v. Bannister* case:

Clinical and analytic experience teaches us that children can fill many different roles in the emotional lives of their parents or of other adults. They may be no more for them than a piece of property which is valued egoistically as an extension of the adults personality, when this happens they serve the adult's needs, while their own developmental needs remain unconsidered. In contrast to this, they may be loved unselfishly, as persons in their own right, with their own needs of paramount importance. Further, they may be no more than a pawn in a game, with no importance of their own, except that possession or dispossession of their persons signifies victory or defeat for the warring factions.

The task of staying focused on describing the child's needs in a custody case is difficult for all adults, including the clinician. One significant source of difficulty is the adult's effort to identify with the child's sense of helplessness in the midst of unrelenting adult conflict. Because of the demanding nature of these cases, many clinicians pace themselves cautiously as to the number of custody evaluations they undertake. Specializing in such difficult work increases the risk that one's approach will become mechanical and superficial. Retaining a generalist's view lowers that risk and emphasizes that each case will be evaluated as unique.

In the consulting room with the family, it is useful and appropriate to review the purpose of the evaluation, its lack of confidentiality, the legal motives for the evaluation, and the requirement of submitting a written report to the court. Similarly, it is important to clarify that the report and testimony, where indicated, is designed to assist the judge because the judge, not the evaluator, has the authority and responsibility to make decisions.

The evaluator begins by meeting with the child's parents, usually individually. A sufficiently detailed history is taken to provide a general sense of the parents' own background, personality, and level of functioning. If severe character pathology or a psychiatric illness that interferes with parenting is evident, a more systematic mental status examination and diagnosis may be desirable. This may indicate the need for further interviews and formal psychological testing. The parents are each asked to describe the child's developmental history, to explain how they get along with their child, and to discuss what the parent believes would be the best arrangement for the child. A discussion of the cause of the breakdown of the marriage and an idea of why the parents cannot cooperate with each other may provide further insight by which to gauge the intractability of the conflict and to clarify realistic options for the child.

## EVALUATING THE YOUNG CHILD

The child's age and developmental level influence the interviewing process. The appropriate method for assessment of children younger than 5 years old is through play and the administration of a developmental examination. A systematic developmental evaluation for younger children, such as the Yale Developmental Scales, provides an examination of five domains: gross motor, fine motor, speech and language, adaptive, and social functioning (see [Chapter 40](#)). Such an assessment affords a reliable method of determining the child's level of functioning as well as a way of screening for deviations and vulnerabilities. Constitutionally and environmentally generated difficulties can be identified in formulating a child's special needs.

From the history, the developmental examination, and the play situation with younger children, useful inferences can be made about the child's patterns of attachment, separation, mood regulation, and bodily functions. In this systematic way, the clinical child expert prepares an inventory that becomes the basis for making recommendations to the court as well as for acknowledging the limits of what can be determined in such consultations. It is both tactful and useful in maintaining the primary focus on what is the least detrimental alternative for the child, to avoid "scapegoating" the parent who the expert feels should not be the custodial parent.

The developmental and clinical (play) assessments are also used to explore how well each contending party meets the child's needs for feeling wanted, for providing continuity of affectionate care, for uplifting expectations, and for safety. Having at least one adult who meets these needs of the child is essential in supporting the child's capacities for self-regulation and in establishing development-promoting attachments. In turn, these capacities enhance the child's ability to be comforted and soothed, to engage in age-appropriate contacts with peers, and to feel comfortable in the care of substitute caregivers.

## EVALUATING THE SCHOOL-AGE CHILD

Both the developmental and play assessments of a younger child usually occur in the presence of a parent, and this provides the opportunity to observe and differentiate the child's experience with each parent. The school-age and preadolescent child should be interviewed individually as well as together with each parent. Some evaluators find it useful to structure the interview with the parents to include a "task" the child and parent are asked to work on together. Leaving the interview unstructured can provide an opportunity to observe the child and parent in spontaneous interaction such as at play together, in conversation, in silence, and in conflict. In these observations, the quality of the child's relationship to the parent can be noted: Is he or she engaged, distant, apprehensive, responsive, avoidant? The play interview is generally considered the most useful process in assessing a child of this age who has not yet developed the cognitive ability to rely on conceptual thinking and on language for full expression.

Discussion with the school-age child of the reasons for the evaluation, including the courses interest in the custody or visitation issue, can be informative and fruitful when comfortable and handled sensitively. The interview may include drawings, thematically developed play, and occasionally the opportunity to evoke tactfully, often indirectly (e.g., "let's pretend"), the child's opinions and desires with respect to the custody and visitation issues. Play and drawings are phenomena that may reflect a child's imagination, fantasies, conflicts, and life experiences, as well as developmental level and intelligence.

Direct questioning of the child about a preference in living arrangements is risky because it often increases the child's anxiety about loyalty conflicts. Asking the child to choose one parent over the other may increase the child's fear of losing the other parent, thus involving a painful confrontation with the child's strong wish to have the parents stay together, albeit more as mother and father than as husband and wife. When the child's preference can be determined, it is taken into account as an important but not decisive factor. The weight given to the school-age child's preference should be assessed individually in each case.

## EVALUATING THE ADOLESCENT

Adolescents need not be seen routinely in custody assessments, because they are considered able to play an active and often decisive role in making their own choices. Occasionally, in special circumstances in which issues of physical safety, delinquent or behavioral problems, or a parent's mental illness are involved, an assessment may be required. Before the age of formal operational thought, which occurs around 11 years, children have limited ability to project the idea of themselves in the future and to sense how the past will influence the future. Beginning in early adolescence, cognitive and psychological development, including the push toward increased independence, will enhance the adolescent's capacity to be more active in custody decisions. With support, the older child and adolescent can usually begin to assess his or her own needs and to form sound judgments based on actual life experiences about custody and visitation arrangements (Schowaher, 1979).

## COURT REPORT

Once the clinical evaluation is completed, the report is prepared for the court. It reiterates the court's questions, cites all reviewed reports and documents, identifies all persons interviewed and specifies the dates and time spent in all interviews and reports, summarizes historical and clinical interview material, and concludes with a summary and recommendation. Court testimony is discussed in [Chapter 114](#). In child custody and placement cases, it is particularly important for the expert to review his or her testimony with the child's attorney when possible, to remain focused on the child's point of view, and not to go beyond professional expertise and knowledge. The court's interpretation of a New Jersey statute, for example, requires the expert to testify to a prediction that a child's removal will cause irreparable harm. This poses a dilemma for the expert because no one can predict with accuracy the long-term future outcome of such a placement change or the development of future relationships (1). As child experts, it is essential and valid to use the capacity for short-term predictions to indicate what immediate psychological injuries can occur if the child's best interests are corroded by the passage of time. The child should not be exposed to the risk of avoidable injury to put fairness to the contending

adults ahead of what would be least harmful to the child.

The nature of the child's relationship with each of the contending adults may enable the expert to document that one parent is more of a primary psychological parent than the other, despite socioeconomic consideration, or that each of the contending adults, for different reasons, is a primary psychological parent. In the latter instance, if the parents cannot decide and prefer that a stranger, the judge, decide, the expert should indicate that each of the parents is a primary psychological parent, equally competent for different reasons. If the parents or contending adults cannot decide or agree, the court should use the principle of least detrimental alternative to meet the best interest standard of making a decision and should not allow the passage of time to be corrosive to the child while adults debate how to be fair to each other.

## PLACEMENT EVALUATIONS

Unlike the desirability of private dispute resolution involved in divorce cases, foster care cases involving placement disputes are more regularly subject to court process and decision making. The court regulates the functioning of the state child welfare bureaucracy by imposing time limitations on temporary custody arrangements. Through its terminations of parental rights process, the court legalizes permanent placements for children who cannot return to the care of their biological parents. The questions are as follows: What is the best permanent placement for the child? Can the child ever be returned to the biological parents?

The child expert evaluating cases of abuse, neglect, or abandonment follows the previously discussed placement principles. The need for permanency and security is essential in these cases. Whereas divorce conflict cases pose the difficulty of raw familial passions, child welfare cases present a different challenge. Often, the children to be evaluated have already suffered grave psychological damage as a result of chronic deprivation, multiple placements, and other conditions noxious to the developing child. It may be frustrating to the evaluator to recommend an outcome for the child that, although it may be the least detrimental, seems so far from ideal. An evaluator's inability to tolerate the available least detrimental alternative for the child can lead to harmful delays and postponements and recommendations for an unknown or unrealistic solution. Such delays and indecision can inflict further psychological damage on the child. The child's sense of time should be taken into account in not delaying, beyond the younger child's tolerance, the finding of at least one qualified adult who can provide the continuity of affectionate care as described earlier. It is important to observe the child's current realities and to make the best of what is available.

Evaluations involving allegations of sexual abuse, when there is a finding of physical damage, require the child to be ensured of protection from further abuse ( [Solnit et al., 1992](#)). This means exclusion of the abuser, if that person can be identified, or a documented change in the child's circumstances that addresses the source and cause of the problem, as much as it can be determined. When the pediatric examination has been unable to document physical injury, the evaluator is unlikely to be able to know with certainty whether abuse occurred. Therefore, the mental health expert should not accept a request to determine whether sexual abuse has occurred, but should suggest the request be refocused to a psychological assessment of the child's general development and relationship with the caretakers for the purpose of determining safety, placement, visitation, or custody issues.

---

### CASE ILLUSTRATION: *Ireland v. Smith*

In this Michigan case, a 15-year-old unmarried adolescent girl gave birth to a daughter who was raised in the mother's home with the mother as the custodial parent, assisted in child care by the maternal grandmother and the maternal aunt, while she completed her high school education. When the child was 1 year of age, the father, who had acknowledged paternity at birth, began to visit.

When the child was 3 years, 2 months of age, the mother filed a suit seeking the father's child support in preparation for her anticipated move to pursue a college education and to live independently with her daughter. The father then petitioned for custody of the child.

The judge found that the mother had established a custodial environment for the child, that is, that the child looked to the mother for guidance, discipline, and the necessities of life. He found that the day-to-day care of the child was provided by the mother and that the child was acquainted with her father but in a way that was of necessity limited by the structure of the visiting relationship.

### Comment

In this case, the judge described himself as attempting to reach a decision that would represent "the child's best interest." He followed the state statute in examining the relative abilities of each parent to provide affection, guidance, and other material needs. He found the central issue to be maintaining continuity, but he construed continuity to mean of physical environment rather than of the child's primary tie to the mother. He wrote:

The mother's program would require that the child be in day care. The child was in a program at the University of Michigan which apparently was appropriate and resulted in the child having a meaningful experience. It would be the mother's intention to continue this on until such time as she either graduates, as previously stated, or her marital circumstances somehow change. For the purpose of deciding this case, the Court would have to assume that it is the mother's intention to maintain the child at the University of Michigan for some considerable number of years. This issue is pivotal.

The judge decided to intrude into and violate the integrity of this child's ongoing adequate family and concluded that the child's best interest was to be moved to the father because, during the day when the mother was in class, the paternal grandmother, a "blood relative," would be preferable to a day care program for the child. Thus, while espousing the central importance of the principle of continuity in the life of a young child who is developing well, he rendered a decision contrary to the principle. The judge did not make reference to any involvement by a child expert whose opinion could have assisted him to accomplish his stated goal [\(2\)](#).<sup>3r</sup> (

---

### CASE ILLUSTRATION: *Prost v. Greene*

In the *Prost v. Greene* case the parents separated after an 8½-year marriage, at first under the same roof and then 9 months later in separate domiciles when the mother received temporary physical custody with liberal visitation for the father. In a lengthy trial, each parent sought divorce, support, property, and custody of their sons 7 and 4 years of age. Even though the children were doing well in a custody arrangement that had been in place for more than 1 year, the judge reversed the custody and awarded sole legal and physical custody to the father. In her opinion, the judge wrote "...it is plain to the court (and should be to any other objective observer) that plaintiff [the mother] is simply more devoted to and absorbed by her work and her career than anything else in her life, including her health, her children and her family."

### Comment

For the child expert, it is instructive to observe that the judge, finding the expert testimony of the child psychiatrist "unpersuasive," complained that the expert "seemed overly focused on the parents' emotional makeup and on the relationship/conflict between them, rather than on the best interest of the children as evidenced by their current psychological status and relationship to each parent." In the absence of convincing testimony explicating the developmental needs of each child and the nature of the children's relationship with each parent, the judge relied on her own intuition, value judgments, and personal reactions to the parents' personalities.

Apparently, the needs of Matthew, age 7, and Jeffrey, age 4, were not credibly articulated in the courtroom and therefore did not form the central consideration in the decision. Rather, the judge in this case wrote:

...Children learn from the intensive presence, participation and involvement of a parent in their lives, from the frequent and sincere demonstrations of a parent's love and concern for them, from a parent's efforts to help them solve their problems, and from their observation that a parent enjoys being with them and, indeed, has fun with them. On all these fronts, the evidence is clear, defendant has it way over plaintiff.

The judge's language demonstrated how, in the powerful current of divorce conflict, there is a tendency to be drawn into taking sides and to focus on the adults. The judge further overstepped the bounds of her role when she chided the parents, "The parties should be ashamed of themselves, but it does not appear that they are." The judge's reproach of the parents prevented her from conveying the "experience, wisdom, and compassion...to fashion an appropriate [3](#).nedy" (

---

### CASE ILLUSTRATION: BABY RICHARD

In this case, Richard's parents began living together in the fall of 1989. Daniella, Richard's mother, became pregnant in June 1990, and Richard was born March 16, 1991. Otakar, Richard's father, lived with Daniella and provided for all of Daniella's expenses during her pregnancy until late January 1991, when he returned to his native Czechoslovakia to attend his gravely ill grandmother. Daniella was informed by a member of Otakar's family that he had reinvolved himself in a romantic relationship with a former girlfriend. Daniella felt so betrayed and distressed by this news that she fled the apartment she shared with Otakar, avoided contact with him, and then informed him that their baby had died. As a single mother, she executed a consent for adoption 4 days after Richard was born. Daniella refused to furnish Otakar's name to the adoptive parents or to their lawyer, although she did inform them that she knew his identity.

When Richard was 57 days of age, Otakar learned that Richard was alive and had been placed in adoption. Otakar married Daniella and immediately began legal efforts to recover custody of his son. For the next 4 years, legal proceedings postponed the decision for Richard. First, the trial court ruled that Otakar did not show sufficient interest in the child in his first 30 days of life and therefore was found to be an "unfit" parent. As an "unfit" parent, Otakar's consent for adoption was not necessary. The appellate court then confirmed the trial court, by citing a best interest standard that at age 2 years, 5 months, Richard's adoptive parents were the only parents he had known. The judge wrote of Richard, "He has not touched or seen Daniella since four days after his birth and he has never spoken a word to her. Nor has he ever touched, seen, or communicated with Otakar. In fact, he is totally unaware of the existence of Daniella and Otakar." He further noted, "Since Richard was a newborn, John and Jane Doe have done everything with Richard that is the essence of being parents, and Richard has done everything with them that is the essence of being a son."

The Supreme Court of Illinois heard the appeal and reversed the decision of the trial and appeal courts, resulting in Richard's placement at 4 years of age with his biological parents, who were total str<sup>4</sup>gers (

### Comment

The psychologically distinctive role of the father begins early on with his anticipation of the child's birth. Through holding, feeding, protecting, and playfully interacting with the baby, he becomes a responsive and competent caretaker, central to the child. The father's presence is positively associated with the child's developmental progress [Pruett, 1987](#)). Separation from such a parent to whom the child is emotionally tied can cause shattering loss, regression, and disruption to the child's sense of stability and security.

In the case of Richard, Otakar could not have been considered Richard's "father" in any but a biological sense. The legal system, by its delay of 4 years and by its awarding a child rather than other compensation to Otakar, failed to uphold its best interest standard. The court recognized that a grave injustice had been done to Otakar—first by Daniella, who concealed Richard's existence from Otakar, then by the state, which concealed Otakar's identity and whereabouts from the adoptive parents and their lawyer, and finally by the failure of the adoptive parents and the various legal representatives to make a decision based on the child's best interests. This case illustrates the way in which the child's best interest comes to be subordinate to the court's priority of fairness to an aggrieved adult ( 4). The best guide for the child expert is: Put yourself in the place of the child.

The epidemiology and prevention of child and adolescent psychiatric disorders are closely tied together. On the one hand, data from epidemiology support the need for effective prevention programs and provide essential data for the prevention enterprise in child psychiatry. On the other hand, the results of prevention initiatives can add to our understanding of aspects of epidemiology such as the identification of true causal risk factors.

*Epidemiology* is concerned with the study of child psychiatric disorders in *populations* of children and adolescents (Lilienfeld, 1976). It differs from clinical work, which deals with children (and their families), usually one at a time, who actively seek help because of troublesome symptoms or behaviors and associated impairments. Epidemiology is concerned not just with the prevalence and distribution of child psychiatric disorders that can be obtained from cross-sectional studies, but through prospective studies, descriptive epidemiology is also concerned with the incidence or new cases of disorder, the temporal sequence of disorders, the discovery of causal risk and protective factors, and the developmental pathways along which risk and protective factors operate over time to produce healthy and unhealthy outcomes. Experimental epidemiology (Robins, 1978) moves into the prevention area, with its concern of establishing whether or not a risk factor is causal for a disorder. It accomplishes this by determining whether an intervention program aimed at reducing the incidence of the risk factor results in a reduction in the incidence of the disorder of interest. Figure 116.1 draws attention to the two uses of epidemiologic data, scientific and administrative or related to service (Earls, 1989; Robins, 1978). On the administrative side, the figure illustrates the differences among primary, secondary, and tertiary prevention by pointing out where in the development of the disease process the different strategies apply. Primary prevention comes into play before the initiation of the pathologic processes in which successful interventions can prevent the onset of disease. Secondary prevention focuses on altering the expression of disease after its onset, whereas tertiary prevention is concerned about minimizing the severity of disease and promoting recovery and remission (Caplan, 1964; Cowen, 1983). The figure also illustrates that, on the scientific side, epidemiology is concerned about causal risk factors involved not only in the onset of disease or disorder, but also in its subsequent course in terms of persistence, remission, and relapse.

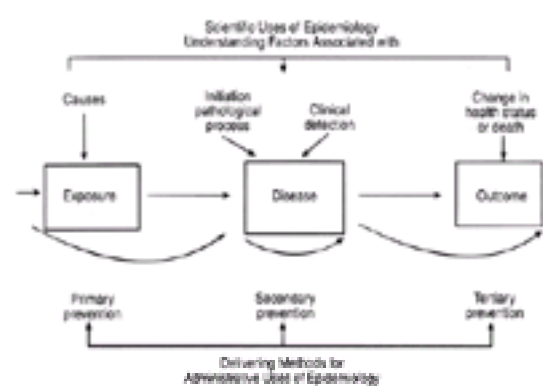

Figure 116.1. The uses of epidemiology.

The case for prevention of child psychiatric disorder rests on the limitations of clinical services to reduce the burden of suffering from these conditions. In the first instance, there is a mismatch between the number of children in the community with clinically important psychiatric disorders and the ability of clinical services to assess and treat them (Boyle and Offord, 1988; U.S. Congress, 1986). Findings from community surveys indicate that the prevalence of one or more psychiatric disorders varies between 17.6% and 22.2% (Costello, 1989; Costello et al., 1996). Further, in a more recent article of 52 separate studies with data on the prevalence of psychiatric disorder in children and adolescents in community populations, the mean prevalence was 15.8% (Roberts et al., 1998). The prevalence rate drops, of course, in one study to 11%, if the diagnostic criteria require significant functional impairment at home, at school, and with peers (Shaffer et al., 1996). It is estimated, however, that approximately 6 million to 9 million children in the United States have serious emotional disturbances (Friedman et al., 1996; Lavigne et al., 1996), and this accounts for 9% to 13% of all children (Friedman et al., 1996; Friedman et al., 1998). Given these prevalence estimates, it is very unlikely that a jurisdiction will be able to finance and staff the clinical services required to serve children with established psychiatric disorders adequately. To support this contention, many young people in the United States with a diagnosable mental disorder do not receive any mental health services at all (Burns et al., 1995; Leaf et al., 1996). A report in the mid-1980s (U.S. Office of Technology Assessment, 1986), indicated that approximately 70% of children and adolescents in need of treatment did not receive mental health services. A more recent report (Burns et al., 1995) indicated that only one in five children with a serious emotional disturbance used mental health specialty services, and most of these children failed to receive any services at all as reported by their families. A second limitation of the clinical enterprise centers on rates of compliance with assessment and treatment regimens. For example, many parents of children at high risk of emotional and behavioral problems do not enroll in parent training programs even when they are widely available (Cunningham et al., 1995; Cunningham et al., 2000; O'Donnell et al., 1995). Further, of families who begin treatment because of their child's emotional or behavioral problems, 40% to 60% terminate treatment prematurely (Kazdin, 1996). In addition, Armbruster and Fallon (1994) found that most children who enter outpatient treatment attend for only one or two sessions. Third, considerable time can elapse between when parents seek help for their child and when they actually receive assessment and treatment services. During this time interval, the child and his or her family can be expected to suffer, and perhaps the disorder and associated impairments will worsen and become more entrenched. Fourth and last, although considerable progress has been made in discovering promising treatments for child psychiatric disorders (Kazdin and Weisz, 1998), research is needed to demonstrate the effectiveness of treatments for children in actual practice settings as opposed to evidence of efficacy in controlled research settings (Weisz et al., 1995). In addition, there is no evidence that enriched systems of care for child mental health problems result in improved clinical or functional outcomes, (Bickman et al., 1997; Bickman et al., 1999). The considerable limitations of clinical work alone to reduce the suffering from emotional and behavioral problems in children has motivated not only researchers and policy makers but also clinicians to examine carefully the possibilities of developing and evaluating prevention efforts (Durlak and Wells, 1997; Institute of Medicine, 1994).

This chapter first covers selected aspects of epidemiology and then moves on to issues and findings in the prevention field. The epidemiology section begins with a

discussion of issues and then provides a summary of major findings.

## ISSUES IN EPIDEMIOLOGY

Using data on the epidemiology of conduct disorder, hyperactivity, anxiety disorder, and affective disorder, selected issues in child psychiatric epidemiology are now discussed.

### Measurement of Disorder

#### BOUNDARY BETWEEN NORMAL AND ABNORMAL

Two different approaches are used for identifying disorder in child psychiatric epidemiology ([Achenbach, 1997](#); [Jensen et al., 1999](#)). In the first, termed the *categorical approach*, the nosologic categories of psychopathology are chosen by a committee of experts who then decide what criteria are required to be fulfilled for an individual patient to qualify for a particular disorder. This strategy is viewed as a “top-down” approach, whereas the second strategy, the *empirically based approach*, works from the “ground up.” Statistical techniques are used to derive sets of items that occur concomitantly and thus can be viewed as syndromes. The validity or usefulness of the resulting diagnostic categories is judged by the extent to which the placement of a child in a diagnostic category provides some added information about the cause, course, prognosis, and response to treatment in the child with the disorder. These approaches mirror the debate about whether child psychopathology is better conceptualized as a categorical or a dimensional phenomenon. More recent work suggests that both approaches are useful ([Achenbach, 1997](#); [Jensen et al., 1999](#)).

Regardless of which of the two approaches is used, clinicians, administrators, and policy makers want to be able to know when a child qualifies as having a clinically important psychiatric disorder. This necessitates setting a threshold based on symptom frequency and severity that, when a child exceeds it, leads the clinician to state that the child is said to have a disorder; when the child is below the threshold, he or she is classified as not having a disorder. The setting and justification of a threshold identifying children with and without disorder are critical issues in child psychiatry. For example, changing a threshold for disorder even slightly can have noticeable effects not only on prevalence rates but on patterns of correlates and comorbidity ([Boyle et al., 1996a](#); [Robins, 1985](#)). The threshold problem extends beyond symptoms to other aspects of criteria for disorder such as impairment. Again, measures of impairment usually are on a continuum, and the issue of where the threshold should be set to identify clinically important impairment must be addressed. Unfortunately, there is a paucity of data justifying existing thresholds for disorder in child psychiatric epidemiology. This immediately raises the issue of the meaningfulness of cases identified in community surveys and, in turn, raises questions about the implications of the results of these surveys for estimating service needs.

#### COMORBIDITY

In cross-sectional epidemiologic studies of children in the general population, rates of concomitant occurrence of child disorders, far in excess of chance, have been reported ([Anderson et al., 1987a](#); [Bird et al., 1993](#); [Costello et al., 1988](#); [Costello et al., 1996](#); [Fergusson et al., 1993](#); [Offord et al., 1987a](#); [Velez et al., 1989](#)). In the Ontario Child Health Study, 67.8% of the children, 6 to 16 years old, with a diagnosis of at least one of the four psychiatric disorders had one or more additional diagnoses ([Offord et al., 1989](#)). More recently, in the Great Smoky Mountain Study, 100 of the 307 children with a diagnosis had more than one disorder, and of those with behavior disorder, comorbidity was 38% ([Costello et al., 1996](#)).

Certain factors can promote high rates of comorbidity ([Caron and Rutter, 1991](#)). They include the following: setting low thresholds so prevalence rates of individual disorders are high; detection artifacts; problems of classification, for example, using the same symptoms to define different categories of disorder; and when two disorders coexist in cross-sectional studies but one of them is an early manifestation of the other. The high rates of comorbidity have raised the issue of the extent to which individual disorders are separate entities, that is, with a distinctive origin, pattern of family history and associated features, prognosis, and response to treatment ([Robins and Guzé, 1970](#)). Although, as just noted, methodologic factors can contribute to high rates of comorbidity, current evidence strongly supports the idea that methodologic factors are not a major cause of comorbidity ([Angold et al., 1999](#)). Developmental psychopathologists use the concepts of homotypic and heterotypic continuity ([Angold et al., 1999](#)). This approach leads to two types of comorbidity, namely, one that examines comorbidity between disorders within a diagnostic grouping (homotypic; e.g., oppositional defiant disorder and conduct disorder), and another that deals with comorbidity between disorders from different diagnostic groupings (heterotypic; e.g., depression and conduct disorder). An elegant review ([Angold et al., 1999](#)) not only discusses the causes of homotypic and heterotypic comorbidity but summarizes the literature on comorbidity rates of different disorders. An important deficit in the comorbidity literature is the lack of knowledge about the sequence of psychiatric disorders in childhood, although evidence indicates that hyperactivity precedes conduct disorder ([Offord et al., 1992](#)).

#### DISAGREEMENTS AMONG INFORMANTS

There is a low agreement among informants about children's behaviors. This finding applies to both self-administered problem checklists ([Achenbach et al., 1987](#)) and lay-administered structured interviews ([Boyle et al., 1993a](#); [Edelbrock and Costello, 1988](#)), and it cannot be accounted for by poor reliability or lack of validity of assessment procedures. The correlations among informants are usually less than 0.30, and thus no one informant can substitute for all others ([Achenbach, 1997](#)).

A corollary of the lack of agreement among informants is that how many children and which children are identified as having a disorder depend on which informant has provided data for the assessment. For instance, in the Ontario Child Health Study, the prevalence of parent-identified conduct disorder for children 6 to 11 years old is 1.4%, whereas the prevalence of teacher-identified conduct disorder is 4.9%, and further, low family income has a strong independent relationship with teacher-identified conduct disorder, but not with parent-identified conduct disorder ([Offord et al., 1989](#)). Thus, both prevalence rates of disorder and their associated features will be affected by the informant who provides the data. Further, the predictive value of assessment data used to classify disorder has been reported to vary by informant ([Boyle et al., 1993b](#); [Loeber et al., 1991](#)).

These findings suggest that the identification of childhood disorder is influenced by both the contexts in which the assessments are carried out and the perception of informants. Unfortunately, the factors influencing informants' perceptions of children's behaviors are not well understood. For instance, whereas some studies have found that a mother's mental health (particularly her level of depression) is a strong predictor of mental health problems expressed by her children, the validity of the finding is in doubt because most of these studies have relied on maternal reports as indicators. However, a recent study ([Najman et al., 2000](#)) reports that anxious or depressed mothers of 14-year-old children tend to report more cases of child behavioral problems than not only their mentally healthy counterparts but also the children themselves. This finding raises questions about the validity of reports of child behavior by persons who themselves are experiencing emotional distress. It is not known which informants provide the best information for classifying children into groups that are valid and provide useful data on the usual criteria of etiology, prognosis, and response to treatment. Several strategies have been developed to deal with the dilemma that different informants identify different children as being disordered. They include the following: combining information, that is, giving value to any positive rating regardless of informant; giving priority to different informants about different kinds of behavior, for example, assigning priority to the child's report of internal mood and to the parent's report of behavior problems; assigning a confidence rating to each behavior proportionate to the amount of agreement among observers; and considering disorders informant specific and making no attempt to combine reports from different informants to provide an overall classification independent of informants ([Institute of Medicine, 1989](#); [Offord et al., 1989](#); [Offord et al., 1996](#)). Again, as with data from individual informants, it is not known which of these approaches of combining inputs from different informants results in the most useful and valid classification system.

#### INSTRUMENTATION

Three types of instruments are used to measure psychiatric disorder in community surveys: structured interviews (e.g., the Diagnostic Interview Schedule for Children) ([Shaffer et al., 1996](#)), semistructured interviews [Schedule for Affective Disorders and Schizophrenia for School-Age Children e.g., the (K-SADS)] ([Chambers et al., 1985](#)), and checklists (e.g., those used in the Ontario Child Health Study) ([Boyle et al., 1993a](#)). Checklists have a major advantage and disadvantage compared to interviews. Because they are self-administered, they are cheaper, but there is no opportunity to clarify wording or to probe responses, for example. Three studies compare the classification of psychiatric disorders by checklists versus structured interviews among children and youth in community populations, and in none of the studies was one strategy superior to the other, although they classified many different children as being disordered ([Boyle et al., 1996b](#); [Boyle et al., 1997](#); [Gould et al., 1993](#)). Further, the two kinds of interviews resulted in different prevalence rates of disorder ([Edelbrock and Costello, 1988](#)). Semistructured interviews focus on specificity, with higher thresholds and fewer children exceeding the cutoff for disorder, whereas structured interviews center on sensitivity, with lower diagnostic thresholds, resulting in more children reaching criteria.

Two major issues in this area are the difficulty in assessing psychopathology in young children and the unsureness of what to use as the “gold standard” in deciding

on the validity of cases identified in community surveys. Everyone agrees on the importance of obtaining the child's viewpoints of his or her emotions and behaviors, and there is an understanding that data from informants such as parents or teachers cannot substitute for information received directly from the child ( [Harter, 1982](#)). One problem is that it is difficult to obtain reliable interview data from children less than 11 years of age ( [Achenbach et al., 1987](#); [Edelbrock et al., 1985](#)) unless one uses a pictorial instrument such as the Dominic questionnaire ( [Valla et al., 1994](#); [Valla et al., 2000](#)). Concerning the second issue, establishing the standard for evaluating the validity of diagnostic categories identified by instruments in community surveys, usually the clinician workup is the standard that applies. Regardless of what data the clinician uses to arrive at a clinically important diagnosis, the procedure must have adequate reliability, both interrater and test-retest reliability.

### Measurement of Other Variables

All the issues that apply to the measurement of disorder pertain to the measurement of other variables. For example, as noted previously, the measurement of impairment is on a continuum, and what is needed, as with disorder, is a meaningful threshold that distinguishes children with and without clinically important impairments. Further, data on the presence, type, and severity of impairments are informant specific ( [Sanford et al., 1992](#)). There is a high degree of agreement between the presence of disorder and impairment within a particular informant and a low level of agreement between the two across informants. What is required are reliable and clinically important measures of impairment that are objective, that is, independent of data from parents, teachers, and children. One last point is that measurement error in correlates plays an equally important role to error in the measurement of disorder in distorting the strength and form of the relationship between a correlate and a disorder. Improving the reliability of measurement has been shown to result in larger associations between correlates and childhood psychiatric disorder, and it may increase the opportunity of revealing differential associations among variables ( [Boyle and Pickles, 1998](#)).

## FINDINGS IN EPIDEMIOLOGY

### Selected Correlates

#### INDIVIDUAL CHARACTERISTICS

##### *Age and Sex*

The prevalence of one or more psychiatric disorders in children and adolescents increases with age. In one review ( [Roberts et al., 1998](#)), the mean prevalence rates for preschool children, preadolescents, and adolescents were 10.2%, 13.2%, and 16.5%, respectively. Regarding sex differences, findings from community studies indicate that externalizing problems are more prevalent in boys, and internalizing problems are more prevalent in girls ( [Achenbach et al., 1991](#); [Anderson et al., 1987b](#); [Offord et al., 1987b](#); [Verhulst et al., 1985](#)). In the preadolescent age group, psychiatric disorder is more common in boys because of the high rate of externalizing problems in boys; in adolescence, girls have a higher rate of disturbance than boys, primarily because of the marked increase in internalizing problems among girls ( [Offord et al., 1987b](#); [Zahn-Waxler et al., 2000](#)). Studies have shown considerable stability of externalizing problems over several years ( [Cohen et al., 2001](#); [Feehan et al., 1993](#)), and recent evidence suggests that the stability of internalizing problems may be at least as high from childhood to young adulthood ( [Hofstra et al., 2000](#)). These findings support the contention that the early onset of problems is prognostic of chronic and serious problems in adolescence and beyond ( [Moffitt, 1993](#); [Rutter, 1997](#)). Because most of the studies of internalizing problems have focused on girls, and most studies of externalizing problems have focused on boys, little is known about gender differences on timing of onset of specific disorders and their subsequent mental health outcomes.

##### *Racial and Ethnic Minorities*

The prevalence of child psychiatric disorders has been reported to vary by race and ethnicity ( [Costello et al., 1997](#); [Roberts and Chen, 1995](#)). A survey of high school students in New Mexico found that depressive symptoms were more common in Mexican-Americans than Anglo students ( [Roberts and Chen, 1995](#)). A previous population survey of 10-year-old children in an inner London borough revealed that, based on teacher data, but not on parent information, there were elevated reports of behavioral problems, but not internalizing symptoms in West Indian children ( [Rutter et al., 1974](#)). However, not all groups of nonwhite children have increased rates of psychiatric disorders. For example, in a sample of 181 Chinese-American children, ages 5 to 17 years, attending a Chinese school in New York city, the rates of internalizing, externalizing, and total problem scores were significantly lower than Achenbach's American norms by age and sex ( [Chang et al., 1995](#)). Two major limitations of this work are the low response rate to the study (38%) and the inclusion of only one school. Prevalence rates of emotional and behavioral problems in Native North American children vary markedly among tribes and regions ( [Yates, 1987](#)). Finally, in a report from the public-use subsample of the National Longitudinal Study of Adolescent Health (Ad Health) ( [Bearman et al., 1997](#)), the authors compared the psychosocial adjustment of U.S. adolescents, grades 7 to 12, among three groups: single-race white (both parents white only), single-race minority (parents of same minority status), and multiracial (parents of differing racial or ethnic background) ( [Cooney and Radina, 2000](#)). Significant differences between the multiracial adolescents and the two groups of single-race adolescents were found on fewer than half of the school, behavioral, and psychological dimensions that were covered, and almost all the differences involving the multiracial adolescents were with the single-race white group. For example, for boys, multiracial adolescents were distinguished from their white peers by higher rates of counseling use, grade retention, suspension and expulsion from school, and depression scores. For girls, the same results applied, except for depression. In this study, the subsample of adolescents included all lived in households with both their biological parents, and thus the possible confounding effects of family structure on adolescents' adjustment were eliminated.

Two causal risk factors play a major role in placing children of certain racial and ethnic groups at increased risk of emotional and behavioral problems, namely, growing up in conditions of family adversity and difficulty in performing satisfactorily in school ( [Offord, 1990a](#)). Nevertheless, the causal risk factors for psychiatric disorder may vary for different groups. For instance, in the Great Smoky Mountain Study of Youth, family mental illness was associated with child psychiatric disorder for Native American and white children, but poverty and family deviance were linked with psychiatric disturbance only among the Native American children ( [Costello et al., 1997](#)).

##### *Chronic Health Problems*

Children with chronic medical illness, especially when the illness is associated with disability, have more than three times the rate of psychiatric disorders and social adjustment problems compared with their peers without chronic illness ( [Cadman et al., 1987](#)). Most children with chronic medical illness are free of psychiatric disorder ( [Cadman et al., 1987](#); [Perrin et al., 1987](#)), and no firm evidence indicates that a certain type of disease is associated with a particular pattern of emotional and behavioral problems. There is, however, broad agreement that diseases affecting cerebral functioning directly produce the highest prevalence rates of psychiatric disorder, and within that group, the highest susceptibility appears to be in cases of epilepsy ( [Hoare and Kerley, 1991](#)).

##### *Temperament*

Children from early on in their lives can differ from each other in behavioral patterns such as inhibition, biological irregularity, emotional intensity, and activity level, and there are stable differences between boys and girls ( [Martin et al., 1997](#)). These early differences in emotional reactivity and regulation can be risk factors for childhood internalizing or externalizing problems ( [Rothbart and Bates, 1998](#)). For example, series of studies have shown that early behavioral inhibition is a risk factor for later internalizing disorders ( [Biederman et al., 1993](#); [Rosenbaum et al., 1993](#)), and infants who are highly reactive to unfamiliar stimuli are more likely to be inhibited at age 4 years and more anxious by age 7 years ( [Kagan et al., 1999](#)). Further, it has been reported that "difficult" temperament in infancy and early childhood predicts externalizing and sometimes internalizing problems in preschool and middle childhood ( [Bates et al., 1991](#); [Prior et al., 1992](#); [Shaw and Winslow, 1997](#)).

The concept of *temperament* (the repertoire of traits with which each child is born) has supported the idea that the child is an active participant in creating his or her environment and is not simply a passive recipient ( [Plomin, 1986](#)). Temperaments can be modified during development, particularly by the interaction with the caretaker and the family. For example, a timid child can become more assertive with the help of parental encouragement ( [Kagan, 1984](#); [Kagan, 1989](#)), and the harmful effects of difficult temperament are increased significantly when children live in dysfunctional families ( [Maziade et al., 1985](#)). Many methodologic issues concerning temperament have to be sorted out ( [Prior et al., 1992](#)), including a major one of operationalizing the concept of temperament so it is separate from the measurement of psychopathology ( [Lengua et al., 1998](#)).

##### *Intelligence Quotient, Learning Disorders, and Educational Retardation*

Children who do poorly in school whether because of low intelligence quotient (IQ) or a specific learning disorder are at increased risk of a wide range of psychiatric disorders, including conduct disorder ( [Rutter et al., 1970](#)), hyperactivity ( [Hinshaw, 1992](#)), and overanxious disorder ( [Velez et al., 1989](#)), as well as delinquency ( [Lynam et al., 1993](#)). The mechanisms by which poor school performance leads to increased rates of psychiatric disorder have been investigated most fully for

externalizing disorders, especially conduct disorder ( [Hinshaw, 1992](#)). Four hypotheses have been identified: externalizing behavior leads to underachievement; the reverse is true; each leads to the other; and finally, underlying variables common to both (e.g., abnormal temperament, cognitive deficits) account for the relationship. Currently, none of the hypotheses can be eliminated, and additional research is needed to understand more thoroughly the causal process involved in producing the relationship between poor school performance and child psychiatric disorder.

## **BIOLOGICAL FACTORS**

Most child psychiatric disorders are thought to be caused by a combination of biological and psychosocial factors ( [Rutter et al., 1999](#)). There are two kinds of biological influences, namely, those that involve changes in brain structure and function and genetic factors. Investigators have recognized many examples of factors that lead to central nervous system dysfunction resulting in increased rates of mental disorders, including environmental exposure to lead ( [Needleman et al., 1990](#)), intrauterine exposure to alcohol ( [Nichols and Chen, 1981](#)), and prenatal trauma ( [Whitaker et al., 1997](#)). Children with brain disorder have markedly increased rates of psychiatric disorder ( [Rutter, 1977](#)), but the causal processes involved, including their relative strength and patterns of interaction, are not completely understood ( [Brown et al., 1981](#); [Wolf and Forsythe, 1978](#)). Genetic factors are covered in the section on parental psychopathology. Biological factors are thought to be especially important in several disorders including early-onset schizophrenia ( [McLellan and Werry, 2001](#)) and pervasive developmental disorder including autism ( [Piven and O'Leary, 1997](#)), and they probably also have an important etiologic role in Tourette's disorder ( [Leckman et al., 1997](#)), obsessive-compulsive disorder ( [Leonard et al., 1997](#)), and social phobia ( [Pine, 1997](#)).

## **PSYCHOSOCIAL FACTORS**

### *Early Rearing Environment*

Infants and preschool children who are not provided with adequate interaction and a stable emotional and cognitively stimulating environment are at risk of a wide array of poor outcomes in the cognitive, physical, and mental health domains ( [Committee on Integrating the Science of Early Childhood Development, 2000](#); [Janus and Offord, 2000](#); [McCain and Mustard, 1999](#); [Young, 1997](#)). Further, the security of attachment as an indicator of the quality of the relationship between the child and the caregiver is thought to be an important predictor of mental health outcomes in children ( [Rutter, 1995a](#); [van IJzendoorn et al., 1992](#)), such as depression, especially when the child is raised in an abusive environment ( [Sampson and Laub, 1993](#); [Toth, 1996](#)), and to later conduct disorder ( [Sampson and Laub, 1993](#)).

### *Parental Psychopathology*

Parents with psychiatric disorders have children with increased rates of psychopathology in general, and conversely, children with psychiatric disorders are more likely than their peers to have parents with psychiatric disorders ( [Rutter and Quinton, 1984](#)). An example of the former is that children of depressed parents are more than three times as likely as children of nondepressed parents to experience depressive disorder ( [Birmaher et al., 1996a](#), 1996b). An example of the latter is that between 20% and 50% of depressed children and adolescents have a family history of depression ( [Kovacs et al., 1997](#); [Puig-Antich et al., 1989](#); [Todd et al., 1993](#); [Williamson et al., 1995](#)). The mechanisms involved in the transmission of psychopathology from parents to children are thought to involve both genetic and environmental factors ( [Weissman et al., 1997](#)). On the environmental side, impaired parenting, marital conflict, and family dysfunction have been identified as variables mediating the relationship between parental depression and psychopathology in children ( [Cicchetti et al., 1998](#); [Cummings and Davies, 1994](#)).

There is mixed evidence about the specificity of the relationship between parental and child psychopathology. For example, parental depression increases not only the risk of depression in children but also the risk of anxiety disorder, conduct disorder, and alcohol dependence ( [Downey and Coyne, 1990](#); [Weissman et al., 1997](#); [Wickramaratne and Weissman, 1998](#)). However, another study gives some support for specificity. In a controlled family study, the children of parents with alcoholism were found to have elevated rates in particular of conduct disorder, attention deficit disorder, and oppositional disorder ( [Earls et al., 1988](#)). Finally, the childhood mental disorders most likely to have genetic components are autism, bipolar disorder, schizophrenia, and attention deficit hyperactivity disorder ( [National Institute of Mental Health, 1998](#)).

### *Family Factors*

Certain family factors have been associated with increased rates of psychiatric disorders in children. They include single-parent status, poor parenting, marital discord, family dysfunction, and large family size ( [Lipman et al., 1996](#); [Offord, 1990b](#); [Reynolds and Rob, 1988](#)). There are three important issues in this area. First, more information is needed to identify those correlates that are true causal risk factors. For example, marital discord and poor parenting are causal risk factors ( [Offord, 1989](#)). Second, a better understanding is needed about the mechanism or mediating variables by which the causal risk factors result in increased rates of child psychiatric disturbance. Third, and last, there has been little progress in demonstrating the specificity of causal risk factors, that is, that certain factors are associated with one disorder but not another ( [Bauermeister et al., 1994](#)). Most of the evidence indicates the existence of common causal risk factors for multiple outcomes. For example, parental psychopathology has been shown to be a causal risk factor for depression, conduct disorder, and anxiety disorders ( [Institute of Medicine, 1994](#)).

### *Socioeconomic Status*

The strength of the relationship between low socioeconomic status and child psychiatric disorder depends on certain factors, including the measure of socioeconomic status and the informant who provides the data on the presence of emotional and behavioral disorders, on whether the poverty is persistent, and on the age of the child. A strong relationship exists between low socioeconomic status and child psychiatric disorder when parental socioeconomic status is measured by the degree of economic disadvantage but not when it is determined by level of occupational prestige ( [Lahey et al., 1999](#); [Offord, 1990a](#); [Offord and Lipman, 1996](#)). The relationship between low socioeconomic status and externalizing disorder is stronger for teacher-identified than for parent-identified disorder ( [Offord et al., 1989](#)). Further, it has been reported that persistent poverty predicts internalizing symptoms, whereas only current poverty predicts externalizing symptoms ( [McLeod and Shanahan, 1993](#)). Finally, the relationship between economic disadvantage and child psychiatric disorder appears stronger in younger children than in adolescents ( [Lipman et al., 1994](#); [Rutter, 1981](#)). Two other points should be noted. First, the factors that place poor children at increased risk of psychiatric disorder have to do primarily with increased rates of parental and family characteristics associated with child psychiatric disorder rather than economic disadvantage itself. Second, the relationship between income level and psychiatric disorder is on a continuum or gradient with increased levels of income across the range associated with decreasing frequencies of psychiatric disorder ( [Offord and Lipman, 1996](#)).

### *Other Factors*

Space limitations preclude coverage of other correlates of child psychiatric disorders including stressful life events ( [Garber and Hilsman, 1992](#); [Garrison et al., 1997](#); [Jensen et al., 1991](#)), child maltreatment ( [Famularo et al., 1992](#); [MacMillan and Munn, 2001](#); [Main and Solomon, 1990](#)), and peer and sibling influences ( [Coie and Miller-Johnson, 2000](#); [Loeber and Farrington, 1998](#); [Patterson and Dishion, 1988](#)).

## **Protective Factors**

Protective factors operate to reduce the incidence or severity of children's emotional or behavioral problems among children at increased risk of developing these difficulties ( [Rutter, 1985](#)). They are products of both the attributes of the child and of the environment. They should not be seen primarily as existing in a cross-sectional snapshot, but should be understood as processes operating over the developmental years and perhaps having their effects in different ways at different points in development. These factors can exist in the child (e.g., above-average IQ, easy temperament), in the family (e.g., a high degree of cohesiveness within the family, a good relationship with one parent), and in the wider community (e.g., excellent schools and nonschool skill-development programs in the sports and arts) ( [Grizenko and Fisher, 1992](#); [Jones and Offord, 1989](#)). The mechanisms by which these protective factors have their effect are through the following main processes: reduction of risk impact, reduction of negative chain reactions, establishment and maintenance of self-esteem and self-efficacy, and opening up of opportunities ( [Luther and Zigler, 1991](#); [Rutter, 1987](#)).

## **Correlations and Interactions Among Risk and Protective Factors**

Risk and protective factors operate in different combinations over childhood and adolescence to produce different developmental trajectories ( [Hertzman, 1999](#)). Biological factors in the child can influence the child's environment (e.g., a child with a "difficult" temperament may promote irritability in the parents and reduce their parenting effectiveness), and aspects of the environment can become "biologically embedded" in the child (e.g., a violence-filled environment in early childhood can

lead to enduring changes in brain structure) (Hertzman, 1999). Similarly, there is evidence that social and environmental risk factors (e.g., early maternal rejection) may combine with physical risk factors (e.g., birth complications) to predispose children to violence (Raine et al., 1996; Raine et al., 1997; Raine et al., 1998). An important methodologic advance in studying the contributions of individual causal risk and protective factors to child psychiatric disorders is multilevel modeling in which the contribution of a variable in one domain (e.g., neighborhood residence) can be determined controlling for the effects of variables in other domains (e.g., child and family) (Leventhal and Brooks-Gunn, 2000). The challenge is to learn more about how risk and protective factors operate as mediating and moderating variables (Kraemer et al., 2001) to produce different developmental trajectories, in which, for example, some children's developmental trajectories begin with a biological risk factor and spiral downward toward morbidity, whereas in other children, who begin with the same biological disadvantage, the developmental trajectories lead to healthy outcomes.

## ISSUES IN PREVENTION

The issues that are covered include definitions, approaches, and selected contributions of developmental psychopathology to prevention.

### Definitions

A major problem with the widely used definitions of prevention initiatives (primary, secondary, tertiary) presented earlier in this chapter is that the distinction between primary and secondary prevention can be blurred. The reason is that determining the threshold indicating the presence or absence of disorder is difficult and tends to be arbitrary when the frequency and severity of symptoms are on a continuum (Offord, 1987).

An alternate classification system centers on who is offered the intervention (Institute of Medicine, 1994; Offord et al., 1998). The three types of programs using this strategy are universal, targeted, and clinical. A *universal* program is offered to all persons, for example, children (and their families) in a geographic area. In a targeted program, certain persons are singled out to be offered the intervention. Two types of targeted programs have been described, namely, *indicated* and *selective* (Institute of Medicine, 1994). In an *indicated* preventive initiative, the high-risk group is identified on the basis of biological or behavioral markers for increased risk of disorder, for example, children with mild antisocial symptoms who do not qualify for conduct disorder, but who are at increased risk of it (Lipman et al., 1998). In *selective preventive* programs, the target group is identified, not on the basis of biological markers or symptom patterns, but on the grounds that persons or a population subgroup are at increased risk of developing psychiatric disorder, for example, children and their families residing in a publicly supported housing complex (Offord et al., 1987a). In a *clinical* program, there is no active reaching out to children, but children (and their families) are referred for, or seek, services.

Each of these strategies has advantages and disadvantages, and they have all been described in detail (Offord et al., 1998). The advantages of a universal program include the following: no labeling or stigmatization; the involvement of the middle class, who will demand that the program be well run; and the "tilling of the soil" or sensitizing the setting for subsequent targeted interventions. The disadvantages of universal programs are several; for example, they will be seen as unnecessarily expensive and as having a small benefit to the individual, and they may have their greatest beneficial effect on those at lowest risk, thus producing the unexpected effect of increasing inequality between the high- and low-risk subgroups within the population.

The targeted approach has the advantages of addressing problems early and is potentially efficient if the targeting can be done accurately. The disadvantages are several. First is the possibility of labeling and stigmatization; second, there are difficulties with recurrent screening including the cost and maintaining a high degree of compliance, especially among those at highest risk; and third is the difficulty of targeting accurately. It is an arduous task to identify accurately in a community population those at increased risk of future disorder and thus the population that should be the focus of targeted interventions (Bennett, 2000; Bennett et al., 1998; Bennett et al., 1999). One strategy to increase the accuracy of the identification of high-risk groups of children is to have continuous risk assessment over time, rather than only one measure of risk status (Herlbrun, 1997). A fourth disadvantage of targeted interventions is that more cases of disorder will emanate from the large number of children at low risk rather than the relatively small number of children at high risk. An unwelcome implication of this finding is that one targeted program, even if effective, cannot be expected to have marked beneficial effects at the population level. The last of the three strategies, the clinical approach, has a major advantage in that the intervention is focused clearly on those children with disorder. The disadvantages to the clinical approaches are covered previously at the beginning of the chapter.

### Approaches

There are two somewhat different approaches to developing, carrying out, and evaluating prevention programs. The first, termed *preventive science*, is covered in the Institute of Medicine Report (Institute of Medicine, 1994). Five steps are outlined in carrying out a prevention initiative, beginning with identifying a problem or disorder, then specifying risk and protective factors, carrying out pilot efficacy studies, launching and evaluating large-scale effectiveness trials, and finally moving toward widespread dissemination of the program in a variety of settings. Participation by community members in planning and carrying out these studies is not emphasized, but academicians are viewed as experts and are usually in charge of the programs. The second model, termed the *collaborative community action research model*, is quite different. Community members are major participants throughout the whole prevention initiative (Kelly, 1988; Tolan et al., 1990). The resulting prevention initiative is community specific, especially in terms of the content and delivery of the program, and thus the program is not necessarily suitable for dissemination to other communities. Because of the limitations of the design, the strength of the scientific evidence supporting the effectiveness of these programs will not be strong (Canadian Task Force on the Periodic Health Examination, 1979). A review of the advantages and disadvantages of these approaches presents suggestions for melding the two of them (Weissberg and Greenberg, 1998).

## Contributions of Developmental Psychopathology

Developmental psychopathology integrates knowledge from several related disciplines including epidemiology, psychiatry, developmental psychology, and clinical psychology. It appeared in the 1980s, and it centers on factors that influence the onset and course of emotional and behavioral disorders in children and adolescents (Stroufe and Rutter, 1984). In this section, we summarize selected contributions of developmental psychopathology under four headings: risk and protective factors; multiplicity, specificity, and timing; theories of development; and life-course studies and causal models.

### RISK AND PROTECTIVE FACTORS

For a variable to be a risk factor for child psychiatric disorder, it must fulfill two criteria: be present before the onset of the disorder and increase the likelihood of future disorder in children exposed to the variable, compared with those who are not. The strongest evidence for determining whether a particular factor is a causal risk factor arises from experimental studies, but descriptive studies can also identify factors that are likely to be causal (Hill, 1965; Kraemer et al., 1997). It is necessary to distinguish causal risk factors from correlates, markers, and noncausal risk factors for disorder (Kraemer et al., 1997; Offord and Kraemer, 2000). Prevention interventions that focus not on causal risk factors, but on correlates, markers, or noncausal risk factors will likely have little effect on reducing the incidence of disorder. The same logic applies to protective factors in which the focus of prevention studies should be on causal protective factors.

Two important measures of the strength of the relationship between a risk or protective factor and a subsequent disorder are the odds ratio and the population attributable risk. The *odds ratio* provides information of the increased risk provided with a particular factor (Streiner and Norman, 1996), whereas the *population attributable risk* provides data on the percentage of all cases of disorder in a population that are attributable to a specific risk factor (Kelsey et al., 1996). Risk factors chosen for intervention in a prevention project should be causal, and, if possible, have both a strong relationship with a disorder (high odds ratio) and a high attributable risk. One last issue should be mentioned. A prevention model starts with a causal risk or protective factor, then a prevention intervention, and finally proximal and distal outcomes. One of the problems with prevention studies is that there is "slippage" at every point in the model that can only then weaken the effectiveness of the intervention (Baronowski et al., 1997). For example, if the causal risk factor selected to prevent conduct disorder is poor social skills, and the intervention program is social skills training, and the proximal and distal outcomes are mild antisocial behavior and conduct disorder, respectively, there will not be a one-to-one relationship at each point in the model. For example, not all conduct-disordered children will have deficient social skills, the social skills program will not be 100% effective, and many of the children with mild antisocial behavior will not go on to have full-blown conduct disorder. Each of these findings will serve to put limits on the effectiveness of a prevention program.

### MULTIPLICITY, SPECIFICITY, AND TIMING

The risk of psychiatric disorder in children depends on both the number of causal risk factors present at any one point in time and their accumulation over time (Hertzman, 1999; Yoshikawa, 1994). As noted previously, there has been little progress in demonstrating the specificity of causal risk factors for specific disorders. Finally, the importance of a particular causal risk or protective factor depends on the developmental stage of the individual. Poor parenting, for example, is thought to

have a stronger influence on producing psychiatric disorder in younger than in older children ( [Reid and Eddy, 1997](#)).

#### THEORIES OF DEVELOPMENT AND LIFE COURSE STUDIES

Longitudinal studies have made three important contributions to the prevention enterprise ( [Institute of Medicine, 1994](#); [Loeber and Farrington, 1997](#)). First, they revealed both continuities and discontinuities in the onset and course of psychiatric symptoms and disorder ( [Rutter, 1995b](#)). Second, longitudinal studies have forced investigators to change from reporting outcomes in terms of number of discrete events to describing developmental trajectories of outcomes over time ( [Kellam and VanHorn, 1997](#)). Third, and last, these studies have highlighted that the links between early risk factors and future psychiatric disorders may be indirect and may hinge on other mediating variables.

#### CAUSAL MODELS

The simple causal chains or pathways that have been used to explain the relationship between causal risk or protective factors and the onset of disorder are now viewed as oversimplified. Investigators currently are moving toward more complicated models that distinguish, for example, between risk factors that act as mediators and those that function as moderators ( [Baron and Kenny, 1986](#); [Baronowski et al., 1997](#); [Holmbeck, 1997](#); [Kraemer et al., 2001](#)).

### PREVENTION OF PSYCHIATRIC DISORDERS

In this section, a summary is presented of the current state of knowledge about the prevention of major disorders in child psychiatry, namely, depressive disorder, anxiety disorder, and conduct disorder. In addition, selected risk situations are covered, namely, child abuse, children of divorce, and environmental contaminants. Further, there are brief discussions of prevention in low-income countries and of the barriers to prevention. The chapter ends with some concluding remarks. For each prevention initiative reviewed, the following issues are discussed: the target population; characteristics of the intervention, including whether it was universal or targeted and whether the program was designed to prevent a specific psychiatric disorder or to promote competence in the cognitive and behavioral areas; the strength of the research design; and the findings to date. The design of almost all the studies included in the review is a randomized controlled trial. This design, when executed well, is the strongest in preventing biased estimates of program effectiveness ( [Jadad, 1998](#)).

#### Depressive Disorder

No universal programs have been shown to be effective in preventing the onset of depressive symptoms or depressive disorders ( [Harrington, 1997](#)). There are, however, targeted prevention programs, both of the selective and indicated subgroups. Beardslee and colleagues ( [Beardslee et al., 1993](#); [Beardslee et al., 1996](#); [Beardslee et al., 1997a](#); [Beardslee et al., 1997b](#)) have been involved for several years in the selective type of a targeted program in which the children, ages 8 to 15 years, are identified as being at increased risk of depressive disorder on the basis of being the child of a parent with a recent history of affective disorder. Children were randomly assigned to one of two psychoeducational interventions, clinician-facilitated or lecture-group discussion, both of which were planned to prevent childhood depression and other related problems through promoting resiliency and reducing the effects of risk factors. The lecture-group discussion consisted of two 1-hour lectures, whereas the mean number of clinician-facilitated intervention sessions was 7.7. The latter intervention had a strong cognitive approach, and a primary goal was to increase family members' understanding of the illness through individual sessions with the parents, family meetings, and an individual session with each child. In the most recent report ( [Beardslee et al., 1997b](#)) on the first 37 families, positive results, as would be expected, were more marked in the clinician-facilitated group. It will not be known for several years whether these interventions actually reduce the incidence of depressive disorder and other morbidities in these high-risk children.

A group of investigators carried out a series of indicated targeted intervention studies in which children at risk for depressive disorder were identified on the basis of self-reports of elevated levels of depressive symptoms ( [Clarke et al., 1995](#); [Gillham et al., 1995](#); [Jaycox et al., 1994](#)). In the most recent of these studies ( [Clarke et al., 1995](#)), 1,652 adolescents were screened in a two-stage procedure, and 150 were identified as experiencing depressive symptoms but did not meet the criteria for depressive disorder. The intervention consisted of a 15-session cognitive-behavioral intervention (three sessions per week for 5 weeks), and data were collected after treatment and 6 and 12 months later. The program emphasized training adolescents in cognitive-restructuring skills to increase their ability to reduce mild levels of negative cognitions before they reach depressive symptoms of clinical proportions. Overall, the incidence of either major depression or dysthymia at follow-up was significantly less in the treated group compared with the control group, 14.5% versus 25.7%, respectively.

#### Anxiety Disorder

The literature on the prevention of anxiety disorders is sparse ( [Spence, 1994](#)). Although there are no well-controlled experiments of universal interventions to prevent childhood fears, some programs are aimed at preventing fears in specific situations such as dental visits ( [Melamed et al., 1975b](#); [Melamed et al., 1975a](#); [Milgrom et al., 1992](#)), medical procedures ( [Jay et al., 1987](#)), test anxiety ( [Tryon, 1980](#); [Van der Ploeg-Stapert and Van der Ploeg, 1986](#)), and transition to a new school ( [Felner and Adan, 1988](#)).

The Queensland Early Intervention and Prevention of Anxiety Project ( [Dadds and Spence, 1997](#)) is a randomized controlled trial aimed at preventing the onset and development of anxiety problems in children ( [Dadds and Spence, 1997](#)). Of the total sample of 1,786 children in grades 3 to 7 (ages 7 to 14 years) in eight primary schools, 121 were selected for the trial on the basis of having anxiety symptoms (but not severe anxiety disorder) as a consequence of the results of a complicated and extensive four-stage screen that used data from teacher nominations and children's self-reports. Selected children were allocated to the intervention and control groups on the basis of school. The intervention was based on the *The Coping Koala: Prevention Manual* ( [Barrett et al., 1994](#)), and it consisted of 1- to 2-hour sessions with the children over 10 weeks (five to 12 children in a group) in which the children were taught strategies for coping with anxiety using a cognitive-behavioral approach. In addition, four parent sessions focused on teaching skills to manage their child's anxiety. The authors reported that the intervention was successful both in reducing rates of disorder in children with mild to moderate anxiety disorders and in preventing the onset of anxiety disorders in children with some anxiety symptoms. Furthermore, the differences between the experimental and control groups were present at the 24-month follow-up. The labor-intensive four-stage screen is an obstacle to wide adoption of this promising indicated targeted prevention program for childhood anxiety disorders.

#### Conduct Disorder

Most of the prevention programs for child psychiatric disorder focus on conduct disorder. Relevant programs are reviewed according to the age of the children involved: less than 5 years; 5 to 11 years; and 11 years and older.

#### PROGRAMS FOR CHILDREN YOUNGER THAN 5 YEARS OLD

Three major programs involve this age group. They have four characteristics in common: they begin early and are intensive; they focus primarily on markedly economically disadvantaged, commonly African-American preschoolers; the sample sizes are small; and the results are encouraging.

The Perry Pre-school project was designed in the 1960s for poor, black 3- and 4-year-old children to improve academic and social outcomes ( [Schweinhart and Weikert, 1988](#); [Schweinhart and Weikert, 1989](#)). The intervention lasted 2 years and consisted of a daily preschool program (90-minute classes 5 days per week) and a weekly home visit provided by trained teachers. The preschool element aimed to promote physical, academic, and social development, whereas the purpose of the home visits was to help parents reinforce the preschool curriculum. The program was evaluated in a randomized controlled trial (58 children in the experimental group and 65 in the control group) in which the children were followed-up into adulthood. Although the initial IQ gains in the experimental group disappeared, long-term follow-up at ages 19 and 27 years showed marked differences on measures of antisocial behavior including fewer lifetime arrests in the experimental group compared with the control group (31% versus 51%, respectively), and a reduced rate of being arrested five or more times (5% versus 35% in the experimental and control groups, respectively). In an economic analysis, the benefits of the program were found to exceed the costs ( [Barnett, 1998](#)).

The Carolina Abecedarian Project also focused on poor African-American children ( [Campbell and Ramey, 1994](#)). A very intensive intervention throughout the first 5 years of life consisted of a range of services offered through a day care center including an enriched day care curriculum, parent groups, home visits, and medical care and social services. Beginning in kindergarten and extending through grade 2, the parents received 15 home visits per year from a home-school resource teacher. The program was evaluated in a randomized controlled trial in which the outcomes of four groups of children were compared: group 1, birth to age 5 program plus kindergarten to grade 2 program (n = 25); group 2, birth to age 5 program only (n = 22); group 3, kindergarten to grade 3 program only (n = 21); and group 4, no program (n = 22). There were two major results of the study. First, the children who received the full program did better on measures of IQ and school achievement

than children in the other three groups. Second, the interventions that began in the first 5 years of life were more effective than the intervention that began in kindergarten, in terms of IQ and school achievement at ages 8 and 12 years. Although these investigations did not assess antisocial outcomes, the characteristics of the intervention and its positive effects on academic outcomes suggest strongly that it holds promise as an intervention strategy for antisocial behavior.

The third study provided nurse home visitation for poor unmarried pregnant women (Olds et al., 1998a). In a randomized controlled trial, children at age 15 years who received home visits by a nurse (during the mother's pregnancy and up to age 2 years) were compared with those who did not. Based on youth self-reports, the youths in the experimental compared with the control groups reported lower rates of arrests (56% reduction), convictions and violations of probation (81% reduction), running away (60% reduction), lifetime sexual partners (63% reduction), and alcohol consumption (56% reduction). Parents also reported lower rates of behavior problems associated with alcohol and other drugs (56% reduction). This same prevention program is reviewed later in this chapter, in the discussion of child abuse.

Two issues need to be addressed with these types of programs. First is a requirement to understand the mechanisms by which these programs exert their effects, and this necessitates the formulation of a more coherent and conceptual basis for these initiatives (Ramey and Ramey, 1998). Second is a need to test these approaches in other populations of children when the levels of economic disadvantage and associated risks are less extreme. Data on the costs and effects of interventions of this type on these latter populations are necessary to guide policy decisions about the extent to which widespread dissemination of these programs is desirable.

#### PROGRAMS FOR CHILDREN 5 TO 11 YEARS OLD

Most of the programs for children in this age group are offered in the school setting. Four different types of approaches are employed: single-factor, multiple-component, competence-enhancement, and school development.

Single-factor approaches focus on one risk or protective factor in one context, and when they are evaluated in randomized controlled trials, they have shown small to moderate effects on antisocial symptoms. Examples include social skills programs (Grossman et al., 1997), peer mediation (Cunningham et al., 1998), and a classroom-management strategy (Kellam et al., 1994).

Multiple-component strategies focus on multiple risk and protective factors, and they operate in more than one context. The Montreal Longitudinal-Experimental Study evaluated a targeted intervention for high-risk kindergarten boys (Tremblay et al., 1995). Two risk factors were addressed, one at the family level (parenting skills) and one at the child level (social skills training). Boys in 53 Montreal schools who showed increased rates of antisocial behavior on a teacher questionnaire and whose parents were French speaking and had less than 14 years of formal education were randomized to one of three treatment groups: a 2-year intervention program consisting of the social skills and parent training sessions, an attention-control group, and a control group. Initial results in elementary school showed that intervention-group boys did better on measures of school adjustment, but by age 15 years, 6 years after the conclusion of the program, intervention-group members were no different from those of the control group on teacher-rated disruptive behavior and frequency of involvement in the juvenile court.

The Tri-Ministry Helping Children Adjust Project was designed as a universal program to address three risk factors for emotional-behavioral maladjustment in childhood: poor reading skills, poor social skills, and poor parenting skills (Boyle et al., 1999). The initial elements of the intervention program were a reading partners program, a social skills program, and a parent management program. However, the uptake of the parent management program was so poor that it had to be dropped after the first year of evaluation. Thus, the programs compared in the randomized trial (in which the unit of intervention was the school) were reading partners alone, social skills training alone, and a combination of both reading partners and social skills training. Program duration was a minimum of two school terms, and the results after 1.5 to 3.5 years of follow-up revealed that the effects of the intervention were modest at best. Playground observations showed statistically significant increases in prosocial behavior and some reduction in externalizing symptoms (Hundert et al., 1999).

Fast Track is another multicomponent, multilevel approach (Bierman et al., 1999a; Bierman et al., 1999b). The intervention program focuses on multiple levels (child, family, school, peer group, community) and factors (academic skills, social skills, parenting skills, family support) and includes a universal and targeted components. The program begins in grade 1 and is planned to continue through middle school. Fast Track is currently being evaluated in a large, randomized controlled trial involving 54 schools in four separate geographic sites in the United States. Results based on outcomes at the end of grade 1 are encouraging, and it will be interesting to learn whether the Fast Track prevention initiative will result in reductions in conduct problems that are important in both clinical and policy terms, as the children move into adolescence and adulthood.

Competence-enhancement intervention strategies do not address emotional and behavioral problems specifically, but they promote social competence. An example of such a program is the Seattle Social Development Project, which consists of three components to increase social competence: teacher training, child social skills development, and parent training (Hawkins et al., 1999). The program is offered from grades 1 through 6. The results of a nonrandomized controlled trial showed that, at age 18 years, adolescents who had participated in the program self-reported fewer delinquent acts (19% reduction), less heavy drinking (40% reduction), and fewer sex partners (19% reduction) and pregnancies (35% reduction) compared with control students. Another promising competence-enhancing program is the Social Competence Program for Young Adolescents (Weissberg and Greenberg, 1998), which resulted in reductions in self-reported antisocial and delinquent behavior among middle-school students who received the 2-year program compared with those who did not.

The final strategy is school development, which has been applied in elementary schools and may result in reduced rates of antisocial behavior. The School Development Program, developed by Comer and colleagues (Comer, 1985), has three components: a school planning and management team, a mental health team, and a parent program. The focus here is on mechanisms or processes to support change, and the specific content of the program is not defined but is left up to the teams. The hope is that this strategy will improve school climate, thus promoting positive behaviors and minimizing negative health and social outcomes. The Comer approach, when evaluated in a nonrandomized controlled study, revealed superior school outcomes for children attending the program schools compared with those who did not (Comer, 1985).

In summary, it is clear that the school is a promising setting in which to launch prevention programs for conduct disorder. There are tradeoffs between single-component and multicomponent strategies: the former are simple and straightforward to implement but are unlikely to have a major impact on reducing the incidence of an etiologically complex condition such as conduct disorder, and the latter, although they address multiple risk and protective factors, are complex and expensive, and currently the magnitude of the benefit in relation to cost is uncertain (Hundert et al., 1999). Finally, the competence-enhancing and school development approaches could benefit from more rigorous evaluations.

#### PROGRAMS FOR CHILDREN MORE THAN 11 YEARS OLD

In older children, the emphasis on reducing the burden of suffering from conduct disorder is through treatment programs, not prevention initiatives. Two prevention programs are summarized here: one that shows promise and one that has been shown to be ineffective. The PATHE program (Positive Action Through Holistic Education) (Gottfredson, 1986) is a school development model focusing on this age group that has been shown to influence antisocial outcomes. The program consists of several components focusing on high-risk students: a school team composed of school and agency personnel and parents, development of school and classroom goals, schoolwide academic innovations, schoolwide climate innovations, and mental health and academic services. In an evaluation using a nonequivalent comparison group design, student reports suggested that the program results in fewer delinquent acts and lower rates of drug use and school suspensions. Further work is needed on this promising school reform strategy.

Finally, the Cambridge-Somerville Study is important because the results indicate that the intervention was probably harmful. In this program, which began in the 1930s, boys approximately 11 years old were randomized to be assigned or not to a social worker (McCord, 1992). The social worker's role was to build a close relationship with the boy and to provide counseling assistance to the boy and his family. Follow-up in adulthood, when the participants were 40 to 50 years of age, revealed that the treatment-group boys had worse outcomes in terms of death before age 35 years, conviction of a crime, and psychiatric disorder than the controls. The reasons that this program failed are not completely clear.

#### Risk Situations

There are markers or indicators of increased risk for child psychiatric disorders, and attempts have been made either to reduce the risk itself or to modify the effects of the risk. Some of the markers are intrinsic (within the child), such as low birth weight, developmental delay, brain damage, epilepsy, and chronic medical illness, and others are extrinsic (outside the child), such as parental psychiatric disorder, physical and sexual abuse, divorce, and residence in economically disadvantaged neighborhoods (Offord et al., 1998). Because of limited available space, only three situations are covered briefly, namely, child abuse, parental divorce, and

environmental contaminants.

### CHILD ABUSE

Prevention studies focus either on the prevention of physical abuse or neglect or on the prevention of sexual abuse and abduction ( [MacMillan et al., 1994b](#)). Universal programs to prevent physical abuse and neglect center on making available child development and parenting resource centers for children, from birth to 5 years of age, and their parents. The provision of these resources for selected groups of impoverished preschool children results in improved health and well-being ( [McCain and Mustard, 1999](#)), but the effects on reducing physical abuse specifically are not known ( [Leventhal, 1996](#)).

Targeted interventions have focused on home visiting, and evidence indicates that extended home visitation can prevent physical abuse and neglect among disadvantaged families ( [MacMillan, 2000](#); [MacMillan et al., 1994a](#); [MacMillan and Canadian Task Force on Preventive Health Care, 2000](#)). The most thoroughly evaluated home visitation program, the Prenatal and Early Childhood Nurse Home Visitation Program, has been evaluated in two randomized controlled trials in Elmira, New York and Memphis, Tennessee ( [Karoly et al., 1998](#); [Kitzman et al., 1997](#); [Olds et al., 1993](#); [Olds et al., 1997](#); [Olds et al., 1998a](#); [Olds et al., 1998b](#); [Olds et al., 1999](#)). Among the several positive results, rates of child maltreatment from birth through the child's 15th year were reduced by 79%. The essential ingredients of successful home visitation programs have been discussed ( [Leventhal, 1996](#)), as have been their limitations ( [Guterman, 1997](#); [Leventhal, 1996](#)).

The relatively small literature on the prevention of child sexual abuse reveals one central finding: educational programs, usually delivered in the school setting, can improve safety skills and knowledge, but no study has furnished results that educational programs reduce the occurrence of sexual abuse ( [MacMillan, 2000](#); [MacMillan et al., 1994a](#); [MacMillan and Canadian Task Force on Preventive Health Care, 2000](#)).

### CHILDREN OF DIVORCE

Children of divorce are increasing in numbers. In the United States, the proportion of children growing up in homes with two biological married parents fell from almost 90% in the 1960s to about 40% by the mid-1980s ( [Wadsworth, 1986](#)). In the United States in 1996, divorce and annulments involved more than 1 million children ( [National Center for Health Statistics, 1997](#)). The effects of divorce on the psychosocial adjustment of children have been reviewed ( [Hetherington and Stanley-Hagan, 1999](#)). A metaanalysis of 95 studies revealed that, on average, children of divorced parents are less well adjusted socially, emotionally, and academically than children of nondivorced parents ( [Amato and Keith, 1991](#)). However, not only do children's reactions to divorce vary widely, but also most children do not show severe or enduring behavior problems ( [Hetherington, 1993](#); [Hetherington et al., 1992](#)).

Reviews of interventions for divorced parents and their children show that adequate research in this area is scarce ( [Emery et al., 1999](#); [Grych and Fincham, 1992](#); [Hetherington and Stanley-Hagan, 1999](#)). Interventions for children usually occur in the school setting, involve groups of children of divorced parents, consist of both educational and therapeutic activities, and are of short duration. In the most thoroughly evaluated school-based program in which children in grades 4 to 6 from four suburban schools were randomly assigned either to an immediate 12-week intervention group or to a delayed intervention group, reports by teachers, group leaders, and the children themselves reported fewer anxiety symptoms and behavior problems in the experimental group compared with the control groups ( [Alpert-Gillis et al., 1989](#); [Pedro-Carroll and Alpert-Gillis, 1997](#)). Positive results were also obtained when the intervention was extended to urban children, with diverse ages, ethnicities, and socioeconomic backgrounds ( [Pedro-Carroll and Cowen, 1985](#); [Pedro-Carroll et al., 1986](#)). One child-focused program that has been widely disseminated showed few positive results in a single-group before-and-after design ( [Kalter et al., 1984](#); [Kalter et al., 1988](#)). Parent-focused group interventions have the goal of helping parents deal more effectively with the stresses of divorce, and only secondarily are they aimed at improving parenting and family relationships ( [Hetherington and Stanley-Hagan, 1999](#)). One of the few randomized controlled trials, in which the intervention was 14 parent-group sessions, indicated that mothers in the intervention group reported improvements in maternal discipline, and teachers reported improvements in children's behavior ( [Forgatch and DeGarmo, 1998](#)). A third type of intervention, focusing on legal issues, namely, mediation and coparenting, reveals no evidence that mediation compared with adversary settlement results in improved adjustment of children ( [Kelly, 1989](#)), and there are no consistent findings of an association between type of custody and children's adjustment ( [Grych and Fincham, 1992](#)).

The intervention literature on the children of divorced parents has major weaknesses. Well-done randomized controlled trials are rare, the outcome data are provided by informants who are not blind to the intervention status of the children, and the follow-up periods are short. In addition, most of the children of divorce do not exhibit adjustment problems, and thus for them the intervention is not needed, and indeed it may be harmful because of labeling and stigmatization.

### ENVIRONMENTAL CONTAMINANTS

Lessening or eliminating environmental contaminants is an important universal prevention initiative in the child psychiatric domain ( [Environment Leaders of the Eight, 1998](#)). Not only do children of poverty endure an inordinate impact from environmental health threats ( [Chaudry, 1998](#); [Mott, 1995](#)), but also children in general are especially vulnerable to the noxious effects of these environmental agents because of their early reliance on breast milk, which can become contaminated ( [Sonawane, 1995](#)), and because young children engage in crawling activities and spend most of their time indoors. There are several examples of the adverse effects of environmental toxins on children's development, including methylmercury ( [Rice, 1998](#)), phencyclidine hydrochlorides (PCPs) ( [Stern et al., 1994](#); [Ware et al., 1986](#)), air pollution ( [Brunekreef et al., 1997](#); [Raizenne et al., 1998](#); [Wang et al., 1997](#)), and, of course, lead. Lead poisoning not only produces deficits in IQ ( [Needleman, 1998](#); [Schwartz, 1994](#)), but also has been reported to result in attentional and language problems and perhaps social adjustment difficulties ( [Rice, 1998](#)). The removal of lead from gasoline in 1990 in the United States has been proclaimed as one of the public health triumphs of the 20th century ( [Needleman, 1998](#)).

### Low-Income Countries

The topic of the prevention of emotional and behavioral problems in children in developing countries is immense and important. It is included here not to provide, by any means, complete coverage of the subject, but rather to alert child psychiatrists and their mental health colleagues to the issue that prevention of child psychiatric disorders is a worldwide issue. Child mental health problems have probably worsened in low-income countries over the past several decades even though physical health and schooling have improved ( [Desjarlais et al., 1995](#)). It cannot be assumed that effective interventions in wealthy countries will necessarily be effective in poor ones ( [Dans et al., 1998](#); [Rahman et al., 2000](#)). Four universal interventions show promise in improving the quality of life of children in general and decreasing mental health problems in particular in these severely disadvantaged populations. First, there should be efforts to improve maternal education ( [Caldwell, 1986](#); [Hobcraft, 1993](#)). Possible mechanisms by which this improvement will lead to increased child well-being include later age of marriage and birth of first child, fewer children, and increased responsiveness to modern hygienic practices ( [Hobcraft, 1993](#)). Second, there should be better family planning. The greater the number and the more closely spaced the pregnancies, the greater is the risk of maternal and infant mortality and of poor developmental and mental health outcomes among the children ( [Desjarlais et al., 1995](#)). Third, the efforts to enrich the first 5 years of life of these children should be continued and expanded through the provision of early child development and parenting programs resulting in improvements in nutrition, cognitive stimulation, and parenting ( [McCain and Mustard, 1999](#); [Young, 1997](#)). Fourth and last, efforts should continue to increase the percentage of children enrolled in schools and to decrease school dropouts ( [Carnegie Commission, 1992](#)).

### Barriers

Two obstacles make it difficult for child psychiatrists to carry out prevention studies. The first is that, in most instances in North America, child psychiatrists are funded on a fee-for-service basis, and thus there is no remuneration for time spent in planning and carrying out prevention projects that do not involve direct clinical contact. A second barrier is that child psychiatrists are usually not trained to do prevention work ( [Group for the Advancement of Psychiatry, 1999](#)). However, one can make the case that child psychiatrists should know the prevention literature thoroughly so they can consult with groups planning and launching prevention projects ( [Group for the Advancement of Psychiatry, 1999](#); [Harrington, 1997](#); [Offord et al., 1999](#); [Rae-Grant, 1991](#)). A third barrier to prevention initiatives is the presence of an uncivic community ( [Offord et al., 1999](#)). When the setting in which the prevention program is to be located, whether it be a school, a geographic area, or an entire country is severely disorganized or dysfunctional, the chances of success are minimal. For example, initiating and maintaining a social skills program in a school that is disorganized and demoralized are not possible.

### CONCLUDING REMARKS

Although important progress has been made in the prevention of child psychiatric disorders, some remain. First, there has been little or no success in moving from successful small demonstration projects carried out under more or less ideal conditions (efficacious programs) to large-scale programs carried out in a variety of settings (effectiveness programs) ( [Tugwell et al., 1985](#)). Second, if efficacious programs are to be successfully disseminated, the fidelity of the intervention should be

monitored and maintained (Moncher and Prinz, 1991). Further, if the intervention is changed, for example, "watered down" to save costs, there is no assurance that it will be effective. Third are particular problems in demonstrating the effectiveness of universal programs, and they have been discussed in detail (Hundert et al., 1999). Fourth, effective programs tend not to be maintained, let alone disseminated (Offord, 1996), and, just as disturbing, prevention programs without proven effectiveness end up being widely disseminated (e.g., Kalter et al., 1984; Kalter et al., 1988). Fifth, and last, it is clear that meaningful reductions in the immense burden of suffering from emotional and behavioral problems will need the best cooperative efforts of researchers, clinicians, and teachers in both the treatment and prevention domains.

## 117 MENTAL HEALTH DELIVERY SERVICES FOR CHILDREN AND ADOLESCENTS

Jerry M. Wiener, M.D.

---

### [Chapter References](#) [Appendix/Questionnaire on Child Services](#)

It is appropriate at the beginning of the new millennium to take some stock of the state of mental health services for children and adolescents across a variety of national boundaries and within their different cultures. Expected would be variations reflective of ethnic, political, economic, religious, cultural, and social forces, and these findings also might represent something about the status and role of children and children's general health issues in a particular sociopolitical/cultural environment.

An editorial in the *New York Times* of May 20, 1971 states that the treatment of the mentally ill, the brain injured, and the mentally retarded “. . . is a test of how humane any society really is.” By this standard and by the limited data available, one could conclude that there are very few adequately humane societies if judged by the mental health, healthy development, and adequacy of clinical services for a large majority of the world's population of children and youth, which occupy a very low priority level, almost no matter what the type of government, culture, dominant religion, and socioeconomic circumstances.

Results are reported in this chapter from an informal survey of child psychiatrists from 10 countries around the globe conducted by the author, and from a more formal study of general mental health services and research in Arab countries, reported by [Okasha and Karam \(1998\)](#). For the informal survey, a questionnaire was completed by psychiatrists knowledgeable about the type, adequacy, and funding of services for children and adolescents in their respective countries. These countries include the United States, Canada, Sweden, Mexico, Argentina, Chile, Turkey, Israel, Egypt, India, China, and South Korea, not selected to represent any formally constructed sample, but rather countries around the globe representing both very different and overlapping populations, cultures, ethnicities, and forms of government. The questionnaire ([Appendix 117.1](#)) tapped information about each country's major population groups, type of government, sources of payment for child and adolescent health services, and whether patients had any choice in health care provider, and asked questions regarding availability and access to child and adolescent specialized psychiatric services.

Beginning with the United States as a model, the questionnaire reveals the following information. The population of 260 million is very heterogeneous in terms of ethnicity, religion, culture, and socioeconomic status. In order, white, Hispanic, African-American, and Asian ethnicities encompass a myriad of religious practices within Christian, Catholic, Jewish, and Muslim religious affiliations. All these ethnicities and religions are bound together in an elected democratic form of government. The most common and most important source of payment for health care for children and adolescents is insurance paid for by employers, but “managed” by contracted intermediaries; then, a combination of employer/employee contributions; followed by government-paid programs for the poor, such as Medicaid; and then paid for out-of-pocket (“self-pay”) but often reimbursed by individually purchased insurance. A significant portion, if not the majority, of the population has some degree of choice of health care provider, but often the choice is limited by contractual agreements or financial disincentives.

Child and adolescent psychiatry is an identifiable subspecialty of general psychiatry with accredited training programs readily available throughout the country, including Puerto Rico and Hawaii. These programs vary from highly competitive and generally sought after, to others with unfilled positions. A middle-class parent with concerns about a child's development/mental health/behavior would most likely initially consult a pediatrician or family practitioner, and in most urban areas also could seek help directly from a child psychiatrist or other mental health practitioner, often depending on type of insurance. Almost all indicated and recommended services would be available within a reasonable distance in most parts of the country, including inpatient, outpatient, residential, hospital consultation, school-based counseling, and special education programs.

Unfortunately, a wide divide has developed between availability and access; since the 1980s, access and benefits for all health care and especially for all mental health care have come under the increasing scrutiny and control of a so-called managed care intermediary or the limitations of a capitated carve-out. In both instances, the financial incentives reward delay, deferral, and denial of care, especially care provided by referral to a specialist (general psychiatrist) or subspecialist. It is paradoxical that the world's strongest economy, and by far the largest per capita child and adolescent psychiatry work force, has at the same time been unable to provide parity, has reduced access to services, and generated an uninsured population of approximately 45 million or 1 of every 6, largely among low-income families with a disproportionate share of children.

Moving to North America, Canada is the country closest to the United States in economy, population, and many aspects of culture. The population of Canada is 28 million, or approximately 1/10 of the United States; most are Anglo-Saxon, followed by French Canadian, Asian, and East Indian. The government is a constitutional monarchy led by a prime minister, with separation of church and state. Health care is dominantly provided by the government as single payor, with some coverage through employer/employee insurance or insurance paid by employers. The significant majority has a choice of physician/health care provider, but family physicians are the gatekeepers through whom referrals to specialists must be funneled. Child/adolescent psychiatry is a recognized practice entity with a number of special training programs, but only recently have “added qualifications in child psychiatry” been recognized by the Royal College of Physicians and Surgeons in Canada. If a family is concerned about a child's mental health or behavior, referral to a child psychiatrist depends on the gate-keeping function of the family physician or pediatrician. Such services then are paid for through the provincial governments.

Outpatient and hospital-based consultation services usually are available; all other services (inpatient, day-treatment, school-based) are either very scarce or unavailable. Child psychiatrists are very scarce outside the large cities, and even in these cities the waiting time in the queue is very long—months to years. Nonphysician mental health services are not included in the national system, so psychologists and social workers can be accessed without a wait if paid out-of-pocket.

Before moving southward to Central and South America, Sweden is included as a model of a democratically elected social welfare state. The population of 8.6 million is predominantly ethnic Swedes, with Lutheranism as the dominant but not very widely practiced religion. Because Sweden has a liberal immigration policy, there are numbers of families from the world's trouble spots.

Health care is provided by the government, everyone is covered, and doctors and hospitals are funded by public monies. There is a small out-of-pocket payment sector. The population does have reasonable freedom of choice of physician/health care provider within those programs funded by the government. Child and adolescent psychiatry is an established subspecialty with accredited training programs that tend to be highly sought after. A full range of services for child and adolescent disorders is funded by the government and is available and accessible, including inpatient, partial hospitalization, residential treatment, outpatient, and special education services. A special feature of the Swedish system is mental health services in the government-supported child day care programs, providing the opportunity for primary, secondary, and tertiary prevention. The success of Sweden's system reflects a relatively homogeneous and small population in a prosperous economy.

Three countries from Central and South American were surveyed—Mexico, Argentina, and Chile. Their commonalities include language, Catholicism as the dominant religion, and the makeup of their populations, including Native Indian origin, Spanish and other European immigrations, and mixtures (Mestizos). Since at least 1990, all three of these countries have had a popularly elected democratic form of government, although Argentina and Chile both have a prior long history of oppressive military dictatorships.

In Mexico, with a population of 90 million, the dominant form of payment for health services is employer/employee contributions to purchase insurance, followed by a public system in which physicians and hospitals are paid by government funds, and there are government programs for patients with acquired immunodeficiency syndrome, for the poor, and for children. But the significant majority of the population does not have a choice of physician or health care facility; this choice is available mostly to those with individual policies or who pay out-of-pocket.

Child and adolescent psychiatry is an identifiable subspecialty of psychiatry, and there is one special training program for subspecialization. However, services, practitioners, and training are concentrated in Mexico City, and training in child psychiatry is not very much sought after. A middle-class parent would most likely seek help from the family physician or pediatrician and much less, if not least likely, from a child and adolescent psychiatrist. Most child psychiatry services are paid for by government funds (i.e., are in the public sector). Outpatient evaluation and inpatient services usually are available for children, as are mental health services in general and in children's hospitals. All other services—especially for adolescents—are described as scarce to unavailable (e.g., partial hospitalization programs).

In Chile, the government is the dominant single payor for health care, followed by employer/employee combinations to purchase insurance from private companies. A significant majority of the population of 13.5 million has a choice of physician/health care provider in the government system; freedom of choice is more limited in the private insurance sector. Child and adolescent psychiatry is a recognized subspecialty; there is a program offering subspecialty training and this training is in general sought after. A middle-class parent would seek consultation preferably from a psychologist or a child and adolescent psychiatrist and less likely from a pediatrician or family physician.

In terms both of a severe shortage of trained child psychiatrists and a concentration of services in the capitol, Santiago, essentially all specialized psychiatric clinical services for children and adolescents range from unavailable to scarce. The only exception is the generally available special education services for the learning disabled and "emotionally disturbed."

Moving across the Pacific to the East, included are South Korea as a relatively small technologically advanced country, and the two most populous nations in the world, India, a parliamentary democracy, and China, a communist autocracy.

South Korea is a country of 45 million constituted almost entirely of one ethnic group and divided among Buddhist, Protestant, and Catholic religions. Its government is democratically elected and somewhat similar to the United States model. Essentially all health care is paid for and provided by the government, with some participation by large employers. The mechanism for this is the National Medical Insurance Corporation, which in essence provides every citizen with health/mental health coverage through employers, or by the Department of Social Welfare for the poor, disabled, and special populations. Most of the population does not have a choice of physician; this is determined by the government or employer. Child and adolescent psychiatry is a recognized subspecialty with special training programs available in the major University Medical Centers, and these programs are described as very sought after. Surprisingly, it is reported that a middle-class family with concerns about a child's development or behavior would be roughly equally as likely to consult with a child psychiatrist, psychologist, or pediatrician. As with general medical services, child and adolescent mental health services are funded by the government, with occasional out-of-pocket payment in a limited private sector. Outpatient and inpatient services are generally available. Partial hospitalization, school-based mental health services, and special education programs in schools are available but scarce. Residential treatment programs are unavailable.

China is of course the behemoth of 1.2 billion in population and the third largest after Russia and Canada in size (second largest, if Tibet is included). Over 90% of the population is ethnic Chinese (Han race), traditionally Buddhist but mostly nonpracticing, and with small percentages of Western religious denominations. The government is an autocracy with very tight central control by the Communist Party. Essentially all health care is paid for and provided by the government through government-run services. Even where there is a program of employer-sponsored insurance or health services, all significant production still is owned by the government. Choice of health care provider and location is limited within health care sectors. Child and adolescent psychiatry is recognized as a subsidiary practice entity in psychiatry; there are no formal residency training programs but a form of mentorship training, which takes place after medical school and job assignment. These mentorships in child psychiatry are considered not very desirable or sought after. Parents with concerns about their child might very well consult initially with the child's teacher, then a pediatrician or psychiatrist. Psychologists, social workers, and nurses are not a part of the provider chain of mental health services. Services are paid for through the hospital in the patient's health care sector. All psychiatric hospitals are government-owned public hospitals and are separated from general hospital services. Consultation is difficult to arrange in the general medical setting, and realistic concerns about confidentiality are a major issue. For all practical purposes of population and geographic size, all mental health specialty services for children and adolescents range from scarce to unavailable or nonexistent.

India dominates the Asian subcontinent with a population of 900 million, politically and religiously divided predominantly between Hindus and Sikhs, but also with significant Muslim and Christian populations. Since independence from Great Britain in 1947, the form of government has been a parliamentary democracy with two large dominant parties. Health care is provided in two ways: a private sector paid for largely out-of-pocket directly to the physician, and a system of government hospitals and clinics for those unable to afford private care funded by the government on a sliding scale fee basis. A more extensive employer/employee-based insurance system is in a relatively early stage of development and acceptance. Choice of physician, health care provider, and hospital are based on ability to pay. Although child and adolescent psychiatry is a recognized subspecialty, there are only a handful of special training programs (National Mental Health Institute in Bangalore, All India Institute of Medical Services/AIIMS in New Delhi, and the Post-Graduate Institute/PGI in Chandigarh), and these are not very sought after by medical graduates in terms of the linked considerations of status and stigma. Likewise, a concerned middle-class parent would most likely first consult a religious leader or respected family member and then a pediatrician or family physician, and very unlikely a psychiatrist or psychologist.

Bordering the Mediterranean, the three countries of Turkey, Israel, and Egypt, among others, are quite different in population, culture, government, and provision of health services.

Turkey is a large country of 60 million straddling the connection between Europe and the Middle Eastern countries, and has served as a "crossroads" for many centuries, encompassing many diverse ethnic and religious identities. Native Turks, both secular and Muslim, are the dominant population group, followed by Muslim Kurds, various Christian groups, and a historical Jewish population. The form of government is parliamentary democracy and, together with Israel, is unusual for its part of the world in having a freely elected parliament and Prime Minister. It also is a fiercely secular government and forbids any crossover between state and religion.

Health care for children and adolescents, as all other health care, is funded and provided by the government in combination with a "private" system of employer/employee-purchased health insurance. Employer-purchased insurance and direct self-pay are lesser parts of health care funding. Although most of the population has a choice of health care provider, the choice is limited for many, if not most, by geography (facilities, distribution, and quality are heavily weighted to the western half of the country) and paradoxically by the type of insurance determining which clinic or hospital can be accessed.

Child and adolescent psychiatry is an identified subspecialty with special training programs postresidency in general psychiatry. These programs are not highly competitive with other specialties for trainees. A middle-class family would most likely first consult a pediatrician or go directly to a child psychiatrist or psychologist. Outpatient specialty services, both evaluation and treatment, are generally available, as are hospital-based consultation programs. Inpatient and school-based mental health services are available but scarce to rare, likewise for day treatment and residential treatment programs.

By considerable contrast, Israel is a very small country of 4.8 million made up of 80% Jewish and 20% Muslim Arab populations. The government is a parliamentary democracy with extensive intermingling of state and church, the latter in the form of Orthodox Judaism. Health care is essentially funded by the government—both facilities and physicians—with some payment out-of-pocket directly to the physician. By contrast to almost all other government-funded programs, in Israel there is extensive freedom of choice of physician or other health care provider.

Child and adolescent psychiatry is an identifiable and vigorous subspecialty with special postresidency training programs. A middle-class family with concerns about a child's development or behavior has many options to choose from among a large and diverse number of health care providers, and is most likely initially to consult a pediatrician, then a psychologist, child psychiatrist, or general psychiatrist, in that order. Services are paid for by the national health insurance plan or out-of-pocket. All important services—outpatient, inpatient, day hospital, hospital consultation, and special education services—for children and adolescents are generally available, perhaps more so in Israel than in any other country surveyed except for urban centers in the United States.

Egypt, with a population of 55 million, is arguably the most substantial and influential country in the Arab world of nations. It is a predominantly ethnically homogeneous society where the main religion is Islam, with 6% to 7% practicing Coptic Christianity. The government is democratically elected but dominated by one party since the monarchy was overthrown in 1952. The major sources of payment for health care/mental health care for children and adolescents are predominantly out-of-pocket directly to the physician, followed by individually owned insurance and government funds, in that order. Most of the population has little if any choice in obtaining health care. Although child psychiatry is an identifiable practice entity in Egypt, there are no training programs in Egypt for this subspecialty. A concerned family would consult first with a pediatrician or family physician, very unlikely with a child psychiatrist. If used, such services would be paid for out-of-pocket. Through self-pay and government funding there are outpatient and inpatient services available, along with hospital-based consultation services. All other services, including

school-based and special education services, are essentially unavailable.

As the result of a survey of mental health services and research in the Arab world conducted by Okasha and Karam in 1998, more comparative information is available among countries in the Arab world than for any other large geographic area, such as Eastern Europe.

It is clear that among these countries, of which only Egypt and Lebanon have an elected government, there are very wide variations in per capita numbers of psychiatrists and other nonmedical mental health providers, ranging for psychiatrists from 1/45,000 population in Lebanon to 1/131,000 in Egypt and, at the lowest end, 1/500,000 in Yemen. This contrasts to approximately 1 psychiatrist per 5,000 population in the United States (and 1 child psychiatrist per 30,000 child and adolescent population). In the countries surveyed, several of their concerns and needs overlapped. A consensus agreed on the need for more extensive public education about mental illness, on increasing the number of psychiatrists, upgrading the training of all groups of mental health professionals, developing community mental health services, and the passage of a Mental Health Act. Child and adolescent psychiatry, geriatric, and especially substance abuse programs are in high demand.

The sample data make it abundantly clear that specialized services, programs, and facilities range from scarce to unavailable for the vast majority of the world's population of children and adolescents and their families. This is the case more or less independent of the form of government, culture, religion, economy, or source of payment. There are gradations, of course, from the relatively enriched circumstances in the United States and Israel to the abject absences or severe shortages characteristic of China and a number of Middle Eastern countries. This is so despite significant wealth in a number of the latter, so that the issue is not invariably the economy *per se*. What factors might be considered to explain the worldwide impoverishment of mental health services for children and adolescents (see [question 13](#) in the survey)?

An aphorism that comes to mind is "that nothing is too good for our children...except money." But, as hinted at earlier, money alone is not the entire story.

What, for example, might be the relationship between the form of government and the support for psychiatric and child psychiatric services? The more autocratic and dictatorial the regime, the more control there must be over what information can be available and limits on how much importance can be placed on the individual versus the state and on how much tolerance there can be for freedom of expression or of thought. Also, there must be limits to confidentiality and privacy, and placing trust in others is not a governmentally supported or safe activity, including even within the family. Under these circumstances, the government could support either incarceration of the mentally ill or the use of psychoactive medications, or the misuse of psychiatry to control thinking, but could hardly support the encouragement of self-exploration, increased autonomy, expanded freedom to feel and think, and independent judgmental capacity under circumstances of confidentiality and privacy. China would be an example, where psychiatry is almost exclusively biological and there is no entity or training program in child psychiatry.

Looked at another way, in those countries where the form of government reflects a society that most highly values the importance of individual rights and free expression of ideas over the importance of submerging individual rights for the best interests of the group (the government), there will be greater support for and access to psychiatric and mental health services for children and adolescents. That correlation is best exemplified by the United States, Canada, and Israel.

Another perspective is that afforded by the extent of overlap versus separation of church and state. The smaller the degree of separation, the more conservative, orthodox, and absolute the religious influence is likely to be, and the more, once again, there would be little value placed on or encouragement given to the development in the child of strivings for autonomy, independence, and challenge to or questioning of authority. Only one belief system can exist. Under such circumstances, such as in countries whose governments and cultures are dominated by a fundamentalist religious orthodoxy, either Eastern or Western, one finds state-sanctioned gender discrimination, severe punishments for deviation, strict control of communication, and little opportunity for child psychiatric services to be valued or supported.

The worldwide child and adolescent psychiatric community, led by the American Academy of Child and Adolescent Psychiatry and by the International Association of Child Psychiatry, has both an opportunity and a responsibility to support the development of mental health services for children, adolescents, and their families to the maximum extent possible and wherever possible. Many initiatives already have been undertaken, but perhaps not in as organized, systematic, and strategically planned a way as is needed and could be undertaken. Various possibilities could include offering consultation to the health planning authority in targeted countries, initially *pro bono* with monies raised independently to support such an initiative, and support to send leading child psychiatrists on lengthy visits or sabbaticals to undeveloped countries to offer educational programs and assistance in introducing the core aspects of child psychiatry and psychopathology into the health care system.

## Appendix/Questionnaire on Child Services

---

Name: \_\_\_\_\_

1. Date: \_\_\_\_\_
2. Country of Report: \_\_\_\_\_
3. List four major ethnic and/or religious groups making up the population, in order of importance in the country:
  - a. b.c.d.4. Type of government: Please provide a brief description of the current form of government, and if different, the form of government during most of post-WWII history:
5. What are major sources of payment for health care for children/adolescents, (rate 1 to 6, with "1" being the *most* important, "6" being the *least* important):
  - a. \_\_\_\_\_ Doctors and hospitals paid for by government funds for everyone (e.g., single payor)
  - b. \_\_\_\_\_ Insurance paid for by employers
  - c. \_\_\_\_\_ Paid for by individually owned policies with payment directly from the purchaser
  - d. \_\_\_\_\_ Paid for by combination of employer/employee contributions to insurance
  - e. \_\_\_\_\_ Paid by patient out-of-pocket directly to physician
  - f. \_\_\_\_\_ Government programs for specific groups, for example: children, elderly, poor, disabled, and, if so, which groups
  - g. \_\_\_\_\_ If none of the above are adequate to describe the most important, please give a brief description

\_\_\_\_\_

\_\_\_\_\_

\_\_\_\_\_
6. Does a significant majority of the population have a choice of physician/health care provider?

Yes \_\_\_\_ No \_\_\_\_

7. Is choice limited in some way?

Yes \_\_\_\_ No \_\_\_\_

If "Yes," please comment:

8. Is child/adolescent psychiatry an identifiable specialty or practice entity in this country?

Yes \_\_\_\_ No \_\_\_\_

9. If "Yes," are there special training programs for child psychiatry in post-medical school residency training?

Yes \_\_\_\_ No \_\_\_\_

10. If "Yes" are these programs:

- a. Very sought after
- b. Generally sought after
- c. About average
- d. Not very much sought after

11. List, by order of likelihood, who would a middle-class parent consult regarding a concern about a child's mental health, development, behavior, etc., with "1" being the *most* commonly considered option:

- a. \_\_\_\_ Family doctor
- b. \_\_\_\_ Pediatrician
- c. \_\_\_\_ Psychiatrist
- d. \_\_\_\_ Child/Adolescent Psychiatrist
- e. \_\_\_\_ Psychologist
- f. \_\_\_\_ Social Worker
- g. \_\_\_\_ Nurse
- h. \_\_\_\_ Other

12. How are child psychiatry services typically paid for? \_\_\_\_\_

\_\_\_\_\_  
\_\_\_\_\_

13. Number which of the following services are:

- 1. Generally available
- 2. Available but scarce
- 3. Rare or unavailable

- a. \_\_\_\_ Outpatient evaluation
- b. \_\_\_\_ Outpatient treatment
- c. \_\_\_\_ Inpatient services
- d. \_\_\_\_ Partial Hospitalization (include day-treatment)
- e. \_\_\_\_ Residential Treatment Programs
- f. \_\_\_\_ Mental Health Services in general and/or children's hospitals
- g. \_\_\_\_ Mental Health Services in schools
- h. \_\_\_\_ Special Education Services in schools for learning disabled and/or "emotionally disturbed."
- i. \_\_\_\_ Other (Please Specify)

14. Comment. (Please feel free to do so. Please add any description of the system which you would consider important and want to include.)

\_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

Thank you for your help.

# 118 NATIONAL POLICIES FOR CHILDREN, ADOLESCENTS, AND FAMILIES

### [Chapter References](#)

Since the 1970s, researchers and clinicians in psychiatry, developmental psychology, and other disciplines related to mental health have become increasingly involved in the shaping of policies and legislation designed to address the mental health problems of children and youth. Although the focus of legislative action on behalf of children is not new, the presence of researchers and clinicians in the debate adds a different dimension and offers new opportunities for interaction between research and policy. Mental health professionals are directing their work toward the understanding of how contemporary social problems contribute to mental dysfunction in children, and they are not only reporting their research but also underscoring the policy implications inherent in their findings and suggesting a course of action. By participating in the policy process and by conducting studies relevant to social issues, they are contributing to the accumulation of knowledge and are thus enhancing their understanding of development as well as improving the nation's capacity to address the needs of children.

In this chapter, we discuss some of the social changes we experience in our society, their impact on children and families, and policy responses to address these. We also discuss the role of mental health professionals in the policy arena. It will become apparent in the course of the chapter that there are benefits as well as problems inherent in the use of mental health research in policy settings. Numerous opportunities exist for mental health professionals to contribute to the development of policies for children and families. However, their effectiveness in this regard is dependent not only on their knowledge of scientific principles and findings from mental health research but also on their familiarity with the social policy process and their ability to work with policy makers.

## **FOCUS ON MENTAL HEALTH DISORDERS IN CHILDREN**

Interest in social policy among mental health professionals was precipitated by several developments. One of these was the implementation during the 1960s and 1970s of federally sponsored social programs such as Project Head Start ([Zigler and Muenchow, 1992](#); [Zigler and Styfco, 1993](#); [Zigler and Valentine, 1979](#)). The proliferation of such programs, and the funds made available for them, enabled researchers and clinicians to apply their knowledge and training to such areas as program development and evaluation, which had not previously received their attention ([Phillips, 1987](#); [Salkind, 1983](#); [Takanishi et al., 1983](#)). A related development, noted by [Zigler \(1998\)](#), is that to secure funding for research, it is often necessary to demonstrate the practical application of findings and their potential to address societal needs.

Another development that fueled the interest in social policy was the recognition that children develop within the social context; they are influenced by various aspects of their immediate environment as well as by the more remote social institutions such as the school, the workplace, government, and the mass media, areas over which children and parents have little, if any, control ([Bronfenbrenner, 1979](#)). This realization gave impetus to ecologic studies and the compilation of information on children's behavior, achievement, and physical and mental health ([Garbarino and Kostelny, 1995](#)). On the basis of data generated by these efforts, it has become apparent that ever-growing numbers of children and adolescents in the United States face serious problems that often result in mental dysfunction ([Miringoff, 1993](#)).

### **Scope of the Problem**

The magnitude of the problem has been noted for some time: a committee of the [Institute of Medicine \(1989\)](#), convened at the request of the National Institute of Mental Health, studied the mental health status of children and adolescents. It found that at least 12% of children less than 18 years of age (7.5 million children) have a diagnosable mental illness, and many other children exhibit broader indicators of dysfunction, including substance abuse, teen pregnancy, and school dropout, which the committee defined as consequences of or risk factors for developing mental disorders. These findings are echoed in more recent studies. One of these studies estimates that 20% of youths aged 9 to 17 years have a diagnosable emotional or behavioral disorder, and 9% to 13% of them suffer from serious emotional disturbances that interfere with their daily functioning ([Manderscheid and Sonnenschein, 1996](#)). Another study, by [Kazdin \(2000\)](#), focuses on even younger children, indicating that 10% of 3- to 17-year-old children and adolescents in the United States receive treatment for emotional and behavioral disorders.

That so many children are affected by mental disorders suggests that the problem is of national concern. The costs involved in treating mental health disorders are difficult to estimate, in part because of comorbidity with other problems such as substance abuse, a situation that makes it difficult to separate the costs of care associated with each disorder. Additionally, the information needed to calculate the personal, social, and other costs of childhood mental disorders has not been systematically collected, thus rendering any cost analyses conservative estimates at best. Nevertheless, the studies that are available suggest that the costs of childhood mental disorders are staggering. [Rice et al. \(1990\)](#) found that treatment services for mentally ill children aged 14 years and younger exceed \$1.5 billion a year. Other investigators suggest that the costs of mental illness in children are much higher because, besides treatment costs, there are indirect costs and costs for nonhealth services, which are borne by families, the schools, the juvenile justice system, and other social institutions ([Office of Technology Assessment, 1986](#)). As an indication of the costs involved, the estimated direct and indirect cost of mental illness for the total population of the United States was \$150 billion in 1996, the latest year for which data are available ([U.S. Department of Health and Human Services, 2000](#)). Clearly, more definitive analyses are needed to establish the actual costs of childhood mental disorders, and such information is important if we are to have a context within which to make decisions about the care of mentally ill children and the allocation of funds to address their needs.

This is a critical issue, given the widely held belief that many children do not have access to mental health services. Two major points are noted in this regard. First, only a small proportion of the overall health budget is directed toward children ([Deal et al., 1998](#)). Second, the health care reforms that have replaced fee-for-service care with managed care have had both positive and negative impacts on mental health care for children and adolescents. According to the National Health Care Reform Tracking Project, a 5-year study of the impact of managed behavioral health care, access to health services in general has increased for young people ([Stroul et al., 1998](#)). However, with the emphasis on brief, problem-oriented approaches, it has become more difficult for children with serious emotional disorders (the "high users") and the uninsured to obtain the care needed. Additionally, 90% of health care expenditure for children is consumed by the 15% of children who have chronic illness and disability, and this leaves little for mental health care. In budget allocation decisions that are made, for example, when Medicaid funds are decreased, mental health services are often eliminated.

### **Contributing Factors**

Perhaps even more significant than the findings on the prevalence and potential costs associated with childhood mental disorders are the findings on the factors that contribute to the development of such disorders. More research is needed to unravel the causes and determinants of childhood mental illness. However, much progress has been made since the 1980s, including multiple lines of evidence that suggest that various biological, psychological, social, and environmental factors are involved as causal agents, and, in some cases, an interaction among these factors exacerbates vulnerability to mental disorders. Of significance is that in increasing numbers of children, social and environmental risk factors are implicated in the onset of mental dysfunction ([Galston, 1993](#); [Tuma, 1989](#)). Included among these risk factors are prolonged separations between the parent and child ([Tennant, 1988](#)), physical or sexual abuse ([Rutter and Smith, 1995](#); [Widom, 1998](#)), poverty ([Brooks-Gunn and Duncan, 1997](#); [Garmezy, 1985](#); [Rutter, 1976](#)), marital discord ([Wallerstein, 1988](#); [Wallerstein and Corbin, 1996](#)), parental psychopathology ([Beardslee et al., 1998](#)), instability in the family environment ([Rutter, 1987](#)), and various other stressors related to family life ([American Psychiatric Association, 1987](#); [Institute of Medicine, 1989](#); [Tuma, 1989](#)). [Rutter \(1980\)](#) points out that children who experience one of these risk factors may not be any more likely to suffer serious

consequences than children with no risk factors. However, the more risks or stressors that are present in children's lives, the greater is the probability of damaging outcomes.

In addition, some risk factors compound other problems, such as low birth weight and central nervous system difficulties, which, when they occur in isolation, may have no negative effects. Infant central nervous system difficulties, for example, may be overcome if the child is reared in a stable and supportive environment, but they are exacerbated if the child is raised in an unstable, poorly educated, low-income, or otherwise stressful family environment ( [Hughes and Simpson, 1995](#); [Sameroff et al., 1987](#)). Likewise, premature babies of low birth weight, who are more vulnerable to environmental insufficiencies than are full-term babies, may experience developmental problems if they are reared by unresponsive adults, but these infants may suffer no negative consequences if they receive appropriate care ( [Hack et al., 1995](#)).

#### *CHANGES IN FAMILY LIFE*

These findings raise concerns because many children today experience potentially damaging experiences that stem from difficult conditions in family life. Since the early 1970s, the society of the United States has undergone vast economic and social changes, which have transformed the structure of the family and the roles and responsibilities of men and women. These changes have created stressful conditions for children and adults.

Consider, for example, the increased fragmentation and isolation of the family. Currently, one of every four children in the United States lives in a single-parent family, and among African-American children, the rate is one of every two children ( [Children's Defense Fund, 1998](#)). The growth in the number of single-parent families is particularly disturbing because it is often associated with multiple stressors for both parents and children. The presence of a female head of household, young children, poverty, and maternal depression are characteristic traits (although not ubiquitous ones) of single-parent families ( [Kagan and Fuller, 2000](#); [U.S. Bureau of the Census, 1988](#)). The rise in single-parent households is attributable largely to the increasing number of births to unmarried mothers ( [Blank, 1997](#); [Hernandez, 1998](#)). Although the birth rate for married women has declined since 1980, the birth rate for unmarried women increased 49% between 1980 and 1990 and remained constant through to 1995, a finding reflecting the growing preference for unmarried status ( [U.S. National Center for Health Statistics, 2000](#)). The percentage of nonmarital births to African-American women is particularly high, at 69.7% ( [Blank, 1997](#)).

Some single-parent families are the result of divorce. Although the rate of divorce has remained constant after a significant rise in the 1960s and 1970s, roughly 40% of children will nevertheless experience the divorce of their parents ( [Behrman and Quinn, 1994](#)). The rate of divorce is higher among African-American families ( [U.S. Bureau of the Census, 1992](#)). Although divorce is not necessarily a disaster for children, stresses arising from the disruption and subsequent remarriage of parents often lead to psychological difficulties among children ( [Emery, 1999](#); [Twaite et al., 1998](#)).

A related change in family life is the relative isolation and lack of social support that have occurred because of the increasing mobility of people in search of employment and other opportunities, as reported by McCullough, in testimony presented to the U.S. Congress ( [U.S. House Select Committee on Children, Youth and Families, 1987](#)). As a result, many families no longer live near or have access to the support and assistance of friends and relatives. Referred to by some as a decrease in "social capital" ( [Coleman, 1987](#)), the lack of social support is notable, because having access to a support system often mediates the negative consequences of stress ( [Brown and Harris, 1978](#); [Garnezy, 1985](#); [Gore, 1980](#)).

#### *IMMIGRATION AND ETHNIC DIVERSITY*

Another important societal change has been the growth in the proportion of immigrants and ethnic minorities in the United States. Currently, 20% of children less than 18 years of age who are living in the United States are immigrants, and this percentage is likely to increase ( [Blum and Berrey, 1999](#)). The profile of immigrants in the United States is changing; they are arriving from increasingly diverse countries of origin and are experiencing more limited economic opportunities upon arrival in the United States than was the case with previous generations of immigrants. Research indicates that, despite the great diversity between and within immigrant groups, many share particular needs arising from the experience of stress, depression, and isolation in the years after their arrival in the United States ( [Board on Children and Families, 1995](#)). Furthermore, because many immigrants lack full access to education, health, and social services, the healthy development of children is jeopardized. There has also been a significant rise in racial and ethnic diversity within the U.S. population, and this development also raises concerns regarding the availability, access to, and nature of social services. It is projected that by 2030, 50% of children living in the United States will be nonwhite ( [Hernandez, 1998](#)). It is thus increasingly important that services for children are tailored to the cultural diversity of the population. The increased diversity also poses a challenge for policy makers to design effective antipoverty strategies because the poverty rate is higher among some racial and ethnic groups than in the general population.

#### *POVERTY*

Poverty is a grave concern because increasing numbers of families with young children are experiencing serious economic problems. This is in part because of the growth in the number of single-parent households, which are the largest and fastest growing family type ( [Blank, 1997](#)). According to the Current Population Survey ( [U.S. Bureau of the Census, 1999](#)) in 1998, children younger than 6 years old who were living with a single mother were five times more likely to be poor than children living with both parents. Other contributing factors are cuts in public assistance and the decline in the real value of family income ( [Blank, 1997](#); [Children's Defense Fund, 1993](#)). The United States provides far less public income assistance to single-parent families than do many other industrialized nations ( [Blank, 1997](#)). Instead, welfare reform initiatives emphasize labor force participation as the route out of poverty. However, whereas in the past, economic prosperity and employment were effective means of reducing the poverty rate, they are no longer sufficient as an antipoverty strategy for single-parent families because of the decline in wage rates, particularly for less-skilled workers ( [Blank, 1997](#)). For example, in the 1980s, each 1% expansion in the aggregate economy correlated with a \$0.32 decline in weekly wages. Comparing two strong economic years, high school dropouts earned 22% less in 1993 than in 1979, whereas high school graduates earned 12% less. This compares to a rise in income of 10% for college-educated men and 22% for men with postcollege degrees ( [Blank, 1997](#)). For two-parent families, the wage decline has been partly offset by the entry of increasing numbers of women into the labor force, but for single-parent families, the escape from poverty is more difficult.

The decline in real income affects adults and children. However, for children the consequences are particularly serious because, as noted earlier, many families in poverty are those with young children. Indeed, even though the overall poverty rate has declined in recent years, poverty among children less than 18 years old remains high at 18.9%, which is 13.5 million children. Children less than 6 years old are particularly vulnerable, with a poverty rate of 20.6% ( [U.S. Bureau of the Census, 1999](#)).

The ramifications of living in poverty are numerous and include assaults on children's physical and mental health ( [Wolfe, 1995](#)). [Klerman \(1991\)](#) found that poor families have no access to health care, and other conditions associated with poverty, such as lack of money to spend on health-promoting activities, hunger, lack of transportation, and inadequate housing, further exacerbate the problem. As a result, poor children experience more health problems and have a higher mortality rate. Several other studies indicate a powerful, albeit indirect, link between poverty and mental health disorders, thus leading mental health professionals to the conclusion that poverty is one of the major risk factors in such disorders ( [Albee, 1986](#); [Rutter, 1976](#); [Webster-Stratton, 1998](#)). Although at one time mental dysfunction, low achievement, and other problems associated with poverty were discussed in terms of assumed negative traits of poor children, researchers now realize that the major sources of psychopathology associated with poverty stem from environmental stresses and feelings of powerlessness and frustration ( [Albee, 1986](#); [Albee and Gullotta, 1997](#)). Moreover, poor families have a high incidence of poor prenatal care, low birth weight, and malnutrition ( [Brown, 1998](#); [Chomitz et al., 1995](#)), which are known to contribute to children's vulnerabilities to environmental stress ( [Institute of Medicine, 1989](#)). Parental depression and substance misuse are also heightened among poor families, and these factors increase the risk of child neglect and abuse and contribute to mental health disorders ( [Johnson and Leff, 1999](#); [U.S. Department of Health and Human Services, 2000](#); [Widom, 1998](#)).

#### **PREVENTING MENTAL HEALTH DISORDERS: POLICY DIRECTIONS**

These stressful conditions are just a few examples of the changed circumstances under which many children live. Other potentially damaging conditions that result from marital discord, maternal employment, and the increasing reliance of families on child care are discussed later in the chapter. Although most families are affected by these changes in family life, social policies in the United States have not kept pace with societal changes. Our society is, as a result, in a state of disequilibrium wherein social policies are not in synchrony with the realities of family life.

#### **Contributions from the Research**

This disequilibrium is creating difficulties for families. Not all mental health disorders in children stem from such difficulties. However, the stressful conditions under which many children live place a burden on children's ability to cope with the demands of school, the family, and relationships with peers. The problems that emanate

from the changing conditions of family life touch on economic realities, traditions, and institutional structures, so solutions may be slow to evolve ( [Zeitlin, 1989](#)). Nevertheless, mental health professionals can have a positive effect on family life in several ways. For example, they can alert policy makers and the general public to how stress in families negatively affects the very core of society. They can also call for further studies of the conditions under which children live and children's responses to these realities. This focus on research is important. It can deepen our understanding of how children are affected by different conditions and of why some children are able to cope with difficulties in their lives whereas other children succumb ( [Garmezzy, 1985](#); [Gunnar, 1996](#)). The research can also enhance our understanding of the ways children cope with problems so we can devise useful strategies for intervention and prevention. To illustrate how scientific research can be a constructive force in the policy process, we discuss some of the studies related to major societal changes as well as associated policy developments that have had a profound impact on family life.

### WELFARE REFORM

The most dramatic piece of legislation for children and families in recent years is the Personal Responsibility and Work Opportunity Reconciliation Act of 1996. By replacing Aid to Families with Dependent Children with Temporary Assistance to Needy Families, the government effectively reduced public entitlement to cash benefits. States are now granted greater flexibility in the use of welfare funds, although they are obliged to impose work requirements and a 5-year lifetime limit on receipt of federal assistance.

What has been the impact on children and families? The plethora of research studies on the impact of welfare reform reveals success in achieving a 40% reduction in the numbers of dependent families, along with a substantial increase in labor force participation by mothers ( [Blum and Berrey, 1999](#)). However, these positive indicators may mask unmet needs. First, a primary implication of increased employment is the need for child care. Research indicates that many parents lack access to high-quality care for their children, either through poor provision or because it is too expensive. These findings were highlighted in the first wave of results from a study of the impact of welfare reform in California, Florida, and Connecticut ( [Kagan and Fuller, 2000](#)). The study noted that most children were in home-based care, and only 13% of this care was deemed to be of good or excellent quality. (The importance of high-quality preschool care for children's development is discussed later in the chapter.) A second implication of the welfare reform emphasis on employment is that some parents who have difficulty in maintaining employment may be rendered ineligible for financial assistance, thus increasing the poverty of their family. For example, the long-term unemployed are likely to require support to maintain their jobs; furthermore, some poor people, through depression, domestic violence, addictions, or mild mental retardation, may be unable to sustain employment. The figures indicating reduction in welfare dependency do not account for those who have been diverted from welfare assistance without entering employment ( [Blum and Berrey, 1999](#)). Third, welfare and immigration legislation has reduced access to noncash services such as Medicaid and Food Stamps, and it has affected 20% of the children living in the United States ( [Blum and Berrey, 1999](#)). [Aber et al. \(1995\)](#) further indicate that overall welfare reform does not appear to have reduced child poverty, despite the increased levels of parental employment. However, the researchers note that some specific groups, such as children of teen parents, may fare well as long as they are provided with sufficient support services to mediate any negative impact associated with welfare reform.

### MATERNAL EMPLOYMENT

Another complex societal change affecting all children, regardless of family income, has been the entry of large numbers of women into the labor force. This phenomenon is especially apparent among women who have children. For women with school-age children, full-time employment has been relatively common for about three decades; more than 70% of such mothers now work out of the home. Among women with infants and preschool children, more dramatic changes have taken place. In 1973, 30% of mothers with children younger than 6 years old and 50% of mothers with school-age children were working. By 1997, these figures had risen to 65% and 77%, respectively ( [Children's Defense Fund, 1998](#)). Among mothers with infants, the rise has been even more dramatic. In 1987, fewer than 30% of women with infants 1 year old and younger were working. By 1998, 55% of mothers returned to full-time work within a few weeks of the baby's birth ( [Children's Defense Fund, 1998](#); [U.S. Department of Labor, 1997](#)).

Research on the effects of maternal employment on children finds that, in and of itself, maternal employment is not necessarily associated with either negative or positive effects ( [Greenberger, 1989](#); [Hoffman, 1989](#); [Zaslow and Emig, 1997](#)). Rather, parental attitudes to the mother's employment are more significant in their effects on children than is employment itself ( [Hoffman, 1986](#); [Hoffman, 1989](#)). However, researchers point out that although maternal employment appears to be benign in its effects on children, in many dual-worker families, both the parents and the children experience an inordinate amount of stress. In general, women have assumed new roles in the workplace, but they have not abdicated their traditional responsibilities to family life and child rearing. This situation has resulted in role conflict and guilt ( [Hoffman, 1989](#); [Moen and Dempster, 1987](#)), as well as in changes in lifestyle and difficulties that permeate the whole family system. Studies have found that almost 40% of employed parents, both women and men, indicate that they experience severe conflict, guilt, and stress ( [Friedman, 1987](#)). For children, this state of affairs means that not only do they have less time with their parents, but also they are affected by the fact that their parents are under stress from trying to do too much.

Other institutions besides the family are affected by the increase in women's participation in the out-of-home labor force. Employers, concerned about worker productivity, are raising questions about women's juggling work and family responsibilities, and some employers are also beginning to realize that they may be losing valued female employees when child rearing conflicts with full-time work. There are also pressures on institutions such as the school, which have to implement changes to accommodate the needs of children not only during school hours but also before and after school ( [Finn-Stevenson and Zigler, 1999](#); [Zigler, 1989](#)). Additionally, changes have occurred in some professions that were previously associated with flexible work schedules that enabled mothers to work and at the same time rear their children. Teachers, for example, are finding that they have to extend their work day and thus disrupt their own family life because many of their students' parents are working and are unavailable for parent conferences and other school events during the day (Zeitlin, 1989).

### Increased Demand for Child Care

Although numerous societal changes are associated with women's participation in the labor force, none are as significant as the unprecedented demand for child care services. Today, child care is one of the most widely recognized social problems. Virtually everyone, from working parents to chief executives of major corporations, is discussing the lack of good-quality, affordable child care services. Child care is also the subject of debate at state and local level governments, where the need for child care services is noted. The attention to the child care issue is not surprising, given the increase in the number of infants and children who need child care. However, it belies the fact that it has been a major social problem for more than three decades. At the 1970 White House Conference on Children, the need for child care services was noted as the number-one priority for the nation to address. However, two obstacles—ideologic arguments against the use of child care and the lack of public awareness of the need for child care services—stood in the way of policy action on the issue ( [Nelson, 1982](#)). As a result, the problem worsened and reached crisis proportions before it finally attracted national recognition.

Notwithstanding the attention the issue now receives, child care continues to be regarded as an individual family problem to be addressed by parents. This is evident in that most businesses do not make provisions to ease the stresses associated with balancing work and family life, and despite the enactment of the Family Support Act and the Child Care and Development Block Grant, which provide needy families with financial assistance for child care, the nation is still far short of having a comprehensive solution to the problem ( [Finn-Stevenson and Zigler, 1999](#); [Zigler and Lang, 1991](#)).

The child care problem has numerous facets, one of these being the high cost of services. This is a major concern for parents, some of whom choose a child care facility solely on the basis of cost. This point is made by [Hofferth and Wissoker \(1992\)](#), who found that parents not only choose child care on the basis of cost, but also switch facilities if the price increases. Precise data on what families spend on child care are not available, but it is known that child care costs are anywhere between \$1,500 and \$10,000 a year, depending on the quality of care and the age of the children. It is estimated that full-time child care for preschoolers costs an average of \$3,000 a year, and for infants, the costs can exceed \$9,600 a year. With the cost of care being so prohibitive, it is not surprising that it is one of the major factors in choosing child care.

From a policy perspective, the high cost of care is significant for at least two other reasons. First, child care costs are a major expenditure for families, and the amount of money families spend on child care is directly related to their income ( [Future of Children, 1996](#)). Low-income families spend less on child care in absolute terms than do higher-income families, but the proportion of the family budget that is taken up by child care costs is greater among low-income families, who have to allocate as much as 27% of their earnings to child care ( [Kagan and Cohen, 1997](#)). Even for middle-income families, the burden of child care costs are great, because these families do not qualify for state subsidies and pay higher taxes on their earnings ( [Betson and Michael, 1997](#)). Second, there is a relationship between the cost and quality of care, with good-quality care costing substantially more than poor-quality, custodial care. This being the case, there are inequalities in the quality of child care children experience, depending on their family's income. The finding that good-quality care is a privilege that only some children are enjoying is of concern because the child care setting is an environment in which children spend a large portion of every day. As such, it has significant effects on children's development and well-being. For example, research highlights the link between educational child care programs and reduced rates of violence and crime ( [Newman et al., 2000](#)).

In an attempt to define good-quality care, mental health professionals make a distinction between developmentally appropriate care that is responsive to the needs of children and care that is merely custodial ( [Phillips, 1987](#)). The determinants of good-quality care have been found to be an age-appropriate ratio of staff to children and group size, as well as the presence of providers who have knowledge of and training in child development ( [Arnett, 1989](#); [Roupp et al., 1979](#)). Training in child development, rather than years of experience working with children, sets apart nurturing providers who respond to the varied and individual needs of young children from providers who are unable to provide children with appropriate experiences ( [Arnett, 1989](#)).

Researchers have used this information in important ways to address the needs of children and to promote national awareness of the lack of quality child care and its impact on children. For example, in the Cost, Quality, and Outcomes Study ( [Helburn, 1995](#)), researchers examined child care centers in four states and looked at the relationships among the cost of child care, the actual experiences of the children in the centers, and the effects of these experiences on children's development. The study noted several disturbing findings, the major one being that although child care centers vary widely, most centers are mediocre in quality and are "sufficiently poor to interfere with children's emotional and intellectual development" ( [Helburn, 1995](#)). Forty percent of the infants and toddlers in center-based care were found to be at risk as a result of poor health and safety standards. In the follow-up to this study, it was confirmed that children in poor-quality care do indeed experience developmental problems that persist when the children are of school age ( [Peisner-Feinberg et al., 1999](#)). Another study focused on the quality of care in family day care homes and in the homes of relatives, which are popular child care choices among parents, especially low-income parents and parents of infants and toddlers. The study found that only one in nine family day care homes offered good-quality care, and that the quality of care by relatives was even worse ( [Galinsky et al., 1994](#)).

Researchers used child care quality indicators in other ways as well, for example, in the development of training programs and accreditation for child care providers and child care facilities ( [Bredenkamp and Copple, 1997](#); [Ward, 1976](#)) and in the establishment of guidelines for the operation of child care programs ( [Provence, 1982](#)) and evaluative tools to assess the quality of child care facilities ( [Harms et al., 1998](#)). [Young et al. \(1997\)](#) used quality indicators to determine whether the standards governing states' child care licensing requirements are adequate. These investigators found that although state regulations represent a basic minimum in terms of ensuring the health and safety of children, the regulations in most states fall below even that minimum. In other words, a child care facility may be licensed by a state, but that does not mean that it provides good-quality care. The researchers not only analyzed states' regulatory standards, but also recommended changes states can make to upgrade the quality of child care.

These and other similar efforts underscore two important points about the link between research and policy: (a) research findings can be brought to bear on social problems and can serve as the impetus for appropriate action ( [Zigler and Finn-Stevenson, 1987](#)), and (b) a thorough understanding of the problem—in this case, the factors that influence quality care—is essential if mental health researchers are to be able to make recommendations for appropriate action.

The research on child care, discussed only briefly in this chapter, has also focused on the effects of child care on infants as well as other issues such as supply and demand and the availability of child care services. The research has been important and provides indications that although the supply of child care facilities for preschoolers has increased since 1977, there are still regions in the United States where demand exceeds supply ( [Kisker, 1991](#)). Studies also suggest that the demand for child care is going to increase, given the growing presence of women in the labor force as well as other demographic factors and employment trends ( [Child Care Action Campaign, 1988](#); [Hernandez, 1998](#)). Additionally, it has been found that in two segments of child care, namely, child care for infants and toddlers ( [National Center for Clinical Infant Programs, 1988](#)) and child care for school-age children, the demand far exceeds the supply ( [Seligson, 1989](#)). On this latter point, the research has led to policy action, with the federal government allocating substantial funds for the establishment of supervised programs for children during time when they are out of school. This is important because, for adolescents, the peak time for violence, crime, and sexual activity is after school hours, between 3 and 6 PM, when many are unsupervised by an adult ( [Besharov, 1999](#)).

#### *Changes in the Workplace to Support Family Life*

The high cost of child care and the lack of good-quality care is an issue not only because of the possible harm to children, but also because it is a source of stress for parents. This situation has prompted discussions of the need to make changes in the workplace to create conditions that are supportive of family life. Several suggestions have been made, including corporate support of child care services. Although a few companies have developed on-site child care centers for their employees, and others partially offset the cost of child care for their employees or provide other supportive services, such as information and referral, the need for child care is too large for corporations to address alone. Corporate involvement can thus be conceived, at best, as only one part of a comprehensive solution to the child care problem.

However, there are other ways for corporations to support family life. For example, some corporations may be able to implement flexible schedules to allow employees time for child-rearing responsibilities ( [Bureau of National Affairs, 1986](#)). Some corporations provide this option to their employees, but most do not ( [Friedman, 1987](#); [Kamerman, 1983](#)). In some businesses, flexible work schedules may prove to be counterproductive and therefore unworkable as a means to enhance family life. However, among some corporations, such changes can be effectively implemented if steps are taken to alert the corporate world to the need and importance of such changes in the workplace. It has been suggested that mental health researchers can help by engaging in relevant studies. Among the questions that need to be addressed, [Stipek and McCroskey \(1989\)](#) note that little research is currently available on the different work schedules that support employees in their role as parents, on the increased productivity, if any, associated with different work schedules, and other important questions, such as how do different work schedules for parents affect the frequency with which children are sent to school ill or are examined by a doctor? This latter research question is important in part because even when parents have good child care arrangements, they need to be at home with their children when the children are ill. Parents' inability to take time off from work, however, has resulted not in any workplace policy changes but rather in the development of child care facilities that specialize in the care of sick children. This is disturbing because children who are ill need to be with their parents. No studies are needed to establish this fact. In fact, the American Academy of Pediatrics indicates that studies substantiate that children's ability to overcome illness and to benefit from medical treatment is directly related to their being with their parents during the illness. However, because of lack of advocacy on the issue, society's response to the care of sick children has been child care for sick children rather than the institution of flexible work schedules for parents.

#### *Parental Leave*

Related to flexible work schedules is the need for parental leave policies that would enable parents to spend time with their infants during the first several months after birth. Any student in child psychiatry is well aware that the first few months of life represent a critical period for the development of attachment between parents and the infant, and within the context of a secure parent–infant relationship, the growing child thrives and is encouraged to become more autonomous ( [Ainsworth et al., 1978](#); [Cicchetti et al., 1990](#)). The first few months of life also represent a very stressful period of life that necessitates the adjustment of all family members to the newborn ( [Brazelton, 1985](#)).

A Blue Ribbon Committee on Infant Care Leave studied the issue and found that increasing numbers of women return to work very shortly after the birth of a baby. The committee recommended that, in the interests of infant mental health as well as parents' well-being, one of the parents should be given the option of a paid leave of absence from work for the first 6 months after the infant's birth ( [Zigler and Frank, 1988](#)). Although the importance of such leave is noted on the basis of medical and social science research ( [Hopper and Zigler, 1988](#); [Zigler and Frank, 1988](#)), adequate parental leave is not available to most parents in the United States.

This lack is despite the passage of the Family and Medical Leave Act in 1993, which granted 12 weeks of unpaid leave in any 12-month period to employees in companies of 50 or more workers. The impact of the federal legislation was limited for three major reasons. First, 34 states had already passed laws before the Family and Medical Leave Act ( [Finn-Stevenson and Trzcinski, 1991](#); [Trzcinski and Finn-Stevenson, 1991](#)). Second, as many as 40% of workers were ineligible for leave because of the size of their companies, because most workers are in small businesses ( [U.S. Department of Labor, 1996](#); [Wisensale, 2000](#)). The business community is adamantly against any interference with their policies and has thus lobbied to exclude small companies from eligibility. Third, the leave granted was unpaid, and research shows that many workers have been discouraged from taking leave for financial reasons ( [Waldfogel, 1999](#)). However, the Family and Medical Leave Act is significant as the first national move toward parental leave, and it has prompted discussions about paid leave at the federal level and in some states, such as Connecticut. Again, the issue of parental leave is instructive, because it reveals how findings from research can influence policy.

#### *DIVORCE*

Another reality for many families is divorce. The rate of divorce, particularly among families with children, rose dramatically between 1965 and 1979. Since 1979, the rate of divorce has declined and seems to have reached a plateau ( [Hernandez, 1988](#)). Nevertheless, it is estimated that half of all first marriages in the United States will end in divorce ( [U.S. Bureau of the Census, 1992](#)). The presence of children is not a deterrent: roughly 60% of all current divorces involve children ( [U.S. National Center for Health Statistics, 1995](#)). Most children will experience the remarriage of one or both of their parents and will live in reconstituted families ( [Emery, 1999](#)).

This is illustrated by the following data. Although 71.8% of U.S. children live with a mother and father figure, the percentage of children living with their biological parents is much lower: 64.9% of white children, 23.6% of African-American children, and 53.4% of Hispanic children ( [U.S. Bureau of the Census, 1992](#) ).

Controversy surrounds the impact of divorce and remarriage on children. [Emery \(1999\)](#) draws four salient points in his review of the research. First, divorce is a source of great stress for children, whether through loss of contact with a parent or because of economic hardship. Second, divorce makes psychological problems up to twice as likely for children: even though children may appear to adapt well initially, there may be delayed negative effects ( [Wallerstein, 1988](#) ; [Wallerstein, 1991](#) ; [Wallerstein and Corbin, 1996](#) ). Third, despite the risks, most children from divorced families function as well as those from married families, a finding demonstrating resilience ( [Twaite et al., 1998](#) ). Fourth, resilience does not preclude vulnerability: children experience difficult feelings despite coping well. The outcomes of divorce for children depend on many factors including age, gender, ethnicity, and socioeconomic status. [Tschara et al. \(1990\)](#), for example, find that children have difficulty in adjusting to the divorce if they are older, have had prior psychological problems, and have parents with more marital conflict. [Hetherington et al. \(1989\)](#) find that the long-term effects of divorce and remarriage appear to be related to numerous factors, including the following: the child's developmental status, gender, and temperament; the quality of the home environment; and the availability of support systems, both to the parents and the child.

The number of stressors the child experiences is also a factor because, as noted earlier, a single stress typically does not carry with it appreciable psychiatric risk, but multiple stressors increase the risk of mental dysfunction ( [Rutter, 1980](#) ). Particular concern is noted for children whose custodial parent experiences extreme economic difficulties for an extended period or whose noncustodial parent fails to pay for child support ( [Emery, 1999](#) ; [Haskins et al., 1985](#) ). In 1991, only 54% of single parents with children had awards for child support, and only half of these awards were paid in full ( [Emery, 1999](#) ; [U.S. Bureau of the Census, 1995](#) ). Even when awards were paid, the average amount was small, at \$3,011. Part of the problem is that the noncustodial parent also may have a low income, but often, noncustodial parents simply refuse to acknowledge financial responsibility for their children.

Children whose parents suffer emotional and psychological difficulties as a result of the divorce are also likely to experience multiple stressors. Researchers have found that parents whose distress is acute fail to attend to the needs of their children, do not recognize the children's painful experience with the divorce, or burden the children with their own adjustment difficulties ( [Kurdek and Blisk, 1983](#) ).

Also at substantial risk are children who are involved in prolonged custody fights. These are the most vulnerable of children of divorce because custody battles can continue indefinitely. Judges attempt to make custody decisions on the basis of the best interests of the child. However, neither judges nor lawyers are prepared for the arduous task of determining the best interests of the child, nor are they trained to interview the child, consider his or her needs and concerns, or weigh the urgency of the child's condition and circumstances ( [Wallerstein, 1986](#) ). Recognizing the child as the hidden client in divorce proceedings, Goldstein et al. attempt to provide guidance to lawyers and judges by incorporating legal considerations within the framework of principles drawn from developmental psychology and psychiatry ( [Goldstein et al., 1973](#) ; [Goldstein et al., 1979](#) ). They recommend that decisions regarding child custody be made quickly, that an effort be made to avoid prolonged proceedings, and that whatever decision is made have a final effect that is not reversible. They further recommend that judges award full custody of the child to one "psychological parent." There is controversy surrounding this last recommendation. Some psychiatrists emphasize the psychological value for some children of maintaining a close relationship with both parents, even those involved in a bitter dispute over custody issues ( [Guidibaldi et al., 1983](#) ). Although some of their recommendations are controversial, Goldstein et al. pave the way for other psychiatrists to think about the use of knowledge and theoretical principles in establishing criteria for practical decisions that involve children.

#### *Mediating the Effects of Divorce*

The need for mental health professionals to consider the policy implications of their work is underscored by Wallerstein ( [1986, 1988](#) ). Wallerstein notes that although increasing numbers of policy makers and legal professionals are seeking guidance from the mental health professions, the accumulation of psychological knowledge has not kept up with rapid changes that have occurred in family law. [Hetherington and Camara \(1984\)](#) make a similar point, by indicating that the knowledge about the effects of divorce on children and on postdivorce parent-child relationships is still fragmentary, with several important questions remaining to be addressed.

Although more research is needed, sufficient information currently exists for us to appreciate the widespread implications of the research and the opportunities that exist to mediate the consequences of divorce. In this regard, the knowledge of how divorce affects children and parents should be disseminated not only among mental health professionals but also among other professionals who work with children. Teachers, for example, need to be alerted to these findings so they can be sensitive to any changes in children's behavior and can offer them and their parents support and counsel about ways they can cope with the changes in their lives ( [Kurdek, 1981](#) ; [Miller et al., 1999](#) ). Additionally, as noted earlier, the legal profession needs to be made aware of the research and its implications. Ideally, psychological support for parents and children should be made available immediately when the divorce proceedings begin. One important policy development has been the use of mediation services in divorce cases. These services are staffed by mental health professionals who have access to legal advice. Although initially begun as a way to curtail the high costs of divorce, families who have used mediation services note that one of the major benefits of the services is the availability of psychological support ( [Bahr, 1981](#) ).

The importance of psychological support for children of divorce should be made known to policy makers, who can make it a national priority to ensure that these children have access to support services. Several successful support programs for children of divorce have been developed in schools across the United States ( [Weiss, 1989](#) ). However, they are few, and they meet the needs of only a small percentage of the children who stand to benefit from such programs. Given the number of children who need such support, these programs should be made available in all schools, or at least in some schools in every community. The federal government can take a leadership role by making available funds that would finance the development of such programs.

#### *PARENTAL PSYCHOPATHOLOGY*

Divorce is only one circumstance under which parents may be unable to fulfill their parenting responsibilities adequately. A substantial body of literature supports the observation that children of psychiatrically impaired or substance abusing parents have an increased risk of developing mental health problems compared with children of normally functioning parents ( [Beardslee et al., 1998](#) ). It has long been recognized that maternal depression is widespread, particularly among families in receipt of welfare ( [Brown and Harris, 1978](#) ). [Kagan and Fuller \(2000\)](#) observed in their sample of 948 single mothers with young children that the incidence of depression was three times higher than the national average, and maternal depression resulted in disengaged parenting practices likely to result in poor development.

Another area of increasing concern is parental substance misuse. An estimated 11 million children less than 18 years old have alcohol-dependent parents, and the number of children whose parents abuse drugs is unknown ( [Johnson and Leff, 1999](#) ). Negative influences are transmitted to children through a variety of mechanisms. One leading area of research addresses the consequences of prenatal exposure to cocaine and identifies disruptions to development such as impaired arousal regulation, which lowers the threshold for coping with stressful conditions ( [Mayes et al., 1998](#) ). Other scholars document the relationship between parental substance abuse and subsequent psychopathology in children and emphasize the role of mediating factors such as family conflict, lack of family rituals, poor home management, ineffective parenting strategies, physical violence, abuse, isolation, stress, and frequent family moves ( [Johnson and Leff, 1999](#) ; [Widom, 1998](#) ). With the rates of drug misuse increasing, it is important to provide medical and social support to families to ensure healthy child development.

#### **OTHER EXAMPLES OF THE POSSIBILITIES INHERENT IN THE INTEGRATION OF RESEARCH AND POLICY: PROGRAM DEVELOPMENT AND EVALUATION**

The importance of support services is noted for many families who encounter different types of stressful life events. Many families, for example, those who have premature or handicapped babies ( [Field et al., 1980](#) ; [Goldberg and DiVitto, 1983](#) ; [Shiono and Behrman, 1995](#) ) or who experience the illness or death of family members, have difficulty coping and are in need of some kind of support. Likewise, many people need assistance with child rearing: many parents need help in gaining the ability to nurture and discipline children simultaneously, or they need assistance coping with transitional problems encountered during different stages of their children's development ( [Albee and Gullotta, 1997](#) ).

Support services are also needed to prevent chronic juvenile delinquency. [Yoshikawa \(1994\)](#) notes an increase in juvenile crime in the United States. There was a 60.1% increase over a 10-year period in arrests of youths less than 18 years old for murder and manslaughter ( [Federal Bureau of Investigation, 1991](#) ). Juvenile crime is linked to the violence that has become part of the daily lives of families, especially those who are poor; it is experienced by increasingly younger children ( [Ososky and Fenichel, 1994](#) ). [Yoshikawa \(1994\)](#) documents several factors that predict chronic delinquency: low socioeconomic status, criminally convicted parents, low intelligence, poor parental child rearing, troublesomeness, and conduct disorders. His review of the research further suggests that programs that combine early family support and education and include, among several aspects, a parent-focused informational and emotional support component, represent a promising direction for the

primary prevention of early-onset, chronic delinquency. Other studies ( [Berrueta–Clemant et al., 1984](#); [Zigler et al., 1992](#)) suggest that early childhood intervention and support programs are linked to the prevention of juvenile delinquency.

## Family Support Programs

In response to the widespread need for such programs, many family support services have been developed and implemented. The programs range from informal, grass-roots, self-help services such as Parents Anonymous and Parents without Partners ( [Whittaker and Garbarino, 1983](#) ), to more formal types of services that include professional assistance ( [Gullotta, 1997](#) ). These programs have been referred to as a “new breed” of programs in that they are rooted in the premise that the most effective way to create and sustain benefits for children is to improve their families and communities. However, this premise is hardly new and can be traced to Project Head Start ( [Zigler and Freedman, 1987b](#) ). Project Head Start, along with other social programs, was initiated in the 1960s in an effort to enhance the lives of young children. It was, and continues to be, an innovative program that includes a cycle of experimentation and revision that helps to ascertain which types of services are best suited for and have the most impact on children. As a result of this cycle of experimentation and revision, and because of research interest in the ecologic study of children, the conventional wisdom about how to address the needs of children has shifted from child-centered programs to programs that focus not only on the child but also on the family as a whole ( [Bronfenbrenner and Weiss, 1983](#); [Zigler and Berman, 1983](#) ).

Although the development of family support programs is conceptually traced to previously developed social programs, these newer programs differ in numerous ways. Most important, many family support programs are nongovernmental initiatives. Rather, they began as grass-roots efforts, initiated and sustained by individual persons in response to stressful situations in their lives, and in the absence of any other form of social support. Although several states have initiated family support programs ( [Powell, 1991](#); [Weiss, 1989](#) ), such programs are still characterized by the lack of government support. Another characteristic of family support programs is that although the programs are varied in the type of services rendered and in the population served, they share a commitment to provide emotional, informational, and instrumental assistance to family members and thus enable persons to cope with whatever problems they may have ( [Weiss, 1995](#); [Zigler and Weiss, 1985](#) ).

### Primary Prevention

In helping in these ways, family support programs exemplify a primary prevention strategy that focuses on the prevention of mental health disorders ( [Caplan, 1974](#); [Albee and Gullotta, 1997](#) ). As noted earlier in this chapter, there is a clear and consistent relationship in research findings between adaptive difficulties and heightened levels of stress ( [Bloom, 1979](#); [Cowen, 1980](#); [Hamburg, 1982](#) ). Other studies have established that both personal and situational variables may mediate this reaction and may enable persons who are vulnerable to become better able to cope. One such variable is social support. Social support has been found to improve a person's ability to withstand stress ( [Albee, 1986](#); [Cassell, 1976](#) ), to mediate the consequences of life crises ( [Gore, 1980](#) ), and to enhance general adjustment and well-being. Social support systems, according to [Caplan \(1974\)](#), should not be conceived of as the propping up of someone who is in danger of falling. Rather, they refer to efforts to augment someone's strengths to facilitate mastery of the environment. [Caplan \(1974\)](#) further points out that social support as a means of primary prevention in mental health should not be perceived as a one-time intervention but rather as an enduring pattern of continuous or intermittent ties that help to maintain the psychological and physical integrity of the individual person.

Families, like individual persons, have a certain life course in which, at particular points, stresses and crises are a natural state of affairs. At those times, support programs can be invaluable in helping family members to use their strengths and to rally to cope with the problem, thus warding off severe family dysfunction and mental health disorders ( [Riessman, 1986](#) ). Although family support programs have this primary prevention potential, the degree to which they are effective in preventing mental disorders is not yet known, because the growth and proliferation of family support programs have not been matched by evaluations of their efficacy ( [Elias, 1997](#) ). The reason for this may be that the programs are grass-roots efforts that were not known to or recognized by many researchers in the field of mental health until recently ( [Weiss, 1984](#); [Whittaker and Garbarino, 1983](#) ). An additional reason is that many such programs are difficult to evaluate. For example, it is often difficult, if not impossible, to select individual persons for participation in a program at random—a basic requirement needed to meet scientific standards.

However, the lack of evaluation data is a characteristic not only of family support programs but also of other types of primary prevention programs. [Cowen \(1986\)](#) notes that evaluation studies are needed to separate some of the good and effective prevention programs now being tried from others that are simply “maintained by inertia or falsely placed conviction.” Addressing the problem caused by the lack of evaluation data, [Zigler and Freedman \(1987a\)](#) observe that although family support programs have proliferated, they have done so without any clear indication concerning the direction their course of growth should take. Moreover, those evaluation studies that do exist are varied in quality of design, appropriateness of data collection measures, and validity of conclusions ( [Roth et al., 1999](#) ). On a more practical level, [Cowen \(1986\)](#) notes that the future of prevention programs in general and family support programs in particular depends on evaluations of their effectiveness, because the funding and therefore the continued existence of many programs often depend on the answer to a single question: Are these programs beneficial and cost effective?

The evaluation of family support programs, although important, is not a simple task. In many cases, the programs have no explicitly stated goals, and this renders an evaluation difficult ( [Weiss and Jacobs, 1988](#) ). Additionally, many of these programs are in the formative stage, too early to evaluate results accurately ( [Rossi, 1998](#) ); these and other problems associated with the evaluation of programs are not insurmountable. Indeed, they are being addressed by many researchers in mental health who are finding that by participating in program evaluation, not only do they contribute to the development of more valid evaluation methods ( [Green and MacAllister, 1998](#) ), but also they contribute to a theoretical understanding of children's development and thereby open up new vistas for research and practice. For example, on the basis of a review of existing evaluations of family support programs, researchers have found that those that are successful in addressing the multiple needs of families have four common features: they are comprehensive; they are flexible; they are located in the community; and they are results oriented, with their ultimate goal to strengthen families ( [Carnegie Corporation of New York, 1994](#) ). These findings about family support services are useful because they provide directions for implementation and the replication of the services on a wider scale ( [Elias, 1997](#); [Schorr, 1997](#) ).

## Children and Violence

Another area of particular concern for researchers and policy makers alike is the “epidemic of youth violence” ( [Marans and Schaefer, 1998](#) ). Although exact numbers are difficult to quantify, there is little doubt that large and growing numbers of children are exposed to violence in their homes, schools, and communities as victims, observers, or perpetrators. For example, a study in New Haven, Connecticut, revealed that 41% of sixth-, eighth-, and 10th-grade students in public schools reported having witnessed at least one violent crime in the past year, and almost all the eighth graders knew someone who had been killed through violence ( [Schwab–Stone et al., 1995](#) ). The findings of such studies are troubling not only because of the threat to children's safety, but also because of the short- and long-term impact on their healthy development. It is not unusual for children exposed to violence to experience disruptions in sleeping, eating, and toileting and to display generalized fear and flashbacks. Repeated exposure increases the likelihood of depression, anxiety, posttraumatic stress disorder, low school attainment, and high alcohol use ( [Marans and Schaefer, 1998](#) ).

### Domestic Violence

Many children also experience violence in their home. Although the issue of domestic violence has been on the policy and research agenda for several decades, the impact on children has received less attention. It is estimated that between 3.3 million and 10 million children in the United States are exposed to domestic violence each year ( [Future of Children, 1999](#) ). Although such violence cuts across the social strata, it is more prevalent among families living in poverty and is associated with multiple stressors including substance abuse and other forms of violence. According to research, in 30% to 60% of families experiencing domestic violence, child maltreatment is also present ( [Edelson, 1999](#) ). Possible consequences for these children include behavioral problems and depression, and in adulthood they may develop low self-esteem and may resort to violence and criminal behavior ( [Future of Children, 1999](#) ). Programs do exist in health care, child welfare, mental health, and law enforcement agencies, but rigorous evaluations have not yet measured their effectiveness.

### VIOLENCE IN SCHOOLS

Media attention has focused on violence in schools ( [Aber et al., 1999](#); [Brener et al., 1999](#) ). Although the high-profile incidents of schools shootings are relatively rare, many young people are exposed to violence of varying levels ( [Schwab–Stone et al., 1999](#) ).

Statistics from the National Crime Victimization Survey and the Youth Risk Behavior Survey indicate a decline in rates of violence that may be partly the result of the proliferation of prevention programs, but rates of violent crime among youth remain high ( [Brener et al., 1999](#); [Federal Interagency Forum on Child and Family Statistics, 1999](#) ). The results from one study indicate no decrease in feeling too unsafe to go to school, being threatened or injured with a weapon on school property, or having property stolen or deliberately damaged at school ( [Brener et al., 1999](#) ). In addition to the immediate consequences of exposure to violence, the longer-term

mental health of young people may be affected. In a survey of 1,100 youth in an urban school, there was a strong correlation between exposure to violence and the development of internalizing and externalizing disorders ( [Schwab–Stone et al., 1999](#)). Children in middle school were found to be particularly vulnerable.

However, although the picture looks bleak, more recent violence prevention strategies have yielded promising results. One of the largest and longest-running school-based violence prevention programs in the United States—the Resolving Conflict Creatively Program—is currently implemented in more than 60 New York City schools and in 12 other school systems across the country ( [Aber et al., 1999](#)). The skills taught in the classroom include communicating clearly and listening carefully, expressing feelings and dealing with anger, resolving conflicts, fostering cooperation, appreciating diversity, and countering bias. A 3-year evaluation of the program indicates positive outcomes when 25 lessons, on average, are taught in a year, according to child and teacher reports and objective measures.

Important policy implications arise from research into the prevalence and effects of exposure to violence among children and youth. Studies of resilience indicate that a key protective factor is a relationship with a caring, responsible adult, usually a parent ( [Gunnar, 1996](#)). However, in some instances, parents may be emotionally or practically unavailable to their children, either because they themselves are the victims or perpetrators of violence or because they are numbed by the exposure to violence in their communities. Therefore, the resources of other adults in the community need to be tapped. Research reveals great potential for school-based programs to lead the way in reducing violence among young people and to promote resilience. Other agencies are also well placed to intervene. One example is the Child Development and Community Policing program (CD-CP) in New Haven, Connecticut, which fosters collaboration among schools, mental health services, and the police department and includes training professionals to work within a developmental perspective ( [Marans and Schaefer, 1998](#)). An evaluation of the Child Development and Community Policing program is currently under way, but anecdotal evidence suggests that the program has reduced fear of crime, has improved relationships between the police and community, has increased referrals of children to mental health agencies, has reduced rates of violence, and has improved adjustment among children ( [Marans and Schaefer, 1998](#)).

## PROBLEMS IN THE USE OF RESEARCH IN POLICY

Mental health professionals have made numerous contributions. For example, school-based programs have been developed by psychiatrists such as James Comer in an effort to prevent affective disorders in children and to ensure responsivity to children's mental health needs. We have also developed a school-based early care and family support program that has been implemented in more than 700 schools across the country ( [Finn–Stevenson and Zigler, 1999](#)). Indeed, as a result of their involvement in program development and evaluation, mental health researchers have accumulated a vast amount of knowledge that “totally transforms the nation's capacity to improve outcomes for vulnerable children” ( [Schorr, 1997](#); [Schorr and Schorr, 1988](#)). This knowledge, derived from more than 3 decades of program development and evaluation, includes evidence of the effectiveness of numerous programs that reduce the burdens of risk factors in childhood and thereby reduce the probability of later damage ( [Price et al., 1988](#); [Schorr, 1997](#)).

Mental health professionals further note evidence indicating that it is not necessary to change everything—the structure of opportunity, the neighborhood environment, and other aspects of the child's life—to make a crucial difference for children at risk ( [Schorr, 1997](#)). However, this knowledge is not being used to alter the life path of many of the children who are growing up under stressful conditions, as noted by Hamburg, in testimony before the U.S. Congress ( [Schorr, 1997](#); [U.S. House Select Committee on Children, Youth and Families, 1987](#)).

The failure to use the knowledge from the research stems from several problems. One problem is that the information on effective programs is generally not shared with the public or with policy makers ( [White, 1988](#); [Zervigon–Hakes, 1998](#)). Thus, these programs, many of them at the demonstration stage, fail to be replicated on a larger scale. Even when programs' potential benefits are known, there is skepticism that such programs, once they are replicated, will continue to be effective. Although this is a valid concern, [Schorr \(1997\)](#) notes that successful programs can be built on if we can attract and train enough skilled and motivated persons, if we devise various replication strategies, and if we resist the lure of replication through dilution. This last point is noted, given that in efforts to serve as many children as possible or because of lack of sufficient funds, programs are diluted, thus diminishing their quality and potential benefits. [Zigler and Berman \(1983\)](#) note that the inclusion of more children at the expense of program quality has occurred even in such well-known programs as Project Head Start. They suggest continued monitoring of programs as a means of ensuring their effectiveness.

This point needs to be conveyed to policy makers and others who are in charge of the allocation of funds for program development and replication. However, although increasing numbers of mental health researchers are working in the policy arena, there is still a rather uneasy relationship between them and policy makers ( [Zigler, 1998](#)). [Maccoby et al. \(1983\)](#) note that policy makers often regard researchers as impractical. From their perspective, they may be skeptical of policy recommendations coming from researchers who do not seem to understand the complexities of achieving a consensus among rival constituencies. Researchers, conversely, seem to regard policy makers as disingenuous and too willing to compromise even when research evidence does not justify such action. [Meltsner \(1986\)](#) also observes that part of the tension and mistrust between policy makers and mental health researchers emanates from the assumption that knowledge from research is value free, whereas policies are made in a value-laden context. However, this characterization of research and policy is misleading. Often, scientific research takes on the values of the investigators, as is evident in the questions asked, the methods employed, and the interpretation and presentation of the findings.

Problems such as these impede the use of research in policy settings. The problems are further exacerbated by the situation that researchers are often perceived as unable to provide clear answers to policy questions, or, looked at from another perspective, that policy makers are unable to ask questions in a way that would lead to valid and reliable research ( [Maccoby et al., 1983](#)). In part, this problem stems from the unrealistic expectations among policy makers and the inability of many of them to appreciate that single studies cannot, in and of themselves, provide definitive answers to questions.

However, researchers also contribute to the problem. [Sheldon White \(1988\)](#) notes that often researchers are unfamiliar with the policy process or are unable to “read” political issues. They hold to long, slow standards of proof and refutation that are, in the policy arena, “obstructive and nihilistic.” [Thompson \(1993\)](#) makes a similar point and notes that, often, policy issues do not lend themselves easily to research, and research findings are often limited in their applicability to policy because of sampling and measurement issues. Although it is imperative that researchers uphold their professional standards and credibility as scientists ( [Zigler and Finn–Stevenson, 1987](#)), there are times when findings from the research, even if they are not entirely conclusive, can nonetheless provide a direction for policy. For example, the early research on the effects of child care on children's development was controversial, yielding conflicting findings that served to confuse the public and policy makers ( [Clarke–Stewart, 1989](#)). Although research on the topic continues, researchers were able to convene and come to a consensus that indicated that as long as young children are in a good-quality child care settings, they will not be adversely affected by their experiences in child care. This led to a policy recommendation for efforts to monitor the quality of care children receive and to ensure that all children receive care that is conducive to optimal development ( [National Center for Clinical Infant Programs, 1988](#)). It is apparent that in certain circumstances, such as the increasing number of children in child care, awaiting definitive conclusions from the research is counterproductive, especially when action can be taken at the same time that research on a particular issue is continuing.

A different problem occurs when research findings are misused by academics or the media to support a vested policy interest. An example is the controversial issue of the importance of the early years in child development. The research on brain development is a case in point. Magnetic resonance imaging and other techniques that were once confined to medical diagnoses have been used to examine the development of the brain. The findings on brain research have been illuminating, although in many cases preliminary, and they have shown the developmental importance of the first 3 years of life. Such studies have captured media and policy attention. Some researchers, excited by the window of opportunity for action on behalf of children, made exaggerated and distorted claims not substantiated by the research. These claims were refuted by [Bruer \(1999\)](#), who noted that some researchers, in emphasizing the potential for brain development in the years between birth and 3 years, ignored other critical periods through to adulthood. However, Bruer himself went to the other extreme, by denouncing the importance of the first 3 years of life and ignoring findings from social science that have shown that prevention and intervention in the early years are critical. The debate has been taken up by the national media, with viewpoints expressed through sound bites, undermining the complex scientific findings of decades of research. In the process, there is danger that the polarization of the issue could result in a policy retreat from children's services and continued misunderstanding of the research on brain development ( [Zigler et al., in press](#)).

## Strategies for Change

Understanding what impedes the use of research in policy is important if mental health researchers are to have an impact in the policy arena. [Lindblom \(1986\)](#) identified four general guidelines for researchers to follow to encourage the use of research in influencing policy directions: (a) that researchers be concerned in a nonpartisan way with the values and interests of society in general and children in particular, (b) that they take a practical approach and suggest policies that are feasible and have a chance of attracting widespread political and public support, (c) that they respond to the needs of policy makers and provide them with recommendations for action on the basis of research findings, and (d) that they become cognizant of and responsive to the policy process.

It is also suggested that researchers make serious attempts to disseminate the findings from the research, not only to policy makers but also to the general public. No

society acts until it has a sense of the immediacy of the problem (Zigler and Finn, 1981). The Great Society programs of the 1960s illustrate this point. During that time, social issues were covered in major newspapers and were in the forefront of national attention. There were daily stories on welfare mothers, reports on poverty, and expositions on hunger in the United States. Hence there was sympathy for the poor and support for the War on Poverty (Zigler and Valentine, 1979).

Although for a time thereafter interest in issues pertaining to children and families was appreciably less, there are indications that this is changing. First, developmental psychologists, psychiatrists, and other mental health professionals are becoming aware of the need for public education on the needs of children (McCall et al., 1984). In a departure from their past practices, many mental health professionals are no longer satisfied with simply sharing information with one another. Rather, they disseminate their knowledge not only by presenting their findings directly to policy makers but also by taking steps to ensure that the information is covered in the popular media. Indeed, the dissemination of research in the context of the popular media has come to be accepted as an important aspect of the training received by some professionals in the field of mental health (Zigler, 1998).

Many mental health professionals are also receiving training in the integration of child development research and social policy, to learn not only about the policy process but also about some of the ways to merge their knowledge with that of policy makers in the formation of programs and policies for children. For example, with support from the Bush Foundation in Minnesota, several training centers were established, one of which is the Bush Center in Child Development and Social Policy at Yale University in New Haven, Connecticut. The Bush Center has prepared doctoral students and postdoctoral fellows in a variety of disciplines related to mental health to apply their knowledge in the policy arena. Many graduates of the Bush Center have gone on to work in the policy arena or in other universities, where they have established courses and programs on the integration of child development research and social policy. The success of the training centers is evident not only in the increased number of researchers who apply their work to the policy arena, but also in the numerous issues, such as child care, parental leave, and the need for family support services, that only a few years ago were not discussed but that now command national attention. The success of these efforts is further evident in that increasing numbers of policy makers are now acknowledging the importance of knowledge from the research in the formulation of policies and are actively seeking the collaboration of professionals in the field of mental health. If mental health professionals and policy makers continue to work together in this spirit of collaboration, we will be able to bring about much needed changes that will assist family life.

## GOAL

This chapter delineates the areas of concern in international child and adolescent mental health and focuses on areas of particular import to child and adolescent psychiatrists and other child mental health clinicians. The goal is to provide a perspective on child and adolescent mental health and to identify areas of particular interest as a reference for further study.

## OVERVIEW

International child and adolescent mental health embraces the diversity of the world view on the place of children in society, the appreciation of diverse behavioral styles and the identification of psychopathology, and the priority setting for the use of scarce resources. Child and adolescent mental health is influenced by the economics of countries and societies within countries, by the internal and external displacement of children and adolescents through war and catastrophe, by the role of the child in the family, and by the place of women in society. New knowledge and greater recognition of the impact on children of exposure to trauma, sexual and physical abuse, inhumane living and working situations, inadequate health care, and drug abuse have heightened interest in approaches to ameliorating the impact on child and adolescent health and mental health of these potentially pathogenic influences. It is a challenge to child and adolescent psychiatrists and allied professionals to be active participants in understanding the nature of the problems faced and in being a part of the solution ( [Sugar et al., 1992](#)).

The overall health and well-being of children are international concerns. More than 179 countries have ratified the 1989 United Nations Convention on the Rights of the Child ([United Nations, 1989](#)). It commits countries to "ensure that all children have the right to develop physically and mentally to their full potential, to express their opinions freely, and to be protected against all forms of abuse and exploitation." It is striking that some democratic societies have chosen to not ratify the treaty out of concern with intrusion on their sovereign rights and others because of traditional views of the child in a dependent position in society. Likewise, in some countries that are party to the treaty, the affirmation of the rights of children has not resulted in benign policies toward the protection of children from harm or the fostering of positive development.

No longer can those interested in international child mental health focus solely on psychopathology as viewed from a Western perspective. Given the diversity of cultural representation in most Western countries, the same caution may apply as a universal maxim. It is simplistic to state, but meaningful to understand; that what may appear pathologic in one country or society may be deemed normative or adaptive in another. This does not imply that it may not be helpful to have a consensus about a frame of reference regarding psychopathologic conditions, but the interested party must keep an open mind in attributing cause to behaviors, interpreting responses to events, or judging parental or familial interactions with children. The complexity of understanding children and adolescents embraces anthropologic, social, psychological, political, and rights dimensions.

In many developing countries, educational institutions represent the most coherent system embracing children and adolescents and provide the primary venue for health-related interventions. As never before, the value placed on education in societies is being emphasized as agrarian pursuits have become commercialized or made nonviable. In developing countries, the impact of technology is differentially affecting parts of society. On the one hand, technologic advance offers an unprecedented opportunity to the educated, but on the other, it accelerates inequality with the less educated. Urbanization combines with the technology revolution further to challenge accustomed ways that may stress individuals and families ( [Rahim and Cederblad, 1984](#)). Children and adolescents, as students or as part of a family, experience new stresses that convey either advantage or disadvantage, depending on access, intelligence, and resources. In response to these changes in society, resilience-building programs in schools, along with primary care health programs in communities, form what is recognized as international child and adolescent mental health programming.

The role and responsibilities of child and adolescent psychiatrists and other child mental health professionals vary in developing countries. The competencies of the child and adolescent psychiatrist must fit the needs of the society in which they exist. For example, epilepsy and mental retardation clearly fall within the expected clinical competencies of child and adolescent psychiatrists in developing countries, but they are not expected competencies of child and adolescent psychiatrists in developed countries. When child psychiatry is a very scarce resource, there may be the opportunity only for a consultative role, limited diagnostic capability, and an inability to be part of or stimulate discussion of national policy. At the same time, child and adolescent psychiatrists brought to developing countries may play a vital role in educating other professionals in medicine, psychology, education, social work, nursing, and the volunteer community.

In understanding the impact of child and adolescent psychiatric disorders, it is not sufficient to understand diagnosis alone. Significant gains have been made in raising the consciousness about the mental health of children and adolescents, as well as adults, by bringing attention to the "burden" of mental illness ( [Desjarlais et al., 1995](#)), when the global burden of disease is measured in disability-adjusted life-years. This approach makes possible a more standardized assessment of the burden of disease as measured by lost opportunity, diminished function, and the cost of treatment and rehabilitation, and it has gained a supportive response from policy makers. From the child mental health perspective, disability-adjusted life-years have limitations in that they do not quantify negative or positive effects of behaviors but only address outcomes. As a result, the importance of behaviors that start during childhood and adolescence but result in disease and death only later in life may be underestimated by this approach.

The importance now attributed to mental disorders and mental health is reflected in the focus of the World Health Organization (WHO) on mental health in its 2001 World Health Report and in a mental health focus for World Health Day in 2001. In addition, the World Bank now considers mental health among its priority areas of concern.

An understanding the culture of the individual is important. For example, [Murthy \(2000\)](#) reports that studies have found that suicide rates among immigrants are more closely aligned to the rates in the country of origin than to the rates in the country of adoption. Generally, suicide rates of immigrant populations are higher than in the country of origin. The methods of suicide are those used traditionally in the culture of origin. [Murthy \(2000\)](#) found that suicide by burning was nearly 10 times more

common in girls and women from the Indian subcontinent than in the overall female population in England and Wales ( [Raleigh and Balarajan, 1992](#)). [Canino et al. \(1991\)](#) also documented the persistence of the importance of culture-bound syndromes.

## EPIDEMIOLOGY

Determining the epidemiology of childhood mental disorders in Western society is a challenge. On the international scene, the ability to determine the precise magnitude of mental disorders is even more complex. Reporting systems are inadequate, the definition or recognition of disorders varies or has variable interpretations, and the cultural component of what constitutes a disorder is only now being more fully appreciated by epidemiologists and researchers. Of significance in developing countries is that any measure of mental disorder takes place against a background of child and adolescent mortality and morbidity that makes the epidemiology of psychiatric disorder not only inaccurate, but often of a lower priority. Thus, in studying the epidemiology of psychiatric disorder in children and adolescents in developing countries, it is important to define not only the prevalence and incidence of the disorders, but also the associated burden of disease as measured in cost to society of lost productivity, cost of care, and lost human potential. No single study or consistent set of independent studies on the epidemiology of child and adolescent disorders since 1980 can be identified as definitive or relevant across societies. Those studies carried out in the 1980s reflect the deficiencies noted earlier and certainly do not reflect the current realities of the countries from which the data were reported ( [Hackett and Hackett, 1999](#); [Odejide et al., 1989](#)).

When one is faced with the realities of developing countries, as noted, there is the danger of becoming a diagnostic nihilist in attempting to understand mental disorders in youth. Responsible investigators have clearly identified disordered mental functioning that meets a set of defined criteria ( [Tadesse et al., 1999a](#)). There is clear evidence that depression, psychosis, and mania can be defined and treated. The problem arises when one considers the context for the presentation of child and adolescent mental disorders. Is a hallucination during a ritual a disturbance in need of treatment? If the hallucination persists, should it be treated? What diagnostic label is appropriate? It is important to bear in mind the study of [Giel and Van Lujik \(1969\)](#), who found, counter to prevailing belief, that mental disorders were diagnosed more frequently than infectious diseases in the health centers in Africa that they studied. Until reporting is adequate and accurate, it cannot be assumed that the current state of mental health in the developing world actually supports the too prevalent minimalist and optimistic view. This sense is supported by the finding from WHO studies of primary care clinicians that showed that many patients seeking care had mental disorders, and their communities were aware of the problem ([Harding, 1980](#)).

### Prevalence

Although it is interesting to consider reports of more esoteric disorders, these are a distraction from the significant burden of disease that needs to be addressed in the mainstream of care. In most studies, the methodologic inadequacies and other constraints do not permit these studies to be of use for program planning or needs assessment. Most countries today have access to appropriate epidemiologic study guidelines, and it is a matter of setting a national priority and allocating resources to ascertain the data. For example, a study in India by [Malhotra \(1995\)](#) used a sophisticated three-stage assessment of the epidemiology of disorders in school children aged 4 to 12 years. In this study, assessments by teachers, parents, and clinicians were compared. The teacher assessment on the Rutter B scale, a generally accepted measurement instrument, had a low concordance rate with the clinical assessment. When children tested positive on both the teacher and parent assessment, there was a diagnostic rate of 92.3% on the clinical assessment. The evidence pointed to a prevalence rate of psychiatric disorder ranging between 7% and 20%. The diagnostic possibilities included enuresis, mental retardation, and epilepsy, among others. Overall, the most conservative estimate of severe psychiatric disorder in India is 10% of the population younger than age 14 years, representing 35 million children ( [Malhotra, 1998](#)).

[Giel et al. \(1981\)](#) demonstrated in four countries (Sudan, Philippines, Colombia, and India) that between 12% and 29% of children aged 5 to 15 years showed mental health problems. The types of disorder identified in these developing countries were reported as being no different from those encountered in industrialized countries. However, recognizable diagnoses were not given in the article. Mothers readily reported the symptoms that made possible the diagnosis of disorders. [Thabet and Vostanis \(1998\)](#) report a pattern of anxiety symptoms and disorders among children living in the Gaza Strip comparable to previous epidemiologic research in Western societies. There are high rates of anxiety disorders and school-related mental health problems. Thabet and Vostanis find the same prevalence rate (21%) of anxiety-related disorders as do [Kashani and Orvaschel \(1990\)](#). [Thabet and Vostanis \(1998\)](#) state that their findings do not support the commonly held belief that, in non-Western societies, anxiety and other mental health symptoms are predominantly expressed through somatizing symptoms. Citing [Nikapota \(1991\)](#), they state that child mental health symptoms do not differ significantly across cultures, and culture-specific mental health disorders are rare. Most recently, [Tadesse et al. \(1999a\)](#) report a prevalence of childhood behavioral disorder of 17.7%. The behavioral disorders are more frequent in boys than in girls. These latter data were gathered with a version of the Reporting Questionnaire for Children developed by WHO ( [Tadesse et al., 1999b](#); [World Health Organization, 1977](#) ). Studies of [Hackett et al. \(1999\)](#) and [Bird et al. \(1989\)](#) find an excess of male patients with externalizing disorders. The findings reflect the Western view of a male predisposition to externalizing disorders. These views of comparability with Western epidemiologic data are at odds with older studies and may reflect new social and economic realities.

What of the disorders that now occupy considerable attention in developed countries such as attention deficit hyperactivity disorder, autism, and anorexia nervosa? There is little doubt that these disorders are seen, but what resources need to be invested in the treatment of these disorders in countries that have little access to the medications or programs that may be indicated? The diagnosis and treatment of these disorders highlight both a weakness and a strength of having an international perspective. The recognition and labeling of disorders come as a result of improved international communication. However, the process of assessment is most complex, taking into account cultural concepts of what is normal or abnormal and how parents perceive the presence or absence of a diagnosable disorder ( [Hackett and Hackett, 1999](#)). In the case of eating disorders, there is clear evidence that the incidence may be affected by Western influences ( [Becker, 1995](#)). Increasingly, the pharmaceutical industry provides local education of providers in countries throughout the world and thus may establish a market for the medication to treat a disorder. This may provide an indirect incentive for the overdiagnosis of disorders such as attention deficit hyperactivity disorder or anxiety. The scrutiny of these practices is quite variable throughout the world.

## SPECIFIC PROBLEMS WITH MENTAL HEALTH IMPLICATIONS

The priority concern of international child and adolescent mental health is often the acute and continuing tragedies that involve youth in armed conflict or the aftermath of conflict. Eighty percent of the victims of war are reported to be children and women ( [Lee, 1991](#)). The result of armed conflict is often displacement. The problems of displacement from homes, families, communities, and countries affect children in a host of ways. [Zivic \(1993\)](#), in a study of Croatian children during war, found significantly higher depressive and phobic symptoms in displaced refugee children than in local children in stable social conditions. [Laor et al. \(1996\)](#), in a developmental study of Israeli children exposed to Scud missile attacks, found higher externalizing and stress symptoms in displaced children as opposed to those able to maintain family and community connections. Children in these circumstances may find themselves without the protection and support of parents at critical junctures in their lives. Children are forced to act in more mature ways far earlier than normal development would dictate or allow. Displaced children are faced with exposure to war and violence that may have seen family members murdered. Less often, but even more horrific, some children have been forced into being the murderers of their family or conscripted to serve as child soldiers. Others find themselves either displaced to other countries or internally displaced and left to fend for themselves. Street children engage in survival tactics that include criminal activity and prostitution. In an effort to find a context for survival, the formation of youth gangs is increasingly evident, especially in societies where there is a lapse in government organization and control. More often than not, the children are the victims rather than the perpetrators.

### Posttraumatic Stress Disorder

It is a challenge that as mental health professionals we know so little about the consequences of exposure to these assaults on healthy development. The literature for adults is consistent in demonstrating persistent negative functional consequences from exposure to trauma. The child and adolescent literature reflects conflicting views on the impact of the traumas noted earlier ( [Mollica et al., 1997](#); [Pynoos et al., 1987](#); [Sack et al., 1999](#); [Weine et al., 1998](#)). The resiliency of children over the long term seems to be a consistent dominant finding, but individual investigators identify specific consequences, with depression, externalizing behaviors, and posttraumatic stress disorder (PTSD) as evident consequences ( [Laor et al., 1996](#)). Diagnostic status does not relate to functional status according to [Sack et al. \(1995\)](#). [Sack et al. \(1999\)](#) not only show persistence of PTSD but also demonstrate a sometimes delayed onset of symptoms. Even in those youth demonstrating delayed PTSD, symptoms of depression diminished over time. So whereas the study by Sack and colleagues notes a persistence of the PTSD diagnosis in youth, over time these children appeared able to function well. [Terr \(1983\)](#) demonstrates persistent effects on children from traumas with lasting functional deficits. Studies related to children from Kuwait ( [Abdul-Khalek, 1997](#)) and Iran ( [Almquist and Brandell-Forsberg, 1997](#)) show the persistence of PTSD. [Nader et al. \(1993\)](#) report moderate to severe PTSD in 70% of Kuwaiti children after the Gulf War. [Thabet and Vostanis \(1998\)](#) find, in the Gaza Strip, that the prevalence among children ages 6 to 11 years of at least mild PTSD is 73%, and 39% present with moderate to severe PTSD symptoms. [Ahmad \(1992\)](#) reports that 25% of displaced Kurdish children evidence PTSD, and [Weine et al. \(1998\)](#) find similar rates in Bosnian adolescents who moved to the United States during the war. [Hussain et al. \(1998\)](#), reporting on the impact of the siege of Sarajevo, note that it is not the exposure to sniper fire, but rather the loss of a family member and deprivation of food, water, and shelter that

have a severe adverse impact on the children. The clinical manifestations of the trauma are avoidance and reexperiencing symptoms.

## Malnutrition

Too many societies are now unable or are only marginally able to feed their populations. Malnutrition is pervasive among preschool children in countries such as Bangladesh, Botswana, Nepal, Zambia, and parts of the Caribbean region ([Galler et al., 1983](#); [Jazairy et al., 1992](#)). The World Bank estimates that the total direct and indirect damage from malnutrition is a least 20% to 25% of the disease burden in children ([World Bank, 1993](#)). The consequences of malnutrition on brain development with delayed cognitive development are known, and more subtle behavioral manifestations of malnutrition are manifest with attentional problems and learning disabilities ([Agarwal et al., 1989](#); [Chavez and Martinez, 1982](#); [Galler et al., 1983](#)). Some studies suggest that the behavior disorders associated with malnutrition are secondary to impaired maternal capacities and not to the malnutrition itself because evidence indicates that malnutrition does not contribute to behavioral disturbance later in life ([Galler and Ramsey, 1989](#); [Miranda et al., 1996](#)). Studies are needed to determine more precisely the consequences for the mental health of children who survive these hardships. Is lowered cognitive functioning the dominant finding? What of survival with other impairments that limit the potential for achievement and create a society unable to be mobilized under improving circumstances?

## Suicide

Suicide in youth is a pervasive world mental health problem. In Western cultures, suicide is overwhelmingly associated with defined mental illness. Elsewhere in the world, it is very difficult to identify the mental illness associated with the suicidal act. Studies of suicide in the West have focused on risk factors associated with cognitive distortions, substance use, and familial factors ([Shaffer, 1988](#)). In trying to assess the high rates of suicide in some developing countries, it appears that the balance in determining suicidal risk may rest with environmental stressors and the perception of "no way out." Expectations may often be more of determinant of suicidal angst than reality (Bertolote J: May 11, 2000, personal communication). The traditional protective effect of religion in certain cultures seems not to operate among the younger generation ([Murthy, 2000](#)), and as noted elsewhere, suicide may be condoned in certain cultures.

It seems more apparent that suicide is viewed by those without demonstrable mental illness as a solution to social and personal dilemmas that bring with them thwarted expectations for a happy or successful life. For example, from this perspective, in India and in other developing countries, the focus of the suicidal individual is not on achieving some exalted goal, but rather on being able to have enough of a dowry to be married, to not be isolated because of rape, or to be successful in passing a school advancement examination. This relative alteration in emphasis is important in the consideration of intervention strategies and in the training of workers to perform triage and to treat suicidal children and adolescents.

---

### CASE ILLUSTRATION

In India, four sisters aged 16 to 24 years committed suicide by hanging after an evening during which they bought sweet cakes and samosas and played word games. The context was that they were part of a once prosperous family in which the father died of tuberculosis for lack of medical treatment. Now they periodically were without sufficient food, but with a mother too proud to ask for help. This family was socially isolated because of parental marriage across religious lines, and they had suffered an unexpected financial downturn as a result of a road-widening project that took their once fertile land. Suicide rates in India, although less than the international average of 16 per 100,000, have been steadily rising. Psychiatrists believe this is in part a result of the accelerating pace of social and economic change. Whereas the biggest risk factor in the West is mental illness, studies in India have consistently found that the dominant risk factor is a combination of social and economic issues. Farmers in debt take pesticide, and ostracized women immolate themselves ([Dugge, 2000](#)).

---

### FAMILY SUICIDE

In Hong Kong, amid the impressive high-rise buildings and fancy stores, reside families barely able to subsist. In this context of economic hardship, the result in part of massive economic adjustment in the Far East, the phenomenon of family suicide exists. Chan reports that families come together and, in a well-planned manner, seal themselves their small apartments and light a charcoal heater (Chan, May 11, 2000, personal communication). In a relatively brief time, the members of the family are asphyxiated. This has become an acceptable form of suicide in that the bodies remain intact and have an attractive appearance because of the monoxide poisoning. To the extent that it has been possible to determine the psychological state of the family before the suicides, major psychiatric disturbance has not been reported.

## Displacement

The global problem of displacement from family, home, community, and country are of enormous importance to the mental health of populations. Displacement by war resulted in approximately 21.5 million refugees in 1999. An additional 30 million, 80% of whom are children and women, were displaced internally. [Fullilove \(1996\)](#) emphasizes the importance of "place" in the healthy development of individuals. [Sampson et al. \(1997\)](#) specifically address the importance of the community as a mediator and contributor to the impact of violence on children and adolescents. The delineation of the importance of collective efficacy in communities is an important concept when one considers the impact of imposed poverty, housing disruption, and displacement in ethnic conflicts affecting previously closely aligned groups. In developing countries, the notion of "place" and community are of equal or greater importance. The disruption of traditional communities by war, famine, and natural disaster leave children and adolescents in vulnerable situations that affect mental health. Internal displacement by war and famine leads to the breakup of families, months and years of uncertainty, disruption of education, and physical illness. Forced emigration and the loss of parents and relatives in war often mean abandonment or orphaning of children and adolescents. Although these stressors may serve to demonstrate the enormous resiliency of youth, they often lead to depression, suicide, and a range of stress responses.

### "Child Soldiers" and Sexual Slaves

In the turmoil of some developing countries, children are now being forced to become "child soldiers," and other others are drawn into the conflict as sexual slaves. These horrific experiences place an as yet undefined burden on the psychological development of the victim. Understanding these experiences may shed additional light on the extremes to which resiliency may allow future healthy development, but perhaps more likely it will demonstrate the more permanent scarring evidenced in disturbed interpersonal relationships, distorted defenses, heightened aggression, reduced empathy, and self-destructive behavior. The data are not yet available to ascertain whether these young people evidence PTSD in the classic sense or whether, because of the early age of induction into the culture of war, they develop in a different way as a survival response.

## Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

In sub-Saharan Africa, Russia and parts of Asia, acquired immunodeficiency syndrome (AIDS) is now a pandemic. Special attention needs to be given to the consequences of AIDS on children and youth. The direct impact on children and adolescents is evident in India, other parts of Asia, and Africa, where sexual exploitation has led to a high incidence of youth infection with the inevitable outcome of death as a result of lack of available treatment. An estimated 1.5 million children less than 15 years old are living with human immunodeficiency virus (HIV) infection or AIDS ([UNICEF, 2000](#)). More than one-fourth of the young population in sub-Saharan Africa is infected. Among the 10 most affected countries, all in sub-Saharan Africa, approximately 6,000,000 children younger than the age of 15 years lost their mother or both parents to AIDS. Those infected but struggling with the illness face the prospect of having to adjust to declining physical and mental functioning and often living isolated lives. Thus, the mental health consequences of AIDS as a chronic and pervasive illness must be considered. There is the obvious concern with the direct effect of AIDS on the youth with manifestations of neuropsychological dysfunction including dementia, depression, and other disorders, which go largely untreated. These children and adolescents living as orphans or in stigmatized environments are vulnerable because of the loss of parent figures, malnutrition, and disenfranchisement from societies that have a stigmatized view of AIDS-affected and HIV-infected persons.

The mental health consequences are similar in the international arena and are well documented in U.S. studies ([Belfer and Munir, 1997](#)). The caution in developing countries is that recognition of the neuropsychological consequences will be overshadowed by the totality of the devastation. This lack of recognition of depression, dementing illness, and other consequences of HIV infection may contribute to the continuing spread of the epidemic. As documented by [Carlson and Earls \(1997\)](#), whether through social policy as evidenced in the Leagane children of Romania or as the consequence of the pandemic of AIDS, the rearing of children in orphanages or in other situations that deprive children of appropriate stimulation and nurturance has potentially long-lasting consequences for societies.

## Substance Abuse

Substance abuse in children and adolescents is a worldwide problem ( [Belfer and Heggenhougen, 1995](#)). In developing countries, the problem is of no less importance than in Western countries and exacts a tremendous toll in terms of morbidity and mortality. Illicit drugs, psychoactive substances not defined as drugs of abuse such as khat, inhalants, and alcohol are used by youth regardless of economic circumstance or religious prohibition (1995). Remarkably, in some Muslim countries, alcohol use and abuse are significant contributors to psychological morbidity. Khat is used extensively in East Africa and the Middle East. In Somalia, Ethiopia, and Kenya, khat is used at all levels of society from about the age of 10 years ( [Alem et al., 1999](#)). Khat may induce a mild euphoria and excitement that can progress to hypomania. In youth, khat use, especially if it is combined with the use of other psychoactive substances, may lead to psychosis.

Solvent and inhalant use is associated with poor economies. In South America, inhalant use is a dominant factor in the presentation of youth affected by psychoactive substances. In Sao Paulo, Brazil, up to 25% of children age 9 to 18 years abuse solvents ( [Carlini-Cottrim and Carlini, 1988](#)). In the Sudan, gasoline is the inhalant of choice, whereas in Mexico, Brazil, and elsewhere in Latin America, paint thinner, plastic cement, shoe dye, and industrial glue are often used. Solvent use is also found among the aboriginal group in Australia and on Native Canadian reservations ( [Cameron and Debelle, 1984](#)). In Mexico, three of every 1,000 people between the ages of 14 and 24 years use inhalants on a regular basis ( [Belasso, 1978](#)). These figures do not include two high-risk groups, the homeless population and those less than 14 years old, whose rates of inhalant abuse are much greater. Several community studies carried out in different parts of Mexico show that starting ages are as young as 5 or 6 years ( [Belasso, 1978](#)). Data suggest that the percentage of young people using inhalants decreases as age increases, and other substances such as alcohol and marijuana are substituted. Inhalant use decreases as educational level increases ( [Cravioto et al., 1992](#)).

### **Mental Retardation and Epilepsy**

Mental retardation and epilepsy are major disorders that often dominate the services of child mental health and pediatric professionals in developing countries. In the 1980s, prevalence rates in developing countries were estimated to be in the range of 8 to 12 per 1,000 for children aged 3 to 10 years ( [Belmont, 1984](#); [Narayanan, 1981](#); [Tao, 1988](#)). Mental retardation and epilepsy are the most common mental disorders in India ( [Lal and Sethi, 1977](#); [Malhotra and Chaturvedi, 1984](#)). The rate of serious mental retardation in some developing countries ranges from 5 to 16.2 per 1,000 population ( [Stein et al., 1986](#)), significantly higher than the rate in the West. Cerebral palsy and postnatal causes of mental retardation are much more common in transitional societies than in developed countries. Untreated epilepsy limits a person's potential to participate in society. Unfortunately, although the cost of medication is relatively low, access to care is often limited. The care of the mentally retarded varies widely in developing countries. In some countries, special effort is made to provide for productive lives with meaningful vocational education, especially in agrarian economies. All too often, the moderately and severely retarded are housed in minimal care institutions where premature death and illness are common.

### **Culture and Assessment**

The concern with accounting for the cultural contribution to the understanding of psychopathology is very great in the West ( [Canino et al., 1991](#)). However, the picture is more complicated in international mental health. There is the danger that attribution to culture of symptoms representing treatable mental illness can deflect energy from the development of effective treatment and prevention efforts. This view has to be balanced with the understanding of less severe psychopathology, in which the observation of [Neki \(1976\)](#) holds true. [Neki \(1976\)](#) states that ethnodynamics determine the psychodynamics. In India, where the cultural ideal of an independent adult is not an autonomous adult, dependency is inculcated from childhood through a prolonged dependency relationship between mother and child. Dependency has a negative, pejorative connotation in Western thought, which is not so in the Indian context. The fostering of dependency is coupled with a high degree of control, low autonomy, and strict discipline, enforced within the broad framework of the family system. When this is identified by clinicians as representing a degree of pathology, decreased emphasis on the expression of thoughts and emotions in children could explain the greater preponderance of neurotic, psychosomatic, and somatization disorders ( [Malhotra et al., 1992](#)). Thus, culture can influence the definition of normalcy or disorder. It proscribes the values and ideals for the behavior of individuals, it determines the threshold of acceptance of pathology, and it provides guidelines for the handling of pathology and its correction ( [Malhotra, 1998](#)).

### **Cultural Differences and Research**

The foregoing illustrates the dilemma of attempting to understand patterns in non-Western, developing countries of child rearing or assessment of pathology through a Western lens. [Nikapota \(1993\)](#) underscores the importance of determining "culture-appropriate" criteria to permit consistency in diagnosis. In doing research, it is important to consider the characteristics of the interviewer as well as the informant. [Munir and Earls \(1992\)](#) articulate a set of ethical parameters for research that must be considered in doing research among children and adolescents of developing countries. To apply a different standard justified by the difficulty of implementing protocols would violate the very support of a rights framework so essential for progress to be made on behalf of children in developing countries.

An area of great interest is the development of assessment tools that incorporate the diversity of cultural parameters. Increasing numbers of instruments have been translated and back translated for use in cross-cultural studies. Instruments exist for the assessment of depression, anxiety, PTSD, quality of life, and other conditions. It remains for there to be a sufficient body of cross-cultural research with modern standards for the conduct of the research that yields information on the reliability and validity of the instruments in their revised versions. Few instruments meet an agreed standard for use across all cultures in their current form.

### **Service Gaps**

Developing countries lack the child mental health personnel to mount large-scale programs of treatment with fully trained staff members. The prospect of training large numbers of child mental health workers remains a continuing goal, whereas the training of child and adolescent psychiatrists to meet the potential need is beyond the realm of possibility. In the interim, what can be done to provide a way to intervene for the promotion of child mental health? Obviously, one focus is on developing prevention programs in general health and education systems. Second, training primary care practitioners from numerous disciplines is needed to provide basic child mental health services. Basic assessment and treatment are possible, with triage of the most severely disturbed.

In some countries, the lack of child mental health personnel has stimulated some remarkable efforts to train persons from diverse backgrounds to be effective in identifying and intervening to ameliorate child mental health problems. In Alexandria, Egypt, child counselors have been trained to develop sophisticated interventions in schools ( [El-Din et al., 1993](#)).

## **PROGRAM ILLUSTRATION**

In Alexandria, the Department of Community Medicine has supported the development of a cadre of school counselors. These counselors come from the ranks of volunteers, social workers, and psychologists. Without prior child mental health training, the workers are provided with course work on common child mental health problems and then are supervised in field placements. The counselors work with parents around children identified by both the school and parents as having some type of behavioral problem. They also serve as contact points for the school, parents, or pediatricians to bring children with more severe behavioral disturbance to the attention of the few fully trained mental health professionals.

Leaders in child mental health programming in developing countries are emphatic when faced with the reality of program implementation that Western models of care by specialists are neither feasible nor desirable. Indigenous methods and models of care need to be developed that are not dependent on specialists. Conversely, the development of these models that use parents, teachers, pediatricians, and others can be informed by the best thinking of child psychiatrists and other specialists. This has led to an emphasis on the training of primary care practitioners. Furthermore, short-term, focused training in specific areas related to diagnosis or intervention can be provided by specialists or through specialized child psychiatric centers that have a broad regional or national area of responsibility.

The development of child mental health training for primary care practitioners is well established. [Murthy \(1998\)](#) describes the use of primary health care providers in developing countries. In India, with 1.5 billion people, there are only 5,000 mental health providers of whom only a fraction are psychiatrists, 35,000 psychiatric beds, and a dearth of emergency services. The primary care provider when adequately trained is a valuable and essential point of contact and treatment for the mentally ill. In India, it has been demonstrated that primary care providers can provide a level of professional care that reduces morbidity and mortality. However, without appropriate training, primary practitioners have been shown to have a poor record of recognizing mental disorders. [Giel et al. \(1981\)](#) report in their study in developing countries that primary care practitioners identified only 10% to 20% of the disorders that the researchers were able to diagnose. WHO has devoted considerable effort to the development and distribution of training manuals to aid primary care practitioners in the recognition of mental disorders ( [Graham and Orley, 1998](#); [Nikapota, 1993](#)).

Moreover, India has developed the *anganwadi* system to provide basic nutrition and educational support in villages. This is both an appropriate preventive

intervention and a way to assess youngsters presenting with disorders (Mathur et al., 1995). The *anganwadi* system focuses on providing essential services to very young children. Like Head Start, the program provides nutrition, basic education, socialization, and a venue for more specialized intervention for children perceived to be at risk or in need of additional services (Jazairy et al., 1992). There must be a concern in the development of these indigenous systems of care that not too much dependence is placed on family structure and support at a time when urbanization and industrialization are eroding the traditional family structure. With the absence of security, and often living at a subsistence level, the new nuclear family faces previously unknown challenges and may be particularly vulnerable over this and the next generation.

Some programs are international in scope. For instance, WHO, as part of its Programme on Mental Health, has fostered the use of life skills education ( [World Health Organization, 1997a](#)). The goal of the Life Skills Program is to foster psychosocial competence. For children and adolescents, the Life Skills Program is taught in schools. The program itself as promulgated by WHO is based on the social learning theory of [Bandura \(1977\)](#). Many similar models are operative throughout the world. A training the trainer component affects the overall resource of a community to provide for the mental health needs of some children and adolescents who are at risk. Among the obvious limitations in the developing world are the absence of universal education and the capacities of the teachers to go beyond essential educational tasks. [Kapur and Cariapa \(1980\)](#) demonstrate that the training of teachers as counselors, in India, was effective.

The prospect for the future of child mental health practice in developing countries is tied to economic growth, health literacy, and reduction of stigma. The creative efforts to develop programs to reach children and adolescents in developing countries need to be supported. Child and adolescent psychiatry will remain a scarce resource to be used in ways that will have a duplicative impact. This means that the training of volunteers, the training of peers, the support of family intervention programming, and the use of community-based early intervention need to be the focus of attention.

## PREVENTION

It appears that prevention of mental disorders is the way to approach the problem of reducing the toll of mental illness in developing countries. However, mental health initiatives in developing countries often depend on outside sponsorship. Such sponsorship, whether in the form of grants from donor countries or foundations, most often requires evidence-based intervention with a definable outcome. The field of prevention in both developed and developing countries offers little support for evidence-based programming for the prevention of mental disorders. Compounding this problem is the investment needed to adapt promising prevention programs for implementation in developing countries. The increased emphasis on mental health and mental disorders in World Bank and WHO planning and program support is some cause for optimism that additional financial and programmatic resources may facilitate the implementation of prevention programming.

Life skills education promoted by the WHO is the backbone of prevention programming in many developing countries ( [World Health Organization, 1997a](#)). Life skills training provides in the context of the school curriculum a program to enhance psychosocial competencies. The training focuses on basic, generic skills such as decision making and problem solving, creative and critical thinking, communication and other interpersonal skills, self-awareness and empathic skills, and coping with stress and coping with emotions. The aims are to promote mental well-being and to enable children to take more responsibility for their lives and feel more effective ([Graham and Orley, 1999](#)). In a collateral program, WHO's Mental Health Program has supported the development and dissemination of a checklist to promote "child-friendly schools" ([World Health Organization, 1997b](#)).

## RESEARCH

[Earls and Eisenberg \(1991\)](#) highlight three areas for enhanced research activity in relation to child and adolescent mental health. First is research to understand how the changes in contemporary society are reflected in the prevalence and incidence of mental disorders. Second is research to enhance the understanding of how different child-rearing methods affect normal and deviant behavioral and emotional development. Third involves research on the design and delivery of mental health services.

As described by [Earls \(1987\)](#), compulsory schooling leads to the need to understand the impact of learning disorders better. The appropriate diagnosis and remediation of these disorders are first-order priorities in countries where technologic advance places a premium on knowledge acquisition and use. As yet, research in this area has not been implemented in developing countries, but the pressure to implement such studies is mounting.

Research into the understanding of the differential impact of child rearing methods should be an area of collaborative inquiry between those interested in mental health and those concerned with the role of women and the family in evolving societies. It is not evident that any one method of child rearing is superior to another. Perhaps developing and developed societies can learn from one another about the optimal methods for child rearing in the presence of the evolution of individual societies. The experience with the effects of urbanization, industrialization, changing roles of women, and increased survivorship of children in developed countries may form the basis for translation into the programs for developing countries. Conversely, the healthy development of youngsters growing up in adversity in developing countries may provide information on how to enhance the understanding and interventions to develop new interventions for children at risk in developed countries.

The issues related to the development of mental health services are addressed elsewhere in this chapter. The diversity of cultures, the acceptance of change, and the continuing availability of resources for program implementation are issues that need to be confronted in international health services research. The development of pilot programs that are not sustainable does not promote infrastructure development, but it does promote a cynicism that erodes the potential for the success of future efforts.

## SYSTEMIC ISSUES

Throughout the world, it is rare to see child mental health incorporated in national health policy. In many countries, developed or developing, no coherent health policy exists that would provide a framework for program development. In countries with a health policy, child mental health rarely rises to a prominent position. Until child mental health becomes integrated into health policy, stable budgetary support for child and adolescent mental health programs will not be realized.

Advocacy for child and adolescent mental health is evident throughout the world, but competition with other interests often forces the issue off the policy agenda. When crises involve children, such as the child soldiers in the Sudan, female genital mutilation, or the case of Elian Gonzalez in the United States, the issue of child mental health for a time gains the spotlight. Unfortunately, the advocacy and concern diminish with time and rarely find a sustaining constituency.

Nongovernmental organizations play an important role in promoting child mental health, in disseminating information, in providing a forum for professional exchange, and in advocating for specific causes. The constituency base of these organizations differ, but they generally have broad representation and provide an opportunity for interested persons to learn more about specific topics or develop ideas in a context of knowledgeable individuals. Many of the nongovernmental organizations have regional affiliated regional organizations that permit ongoing local involvement. The following are some of the more established international nongovernmental organizations: the International Association for Child and Adolescent Psychiatry and Allied Professions, the World Association for Infant Mental Health, and the International Association for Adolescent Psychiatry.

As noted previously, there are many innovative models of integrating mental health in school settings. Whether it is through life skills-related curriculum development or consultative services, programs in the developing world have at hand effective models. The limitation for program implementation is the availability of trained persons for leadership and "training of the trainer." Further, there is the need for these programs to be able to access tertiary diagnostic and treatment services for those with manifest psychiatric disorder.

## LESSONS TO BE LEARNED

It would be very wrong to focus only on the areas where it appears that more could be done to enhance child and adolescent mental health services. Western mental health professionals and program developers can learn from the programmatic necessities and innate capacities of individuals and families in developing countries.

Family participation in the care of the mentally ill or retarded child in developing countries is impressive by any standard. The acceptance by communities of the special needs of affected families is often dramatic. Likewise, the willingness and ability of families to care for children, including the appropriate use of medication, for children with epilepsy and other disorders challenge Western concepts of continuity of care and the role of providers.

Finally, the West has flirted with the enhanced use of primary care providers in the delivery of mental health services, but in developing countries, necessity has led to impressive models for the training of primary care practitioners, as noted earlier. This is true in many countries, notably India and Thailand. Primary care training for specific mental health interventions is also part of a WHO strategy.

Conversely, there is a global trend toward the imposition of managed care on mental health services. This is occurring in countries, such as China and Eastern Europe, that have hardly met their child and adolescent mental health needs. The need is felt to control the cost of mental health services. Perhaps uncritically, economies throughout the world are adopting managed mental health care. From a Western perspective, it is obvious that although all mental health services suffer in a managed-care environment, child and adolescent mental health services are often most vulnerable to reductions and the use of the lowest-common-denominator service. Research into managed care and health services has not had the beneficial impact of stimulating the development of some innovative systems of care, but unfortunately the investment needed to foster these systems of care and the social network needed to provide "wrap-around" services do not exist in developing countries. It remains to be seen whether traditional systems of care can be integrated into a meaningful continuum.

## CONCLUSION

International child and adolescent mental health is no longer an exotic topic for theoretical discussion. With our global village, knowledge of child and adolescent mental health problems throughout the world is an important part of the education of all child and adolescent psychiatrists and allied professionals. The perspective gained from appreciating the stressors of children and adolescents in parts of the world embroiled in conflict and the nature of the responses offers the opportunity to learn more about the resilience of children and adolescents and about what we must do to develop more effective intervention programs.

The dearth of trained child and adolescent psychiatrists and allied professionals in developing countries challenges us to find the most effective means for inculcating knowledge and providing meaningful services. It is unrealistic to assume that any effort will meet the needs of child and adolescent psychiatry as determined by conventional planning assumptions. As services evolve in developed countries, there is probably much that can be learned from the way in which less developed countries have found the means to support families and individual persons to be relatively self-sufficient even when they are affected by mental disorders.

Given the enormity of the challenge to extend child mental health in a meaningful manner globally, the establishment of regional centers of excellence should be considered. These centers would incorporate resource libraries, have access to consultants, support training, and in some instances provide clinical diagnostic functions. Ultimately, the goal is to establish a sufficient cadre of child mental health professionals trained to an acceptable standard with the capacity to relate in a culturally appropriate manner to the mental disorder of children and adolescents and to be able to support the healthy development of children and adolescents.

For many compelling reasons, child psychiatrists should engage actively in school consultation and in related school-based activities that support the mental health of children. The most pressing is that mental health services delivered in traditional clinic, hospital, and private office settings do not reach most young people who suffer from psychiatric disturbance. School consultation provides a unique avenue for helping many children who would not otherwise come to psychiatric attention. It also extends knowledge to educators and other school-based professionals to help them work more effectively with psychiatrically disturbed and psychosocially stressed children. In addition, school consultation can serve as an entry point for the child psychiatrist who is curious about the functioning of schools, the social institution that, second only to the family, bears responsibility for promoting socialization, as well as for other key aspects of development. Finally, through such engagement with schools, the child psychiatrist may have the opportunity to foster ways of thinking and teaching that will, in turn, promote the physical and mental health of young people.

Despite the compelling argument of need and the potential for mutually interesting interchange, the relationship between educators and mental health professionals was described, for many years, in terms such as tenuous ([Mattison, 1993b](#)) or ambivalent and uncertain ([Comer, 1992](#)). The paucity of collaborative research between educators and child psychiatrists and the lack of cross-fertilization by way of publication in each others' journals attested to a relationship that was more distant than collaborative ([Mattison, 1993b](#)). This may have been the result of differences in theoretical orientation, because educators have generally been trained to use behavioral paradigms and psychiatrists, psychodynamic ones ([Mattison, 1993b](#)). Moreover, residual ill or ambivalent feelings may result from the period in the 1960s and 1970s when community mental health centers were mandated to provide consultation to public agencies, an arrangement that led to the sense of psychiatric consultants as uninvited "strangers bearing gifts" to other community agencies ([Borus, 1984](#)). More recently, however, newer models of mental health involvement with schools have emerged ([Rappaport, 2001](#)), and public attention has focused on difficult school problems involving emotional and behavioral disturbance, such as violence in schools ([Mattison, 2000](#)). Whatever the reason or combination thereof, child psychiatrists are being called on increasingly to advise on classroom management, appropriate educational programming for psychiatrically disturbed children, and prevention and early intervention efforts in schools.

In what appears to be a rapidly improving climate for working relations between educators and mental health consultants, it is timely for this chapter to (a) review models that apply to school consultation, (b) consider some unique features of schools that should aid child psychiatrists in consultation work in schools, and (c) discuss the tasks of the child psychiatric consultant in some detail with reference to a frequently requested type of consultation or evaluation for special education services.

## HISTORICAL PERSPECTIVE

In the two decades after World War II, awareness of the expanding population base and the numbers of untreated mentally ill stimulated a sense of urgency to provide community-based psychiatric services. In Caplan's words: "An outstanding challenge which today faces mental health specialists is connected with our realization that the number of actual or potential mentally disordered persons in the population exceeds our current capacity for remedial action" ([Caplan, 1970](#)). With President Kennedy's message to the U.S. Congress on mental health and mental retardation and the subsequent passage of Public Law 88-164, the Community Mental Health Centers Act of 1963, community mental health consultation became, for a time, an obligatory basic service ([Caplan, 1970](#)). Changes in the organization of the mental health care delivery system further stimulated the opening up of mental hospitals and the expansion of psychiatrists into a variety of community settings. The Community Mental Health Centers Act spawned the rapid growth of community mental health consultation, as well as ideas about a range of consultation models.

The discovery of the prevalence of mental illness in the United States did not initially advance the practice of school consultation because the few mental health workers who interacted with schools were pressured to work in places of greater need, such as Veterans Administration hospitals ([Alpert, 1976](#)). Over time, it became clear that, to address the problem of mental illness in the community, intervention in schools would be essential. Through the leadership of Caplan, Sarason, Berlin, and others, a literature on school consultation emerged, documenting the theoretical basis for and common clinical issues encountered in the growing field of school consultation.

## MODELS OF CONSULTATION

After conducting a multidisciplinary literature search, [West and Idol \(1987\)](#) reported finding 10 different models of consultation. In most of these, consultation was conceptualized as an indirect method of problem solving that provided remedial services for current problems and increased the consultee's ability to handle such problems in the future ([Gutkin and Curtis, 1982](#); [West and Idol, 1987](#)). Traditionally, the indirect nature of consultation was considered to be critical to success. However, more recent paradigms have proposed forms of more direct involvement ([Rappaport, 2001](#)): helping school systems to plan on-site interventions (e.g., mental health services in schools, as described later), system and organizational level interventions, and involvement in prevention and early intervention programs.

In both traditional and emerging models, the mental health consultant is often able to reach many more children than would be possible through direct service. Estimates of need for mental health services have ranged in the order of 8 million children and youth in schools, of whom less than one-fourth receive appropriate services ([Kestenbaum, 2000](#); [Mattison, 1999](#); [Rappaport, 2001](#)). Hence, the statement of urgency and level of need articulated by Caplan, even in 1970, are as relevant today as then.

Models of consultation include the classic ones—the mental health model, the behavioral model, and the organizational model—as well as a set of emerging, school-specific models. Although the mental health model in various forms has been most commonly applied, it is also clear that the emerging, broader role engages the child mental health practitioner as collaborator, expert consultant, and partner in prevention, early intervention, and service delivery efforts.

### Mental Health Consultation

Caplan defines *consultation* as "the process of interaction between two professional persons—the consultant, who is a specialist, and the consultee, who invokes his

help in regard to a current work problem with which the latter is having some difficulty . . . . The problem involves the management or treatment of one or more clients of the consultee, or the planning or implementation of a program . . . (for) such clients” ( [Caplan, 1963](#)). An essential feature in this conceptualization of consultation is that the consultee (in this case, the teacher) retains professional responsibility for the client and, in this capacity, is free to follow—or not—the recommendations of the consultant. Inherent in this is the nonhierarchical nature of the relationship between the consultee and the consultant. In the usual arrangement, this is facilitated by the consultant’s being of a different profession from the consultee and by the consultant’s “visiting” rather than membership status in the consultee’s institution ( [Caplan, 1970](#)). Caplan also stresses that the consultant’s goals are both to be helpful with the problem that led to the consultation request and also to impart new knowledge and skills so the consultee will become more capable of handling such problems in the future.

Caplan delineates four basic forms of consultation ( [Caplan, 1963](#); [Caplan, 1970](#)): client-centered case consultation, program-centered administrative consultation, consultee-centered case consultation, and consultee-centered administrative consultation. In client-centered consultation, the consultant brings expertise to bear on problems the consultee is having in working with a client (or group of clients); in school consultation, this is usually a student. Although the consultant may deal primarily with the consultee (school staff), the focus nevertheless is on the client (student). In the program-centered administrative form of consultation, the consultant typically meets with a group of consultees (again school staff) to help reform troubled administrative programs or to advise in the development of a new program or policy. The last two forms of mental health consultation, consultee-centered case and consultee-centered administrative, are parallel in content (case versus program) to the first two forms. They differ in that the consultant focuses on the problems that the consultee (school staff) has with either the client (student) or program rather than on the client or program *per se*. In consultation work in schools, an example of the consultee-centered case approach would be the consultation to a teacher about how he or she may be contributing to problems in working with a student ( [Alpert, 1976](#)). Central to this approach is the idea of theme interference ( [Caplan and Caplan, 1993](#); [Caplan et al., 1995](#)). *Theme interference* refers to problems the consultee is struggling with that interfere with the ability to work constructively with a student client. The consultant focuses on reducing theme interference by addressing the problems of the school staff rather than of the student.

[Caplan \(1963\)](#) proposes four types of problems that can be addressed in consultee-centered consultation: (a) lack of understanding, (b) lack of skill, (c) lack of objectivity, and (d) lack of confidence. As [Caplan \(1970\)](#) and [Alpert \(1976\)](#) point out, in real life the clean distinctions of the four-part typology often break down, with shifts in focus occurring in the course of the consultation process. [Fritz \(1993\)](#) further notes that, in the current climate for consultation work, consultee-centered consultation is difficult to fund, rarely requested as such, and problematic for the maintenance of the egalitarian relationship between consultant and school staff.

Applying principles of dynamic psychiatry to a broad range of consultation situations, Caplan’s writings are filled with rich descriptions of case material and of mechanisms (e.g., simple identification, transference, characterologic distortion) by which the teacher’s work with a student becomes problematic or stymied ( [Caplan, 1963, 1970](#)). Consultation skill lies in the accurate recognition of these processes and in the ability to work constructively with school teachers and administrators toward the goal of increased effectiveness, that is, more effective work on the part of the teacher in the service of the child or adolescent student. Caplan is careful to delineate the major distinctions between consultation work and psychotherapy, which are quite fundamental and involve, for example, the nature of the contract and relationship between the consultee and the consultant, as well as the very different goals of these two activities (improving the teacher’s work with his or her students versus personal cure).

Berlin, another pioneer in school mental health consultation, notes the potentially unique opportunity that the mental health consultant has “to communicate and sometimes to demonstrate mental health principles to teachers,” that is, to teach the teachers ( [Berlin, 1962](#)). Applying principles of ego psychology to the consultation process, Berlin focuses on teachers, with the goal of reducing anxieties and tensions that hinder effective classroom work with disturbed students. He notes that, in sensitive areas, it may be particularly useful to find strategies for externalizing the situation, such as through the use of examples from other contexts. Joint exploration of difficulties in work with a particular student helps the teacher to identify critical choice points and to consider new, more adaptive solutions.

[Sarason et al. \(1966\)](#), recognizing the potential of schools for preventive mental health work, applies a social ecologic approach to mental health consultation. Extrapersonal features of the institution, along with intrapsychic phenomena, are taken into account in examining problems between consultees and clients (students) ( [Alpert and Meyers, 1983](#); [Tindal et al., 1990](#)). Like the approaches of Caplan and Berlin, this approach commonly focuses on changing the teacher’s perception of a problem with a student. Particular emphasis, however, is placed on the role of teachers in schools and on difficulties in relationships within the school as an institution ( [Alpert, 1976](#)).

The school mental health consultation will thus vary somewhat depending on the consultant’s theoretical orientation, but in today’s world it generally focuses on the problems that a teacher is having with a student, with a teacher’s concern about the psychological well-being of a student, or with issues of educational programming for a given student’s educational progress, such as the need for special education. Although consultee-centered consultation is rarely requested using the traditional psychodynamic, ego psychological, or social ecologic models, questions about institutional or program difficulties are generally addressed using models for organizational consultation (see later).

## **Behavioral Consultation**

Bergan broadly defines *behavioral consultation* as “the application of behavioral theory and research in consultation services” ( [Bergan and Kratochwill, 1990](#)). Like behavioral therapists, behavioral consultants focus on changing the behavior of teachers through a problem-solving process designed to attain behaviorally defined goals ( [Bergan and Kratochwill, 1990](#)). Different behavioral consultants subscribe to slightly different problem-solving processes, but most processes are fundamentally similar to that described by Bergan, which involves the following four stages: (a) problem identification, (b) problem analysis, (c) plan implementation, and (d) problem evaluation ( [Bergan and Kratochwill, 1990](#); [Kratochwill et al., 1995](#); [Osterweil, 1987](#); [West and Idol, 1987](#)).

During the problem identification stage, the consultant and teacher determine whether there is a problem and, if there is, how to define it. A problem occurs when the student’s observed behavior is not what is desired and expected by the teacher or other school personnel ( [Bergan and Kratochwill, 1990](#)). When the consultant and the consultee have defined a problem by establishing that a discrepancy exists between current and desired behavior, they establish goals for the resolution of the problem ( [Bergan and Kratochwill, 1990](#)). The consultant is first mainly responsible for defining the problem and for formulating it in behavioral terms.

During the stage of problem analysis, the consultant and the school staff generate hypotheses about factors that influence the behavior and design a plan to solve the problem ( [Bergan and Kratochwill, 1990](#)). Again, school personnel play an integral role in problem analysis and plan development. Next, the plan is put into action. During the plan implementation stage, the consultant and school staff collect data to assist in the final stage, outcome evaluation. During outcome evaluation, the consultant and teacher (or school staff, more generally) determine whether the goals have been attained, whether new problems have arisen, and whether plan implementation should continue, be changed, or be terminated ( [Bergan and Kratochwill, 1990](#)).

Behavioral consultation is popular, especially among educators, and it is the model of choice for many school psychologists. There are several distinctive features of the behavioral model: the consultee (teacher) is viewed as a problem solver who contributes to all stages of the problem-solving process; the client (student) is encouraged to develop problem-solving skills; the goals of consultation involve the teacher’s observation and measurement of incidents of behavior; and the model defines the problems of individuals as related to the environment ( [Bergan and Kratochwill, 1990](#)). There is also a greater focus on evaluation in the behavioral model of consultation than in the mental health model; moreover, evaluation of outcome may be easier because the consultation process involves the specification of certain student behaviors that the consultant and teacher endeavor to change. Behavioral consultants have worked to develop standardized measures to evaluate consultation outcomes ( [Bergan, 1995](#)).

This model, emphasizing observed and measurable behaviors, fits well with educational practices and has been applied in consultation to many special education classroom settings. The behavior-modification plans that are often the product of this type of consultation can be applied to a wide range of student problems, from the more prevalent disruptive behavior disorders to some profound disturbances. For example, a nonverbal 7-year old girl, who was unable to separate from nearly constant physical contact with her mother, was assessed by a behavioral specialist who devised a behavioral program for the child–mother unit. The initial goals involved proceeding through a set of steps toward separation. The specialist’s analysis and explanation of reinforcers and related mechanisms were integral to recruiting school understanding and support for the program, which was administered with slow but clear progress by a special education teacher.

## **Organizational Consultation**

*Organizational consultation* focuses on schools as systems and seeks to facilitate improvement in their functioning through the application of behavioral science concepts and the involvement of system members (e.g., administrators and teachers) in the process of organizational change. According to this model, mental health and learning difficulties are in part symptomatic of a dysfunctional educational system ( [Christ, 1991](#)). [Schmuck \(1995\)](#) notes that systemic problems such as communication breakdowns and ambiguity about responsibilities are common in many schools. These problems can cause a great deal of anxiety and frustration

among school staff.

Achieving optimal organizational functioning by introducing systemwide change is seen as essential to improving the quality of life and facilitating the productivity of individual members. Overall, the goal of organizational development is to build "self-renewing schools, schools that are able to adapt to current changes within the student body, community, and world while continuing to maintain an effective educational program" (Schmuck, 1976). Self-renewing schools are viewed as adaptive and changing and thus are not bound to particular structures and procedures.

An important feature of the organizational consultation process is the involvement of system members (e.g., teachers, administrators) in the assessment, diagnosis, and transformation of the organization (Schmuck, 1976). Consultants work with and advise teachers and administrators to help them change their interpersonal and group methods of interaction. Thus, this model of consultation focuses on the organizational context, including the mode of communication and the quality of relationships within the school. School "culture" is viewed as a powerful influence that must be understood and worked with to ensure the success of educational innovation and reform efforts (Schmuck, 1976). For example, in the late 1960s the consultation and collaboration process described in Chapter 106, known as the Comer School Development Program, examined governance and management in two inner-city, low-achieving schools. Application of ecologic and child development perspectives led to school restructuring and change in the school culture and climate, with positive results in the areas of student self-esteem, motivation, and achievement.

### Emerging Models and the Pressing Need for Service Delivery

Increasingly, there has been a move toward the provision of mental health services in schools. Concurrently, emerging models of school consultation extend beyond the traditional limits of the consultant's role and seek instead a broader involvement, including team membership, as a focus of consultation, or perhaps more correctly, of collaboration (Rappaport, 2001). Thus, it is important for the consultant to be knowledgeable about methods of psychiatric intervention that can be put into place in schools, as well as of prevention and early intervention programs that have been developed for school settings.

School-based mental health services may be offered in school-based clinics that offer a spectrum of health care services to students. It is also possible to provide mental health services in schools following a model involving collaboration between a treatment center and a school.

An example of this type of program is one created as a direct outgrowth of work carried out by a university-affiliated children's outpatient psychiatric clinic in an urban community (Armbruster and Lichtman, 1999; Armbruster et al., 1997; Armbruster et al., 1999). Involvement with the community and with youth-related programs had impressed members of the outpatient clinic with the number of unserved children. A study of attrition in the clinic had found that the inner-city family is at risk for dropping out during the first few weeks of contact with the clinic (Armbruster and Fallon, 1994; Armbruster and Schwab-Stone, 1994). In response to these observations and with the support of the public school system, the clinic developed a school-based mental health program with the goals of providing effective access and outreach to underserved, disadvantaged children and of collaborating more closely with the schools.

Initially, mental health services were established in four inner-city schools, increasing to 37 or almost 80% of the schools over the next 5 years. In addition to responding to clinical need, this project was built on the legacy of school collaboration instituted by a school reform program, the School Development Program, developed by James Comer (1985, 1988) (Chapter 106) and implemented for many years in the local public schools. The Comer project addressed issues of school climate; the clinic provided direct services. The World Health Organization, Division of Mental Health (1994) noted that effective school intervention can implement an environment-centered model (e.g., the Comer project), a child-centered model (e.g., the clinic's service), or, optimally, both. In both cases, the programs worked in concert to provide supplementary services to the school.

Children and families seen in the schools are considered clinic cases. They are ensured the same evaluation and treatment they would receive if they entered the central child guidance clinic. All children seen in the schools are assigned to the central child guidance clinic's weekly interdisciplinary clinical treatment team and hence are subject to the identical review and quality assurance program as cases seen in the central child guidance clinic. In addition to the central clinic's weekly interdisciplinary treatment team, a school-clinic team meets bimonthly. This school-clinic team promotes clinic integration of school-based services, both within and outside the central clinic, because it comprises school-based clinicians in the schools, consultants from the university's clinical departments, and representatives from schools and community agencies. A child psychiatrist provides medication consultation at the school sites and participates in the central interdisciplinary school-clinic team.

Another function of the school-based clinicians is to refer children for medical care, specialized or acute care, and also for recreational activities and tutoring. Hence, the mental health providers may become the informal gatekeepers and conduits to a range of services (Dowden et al., 1997). Furthermore, with the availability of mental health services based in schools, referrals can be made directly and expeditiously after a traditional psychiatric consultation has been conducted. The central clinic also has an immediate access service for visits at the clinic within 24 hours, if the family chooses not to receive services in school during a crisis. A visit to the immediate-access clinic often serves in place of the less efficient and much less appropriate hospital emergency room visit.

Certain elements of this and other innovative models for school-based mental health service delivery have been identified (Rappaport, 2001). These include the following: (a) increased access to services for disadvantaged and underserved youth; (b) systemwide collaboration; (c) the potential for effectively triaging acute psychiatric incidents, thus preventing the need for acute psychiatric intervention; (d) service as gatekeeper for, and conduit to, more acute or specialized care, when needed; (e) systematic program evaluation; (f) training in working with a range of systems; (g) increase in providers' cultural competence and understanding of diversity; and (h) outreach and community-based care. Thus, school-based mental health service is a highly promising strategy for treatment delivery, but research data for therapeutic and cost effectiveness are not yet available (Armbruster and Lichtman, 1999). Nevertheless, evaluation efforts to date have shown that, in this example, school-based services are reaching the targeted disadvantaged population (Armbruster and Lichtman, 1999).

## SCHOOL CONSULTANT AS ADVISOR ON SCHOOL POLICY AND INTERVENTION PROGRAMMING

In an article reviewing research on interface issues between child psychiatry and schools, Mattison (2000) notes that, increasingly, mental health professionals are asked to offer their opinions and advice on a wide array of new programs and policies. In an attempt to aid such consultations, (Mattison, 2000) highlights the psychiatric and consultation implications of four such school-based problems: absenteeism, disciplinary issues, retention, and school dropout.

### Absenteeism

Epidemiologic findings on *absenteeism* point to mental health precursors. It has been shown that nearly half of chronic absentees have a psychiatric disorder, with most expressing either disruptive behavior disorders (greater truancy) or high levels of anxiety (school phobia) (Berg et al., 1993). Despite these substantial associations between absenteeism and mental disorder, very little research has focused on prevention and treatment. From the research available, findings have shown that cognitive-behavioral treatment and educational support therapy can lessen anxiety-based school refusal (King et al., 1998; Last et al., 1998). Psychopharmacology research has failed to draw conclusive findings, but it has been suggested that imipramine may lessen depressive symptoms and may improve school attendance (Bernstein et al., 2000). Although the prevalence of conduct disorder is higher in chronic absentees than is anxiety, research has yet to identify an effective treatment for delinquent truancy.

With respect to excessive absenteeism, Mattison (2000) suggests that the most effective advice to schools is early detection. Determining which students show high levels of absenteeism and then proactively addressing the needs of these children should have the greatest impact. Unfortunately, proven programs to combat truancy are unavailable and often require the coordinated efforts of the broader community.

### Disciplinary Issues

Although *problems with authority* may be a developmentally appropriate behavior that discipline can address, studies have shown that most adolescents who are suspended from school have academic or social deficits (Morgan-D'Atrio et al., 1996) that are unlikely to be improved by suspension. Proactive identification of students at risk (using indicators such as consistently poor grades, high rates of absenteeism, and ongoing disciplinary problems) may help schools to prevent suspensions and expulsions. Through adequate academic and psychiatric evaluation, schools should be able to determine which students should be referred for disciplinary action and which will more likely benefit from therapeutic intervention or extra academic support (Mattison, 2000).

## Retention (Nonpromotion)

Although methodologic issues (e.g., lack of appropriate controls, *post hoc* analysis, and lack of baseline information) make it difficult to assess the impact of *retention*, most researchers have concluded that there is no long-term academic benefit when retained students are compared with students of similar dysfunction who have been promoted (Mattison, 2000). Despite these contrary-to-fact findings, most teachers regard retention positively, and, indeed, national epidemiologic studies show that cumulative totals for retention range between 14% and 19% (Byrd et al., 1997; Meisels and Liaw, 1993), with much higher rates in many urban centers (Alexander et al., 1994; Silver et al., 2001). Very few studies have assessed intelligence quotient, mental retardation, and learning or language disorders among retained students, but it has been shown that students with a newly diagnosed learning disorder frequently have been held back in school (McLeskey and Grizzle, 1992). Thus, without adequate programs and interventions, holding a student back may only delay his or her difficulties in school. Mattison (2000) notes that low intelligence quotient or mild retardation, learning disorders, psychiatric disorders, family dysfunction or stress, and developmental variations are among the factors that characterize the diverse group of retained students. Hence, it is not surprising that the practice of simply “recycling” the child through the same academic curriculum for a second time does not appear to help many children (Mattison, 2000).

## Dropping Out

Although many of the precursors to *dropping out* have been established (low socioeconomic status, minority status, living with a single parent, behavioral problems, pregnancy, chronic absenteeism, weak academic achievement), specific psychological precursors have been assessed only rarely. Relatively little is known about whether the early presence of a learning disorder, psychiatric diagnosis, or concomitant family stressor will germinate into a greater likelihood of dropping out of school. One study of graduating eighth graders who eventually dropped out of high school showed that having a preexisting psychiatric disorder significantly increased the odds of dropping out (Kessler et al., 1995). Barrington and Hendricks (1989) show that poor academic achievement as early as third grade can predict eventual school dropout. Clearly, early identification of students at risk can play a part in lowering dropout rates. Mattison (2000) suggests that such interventions not only should begin early, but also should continue throughout schooling. These efforts should attempt to institutionalize success by creating “curricula relevant to the varying, unique needs of such students.” Although many of the risk factors for dropping out cannot be addressed in the school setting (low socioeconomic status, weak family involvement), academic and psychological risk factors should be identified early and addressed proactively.

## EFFECTIVENESS OF SCHOOL CONSULTATION

Assessing the effectiveness of school consultation is difficult because the practice of consultation tends to be naturalistic, it has varying goals, and consultations are rarely performed in a standardized manner (Brent and Howell, 1983). As a result, consultants often assess effectiveness anecdotally, and empirical attempts frequently suffer methodologic problems (Erchul and Martens, 1997). Nevertheless, some research reviews and results of two metaanalyses have shown school consultation to be an effective means of intervention (Medway, 1979; Sibley, 1986; see also Medway and Updyke, 1985, a metaanalysis of psychological outcome studies that used 54 controlled studies predominantly, but not entirely, limited to school consultation.) One comprehensive review of 46 school outcome studies of all types of consultation models concluded that 67% had reported positive results, in 28% results were neutral, and in 5% the outcomes of all types of school consultation were negative (Sheridan et al., 1996). The two metaanalytic studies compared effectiveness across *different models* of consultation and concurred in the finding that there was *no* evidence for the superiority of any particular model (Medway and Updyke, 1985; Sibley, 1986; West and Idol, 1987).

Studies investigating relative preference for different models of school consultation have found that teachers prefer behavioral consultation to mental health consultation (Jason and Ferone, 1978; Medway and Forman, 1980), although school psychologists view mental health consultation as more effective (Medway and Forman, 1980). Teachers may prefer behavioral consultation because it provides them with a specific and directed plan of action that seems more readily applicable to the classroom setting. West and Idol note that preference for a particular model may depend on the *stage* of the consultation process, a finding lending support “to the concept of consultation as a complex, multi-dimensional process” (West and Idol, 1987), which warrants continued and more sophisticated efforts at evaluation.

## COLLABORATION IN SCHOOL CONSULTATION

A central guiding principal in all models of school consultation is the importance of a collaborative relationship between the consultant and the teacher (Truesdell and Lopez, 1995). However, the meaning of collaboration has never been well operationalized in the literature (Erchul, 1999). After a series of studies in which observational analyses of consultant–teacher dyads led to a questioning of the efficacy of collaboration in school consultation (Erchul, 1987; Erchul and Chewing, 1990; Witt et al., 1991), researchers were forced to reevaluate their long-held assumptions about the collaborative nature of school consultation. Subsequent research has indicated that collaboration in school consultation is a multidimensional construct consisting of at least two continua: one ranging from “coercive” to “collaborative,” the other ranging from “nondirective” to “directive” (Gutkin, 1999). Collaborative–directive consultation is characterized by interactions in which the consultant uses his or her psychiatric expertise to take the lead in prescribing a course of action to the teacher, while at the same time being receptive to the teacher’s input. Such a relationship promotes teamwork between consultant and consultee by highlighting the contribution of each other’s expertise in different fields. Gutkin (1999) argues that the empirical research on school consultation underscores the strength of such a directive–collaborative approach.

Caplan et al. (1995) state that the mental health consultation relationship should be coordinate and nonhierarchical, such that the consultee is free to accept, or not, the recommendations of the consultant. Within this model, however, these researchers maintain that the consultant’s full and expert understanding of the presenting situation should be used and applied. For example, a teacher may displace some of his or her problems onto a particular situation or may harbor unconscious feelings about a student. In such a situation, the consultant may use the student’s problems to address the teacher’s issues in an indirect and nonconfrontational manner (Caplan et al., 1995).

In sum, the relationship so important in school consultation may vary in terms of its directiveness and degree of responsibility and authority. Caplan et al. contrast the characteristics of the traditional mental health consultation model and those of the mental health collaboration model (Caplan et al., 1995). They note that the collaborative model is the most appropriate mode of working together when the mental health specialist is “in-house,” that is, a staff member who as a treating expert also bears responsibility for the client, whereas the mental health consultation model has distinct advantages when the specialist is truly an outside consultant. Regardless, it is imperative that there be understanding and respect between consultant and consultee for each other’s expertise and that the assumptions of the model be clear, so both parties can work together as an effective team.

## PRACTICAL ASPECTS OF SCHOOL CONSULTATION

From the foregoing review, it is apparent that the novice consultant, preparing to embark on school consultation work, has at hand a diverse set of theoretical approaches on which to draw and relatively little evidence from the research literature to constrain his or her work. In many ways, it is up to the consultant to fashion a strategy for this undertaking and to contribute to the evolving process of the consultation relationship.

### Schools as Social Institutions

In engaging with a school or school system to provide consultative services, the consultant is entering a *social system* that has well-specified and unique functions. These functions have developed historically to address society’s needs for socializing and educating its young. Comer says: “The school, like the family, is charged with preparing the young to become successful adult workers, members of families, and citizens” (Comer, 1992). This is a large mission, and accordingly children spend a considerable amount of time in schools each year through the span of the childhood and adolescent years.

Not surprisingly, to accommodate the goals that have been set for them, schools have developed into complex social institutions. They bring together people of different disciplines, levels of preparation, age, and experience (Comer, 1992) to function together to address the developmental needs of children. Viewed this way, an important aspect of the consultant’s preparation is to become knowledgeable about and comfortable moving in this system. For example, schools have traditionally been hierarchical and authoritarian in structure. Although innovative models of school reform are challenging the necessity and efficacy of that type of structure (Comer, 1993), it is nevertheless not uncommon for the consultant to encounter a fixed structure with explicit lines of authority and relatively low tolerance for transgression. It may be useful for the consultant to consider why schools may have developed in this manner, that is, to institute externally a degree of structure that may be necessary to learn at a time when the child’s internal capacities for self-structure and regulation are still developing. At a practical level, this makes it easier to understand what may superficially appear to be unnecessary constraints on times available for meetings with staff or students or the necessity of communicating a seemingly straightforward request through a specific chain of authority. In addition, an understanding of the structure and rules of school life can facilitate the

consultant's ability to work effectively without unproductive conflict and to appreciate the culture of school life as perceived through the eyes of the child.

### School Climate

Although it is useful for the consultant to become familiar with the structural and organizational aspects of school life, it is also important to evaluate the process aspects of its functioning. *School process* refers to the nature and style of relationships and flow of information within the school ( [Purkey and Smith, 1983](#)). The resulting *climate* of the school involves numerous components that have been variously conceptualized and include, for example, dimensions such as orientation toward learning, level of conflict, promotion of independence, and student involvement in school decision making. ( [Kasen et al., 1990](#)). Research suggests that school climate influences both the academic achievement of students ( [Purkey and Smith, 1983](#); [Rutter et al., 1979](#)) and their emotional development ( [Kasen et al., 1990](#)). However, although there is general agreement that the climate of a school has an important impact on its students, it is less clear which specific factors are most influential. In a review of the literature, [Purkey and Smith \(1983\)](#) argue that many of the studies of effective schools focus on very simple factors that have little effect on the development of students (e.g., class size). Important factors deeply rooted in the school's "culture" are slow to change even when sweeping changes in policy are made. Such a process is well-described in [Chapter 106](#) by Comer et al., who detail the mechanisms through which staff and parents engage with the ultimate goal of changing the culture and climate of the school to promote development, teaching, and learning.

From the perspective of the school consultant, evaluating school climate provides essential information that will enhance the consultant's understanding of the experiences of both students and teachers (consultees) who study and work in the school. Over time and with the development of trust, the consultant may have the opportunity to influence decisions and attitudes that will sustain a positive and supportive context for student learning and development.

### School Staff

The *school system staff* that the school consultant typically encounters includes teachers, guidance counselors, school psychologists, school social workers, and administrators (principals and assistant principals). Teachers spend the most time with and know the students best and as a result are an extremely valuable resource for the consultant ( [Mattison, 1993b](#)). Teachers' roles differ depending on the age of the student. In elementary school, students spend most of their day with one teacher, whereas in middle and high school, students usually spend an hour or less with each of their teachers per day.

Guidance counselors, usually former teachers who have degrees in guidance counseling, are often the first school staff members contacted by either student or teacher when a student has a problem ( [Mattison, 1993b](#)). Guidance counselors frequently have access to mental health resources, but their roles and training vary. Although they are familiar with psychological principles, the impact of psychosocial stress, and fairly normative adjustment issues, they may not actually have much experience with psychiatric diagnostic thinking and nomenclature.

School psychologists have degrees in psychology and have probably been trained in the diagnosis and treatment of behavioral problems ( [Mattison, 1993b](#)). School psychologists often perform psychoeducational testing and may be involved in behavioral management or counseling. In working with children with learning disabilities and complex profiles of cognitive deficiencies and strengths, the consultant will often need to rely on the school psychologist's expertise in describing the impact of such conditions on the child's school functioning.

School social workers work with the families of students but may also share with the school psychologist the function of providing psychological interventions, usually in the form of group or individual treatments. The school social worker may be the key link to the family. The likelihood of achieving success with a classroom intervention may be considerably heightened by engaging the social worker to gain the parents' understanding and support for it. School social workers vary widely in their training and experience with psychiatric diagnostic and treatment principles.

Finally, administrators are often alerted to problems with a student, and they may serve as a liaison between the school and the family. A principal's opinion concerning a student or his/her capacity for involvement in the consultation process can determine the course of action taken by a school ( [Mattison, 1993b](#)).

### Students

In beginning consultation work at a school, it is useful for the consultant to spend some time observing the *students* in the school. This can be done by walking the halls, observing classes across the school's grade range, watching children play on the school grounds during recess, visiting the cafeteria, and attending art, music, or other enrichment activities. In particular, the consultant should get to know the special education classes, both the teachers and the students. This background work is essential for developing a sense of the normative experience of growing up and going to school for the population from which consultation referrals will be generated. It provides an opportunity to begin assessing the school climate, as well as educating the consultant about the range of intervention options that exist within that school setting.

The consultant brings to the consultation process his or her expertise in the diagnostic assessment of psychopathology in children and adolescents and experience in identifying and working with dynamic issues. Although the range and specific types of problems that lead to consultation requests are not reviewed here, it is useful to have a framework for thinking about clinical presentations in the school context.

Briefly, a framework that has been found useful focuses on the developmental tasks of childhood, how schools support a normative progression along developmental lines, and why students who cannot meet the challenges posed at certain stages come to attention for special psychiatric help or educational services. Although a full discussion of this model is beyond the scope of the current chapter, a few examples illustrate the general approach.

In the United States, most children are in school by at least age 6 years. Although today kindergarten is a fairly universal experience, and increasingly now children are attending day care and preschool, entry into first grade has generally been considered the beginning of formal schooling, with a more academic curriculum and, in many places, the start of full-day programming. The child entering school faces a fairly extensive set of demands on his or her capacities across developmental lines. These include, for example, the requirement to separate from primary caregivers and to maintain a sense of sustenance and comfort that is sufficient to get through the day relatively emotionally intact. The child must tolerate and comply with what is probably a greater level of structure than has been previously imposed on his or her day. Activities requiring sustained attention are required. Whereas the average 6-year-old is ready cognitively, emotionally, and socially for these challenges, it is also apparent that some children are not so neatly on schedule. Some may be compromised in specific areas, for example, by difficulties with attention or activity regulation and impulsivity. The challenge of separation may overwhelm others with anxiety, or the stress of coping with peer interactions may send the socially immature child into behavioral outbursts. Some, albeit fewer, children, such as those with pervasive developmental disorder, will be unable to function across all or nearly all domains. It is common then for the consultant to become involved with children characterized by a lack of developmental readiness for the challenges at hand. For some children, this is constitutionally based; for others, it may be rooted in stress from home and family issues. Although the pervasively affected child often requires a special classroom and supportive services, those for whom the "fit" problem is more limited may improve with therapy, medication, or merely clarification and reassurance for the teacher and some adjustment of classroom practices. Often, sharing a developmental formulation with the teacher or other school staff is immensely useful and leads to constructive and creative ideas about the classroom management of the student's problem.

Generally, school transitions are points of particular vulnerability because the new setting usually poses a new set of developmental challenges. Again, these challenges are ones that the child who is developing in a roughly normal manner will be able to negotiate with reasonable success. Those who are not ready may come to the consultant's attention over the course of the year after the transition. This can be seen in the transition to middle school, which occurs for most children at age 10 or 11 years. The transition to middle school brings the expectation that the student will function with more autonomy. Children change teachers and classrooms, more homework is required, and expectations are heightened for the student to take a serious and independent interest in learning and schoolwork. Not surprisingly, at this stage, the consultant hears of children who are suffering the cumulative effects of learning failure because they have been referred too late or because successful interventions were not found in their elementary school years. For other children, the family and home have not provided the degree of structure and support needed to develop the internal motivation to apply themselves in the more challenging and less personal middle school setting. For such youth, the lure of street culture may become irresistible for its excitement and promise of easy access to material rewards. The sooner such transition casualties are caught, the more likely they can be helped back onto the track. In addition to the obvious clinical role that the consultant can play in helping school staff work with and refer such youth, the consultant can, over time, educate consultees to adopt a developmental mode for conceptualizing student problems and for initiating timely consultation requests and referrals for treatment.

## SPECIAL EDUCATION CONSULTATION

An important and common type of school consultation for the child psychiatrist is the consultation to determine eligibility for *special education*. The Education for All Handicapped Children Act, Public Law 94-142, was enacted in 1975 and established the right of children with any number of handicaps to an appropriate education and to related services needed for the child to benefit from that education. ( [Chapter 121](#) has discussion of legal background and issues relating to special education.) When a student's emotional or behavioral difficulties appear to be seriously interfering with his or her educational progress, a referral is made for an evaluation for special education. The labels applied in these situations vary; [Mattison \(1993a\)](#) uses perhaps the most common terminology, seriously emotionally disturbed.

On referral for special education, the student enters the special education administrative structure, which prescribes a set of procedures for evaluating eligibility and for determining the services to be provided to the student. In brief, a multidisciplinary team is convened to conduct the appropriate educational, psychological, medical, social work, and other evaluations. When the evaluations are complete, the team meets together with the parent or parents to review the results. The team determines whether the child meets the criteria for handicap on the basis of serious emotional disturbance (and also for other categories of handicap if relevant), and, if so, an appropriate individual educational plan is developed. This plan includes goals to be met, the time expected to meet them, the educational setting that is appropriate, the amount of time to be spent in a separate classroom and in regular classrooms, the related services that are recommended, and other considerations that the team may wish to note formally. In accordance with Public Law 94-142, students who are seriously emotionally disturbed must be placed in the "least restrictive," most mainstreamed setting possible.

[Mattison \(1993a\)](#) notes the need for greater standardization in school consultation and, in particular, cites the need for a formalized approach to the consultation for determining special education eligibility. He emphasizes that these evaluations usually involve children with complicated, serious symptoms who also often have families suffering from major concurrent stressors. The following is an outline of a consultation procedure used for these evaluations. It is very similar to the excellent model described by [Mattison \(1993a\)](#). The reader is referred to this reference for a detailed description of the model and for very useful examples of forms, interview outlines, and a sample final consultation report.

## **Special Education Case Evaluation**

### *Review of Referral Packet*

In the usual case, the consultation is initiated with a referral summary from the school, a copy of the parent's signed consent for psychiatric evaluation (obtained by the school), and results of previous evaluations. Of particular use are the recent and past reports from the school psychological evaluation. The consultant should develop some ability to understand test scores, particularly for basic tests of intelligence and achievement. Of particular importance is the presence of a learning disability, which should be described in the psychologist's report. A social work assessment may be present and may in some instances include an extensive developmental history. Various teacher reports and documentation of special education programming may also be provided. What is missing at times, however, despite the presence of a wealth of information, is documentation of the chronology of events leading to the current clinical state and referral for consultation.

### *Meeting with the Multidisciplinary Evaluation Team*

This meeting allows team members to review their knowledge of the case with the consultant before his or her interviews with the student and parents. For the consultant, it provides an opportunity to piece together the history if, as noted earlier, the chronology was not apparent from the materials in the referral packet. In this meeting, the consultant can also learn about the concerns or worries that are too "soft" or unsubstantiated for staff to write about in their formal evaluation reports. The meeting also provides an important opportunity for the consultant to gauge staff feeling about the student and to assess whether certain programming outcomes are desired by various members of the team.

### *Interview with the Parent or Parents*

The goals of this interview generally resemble those of parent interviews in other types of evaluation. The consultant seeks to gather history about the difficulties that have led to the consultation and to obtain history about other emotional and behavioral problems and treatments (past and present). Also to be covered are a review of psychiatric symptoms, medical conditions, developmental history, family history (including psychiatric conditions and learning problems of extended family members), assessment of the student's current social adjustment, and parental assessment of the student's strengths and positive aspects of coping. Additionally, the consultant should evaluate the parent's understanding of the special education evaluation process and hopes or expectations about the outcome. The level of trust that the parent feels toward school staff may be critical to the ultimate success of an intervention or referral and should be assessed at this time.

### *Classroom Observation*

When one is evaluating an elementary school-age child, it is often useful to schedule a classroom observation, and it is usually best to do this before the individual interview with the child. Such an observation can yield considerable information about the student's capacity to function in the current classroom setting, about his or her peer relationships, and about the teacher's current strategies for dealing with the student's difficulties. It is usually not helpful to observe an older student in his or her classroom, and it can be unduly embarrassing for the student to be observed.

### *Interview with the Student*

This student interview is similar to the general psychiatric interview in covering an explanation of the nature of the interview and the "kind of doctor" the consultant is, a discussion of current and past difficulties, a review of relevant areas of symptoms, inquiry about physical health and health concerns, and a discussion of home, friends, favorite activities, and feelings about school. A mental status examination should be conducted, and [Mattison \(1993a\)](#) notes the value of a systematic minineuroeducational examination covering coordination and basic educational skills (e.g., reading, mathematics, spelling). It is also useful to assess the student's hopes and expectations about the outcome of the current evaluation. An important feature of this type of consultation is that, beyond the conclusion of the evaluation, there is no expectation of a continued relationship with the consultant. As in any psychiatric evaluation, it is important to ask about anything that could shed light on the nature of the student's problems or be of potential use in disposition planning; however, uncovering techniques and extensive probing in affectively sensitive areas should be curtailed if their yield is not of direct relevance to the purpose of the consultation. There will not be an ongoing therapeutic relationship with the student, and he or she must return to school and cope with multiple academic and social demands for the rest of the day.

### *Team Meeting for Presentation of Consultant's Report and Collaborative Planning*

After completing data gathering through the stages outlined earlier, the multidisciplinary team reconvenes to hear the results of the consultant's evaluation. At this meeting, the consultant should present an overview of the history (with the level of detail determined by the group's general knowledge of this). It is extremely useful for the consultant to synthesize and summarize information contained in the initial packet along with the perspectives of the various team members; however, this should be done in a succinct manner that generates a sense of accord about the definition of the problem. Then, results of the parent interview, student interview, and classroom observation are presented, followed by the consultant's formulation. If the team agrees on the formulation, the consultant's program recommendations can often serve as a springboard for the discussion of an educational plan for the student. This phase should be viewed as a collaborative process among professionals with different areas of expertise. The consultant's unique contribution will be in conceptualizing and communicating about potential strategies for dealing with emotional and behavioral issues in the school setting. Together the team will agree on a specific plan and on how it will be implemented.

### *Feedback to the Parent or Parents and Student*

In some places, the parent is present at this team meeting. Agreeing with [Mattison \(1993a\)](#) that it is far preferable for feedback to be given by the consultant accompanied by the educator who will have continued involvement with the student and family rather than in a larger group context, it is nevertheless the case that in some systems there is a strong precedent for having parents at the team planning meeting. When the parent is present, the consultant must present findings in a style that is comprehensible, devoid of jargon, and recognizable to the parents as the story they have told the consultant. When the parent is not present, a separate feedback session should be scheduled relatively promptly, that is, before the team members begin talking about and implementing aspects of the plan. In some instances, depending on the age of the student and the nature of the problem and plans, it will be important to include the student in the feedback session.

### *Consultation Report*

Often schools prefer to see a draft copy of the report at the time of the team meeting but allow some further work afterward, so it can reflect planning decisions that were made collaboratively at the meeting. An excellent model for such a report is provided by [Mattison \(1993a\)](#).

### Referral

In the traditional school consultation process, appropriate clinical services can be recommended to school personnel, who, in turn, can refer the student and family for extended evaluation, possibly leading to treatment. Sometimes the consultant is the best person to make the referral, but it is important to work out the protocol for this with school personnel. In some instances, school staff members fear that if the referral is made in the context of a formal special education proceeding (see later), the school will be held financially responsible for the treatment, a burden that would unfairly and quickly drain special education resources. Indeed, the child is often referred for emotional, behavioral, or developmental difficulties that are not uniquely school matters and that should be handled financially in the same manner as pediatric care. Frequently, it is quite possible to discuss the referral as a noneducational recommendation and to meet after the formal educational proceeding has concluded to discuss privately with the parents (and youth, depending on age and clinical appropriateness) the reasons for referral and suggestions for appropriate clinical settings. What is important is that the clinician show sensitivity to this issue and work out an agreed on procedure with school personnel.

## SCHOOL CONSULTATION: EVOLVING ISSUES

[Jellinek \(1990\)](#) identifies four evolving trends affecting schools in the United States that, in various ways, concern child psychiatrists practicing school consultation. The first is the increasing demand for special services in the face of limited resources to pay for expensive, albeit often needed, services. The second issue is that of rising parental expectations for academic achievement and the expanding role of the school as an institution bearing increased responsibility for nurturing children and for preventing harmful behavior (e.g., substance use, suicide, high-risk sexual behavior). Given this situation, consultants may find it useful to promote avenues for outreach to families, both directly through the consultation process and indirectly through work with consultees (teachers and other school staff). The third issue involves the aging of the faculty of school teachers whose personal pressures and needs are new to school administrations accustomed to a younger faculty and higher rate of turnover. In fact, in the next decade, an estimated 2.2 million new teachers will be hired, according to the [U.S. Department of Education \(1999\)](#). The effective psychiatric consultant will recognize such situations and will engage, educate, and stimulate teachers. Although many aspects of this situation will need to be addressed systemically by schools themselves, the consultant can make a contribution on an individual-by-individual basis through awareness and sensitivity to these social trends and their ramifications. Such efforts may lessen the disaffection of older teachers as well as provide the consultant with the added insight of experience.

The fourth issue is the burden created by the interaction of the foregoing, as well as other complex stresses of modern life. Behavioral issues such as dropout and absenteeism are increasingly being seen as problems for which the mental health consultant may have useful input, thus opening new inroads as consultants are called on to advise on practices and policy, as well as on the needs of individual students.

The increasing recognition of need for mental health expertise in schools, combined with concern about cost effectiveness, is leading to an expansion of the traditional consultation model to a more collaborative model in which mental health experts work from within the bureaucratic structure of schools, not as outsiders ([Caplan et al., 1995](#)). This move toward collaboration involves consultants more deeply in the school system by (a) assigning them official roles in the bureaucratic hierarchy and (b) holding them more accountable for the outcomes of consultation ([Caplan, et al., 1995](#)). When this occurs, the consultant may gain a better grasp of the pressures on the local administration, as well as of the optimal avenues for positive growth and change. Conversely, the mental health professional's role with regard to school personnel differs structurally from that of the traditional consultant, and the basic assumptions of the model for working together differ as well, factors the mental health expert must incorporate in his or her manner of practice.

[Jellinek \(1990\)](#) notes that it is critical for the child psychiatrist to understand the evolving economics, values, and pressures on local school systems, because these affect the lives of the children and families with whom he or she works. Further, these trends reflect the enormous pressures on an essential social institution, but they may also signal a unique opportunity for the school consultant to contribute in new and creative ways to the mental health of many children and to the viability of many schools in our communities.

The Individuals with Disabilities Education Act (IDEA), originally enacted as the Education for All Handicapped Children Act (EAHCA) in 1975 and popularly known as Public Law 94-142, embodies the federal statutory requirements that govern the provision of educational services to children qualifying for special education. The Act provides all children with disabilities the right to a free public education, including special education and related services designed to their needs. The underlying premise of the Act is that all children with disabilities can learn if their education is designed to meet their unique needs ( [1](#) ). Promising individuals with disabilities an opportunity for full participation in the life of their communities, and the right to be as independent as possible and meaningful access to economic self-sufficiency became a national policy ( [2](#) ).

## HISTORY

The Education for All Handicapped Children Act [EAHCA] (popularly known as Public Law 94-142) was enacted by Congress in 1975 in response to the recognition that, of eight million disabled children nationwide, nearly half were not receiving the appropriate educational services to establish equality of opportunity, and one million were excluded from the public school system altogether ( [3](#) ). Children with emotional disabilities were among the most poorly served of disabled students; studies revealed that the educational needs of 82% of children with emotional disabilities were not being met ( [3](#) ). Further impetus for EAHCA were federal lawsuits that challenged the refusal of appropriate education to children with disabilities on the grounds that refusal violated the precedent set by the Brown vs. Board of Education decision ( [4](#) ). The EAHCA, originally applying only to eligible children ages 5 to 21 years, was amended in 1986 to include children 3 to 5 years old.

EAHCA became IDEA in 1991; it was revised mainly in response to a congressional finding that children with serious emotional disturbance (SED) remained severely underserved. Fewer than half the nation's children with SED were being identified and provided with appropriate services ( [5](#) ). Among other changes, IDEA ensured a smooth transition for children moving from early intervention programs (covered in another statute for at-risk infants and toddlers, ages zero to 3 years) to preschool special education programs ( [6](#) ). IDEA stressed the importance of family support and involvement in early intervention and preschool programs. Research indicates that this is a critical provision of the bill, because one of the most consistent factors in successful preschool programs is family support and involvement ( [6](#) ).

Congress added significant amendments to the IDEA in 1997, citing a growing disparity in educational opportunity between white and minority children. In its preface to the substantive changes, Congress cited the increasing need for special education of minority students as the minority population grows relative to the white population. It further noted difficulties in accessing educational opportunity faced by minority children who lack role models in the schools and who are challenged by social disadvantage and poor language skills ( [2](#) ).

## THE INDIVIDUALS WITH DISABILITIES EDUCATION ACT

The IDEA as amended in 1997 defines "children with disabilities" to mean children with mental retardation, hearing impairments, speech or language impairments, visual impairments, orthopedic impairments, autism, traumatic brain injury, other health impairments, specific learning impairments, or emotional disturbance and who, by reason thereof, need special education, but not related services ( [2](#) ). The 1997 amendments granted states the option of extending special education and related services to students aged 3 to 9 years, if it is determined that they are experiencing developmental delay but do not fall explicitly within the definition of "children with disabilities." The areas of delay include physical development, cognitive development, communication development, social or emotional development, or adaptive development ( [2](#) ).

IDEA defines "emotionally disturbed," previously called "serious emotional disturbance," as a condition having one or more of the following over a long period of time, to a marked degree, and which adversely affects educational performance: an inability to learn that cannot be explained by intellectual, sensory, or health factors; an inability to build or maintain satisfactory interpersonal relationships with peers and teachers; inappropriate types of mood or behavior under normal circumstances; a general mood of unhappiness or depression; a tendency to develop physical symptoms or fears associated with personal or school problems ( [2](#) ).

"Related services" under the Act includes transportation, developmental, corrective, and other supportive services as may be required to assist a child with a disability to benefit from special education, including the early identification and assessment of disabling conditions in children ( [2](#) ). Included among the specified services are speech-language, audiology, psychological services, physical and occupational therapy, recreation, social work services, counseling services, and orientation and mobility services ( [2](#) ). Medical services are covered for diagnostic and evaluative purposes only ( [2E](#) ).

"Supplementary aids and services" refers to aids, supports, and services provided in the regular education environment that enable children with disabilities to be educated with nondisabled children to the greatest extent possible (i.e., least restrictive environment) ( [2](#) ).

The definition of "free appropriate public education" (FAPE) contained in the 1997 amendments tracks the language of the EAHCA of 1975. It provides that a free appropriate public education must conform to state educational agency standards and include students from preschool to secondary education ( [2](#) ). The United States Supreme Court has interpreted FAPE to mean such special programming as is "sufficient to confer some educational benefit on the handicapped child" ( [7](#) ).

## THE INDIVIDUALIZED EDUCATION PROGRAM

In order to arrange appropriate education for eligible children, IDEA requires the state to find and evaluate all children with disabilities residing within its borders. The state must see that an individualized education program (IEP) is devised for each eligible child by a multidisciplinary team involving the child's parents, teachers, a local educational representative, and people who have special knowledge about the child.

The IEP must describe the child's current educational performance, and the support he or she is receiving. Annual and short-term goals must be made to address the child's educational needs resulting from the disability ( [2](#) ). The IEP must also stipulate the special instruction and related services that will enable the child to meet those goals ( [2E](#) ), how his or her disability influences involvement and progress in the general education program, and to what extent the child will not be educated in the regular education program ( [2](#) ). Evaluations must be conducted in the language used by the child and may not be racially or culturally discriminatory. The IEP team is required to reevaluate the IEP once every 3 years, or at the parents' or teachers' request, or if conditions warrant, to determine how the child is progressing in the program and whether modifications are needed ( [2](#) ).

When appropriate, children with disabilities are expected to participate in state or district-wide assessments to the best of their abilities. The IEP must posit assessment administration modifications that permit the child's participation; if the child will not participate or the assessment is inappropriate, the IEP must state why the assessment is inappropriate and how the child will be assessed.

The IEP must see that each disabled child's FAPE occurs within the least restrictive context possible ( [2E](#) ), meaning that a child with disabilities is to be educated with

nondisabled peers unless this cannot be achieved, even with supplementary aids and services. A child with disabilities is to be educated in the most residentially proximate public school that he or she would attend if not disabled; however, if the child's particular needs prevent this, another placement may be selected ( [1](#) ). This provision is particularly relevant to children with emotional disturbance who have been removed from their educational settings owing to behavior problems that may or may not be related to their disabilities.

## DISCIPLINARY AMENDMENTS IN 1997

Under the provisions of the pre-1997 IDEA, a great deal of confusion developed with regard to the discipline of children who qualified for special education, especially for those who were identified as having a "seriously emotional disturbance." Courts throughout the country ruled inconsistently on such issues as whether students could be unilaterally removed from school if their behavior is considered dangerous by school authorities, whether students could be removed for conduct that is considered to be dangerous but "related to their disability," and whether schools are responsible to continue educational programming for students who are removed from school for behavior unrelated to the disability.

### Dangerous Behavior

One of the major procedural protections contained in the pre-1997 IDEA was a provision that required educators to conduct an IEP team meeting before initiating a change in the placement of a child. Under prior law, if a disagreement over the proposed change of placement developed between the parents and school officials, the child's last placement remained the placement until a final resolution is reached after a due process hearing and any ensuing court actions. Unless the school authorities obtained a court order enjoining the continued attendance at school by a child whose behavior was considered dangerous by school officials, the child could be suspended for a cumulative total of 10 days, but thereafter the maintenance of placement provision applied and the child had to be returned to his or her last placement ( [8](#) ). That provision of the law was modified by the 1997 amendments.

The authority of school officials was significantly increased under the new amendments. Administrators may immediately remove and place in an alternative setting a child who brings a weapon to school or to a school function, or who sells, uses, or attempts to buy drugs at school or at a school function. The alternative placement is decided by an emergency IEP team meeting ( [2A](#) ). The amendments also include a provision for dealing with other conduct considered to be dangerous. School officials can suspend a child for 10 days and in the interim ask for an expedited administrative hearing at which an order changing placement can be obtained on a showing by "substantial evidence that maintaining the current placement of the child is substantially likely to result in injury to the child or to others" ( [2B](#) ). This process can be repeated during a formal dispute by parents over the change of placement or of the appropriateness of the alternative placement.

The school must conduct a "manifestation determination review" on determining that a change of placement is necessary in response to the behavior of a child. This consists of an IEP team meeting where "all relevant information," including information supplied by the student or the parents, is considered. The team must determine whether the student understood that his or her behavior was inappropriate, whether the student could control the behavior, and whether the IEP and placement had been appropriate ( [2](#) ). If it is determined that the misconduct was not a manifestation of the child's disability, the school may apply the same disciplinary sanctions to that child as apply to children without disabilities ( [2C](#) ). If the conduct is found to be a manifestation of the disability, the school is obligated to continue programming, embodied in an IEP, in the alternative setting ( [2C](#) ). Children subject to discipline, but who have not been evaluated for and/or identified as eligible for special education, but who are suspected of having qualifying disabilities are entitled to the same protections as children already found eligible.

## THE ROLE OF THE CHILD MENTAL HEALTH CLINICIAN

There are many potential roles in the special education process for child mental health consultants ( [Chapter 120](#) ). Child psychiatrists and behavioral pediatricians may be asked to submit diagnostic assessments and medically based recommendations about a child's educational needs. Mental health consultants also may serve an important role in pulling together and interpreting the assessments and recommendations of other medical or psychiatric evaluations. The consultant may suggest specific strategies for the classroom to address the IEP objectives and help parents understand the nature of their child's disturbance, including its implications for functioning at school. School psychologists may be integral in developing creative educational techniques and in conducting functional behavioral analyses, in addition to taking part in manifestation determination procedures ( [10](#) ).

## PARENTS AND CHILDREN'S RIGHTS AND RESPONSIBILITIES

Beginning at age 14 years, the IEP must describe each child's transition service needs, with a focus on the course of study and plan for successful integration into mainstream society. Competent children must be aware of the transfer of rights on age of majority under state law. At age 16 years, the IEP must modify and reiterate necessary transition services and any appropriate interagency responsibilities ( [2](#) ).

Although the IDEA promises all children with disabilities a FAPE that meets their unique needs, this promise is sometimes unfulfilled because of ambiguities in the law. A substantive standard prescribing the level of education that each child should receive is noticeably absent from the law. The law only requires a "free appropriate public education" to meet the unique needs of a child with a disability so that the child may *benefit* from the instruction, but not necessarily reach his or her fullest potential ( [2](#) ). The lack of any clear guidelines regarding what constitutes educational "benefit" has resulted in much school-parent conflict and generated a great deal of litigation. What is clear is that unless the state law provides otherwise, a school does not have the obligation to provide services that will maximize the potential of the child with a disability. The actual benefit level that must be achieved by a child in order to constitute a FAPE is determined on a case-by-case basis and generally requires a meaningful gain and not merely trivial progress (see e.g., Board of Education of East Windsor Regional School v. Diamond) ( [10](#) ).

The IDEA provides extensive procedural protections to parents of children with disabilities, including "the right to participate in the development of the IEP, the right to independent evaluations, the right to inspect educational records" and "the opportunity to present complaints with respect to any matter relating to the identification, evaluation, or educational placement of the child, or the provision of a free appropriate public education to such child" ( [2D](#) ). Such a proceeding, referred to as a "due process" hearing, requires a neutral adjudicator, a right to counsel at the parent's expense, the right to present evidence and cross-examine witnesses. If dissatisfied, either party has a right to judicial review in the appropriate state or federal court. Relief necessary to assure that the child receives a free appropriate public education may take many forms, including reimbursement to parents who unilaterally place their child in a private placement and compensatory education in the form of educational services beyond the age of 21.

## RELATED LEGISLATION

In addition to IDEA, there are other legislative requirements enacted to protect the rights of disabled individuals. The Americans with Disabilities Act of 1990 (ADA) and Section 504 of the Rehabilitation Act of 1973 are civil rights laws that prohibit discrimination on the basis of disabilities. Although the ADA does not focus specifically on FAPE, it requires that accommodations be made to allow students with disabilities to perform essential functions of a job and thus relates to job training/placement and community activities that are components of a student's special education plan ( [11](#) ). Section 504 of the Rehabilitation Act of 1973 protects persons with physical or mental impairment that substantially limits one or more life activities. It requires a free, appropriate public education, which may be either regular or special education programming. Thus, related services may be provided for children with impairments who do not meet eligibility requirements for special education under IDEA ( [11](#) ). Section 504 requires information to be obtained from various sources, decision-making by a knowledgeable group, development of a plan, periodic reevaluations, parental notification, and the opportunity for parents to participate in impartial hearings when they disagree with the process or planning decisions ( [11](#) ).

## RESOURCES

Familiarity with basic aspects of the laws pertaining to special education and their application strongly enhances the child mental health clinician's effectiveness in the consultation process. A comprehensive and thoughtful discussion of these issues can be found in the chapter entitled "The Legal Rights of Children with Disabilities to Education and Developmental Services" by Miriam Berkman ( [12](#) ). Another good source of information is the United States Department of Education at <http://www.gov.ed>. This Website also provides easy access to information about the Americans with Disabilities Act of 1990 (ADA) and Section 504 of the Rehabilitation Act of 1973. Other resources include the National Information Center for Children and Youth with Disabilities (P.O. Box 1492, Washington, DC 20013-1492, 1-800-695-0285) and in most states, the Department (Board) of Education. Susan Etscheidt and Larry Bartlett provide a guide to determining what aids and services to include in a child's IEP in "The IDEA Amendments: A Four-Step Approach for Determining Supplementary Aids and Services" ( [13](#) ).

## FEDERAL RESTRICTIONS AND STATE PREROGATIVES

The Individuals with Disabilities Education Act (IDEA) is a federal statutory scheme that provides federal money to assist states and local agencies in educating children with disabilities. To receive a federal grant, a state must demonstrate to the Secretary of Education that the state eligibility requirements listed in IDEA have been fulfilled and that they have in place "child find" mechanisms for children with disabilities who reside in the state. Infant and toddlers and youth ages 3 to 21 years are included in the 1997 Act in Part C for children's services and in Part B for infants and toddler services.

The federal requirements under both of these sections are flexible in order to address the needs of individual states. Specific programs and policies necessary to attain the goal of IDEA are ordered, but often the methods for carrying out these programs and policies are left open to the states. IDEA provides a list of the lawful uses for grant funds awarded to a qualifying state, but the state may distribute the funds among these uses according to need. The law also allows for states to use IDEA funds to execute school-improvement plans for helping troubled children who do not necessarily qualify as disabled but who are having difficulties in school.

States applying for a federal grant under the IDEA must also guarantee certain procedural safeguards to children with disabilities and their parents ( 2). For example, due process must be guaranteed in the event that a dispute arises, evaluation and placement procedures must be administered in the child's native language, evaluations must use a variety of assessment tools and strategies, personnel doing the evaluations must be trained in those evaluation procedures, and evaluations must be conducted in complete confidentiality ( 2).

States may apply for a grant under the IDEA by submitting a state Improvement Plan, maximally integrated with the Elementary and Secondary Education Act of 1965 and the Rehabilitation Act of 1973, and based on state and local needs for meeting the goals of the state-wide system. Federal law requires that the improvement plan include: analyses of data indicating the academic performance of children with disabilities and employment rates compared to nondisabled children; the state's personnel development needs; analyses of findings relating to improving results for children with disabilities; and analyses of available information about the efficacy of the state's early intervention, special education, and general education services in accommodating the needs of children with disabilities. States must specify paths to achieving federally set goals and plans for achieving general collaboration with institutions and agencies. However, within the federal conditions for a statewide system, states may write their own definitions of developmental delay to be used in appropriate programs, develop personnel according to state certification or professional requirements, and make a number of specific decisions pertaining to the administration of special education programming.

## IDEA AMENDMENTS OF 1997: CURRENT OPINION AND RESEARCH

The practices of the special education reform movement have been characterized as follows: focusing on the child and family's strengths, rather than their deficits; promoting achievement through high expectations and proven instructional techniques and evaluation methods; encouraging collaboration across service-providing agencies in order to reduce bureaucracy; and granting access to these services without labels ( 9).

The finding that prompted IDEA 1991 persists today ( 9), in that emotionally disturbed children and adolescents are still underserved in special education programs. In IDEA 1991, a "child with disabilities" could be one who was "seriously emotionally disturbed"; however, IDEA 1997 dropped the adjective "seriously" ( 2). In one study, adjectives such as "serious" or "severe" were the single negative predictor of the number of children receiving special education service for emotional disturbance ( 14); other studies have argued that definition does not significantly influence identification patterns ( 9). Although results are inconclusive, without the adjective "serious," there might be a substantial increase in the number of students classified as emotionally disturbed ( 9).

States have been allowed to extend the nonspecific category of "developmental delay" to children aged 9 and below since IDEA 1997 was passed. States are free to define the category and specify the criteria that will be used. Some authorities claim that the extension aids young children's access to specialized interventions and strengthens communication between schools and families ( 9). Others believe that this change encourages the local educational authority (LEA) to label students as disabled and serve them as such when their needs might well be met in the general education setting ( 9).

The requirement in IDEA 1997 that children with disabilities participate in state- and districtwide assessments, although promising to advocates of special education accountability, is complex ( 9). Students who are unable to participate fully in the general assessments may take an alternate assessment designed by the LEA. Alternate assessments create the possibility of a "second class" of testing to go along with a lower standard of teaching, the existence of which would be incompatible with the goal of improving educational results for all students ( 15). States must analyze the students with disabilities' results separately from the regular students, which assures support for equality and academic improvement because the results will not be misread in a sample or lost ( 9).

A controversial aspect of the 1997 amendments to IDEA is the inclusion of parents on the evaluation team. One study indicated that as parents of children with disabilities were provided with more information about their children's schools, they developed more negative opinions of those schools ( 16). However, in the same study, frequent and involved parent-educator interactions were correlated with more positive views about school. Some note that the hierarchical system and social organization of schools constitute barriers to successful family-school collaboration ( 12), and it has been suggested that schools adopt a structure where parents, educators, and administrators are equal in decision making ( 17).

IDEA 1997 permits the IEP team to conclude that existing data are adequate for deciding whether a child with disability will continue to be eligible for services. Some argue that this provision helps school districts by eliminating pile-up of documents and advances a reform agenda aimed towards intervention-relevant assessments ( 18). Others reason that relaxing the reevaluation procedure could decrease the surety of placement decisions ( 19). Studies analyzing the effect of reevaluation on categorization and programming have brought forth inconsistent results ( 9).

The broadened IEP requirements of IDEA 1997, including members of the IEP team and IEP document inclusions, are promising to advocates of special education reform, especially regarding experimentally validated instructional approaches and student achievement. On the other hand, some general education teachers may consider the terms overly demanding and refuse to cooperate ( 15). Recent studies indicate that general educators are becoming more actively involved in the IEP process than they were in the past ( 20). The multitude of factors influencing learning that must be considered by the IEP team, although appropriate for special educators, may not be relevant to a general educator's knowledge and constitute a distraction from teaching ( 9,21). Several studies have concluded that the contents of the IEP document and the activities of the school day are not consistent, thereby rendering the IEP impractical ( 22). It has been found that teachers in general education settings are less likely to deliver IEP's agreeing with special education policy than are teachers in other, more exclusive settings ( 23). Some question whether the IEP requirements are sufficient to bring about the goals of IDEA, in terms of special education delivery and student success ( 9).

The discipline amendments were added to IDEA to address misconduct in students with disabilities. Behavioral analysts have known the benefits of functional behavioral approaches to discipline for over 35 years, without widespread acceptance in schools ( 9). It also has been suggested that perhaps the only way to persuade schools to accept proven behavioral techniques is to place experts in applied behavior analysis in schools in order to influence teachers, parents, and government workers ( 24). Because of the emphasis on education rather than punishment in the discipline amendments, schools also may be encouraged to explore more creative and collaborative approaches; for example, alternative schools, to address the needs of students who have behavioral problems ( 9). Although in certain respects, current special education practices and the 1997 amendments to IDEA are a long way apart, it is hoped that increased attention to special education policies and practice will stimulate a new generation of special education practices and research ( 9).

In conclusion, it is important to remember that the overriding goal of the IDEA initiative is provision of free and appropriate education for all children. To best achieve this, each student needs to be in the least restrictive environment that is compatible with learning and educational progress. Understanding the least restrictive environment entails understanding the arguments, benefits, and trials behind both inclusive and special education settings. Supporters of inclusion contend that a separate education denies children with disabilities the opportunities afforded to regular students. The same inclusion advocates can provide data contending that students with disabilities who are educated in general education settings achieve higher social and academic standards than equivalent students in noninclusive settings ( 25). On the other end of the spectrum, opponents to inclusion warn that simple physical presence in a regular classroom fails to lead to full participation in a classroom's intellectual and social life ( 26). Opponents contend that at times, special education programs are superior to general education programs for certain individuals. ( 27). The unique and individual nature of development must be appreciated to insure that special education programming is responsive to the needs of each eligible child in assessing the relative advantages of the various settings and modalities of special education.

[Chapter References](#)

The complex, continuous, and reciprocal interactions between environmental, biological, intrafamilial, and individual factors common to multiproblem families may place children at high risk for poor developmental, psychological, and educational outcomes, including disruption of primary attachments, placement out of the home, and entry into the juvenile justice system. Prevention and intervention efforts that focus on the developmental needs of children in the context of addressing the needs of other family members are consistent with the goals of Public Law 105-89, the Adoption and Safe Families Act of 1997 ( [McCarthy et al., 1999](#)). These goals, which focus on the promotion of safety, permanency, and well-being for children and families, inform multiple contemporary federal and state initiatives. This chapter describes organizing, developmentally based principles for working with families in which children are at high risk, and provides a case example derived from an intervention designed to address the previously stated goals and outcomes.

## HIGH-RISK CHILDREN, ADOLESCENTS, AND FAMILIES

Although there does not appear to be a common description of families in which children and adolescents are at high risk, these families often are described as *at-risk*, *multiproblem*, *troubled*, *low-functioning*, or *families in crisis*. Most authors acknowledge that multiple factors contribute to the inability of these families to function adequately ( [Bowlby, 1953](#)). Factors frequently cited in association with breakdown of the family include parental substance abuse, mental illness, chronic physical illness, domestic violence, cognitive deficiencies, constitutional inadequacies, and social isolation significant for lack of familial and community support ( [Deutsch, 1983](#); [Rutter and Quinton, 1984](#)). When these factors are joined with environmental stressors such as poverty, educational failure, joblessness, homelessness, and racial or ethnic discrimination, the risk of family disintegration increases. Families who share these combined characteristics commonly are identified as multiproblem families ( [Kaplan, 1986](#); [Spencer, 1963](#)). [Kilpatrick \(1999\)](#) argues that these families lack the leadership and control within the family necessary for meeting basic nurturing needs and providing adequate protection for family members.

In recent decades, the ability of families to provide adequately for the needs of their children has been compromised by the convergence of adverse environmental, psychosocial, psychological, physical, educational, and economic factors ( [Ford Foundation Executive Panel, 1989](#)). The prevalence of these stressors on families appears to be increasing in the United States. Between 1979 and 1994, the number of children younger than 6 years of age living in poverty grew from 3.5 million to 6.1 million. During this same period, the percentage of children living in families with incomes below the poverty line rose 39% overall. Between 1979 and 1998, the percentage of U.S. children younger than 18 years of age living in poverty increased by over 3 million, representing an increase in the national child poverty rate from 16.7% in 1979 to 18.7% in 1998 ( [Bennett and Lu, 2000](#)). A report of the National Center for Children in Poverty (1996), based on data from each of the 50 states, found that young children living in poverty are more likely to experience high levels of interpersonal conflict in their homes, be exposed to violence in their neighborhoods, and experience delays in their physical, cognitive, linguistic, and emotional development, which in turn affect readiness for school and ability to learn. Minority young children were found to be five times more likely to be poor than white children; the rate of poverty among young Hispanic children was increasing more rapidly than among other racial and ethnic groups ( [National Center for Children in Poverty, 1996](#)).

The effects on children of growing up in these families are profound ( [Taylor and Newberger, 1979](#)). They are more likely to present with symptoms of neglect and nonorganic failure to thrive. Their health care is more likely to be episodic and illness oriented. Developmental delays, language difficulties, behavioral problems, and school failures are common. For some children, attendance at school may be disrupted frequently owing to family moves or repeated incidents of homelessness. [Klerman \(1991\)](#) reported that poor children experience more of many types of health problems than children from families with more adequate incomes. Rates of infant mortality, sudden infant death syndrome, unintentional injuries, child abuse, and infectious diseases, including acquired immunodeficiency syndrome (AIDS) and human immunodeficiency virus (HIV) infection, are higher among poor children. Poor and near-poor children also suffer disproportionately high rates of problems related to nutrition, asthma, otitis media, and other infectious diseases, as well as increased incidence of dental decay ( [Lewit and Kerrebrock, 1998](#)) and lead poisoning. Economic adversity also is associated with an increased incidence of prenatal risks, prematurity, and accident. The existence of multiple stressors often increases exponentially the impact of any particular stressor and heightens the eventual likelihood of central nervous system dysfunction ( [Kavale and Forness, 1985](#)). Poor children on inadequate diets are likely to experience more frequent infectious disease than the nonpoor, to be sicker longer and be affected more severely by their illnesses ( [National Center for Children in Poverty, 1996](#)). Inadequate nutrition also may affect cognitive development and social behavior; undernourished children may be more apathetic and less responsive in social situations ( [Adnopoz, 1994b](#)). [Kilpatrick and Holland \(1999\)](#) suggests that the best, generally descriptive term of these families is *impoverishea*, where poverty is more complex than a lack of financial resources. These families typically live in a world that is lacking in many resources that others take for granted, such as stability in housing, preventative health care, and, in more recent times, information technology.

Many families, who require additional support or specialized services, are thought to demonstrate similar characteristics ( [Geismar and Lasorte, 1964](#); [Kaplan, 1986](#); [McCroskey and Meezan, 1998](#)). [Kaplan \(1986\)](#) found that these families have “a number of problems that cut across many dimensions of family life.” These families have been found to evidence poor coping skills in intrapersonal, interpersonal, and environmental areas and have demonstrated difficulty in negotiating the interrelationships among these three spheres of functioning. [Belsky \(1980\)](#) proposes a developmental–ecologic model for understanding high-risk families. In this model, risks are present at four levels: individual, family, environmental, and cultural. The individual level includes issues of parental self-perception such as self-esteem, impulse control, and behavioral and health history; individual factors also include the child's personality traits, the fit between the parent and the child, and other special characteristics. The family factors may include interpersonal conflicts or violence, the capacity of the family to provide support, safety, and protection for its members, the nature of the extended family relationships, and the dynamics of family functioning. Environmental influences extend to the family's interactions with external institutions and systems. The cultural context relates to the family's belief system, its values, and its attitudes. The constant interaction of these factors affects the family's ability to parent safely and appropriately and determines the relative risk to the children in the family's care. In this view, in the social ecology of the family's environment, problems transcend a single level and often appear as a “web” or cluster of issues that may eventually threaten to overwhelm the family.

Some believe that these families contribute to the burgeoning costs of social services through their inappropriate use of the programs and systems that have been developed to provide care for them. Some politicians have redefined poverty as a problem that results from the immoral and irresponsible behaviors of individuals rather than an unfortunate economic condition resulting from external social and economic factors, with an emphasis on the need for individuals to change their behaviors ( [Kammerman, 1996](#)). Similarly, [Spencer \(1963\)](#) places the responsibility on the family for its frequent reliance on crisis care, remedial services, and public support. He concludes that chronic dependency on public programs is not only costly but represents an inefficient use of available resources. [Selig \(1976\)](#) suggests that effective intervention can be designed for these families. He suggests that the term *multiproblem family* is a misnomer that places blame undeservedly. He believes that the problem lies within a “multi-problem delivery system” that offers fragmented social services. Selig identifies issues of accessibility, ownership, caregiver attitudes toward inadequately functioning families, lack of coordination between providers, gaps in the service continuum, insensitivity to social and cultural distinctions, and lack of continuity of caregiving as central contributors to a troubled service system. [Overdorff \(2000\)](#) is explicit in describing adversarial relationships that may develop among agencies serving this population. Ineffective serial interventions in the form of uncoordinated, isolated events may result in community “impotence” in changing dangerous situations for children.

## MULTIPROBLEM FAMILIES: PROBLEMS IN INTERVENTION

The association of such major societal problems as poverty, racial and ethnic discrimination, inadequate and substandard housing, and underclass status with families requiring public assistance and support discourages caregivers from working intensively with them. The behaviors of service providers suggest a lack of confidence in both the family's ability to institute change and in the service system's capacity to intervene positively. The providers' cynical attitudes toward these families are unwittingly supported by the families themselves, who because of past unsuccessful, and possibly demeaning experiences with service providers may be unable or unwilling to give expression to their need for help. These behaviors may cause families to appear disinterested in the interventions offered to them, lead them to be labeled as noncompliant, and result in their punitive treatment. Negative caregiver attitudes may be perpetuated by the frequency with which issues of distrust, noncompliance with treatment regimens, and failure to keep appointments arise in working with these families. Families are blamed by providers for behaviors and attitudes that are in actuality rudimentary attempts by families to defend against the attitudes and behaviors of providers who are expected to serve them, rather than symptoms of the family's inability to accept responsibility and respond appropriately to the needs of its children. For example, a mother who fails to visit regularly her hospitalized child may be made to feel like a negligent, inadequate parent by the floor staff when she does come on the ward. Her failure to visit regularly may represent an attempt to protect her own fragile sense of competency and self-esteem in the face of what she perceives as the uncompromising and judgmental demeanor of the staff, rather than an uncaring, neglectful attitude toward her child. The frustration of providers, who recognize that the child in their care has a deep wish to be cared for by his or her parents, may interfere with their knowledge that parents also have a need to be supported by others and made to feel competent in the parental role.

There are additional barriers to successful intervention; some families may be resistant to interventions provided by "outsiders" who come from cultures, races, or socioeconomic groups from whom they feel alienated. Services may be inaccessible, especially for parents who have no alternative source of child care and must travel unassisted, with several small children. Language barriers may make communication between families and caregivers difficult. Caregivers may have little if any knowledge of the cultural differences, customs, and strongly held beliefs of the families they treat. Significantly, the service system may focus on the family's failure, without assessing the family's strengths and attempting to build on them. Although families do share responsibility for their situations, blaming the family for being in trouble is not useful.

Traditional social service delivery systems have proven inadequate to meet the complex needs of inadequately functioning families. Unidimensional interventions designed to address specific problems in single spheres of functioning have not provided an effective means of confronting the multidimensional problems that categorize these families. Recent legislative, child welfare, and mental health initiatives have challenged service providers to find innovative ways to address the multidimensional needs of troubled, difficult-to-serve families. The Adoption Assistance and Child Welfare Act of 1980 (Public Law 96-272) required states to make "reasonable efforts" to keep children from out-of-home-placement; the Education for All Handicapped Children Act of 1975 (Public Law 94-142), rewritten in 1990 as the Individuals with Disabilities Education Act, requires that placement decisions be made on the basis of the least restrictive setting; the Child and Adolescent Service System Program (CASSP) of the National Institute of Mental Health, created in 1983; and the Mental Health Services Program for Youth (MHSPY), initiated in 1989 by the Robert Wood Johnson Foundation in 1989, all support the development of integrated, comprehensive service systems ( [Solnit et al., 1997](#)). The failures of the foster care system, combined with a rise in the number of children referred for placement ( [Knitzer and Cole, 1989](#)), placed increased pressures on policy makers and professionals to find new models of service capable of responding to the needs of children and families.

In August 1993, the United States Congress enacted Subpart 2 of Title IV-B of the Social Security Act, entitled Family Preservation and Support Services. This legislation strengthened the Adoption Assistance and Child Welfare Act of 1980, and authorized funding to serve as an added stimulus for states to engage in broad-gauged consensus building, collaboration, and systems reform by providing family support and family preservation services ( [Adnopolz, 1994a](#)).

New programs emerged that were designed to reduce the barriers to effective use and change the systems by which services were to be delivered. These programs embody principles first articulated in the CASSP and are expected to be family oriented, child centered, strength based, developed in partnership with the family, delivered in the child's home and community, and provided through collaborative service networks. Crisis intervention, case management, skill building, respite, mentoring, and concrete services are standard core treatment elements. Services are informed by the presumption that permanence, safety, and a consistent relationship with a caregiving adult are essential to the healthy growth and development of all children. As a result, the most appropriate placement for a child is thought to be an adequately functioning family, preferably the child's biological family, to ensure continuity of caregiving and maintain the child's ties to his family's culture, history, and belief system. When this is not possible, adequate care of the child relies on the ongoing support of the appropriate service systems to ensure a committed, permanent alternative placement. Assisting isolated, disaffected, alienated families to function well enough to care adequately for their children or to support the child's permanent placement elsewhere has been found to require a flexible, enlightened, and integrated service system whose purpose is clear and unambivalent. [Weber \(1998\)](#) argues that this integrated system should be community based, relying on "a network of services and supports offered by partnerships involving multiple sectors of society" (p. 129).

Other factors in the environment have had a negative impact on attempts to meet the needs of children who are at risk but who can, with adequate family supports and intervention, remain with their families. The unfortunate, well publicized deaths of children who had been allowed to remain in their homes by protective service workers attempting to support the integrity of the family has engendered an adverse response to family preservation ( [Gelles, 1996](#); [Murphy, 1993](#)). However, thoughtful, clinically informed risk taking has been successful in preventing placement of some children, whereas in other cases, clinical judgment has led appropriately to removal and placement. The significant cuts in federal spending for low-income children and their families and the devolution of primary responsibility for low-income children and families from the federal government to the states ( [Kammerman, 1996](#)), coupled with the serious constraints of managed care, particularly in relation to mental health services, place children and families at elevated risk of poor developmental outcomes.

## TWO ORGANIZING PRINCIPLES FOR WORKING WITH MULTIPROBLEM FAMILIES

The doctrine of the best interests of the child constitutes the first of two organizing principles that have guided a home-based, family support and preservation intervention that was developed by the authors for families in which a child is at risk of placement. The second principle recognizes the strengths of the ego support lent to the parent by the therapeutic team, whose role is to engage with the family and build a relationship through which the path to behavior change can be negotiated ( [Lewis and Stark, 1966](#); [Soule et al., 1993](#)).

### The First Principle

The family unit is the primary means through which the needs of the child can be addressed. [Anna Freud \(1965\)](#) has stated that the best interests of the child are satisfied when the child's needs for affection, stimulation, and object constancy are met. The family unit is the institution society considers best suited to respond to these needs and to guide the child from dependence to independence ( [Caplan, 1978](#); [Provence, 1979](#)). Some families are unable to assume these responsibilities and to provide an environment supportive of healthy child development. Children need adults (usually parents) to attend to their physical needs, provide nurturance, protection, and guidance, and demonstrate that they are prized and respected.

Parents also have needs. [Solnit \(1968\)](#) has described these as needs for evidence of their competence as parents and for effective, esteem-enhancing assistance from their community in times of crisis. In the best of cases, children's needs are met in relatively strong, relatively self-sufficient families by parents or other adults who are capable of nurturing and committing themselves to them. In the best of cases, parents' needs are met in turn by familial and social networks and by other support systems. When parents are able to meet children's needs, children are more likely to feel secure and valued. They are more likely to be equipped for the challenges of school and better able to make successful adaptations throughout life. Importantly, they are more likely to grow into adulthood with the ability to nurture others.

However, children and families who experience a confluence of parental inadequacies and environmental stressors are at greater risk of being distanced from the mainstream of familial and societal supports and the positive reinforcement that such support elicits. The resultant social isolation may lead to pervasive feelings of futility, impotence, and desperation. [Erikson \(1964\)](#) has noted that

Defenseless as babies are, they have mothers at their command, families to protect the mothers, societies to support the structure of families and traditions to give a cultural continuity to systems of child care and training. All of this is necessary for the human infant to evolve humanly, for his environment must provide that outer wholeness and continuity which, like a second womb, permits the child to develop his capacities in distinct steps, and to unify them.

If a child's environment does not provide that "outer continuity," the child's chances of growing and developing in a healthy way are diminished. When families lack the resources and capacities to satisfy the needs of individual family members, they cannot perform their crucial function as socializing agents for children. If they cannot perform that function, the individual family and society as a whole suffer important losses ( [Schorr and Schorr, 1988](#)). The situation is particularly egregious for the children of poor families ( [Kaplan, 1986](#)).

The argument for interventions that support the structure of the family is made even more compelling by the human and economic costs involved. The inability of families to meet the basic needs of their children may lead appropriately to foster care placement and a consequent break in the child's relationship with the primary object. For some children, out-of-home placement may be clinically indicated. For most, however, the first separation can be expected to provide an easy pathway to additional placements and the loss of any possibility of maintaining stable, affective ties to their caregivers. The current shortage of foster homes and the inability of public child protection programs to ensure continuity of placement once a child is removed make any removal of a child a significant risk, to be balanced carefully against maintenance of the child within the family. In addition, inadequately functioning families use public services such as crisis health care, police, special education, and mental health programs more frequently than other families. Therefore, efforts to stabilize these families and to improve their capacity to manage have important social and economic implications as well. [Tracy and Whittaker \(1987\)](#) and Tracy (1990, 1991) have demonstrated that identifying families appropriate for intervention and developing social support resources with those families has helped to stabilize and improve their capacity to manage with potential social and economic benefits.

### The Second Principle

The centrality of relationships in human functioning constitutes the second organizing principle for effective intervention. The relationships between parents and children, between the family and the community, and between the family and the service systems are influential and diagnostic. The achievement of behavioral change in the family unit may be accomplished best through the development of a working alliance with a clinician able to engage with the parent. However, families may be reluctant to accept assistance of any kind initially and introduce barriers intended to frustrate attempts at intervention. The process of engagement frequently begins with the clinician's demonstration of willingness to accept the family as they are and to withstand the family's repeated tests of personal commitment. The empathy, support, acceptance, and understanding extended to the parent by the clinician, perhaps for the first time in her history, enables the parent to enter into a trusting relationship, even if tentatively, and make the initial move toward a higher and more appropriate level of functioning ( [Soule et al., 1993](#)).

## INTERVENTION MODELS FOR WORKING WITH MULTIPROBLEM FAMILIES

As previously noted, pressures to reduce out-of-home placements and other expensive services have increased as the numbers of children requiring protection and support continues to rise. The striking increase in children affected by parental substance abuse and HIV/AIDS has overtaxed the foster care system and created a placement crisis ( [Nelson, 1996](#)). The number of family support and family preservation programs designed to help inadequately functioning families parent more effectively has increased dramatically. The CASSP principles of integration, collaboration, and coordination have been used to bring families and providers together to develop community-based programs and strategies to help families cope more successfully in stressful environments. Because a negative synergism often exists in the complex, dynamic interrelationships among the family, its members, and the environment, interventions that are focused only on one problem area may be futile. Practice has come to reflect the clinical knowledge that effective program strategies address the interrelationship of problems in intrapersonal, interpersonal, and environmental domains. For example, programs designed to address the needs of substance-abusing women and help families to provide safety, stability, and permanence for their newborn children may provide parent education, health and family planning, infant day care, developmental assessment and evaluation, transportation, job training, individual treatment, and legal services in addition to access to formal drug treatment ( [National Abandoned Infants Assistance Resource Center, 1999](#)). Attempts to engage parents in meeting the needs of their children may be unsuccessful if long-standing parental issues such as marital or partner conflict, past child abuse or neglect, incest, alienation, or absence of supportive personal relationships are not addressed. In addition, a history replete with persistent failures of social service interventions, limited access to and availability of services, and institutional racism and sexism may present barriers to engagement and family involvement.

Several of the programs designed to serve inadequately functioning families make use of a generic model of family-centered, home-based services that seek to accomplish the goal of preserving the family while addressing its interlocking problems ( [Edna McConnell Clark Foundation, 1985](#)). [Kaplan \(1986\)](#) offers descriptions of several exemplary home-based, family-centered programs that have proven to be successful with multiproblem families. These programs have several common elements:

1. The family system is seen as the primary unit of treatment ( [Kaplan, 1986](#)).
2. Services are provided to the family in their own home.
3. It is assumed, according to a growth model, that change in the family is possible; family strengths, not weaknesses, are pursued ( [Kaplan, 1986](#)).
4. Services are provided on a goal-oriented, time-limited basis.
5. Services focus on keeping families together and preventing unnecessary foster placement of children ( [Edna McConnell Clark Foundation, 1985](#)).
6. Services are intensive; caseloads are low.
7. Concrete services and child and family advocacy are included in the range of offered services.

Although clinicians may draw on a number of theories to guide the intervention with families, Grigsby ( [1993, 1994, 1995](#)) argues that social attachment theory ( [Bowlby, 1969, 1973, 1980, 1988](#)) is most useful as a guide for working with families of this type.

A number of these principles were incorporated into one of the earliest home-based family preservation programs, The Homebuilder Program, first implemented in 1972 in Tacoma, Washington. The program was designed to avert out-of-home child placement of children, most of whom were in acrimonious disputes with their parents, by offering intensive, short-term, home-based therapy and casework to families experiencing a crisis of placement, using a single, master's-level therapist as the in-home worker. The program model spread across the country rapidly and has been implemented on both coasts, although its efficacy only recently has been tested experimentally. Other models of intervention have been developed as well, with similar strategies but with somewhat different programmatic elements. The duration of the intervention may vary from 4 weeks to 6 months; services may be provided either by individual clinicians, therapeutic teams, or paraprofessionals, and time in the home may vary from 5 to 18 hours weekly. Nelson (1990a, 1990b) and [Nelson et al. \(1990\)](#) offer descriptions of various service models and discuss their effectiveness.

Common to all programs is the provision of therapy in the home and its availability to all family members. Although the modality may differ, the move of the clinician from the traditional office or institutional setting to the family's setting has lessened resistance to treatment for parents and children. In addition, it has enabled the clinician to observe the family in its own environment and to identify more clearly and more quickly the range of the family's needs. Given the particular characteristics of multiproblem families and their historic rate of treatment failures, the ability to intervene clinically in the home environment appears to offer significant promise for improved outcomes.

As a result, most have viewed these programs optimistically. Some researchers ( [Frankel, 1988; Gelles, 1996; Wald, 1988](#)), have raised questions as to whether these programs actually are helping the children and families they are designed to serve. [Wald \(1988\)](#) argues that "family preservation cannot be an end in and of itself" and that "family preservation is appropriate only when it serves to protect and promote" the goal of the child's well-being. This is consistent with the point of view that the focus of family preservation programs should be the best interests of the child ( [Goldstein et al., 1973](#)). One model program with such a focus is the Family Support Service (FSS) developed by the authors.

## FAMILY SUPPORT SERVICE

The FSS is a time-limited, 24-hour, in-home, voluntary program for families in which a child is at imminent risk of placement outside the home. The program has been operated continuously since 1985 by the Yale Child Study Center in collaboration with the Connecticut Department of Children and Families. The genesis of the FSS came through the support of the Edna McConnell Clark Foundation, which has played a significant role in the family preservation movement nationally. The program is staffed by master's-level social workers or psychologists who join with trained, crisis-oriented lay family support workers to form a therapeutic team around each family in the program.

Six operating assumptions inform the work of the FSS. First, there are existing strengths in families that, once identified, can be used effectively by the therapeutic team. This assumption is significant because it represents a reversal of the traditional position of state child protection agencies, which by virtue of their legal mandate

seek to identify family weakness, parenting failure, and degree of risk.

Second, use of a therapeutic team is a particularly effective means of serving multiproblem families because it addresses the environmental and intrapsychic needs of the family simultaneously, while also providing mutual support for the team itself. Third, the work of the family support worker is central to the program's ability to effect change in the family. Families who often are socially isolated members of society's underclass, with previous histories of health, mental health, addiction, domestic violence, and other problems, and a historic inability to use the service system effectively, have significant difficulties in accepting and relating to traditional service providers. The FSS worker, a role model with whom they can identify, works with the families in their own homes, uses their own language, and understands their lifestyle. He or she is a critical and essential resource in breaking the cycle of isolation and reducing the distrust and distance that frequently have characterized families' past relationships with other helpers.

Fourth, team members play flexible roles. They may function as psychotherapist, diagnostician, evaluator, case manager, service broker, or advocate; they may meet with family members individually, as couples, or in family therapy; the specific clinical role is determined by the needs of each individual case. The intervention takes place in the home and in the community; the working relationships may be developed while driving to appointments, shopping for necessities, or attending a school visit.

Fifth, collaboration with other agencies is essential to the success of the intervention. FSS intervention is brief (no longer than 16 weeks); it does not replace existing services and programs. Work with community agencies from the time of referral to the time of discharge is expected and necessary if the goals for the family are to be attained during this brief period and maintained over time. Sixth and last, planning for discharge must begin at time of intake. Well planned, intensive, and brief involvement is a potent vehicle for change. This final operating assumption is embodied in the first question asked when a case is accepted into the program: What are the criteria for discharge? The brevity of the intervention is intended to minimize the intrusion into the family. It also capitalizes on the crisis that commonly exists at the time of referral by bringing the problem areas into sharp focus and stabilizing the family so that it can go on to use other, less intrusive and more familiar means of support.

The FSS program categorizes a family's risk for having a child removed in the following ways:

1. The referring child protection agency has decided that a child will be placed outside of the home within 5 days unless the family's resources can be rallied immediately.
2. A child already has been removed as a crisis response, but immediate return home may be indicated if additional internal or external support can be put into place quickly.
3. A referring worker's persistent discomfort about a child's health or safety propels a move toward placement, even though there may be significant clinical uncertainty about the benefit to the child of removal from the biological family. These often are cases in which significant parental dysfunction coexists with evidence of a positive child–parent attachment.

The FSS process begins with an intake assessment in the family home. At this time, the parent(s), the FSS worker, the clinician, and the referring worker jointly establish the goals for the intervention. Initial visiting schedules are established, task assignments are made, and roles are clarified.

Family support workers visit with their family clients twice weekly at a minimum, often more. The worker attempts to begin to establish a nonjudgmental, empathic relationship with the parent (or parents) and to arrange for concrete services for the family.

The social work clinicians screen and assess children and families for their service needs, keeping in mind the multiple environmental and intrafamily issues with which these families present. The family plays a central role in identifying the goals of the intervention and prioritizing the order in which the identified problems will be addressed. Ongoing communication between the family and the team is essential. Team members are available by beeper 24 hours a day, 7 days a week. Because consistent relationships are highly valued, team members are expected to respond to after-hours crises themselves, and do not rely on outside crisis responders. In actuality, once a working relationship is established with a family, workers receive minimal numbers of after-hours calls.

The FSS also has available a contingency fund for items such as security deposits, refrigerators, furniture, diapers, and food. The therapeutic team requests funding for its clients when such expenditures are thought to be important to maintaining a child in a family. For some families, this fund is used as a non–interest-bearing loan; for others it is given as a grant.

### **The Roles of the Family Support Team**

All of the work of the FSS team is clinically informed and theory based. The role of the social worker or psychologist is to apply clinical knowledge to the tasks of understanding underlying family dynamics and identifying both the parental behaviors and the environmental stressors on which the intervention can be focused. The clinician may be involved directly with the parent in brief individual treatment, parent guidance, or family therapy. A task of the family support worker may be to relate empathically to the parent/client as a nonjudgmental, caring role model and to assist the parent to obtain concrete services and negotiate appropriate service systems. The social, cultural, and personal background of the FSS worker may resemble that of the client. This similarity can enhance the client's acceptance of the FSS worker as a trusted and knowledgeable person. However, as stated previously, the roles of the team members are flexible, rather than fixed, depending on the individual case and the relationships that develop between the family and the members of the team. The pairing of the family support worker with the clinician focuses the work in a specific and goal-directed way that is based in the family's reality. Attention is first directed toward identifying and meeting the immediate basic needs of the family. After issues of food, clothing, and shelter are addressed, other issues can be seen more clearly and the intrafamilial work begun. In the process of assisting the family to obtain the necessary concrete services, the worker and parent begin to establish the relationship out of which real change can come. This approach assists families to cope with the immediate crisis, avoid further deterioration, work to gain some insight into the family situation, and achieve reorganization at a higher level.

In addition to assessing the immediate needs of the family, the team also assesses its needs beyond the time of intensive intervention. Together the family and the team identify other voluntary community resources that are appropriate, accessible, and available to address the family's longer-term needs. The professional status of the clinician facilitates access to certain services and makes possible more efficient case planning and transition. The FSS worker, with a working knowledge of grassroots resources, often is able to cut through bureaucratic red tape to obtain services by using contacts with line staff. The ability of the therapeutic team to relate to systems and services at two levels simultaneously makes possible more effective negotiation of the boundaries between agencies and systems than could be accomplished by either individual working alone. The use of the team thus seems to address both the concrete and psychodynamic needs of families in a way that mobilizes difficult-to-reach multiproblem families effectively.

Because threatened placement is a primary consideration for referral to programs such as FSS, it can be assumed that there is an existing concern for a child's safety. The active and continuous involvement of the FSS team with the state child protection agency is designed to encourage careful consideration and decision making focused on maintaining the child in the home when appropriate and possible, taking enlightened risks in the interests of continuity and consistency, and unraveling and ameliorating the complex web of environmental and intrafamilial problems that beset these families. The team provides a level of support and knowledge that enables the child protection worker to weigh alternatives carefully and to feel less anxious about leaving the child in the home. All those involved with the family thus can attend better to the real needs of the child and family. At the same time, the active involvement of the team ensures a watchful presence in the home and provides an assurance that concrete efforts will be made to improve the environment.

In summary, the team-structured FSS model holds promise for being an effective intervention for multiproblem families with children at high risk for poor developmental outcomes. The relationship-based, family-focused, child-centered approach central to FSS has been successful in maintaining these children in their homes and communities and addressing the constellation of needs identified by their families or revealed through careful clinical assessment of each child's health, mental health, or educational status.

---

#### CASE ILLUSTRATION

This case illustration offers an example of an in-home, time-limited, team-structured intervention with a family whose children were at risk because of the multiple problems that affected the mother's ability to care for them appropriately. This example should be relevant for child psychiatrists or mental health professionals who are asked to evaluate, assess, or treat a child where the locus of the actual problem may be in the immediate family or family environment.

Mrs. M., a 32-year-old Hispanic mother of six children who ranged in age from 2 to 10 years, was referred for in-home family service 2 weeks after the sudden death of her husband. Mr. M. had negotiated all of the systems for her and for her family during his

lifetime. Mrs. M. spoke only Spanish, was illiterate, and was reported by the Association of Retarded Citizens as being mentally retarded and probably unable to manage the affairs of her family.

At the time of the initial home visit, Mrs. M. was in a deep state of mourning. Her children were reported to be delayed developmentally, to lack age-appropriate social skills, and to have little expressive language. In addition, the 7-year-old daughter, Maria, had difficulty controlling her impulsivity and aggression, and 2-year-old Juan appeared developmentally delayed, although further evaluation was needed to confirm the diagnosis. The primary supports for the family were Mrs. M.'s minister and some paternal family members. However, the minister, who was a key influence in this family, strongly doubted that Mrs. M. could provide for the children adequately enough for them to remain at home.

Working together with Mrs. M. to identify the strengths of the family, the clinician and the family support worker made an initial assessment that Mrs. M. might possess the ability to function adequately as a parent if she had assistance in negotiating the various provider systems that would be essential to her family's health, welfare, and well-being. She would need help in such basic areas as managing money, making the home safe for her children, making and keeping appointments, and advocating for the special educational needs of her children. This initial impression was derived from Mrs. M.'s clear devotion to her children and their apparent attachment to her, her insistence that she was able to protect them in a dangerous neighborhood, and the clinician's awareness of the fear and isolation Mrs. M. suffered because of her illegal alien status.

Because Mrs. M. already was in psychotherapy at a community clinic, the FSS clinician assumed the role of case manager and not of therapist. The family support worker began a twice-weekly schedule of visitation. Both the clinician and the family support worker offered assistance in obtaining concrete services. The family support worker transported her to the appropriate state agencies to help her qualify for survivor's benefits. She was accompanied to the housing project administration to report a problem toilet and sink and to the Department of Income Maintenance for the budget verification required to clarify her rental status. The clinician visited Maria's school to discuss the appropriateness of her school placement with the principal. With the school's support, the clinician gained Mrs. M.'s permission to refer Maria to a child guidance clinic for a full psychiatric evaluation.

During the first month of FSS involvement with this family, Mrs. M. felt increasingly overwhelmed by the problems stressing her family. Mrs. M. believed that she was approaching a "nervous breakdown." Shortly afterward, while Mrs. M. and the family support worker waited together for the children at the bus stop, Mrs. M. confided that she would like to place all her children in foster care and arrange to see them only on the weekends. Although the aide was surprised and discouraged, she told Mrs. M. that she would bring her information that would help her to begin the placement process. At the next visit, the family support worker suggested the alternative possibility of a day care program for the children and a homemaker for Mrs. M. Mrs. M. was interested in exploring these possibilities because she had realized that, in fact, she did not want her children to be placed away from her. She recognized that when she had spoken about placement she had been overwhelmed by the thought of caring for them by herself and had not been able to envision any other alternative. She also recognized that she needed help to keep her children with her.

With the goal of maintaining the children in the home now established, both the clinician and the family worker began to negotiate with other systems to find an appropriate homemaker as well as an affordable day care program. The family's food stamps, which were suspended temporarily because of their illegal immigrant status, had to be restored. The team visited the neighborhood health clinic to coordinate the family's health care and simplify the family's access to the health care system. Termination took place after the successful completion of the goals of the intervention. The home was considered to be safe, the children's relationships with their mother appeared to be stable, a homemaker provided Mrs. M. with assistance in managing her domestic responsibilities, and the children were in appropriate day care and school settings. At a discharge planning meeting attended by all of the service providers working with the family, Maria's therapist agreed to act as ongoing case manager. With these supports in place, the work of the FSS team was concluded.

#### **Comment**

There should be no illusion that this 12-week intervention provided a "cure." Mrs. M.'s limited intellectual functioning, her depression, and her continued mourning suggest that her functioning over time will be impaired. However, she had taken responsibility when in the past she had taken none, and she had begun to play a more active role in caring for the multiple needs of her children and herself. A support system had been developed and activated for Mrs. M. and her children that required her to relate to only two primary caregivers: the pediatrician and the child guidance clinic. Six children were then enabled to remain together with their biological parent. The mother's potential dependency and inability to function were modified, and multiple problem areas were addressed with positive results. The alternatives for the M. family might have more than doubled the sense of loss and abandonment that the death of their father already had occasioned and left them even more vulnerable.

---

## **CONCLUSION**

Multiproblem families present a challenge to service providers because of their difficulties across multiple spheres of functioning. The families often are in a state of chronic dependency on public health, welfare, and social service systems that contributes to the current burgeoning costs of health and mental health care. These families also may exhibit a persistent failure to respond to help when it is offered, adding to the frustration of the service providers, who may already have a lack of confidence in the family's ability to institute change and in the service system's capacity to intervene effectively.

Because of the complex web of problems with which these families present, traditional treatment approaches are likely to be inadequate. Unidimensional interventions, whether psychotherapeutic, social service, or educational, designed to address individual problems in isolated domains, have not been effective in ameliorating the multidimensional problems of these families. A family-focused, child-centered frame of reference structures the intervention, supports the measurement of goal setting and goal attainment, and contains the scope of the work. Without such focus, the work can be diffused, less purposive, overgeneralized, and difficult to assess.

Many families experience problems in more than one domain. Some are able to use services and mobilize their inherent strengths on their own behalf; others are unable to recognize and draw on their own strengths or make use of other resources that might be helpful to them. Although we can map the combination of factors leading to either effective, adaptive functioning or chronic dysfunction with increased skill, we are not expert at making available preventive and interventive approaches that will promote healthy development and ameliorate the effects of negative familial and societal influences. Models such as FSS potentially offer to both family and service systems significant hope of breaking chronic patterns of maladaptive family interactions and coping.

The development of a therapeutic alliance also has proven to be a central element in effective intervention with multiproblem families. The relationship between the parents and the clinical team, similar in concept to the psychoanalytic use of the auxiliary ego, lends support to the parent as he or she moves toward a higher level of functioning ([Lewis and Stark, 1966](#)). The willingness to move the site of clinical treatment from more traditional clinic and examining room settings of to the family's home has been found to reduce resistance to engagement and reduce treatment disruptions.

Working with multiproblem families requires new, flexible approaches to treatment and reallocation of clinical resources. Implementation of these approaches has important implications for the training and practice of psychiatrists and other mental health professionals. The FSS program at the Yale Child Study Center has intervened successfully with these families since 1985. This success is reflected in the program's ability to prevent out-of-home placement of children in over 85% of the families served ([Adnopolz, 1994a](#)). Other program models appear to be equally effective ([Pecora et al., 1990](#)); however, [Dore \(1993\)](#) argues that extremely poor families may need more and continuing service. [Berry \(1992, 1993\)](#) has shown that these types of programs may not be as successful with chronic, long-term neglecting families. It is the authors' belief that although there still is much to be learned about these programs, investment in families previously believed to be unavailable for treatment offers our best hope of preserving and assisting families in crisis.

[Chapter References](#)

Approximately 1 million adolescents in the United States run away from home and live on the streets for at least part of each year. Perhaps 10% of all teenagers run sometime ([Edelback, 1980](#)). Many of these youths suffer significant and long-lasting physical and psychological damage; yet receive little or no care from any public or private agency ([Robertson, 1988](#)).

Our ability to anticipate and prevent running, and to remedy the effects of this experience, has been limited. In part this reflects a scarcity of careful empirical studies. However, it also reflects the impact of the runaway experience: Life on the street is so traumatic that when we study runaways it becomes difficult to distinguish which clinical features were antecedent and which were consequent to the runaway ([Justice and Duncan, 1976](#)). In spite of this, there is a growing appreciation of who these children are, what motivates them, what interventions will help, and, to a lesser degree, what the outcome of running away during adolescence is likely to be.

## PREVALENCE

Runaway teenagers come from all social groups and geographical regions but most are urban youths from lower socioeconomic status (SES) levels. Fewer than half live with both parents, and those who do are likely to come from very large homes ([Johnson and Peck, 1978](#)). More than one-quarter comes from single-parent homes, whereas another quarter comes from foster or group homes. Although the statistics are in dispute, girls predominate by a slim margin in most categories of runaways ([Garbarino et al., 1985](#)). Ninety percent of youths run fewer than 50 miles from home. Seventy percent of runaway episodes are brief (lasting 1 to 6 days), and follow a triggering incident (usually an argument with the parents); the child's focus remains on the home. However, as many as 15% of runaway adolescents are absent from home for many weeks or months: They develop an alternative identity that is streetwise and independent of their families. These youths may never return home. An additional group of runaway adolescents come and go from home numerous times over their teenage years; a dozen or more runaway episodes are not unusual. This group is more likely to come from an abusive environment and have their instability complicated by drug and alcohol abuse.

Such a variable pattern of running away causes the figure of 1 million runaway adolescents in the United States each year to be very approximate. Definition is crucial. Fewer than 400,000 youths are absent from home for months or years. On the other hand, many adolescents who leave home briefly (usually to the house of a friend or relative) are never reported. To include them might swell the number of runaways into the millions. Also, those children who run numerous times further confuse the statistics. Perhaps the key point is that running away is a substantial problem badly in need of interventions, particularly considering the negative consequences of even a brief period of time spent on the streets.

## RUNAWAY TYPOLOGY

Several detailed taxonomies are available that, with mixed success, attempt to categorize the complex phenomena of adolescent runaway ([Adams et al., 1985](#); [Dunford and Brennan, 1976](#); [Homer, 1973](#); [Jones, 1988](#); [Miller et al., 1990](#); [Roberts, 1982a](#)). Each incorporates one or more of the following organizing principles: the putative cause of running away, family dynamics, individual dynamics and/or psychopathology, sociocultural variables, age of the adolescent, and length of the runaway period.

The recent use of "runaway" as a diagnosis has been confused. Although DSM-II included the category of runaway reaction of childhood or adolescence, this was subsumed within conduct disorder, undersocialized nonaggressive type, in DSM-III. This latter diagnosis then disappeared completely in DSM-III-R and remains absent from DSM-IV, except as one of many possible criteria for conduct disorder. Runaway adolescents currently are to receive diagnoses for any specific conditions from which they suffer but not for their runaway behavior itself. At the very least, in most cases, this requires the "V" code of Parent-Child Relational Problem.

Although no single classification scheme has emerged as ideal for all purposes ([Hartman et al., 1987](#)), a typology based on the youth's reasons for running may be the most clinically useful, particularly when enriched by correlations with other important variables. Such a scheme must have at least two major categories: adolescents who "run from" home (runaway) and adolescents who are "pushed from" home (throwaway). It is essential, for clinical purposes, to know whether a child has chosen to leave home voluntarily or has been forced to leave by abusing or rejecting parents, even though this distinction frequently blurs in individual cases.

### Runaway Youth

Most adolescents on the street have run from home rather than been driven out ([Sharlin and Mor-Barak, 1992](#)). Moreover, most of these youths have come from turbulent homes with fractured family relations and are actively escaping a situation perceived as intolerable ([Council on Scientific Affairs, 1993](#)). A smaller percentage are adventure-seeking teenagers who are actually "running to" the exciting life on the streets. In some cases there is intergenerational transmission of running away, as sequential generations of children from one family "hit the streets" ([Plass and Hotaling, 1995](#)). Although both groups deserve clinical attention, the former may be more in need of, and responsive to, intervention.

### "RUNNING FROM" YOUTH

Many different situational and personal characteristics can predispose to runaway. Moreover, what a youth judges to be an acceptable reason for running differs with the culture and expectations of the youth's immediate peer group.

The most common reason for running away is a difficult home situation. A few adolescents are in homes that are truly intolerable by any standard; to escape from them may be both rational and healthy. These youths may be fleeing chronic physical or sexual abuse ([Famularo et al., 1990](#); [Farber et al., 1984](#)), often at the hands of antisocial, alcoholic, or drug-abusing parents. They may suffer equally severe psychological abuse by rejecting, punitive, or chronically neglectful parents. A few homes are so disorganized that the children are essentially without a history; they watch a parade of adults pass through their lives and do not know in some cases even who their natural parents are. Such families are frequently well known to community agencies and the children are often removed before they have a chance to run. Occasionally, however, the children must escape by their own means and thus end on the streets as runaways. They may find more warmth and caring on the street than they ever encountered at home, and if they become part of a "substitute family," their run may become permanent. In recent years, the substitute family willing and eager to adopt such disaffiliated youth has been one of the antisocial gangs that grace the midsize and major cities in the United States. In fact, the majority of gang members seem to have come from such dysfunctional families.

More commonly, the homes of runaways are characterized by a lesser degree of turmoil and by verbal abuse and poor communication. Typically the children and parents battle over one or more issues that neither seems able or willing to resolve. Parents identify problems with the teenager's behavior that range from the mundane (dinner table deportment, jewelry selection, hair style) through the expected (school performance, dating habits, curfew) to the profound (drug and alcohol abuse, illegal activities). The adolescents, on the other hand, feel themselves unheard, controlled and powerless, and without respect. Common to all these settings,

however, is reliance by both parties on the child's leaving home to resolve interpersonal conflicts. Girls predominate, perhaps because parents are more controlling and demanding of them. Family ties are usually intact, although loose, and reconciliation typically remains possible.

Alternatively, a crisis in the home can precipitate a runaway. Divorce, infidelity, financial disaster, or tension among other family members can cause an adolescent to flee. This may occur if the youth senses a loss of support when most family resources are directed elsewhere, but it also may represent the adolescent's need to call attention to the family's distress in an effort to get help. With otherwise stable parent-child relations, such running away is usually brief but may recur if the crisis persists or returns. However, if the child personally experiences the crisis (pregnancy, sudden trouble with the law, homosexuality revealed), the likelihood that he or she will run depends primarily on the reaction of the parents or expectation of an unacceptable reaction—and this depends in large part on the quality of the communications between parents and child.

Finally, some teenagers run from home as a manipulation. They may be seeking attention, trying to avoid punishment for a minor infraction, or trying to "let their parents know who is boss" (and have some fun while they are at it). This may occur with the adolescent whose parents have finally decided to crack down on increasingly unacceptable behavior. Such an episode is usually brief and done safely (e.g., run to a friend's house); it may be repeated if felt to be successful.

## **"RUNNING TO" YOUTH**

A significant minority of youths run away from home initially to exercise their independence, to escape boredom and seek excitement, and because of the allure of being "on the street." Home life for most of these adolescents is not supportive and as likely to be characterized by minimal control and parental indifference as by over-control and abuse, although some of these youths appear to have normal relationships with their parents and come from homes that seem relatively stable. Moreover, some report adequate (and even exceptional) school performance and uneventful peer relations. This diverse group of teenagers range from naive youngsters who have been inordinately influenced by pressure from their peers (and who often quickly return home after a brief adventure) to frankly antisocial adolescents for whom life on the streets differs little from the life they led before leaving home.

### **Throwaway Youth**

Approximately one-quarter of runaway children are actually throwaways (abandoned, castaways, homeless, pushouts) ([Gullotta, 1978](#)). These difficult, traumatized adolescents have either been encouraged to leave or been forcibly ejected from their homes. They are slightly more likely to be girls, to be older than more typical runaways, and to display high levels of conduct disorder, school failure, and drug and alcohol use. Typically their homes are very disturbed and marked by abuse, violence, and neglect. However, infrequently the homes are relatively stable, but the child has been scapegoated: identified as the "bad seed," whose removal from the home will solve the family's problems. In either case, relations between parents and child are chronically impaired, and neither party sees hope. Efforts to repair the family are usually unsuccessful.

## **CLINICAL DESCRIPTION**

Although several efforts to develop a psychological profile of adolescent runaways have been made ([Adams and Munro, 1979](#); [Jenkins, 1971](#); [Pietropinto, 1985](#); [Roberts, 1982a](#)), no single description can encompass the diversity of runaway youths. However, those large groups of runaway/throwaway youths who come from abusive and emotionally impoverished homes share some common psychological features.

Most studies find the majority of runaways to be demoralized and to have a poor sense of self. They are insecure and frightened in spite of a spirit of bravado and defiance. They frequently see themselves as inadequate, not only academically and occupationally, but also socially and interpersonally. This often reflects reality because many of these youngsters have a long history of failures: Almost all have been poor students or had significant school difficulties, and many have received limited occupational training. They typically are uneasy around and avoid adults. They are likely to be ostracized as "losers" by their more successful peers and are most comfortable with an equally impaired peer group. Compared to their peers, they typically choose maladaptive ways of coping with stress, including running away ([Roberts, 1982b](#)). Finally, in spite of the apparent independence required to run away, many such youth are passive and dependent when given the chance ([Benalcazar, 1982](#)).

Coincident with this self-image of incompetence is a sense that they have little impact on their environment. They frequently feel powerless to influence their parents, and this also may have a basis in reality because many of their parents are controlling and abusive or, alternatively, neglectful and disinterested. Nor do they feel that other adults in their environment, such as schoolteachers, respect them. As a result, leaving home becomes in part an effort to establish a sphere of self-esteem.

As might be expected, dysthymia and depression occur with increased frequency ([Feitel et al., 1992](#)). Estimates of depression among this population range from 20% to 80% ([Hersch, 1988](#)). Suicide attempts may occur in over one-third of this population ([Rotheram-Borus, 1993](#)). A key contributing factor to this pattern may well be the high incidence of previous and concurrent sexual abuse among runaways of both sexes ([McCormack et al., 1986](#)). As many as two-thirds or more of runaway females and one-third or more of runaway males ([Janus et al., 1987](#)) have been abused. Such experience is known to bring in its wake significant depression but also is associated with symptoms such as anxiety, dissociative episodes, sexual dysfunction and sexual acting out ([Seng, 1989](#)), substance abuse, conduct disorder, fear of adult men (by both males and females), and difficulty with close interpersonal relationships. These symptoms are frequently observed among runaways; past sexual exploitation may have contributed to the current clinical presentation of such a youngster.

Not only do they experience broad-based failure, but also they actively adopt, or are forced to adopt, self-destructive behaviors likely to worsen that course ([Greenblatt and Robertson, 1993](#)). They frequently abuse alcohol and a variety of drugs even before they run from home, further compounding their problems. In fact, substance abuse may occasionally dominate the clinical picture, leading to daily disruptions and generalized failures and resulting in expulsion from the home. Chronic truancy and status offenses are also common; the typical runaway is more likely to be a petty rather than a serious offender. The increase in conduct disorder among runaways, although real, may partly reflect the runaway experience itself. Adolescents for whom the fundamental problem is conduct disorder are more likely to have run at an earlier age, stay away longer, and get into more serious trouble.

Although by far the most common psychiatric conditions to be found among runaways are depression, substance abuse, and conduct disorders, other psychopathology also occurs with increased frequency. Some youths are markedly anxious and deserve an anxiety disorder diagnosis. These adolescents also seem to be more likely to suffer from attention deficit hyperactivity disorder and learning disabilities, yet good evidence is currently not available. Certainly, though, studies have found the runaway adolescent to be restless, demanding, and impulsive ([Goldberg, 1972](#)). Deeply disturbed or psychotic children living on their own in the community are present with a modestly increased frequency. That they are not even more common probably reflects both their likelihood of being institutionalized once recognized and the difficulty such youngsters with significant psychological disorganization have surviving on the street.

Although the majority of runaways can be contained within the preceding description, a sizable subpopulation of adolescents better fits another general description entirely. These are the youths who envision running as an adventure (the "running to" group) and have a value system consonant with life on the streets. They frequently are excitement-seeking, moderately antisocial adolescents who are likely to come and go from home as the mood suits them or to stay on the street for months or years if they find a niche of their own there. These are the teenagers most likely to exploit those around them and slip into a more permanent antisocial lifestyle.

Finally, some runaway adolescents are indistinguishable from normal. They have a generally good relationship with their parents and maintain close ties throughout one or more runaway episodes. They have strong ties to their peers (who may be confused by, or participants in, the running behavior) and perform well in school. Psychopathology is not evident, and the behavior produces few psychological repercussions because the running episodes are brief, infrequent, and safely performed.

### **Parental Patterns**

To understand the runaway teenager, it is necessary to recognize that the parents' role in generating disturbed family interpersonal relations is usually at least as important as their child's. A poor parent-child relationship is the most consistent finding in the home of a runaway. Although some homes and parents are psychologically unremarkable, often the parents of the more persistent runaway adolescents have features in common.

Most of these parents are exceptionally critical of and dissatisfied with their children. Parent-child communications typically are negative; the parents provide little in the way of compliments or support (and the child reciprocates in kind). They establish a standard for behavior (often poorly defined) that the teenager often finds

unattainable but then provides little help or counseling when the child fails. Their frustration and demands typically take the form of verbal abuse as well as occasional shoves or blows.

The communication of perpetual dissatisfaction with their child is usually accompanied by inconstant discipline. They are quite capable of being restrictive at times, particularly around specific issues such as dating and curfew, and lax at other times. The teenager interprets the restriction as parental rigidity and control and then rebels (or runs away). However, these efforts by the parents to make demands on their children typically are overlaid on a more fundamental pattern of disinterest and lack of supervision. Runaway adolescents are as likely to report that their parents have no time for or interest in them, as they are to report that their parents are too demanding. Many of these parents are absorbed in their own problems and desires and give little time or energy to their children (latch key children). They are not there to help with schoolwork, intercede with teachers, or discuss problems. The children rightfully see themselves as incidental to the parents and are less willing to adapt themselves to their parents' wishes. There is little real comfort to be had in these families; consequently, the child looks elsewhere.

A significant minority of these parents displays real psychopathology as well. Antisocial personality disorder and drug and alcohol abuse are common. Parental disorganization and instability may also result from depression, psychosis, or low intelligence. In any case, the parents may need intervention separate from work with the family.

## THE CONSEQUENCES OF RUNNING AWAY

Most teenagers leave home with a plan in mind. Unless their departure is precipitous, they usually are running to a friend's house, a distant relative, or a known location or town. Alternatively, they may be "hitting the road," but usually with one or more friends with whom they have planned their runaway. Girls frequently run to or with their boyfriends, who often provide them with money and a place to stay. Episodes of running often end when the money runs out. Many teens are quickly returned home by acquaintances or the police, or they end up in shelters as a way station to home or alternative residential placements. These well-contained runaway episodes generally do little long-lasting damage, occasionally provide the teenager with enhanced self-esteem, and may be beneficial by mobilizing the family to get help. (Unfortunately, many first-time runaway youngsters return to angry parents who decide to "crack down," producing a worsening spiral.)

Prolonged runaway attempts are less benign ([Young et al., 1987](#)). Few adolescents survive on the street for lengthy periods without trauma; the street is a great leveler. Unless friends or family provides for a youth, the dominant issue of living on the street quickly becomes survival. One estimate suggests that a youth on the street without resources will have to turn to crime within 1 month to survive ([Hersch, 1988](#)). This means turning to theft and street hustles, prostitution, pornography, drug selling, and the exploitation of others. Among chronic street adolescents, three-quarters have been involved in prostitution, three-quarters with selling drugs, and three-quarters have been incarcerated. The longer adolescents are on the street, the more likely they are to find their way into trouble and the courts.

More important, however, is the sheer physical danger of being on the streets. Violence (assault, battery, rape) and its associated injuries are the most serious problems a youth faces. Most street youths will be beaten or raped at some point. Some will become pregnant; some will receive permanent injury; some will be killed. In addition, their physical health will deteriorate. Skin infections, parasitic infections, respiratory and gastrointestinal diseases, dental problems, nutritional deficiencies, and medical conditions associated with drug abuse are common ([Council on Scientific Affairs, 1989](#)). They risk exposure to the elements, exhaustion, and musculoskeletal problems because of their hand-to-mouth existence. To make matters worse, hunger, fatigue, and drug-related cognitive impairments all compromise the teenager's ability to cope with routine stresses, let alone with the major challenges they face on the street.

All of these physical disabilities occur during a time when they have limited access to health care and limited ability to pay for it. Although some care can be provided to minors without parental consent in some states for certain conditions (e.g., pregnancy, venereal disease), most nonemergent care is unavailable unless the individual is an emancipated minor. Nevertheless, even if emancipated, they have the same difficulty in obtaining health care, as does anyone who is indigent.

Besides violence and drug abuse, the other major risk to the physical health of the runaway is sexually transmitted disease ([Rotheram-Borus et al., 1992a](#)). Runaway youths are perhaps the most sexually active of all teenagers, and their rates of syphilis and gonorrhea are the highest of any group ([Rotheram-Borus et al., 1992b](#); [Zylke, 1989](#)). This sexual activity, coupled with high rates of drug abuse, places runaways at high risk of exposure to acquired immunodeficiency syndrome (AIDS). Although an epidemic of AIDS among runaway teenagers is unlikely owing to the long latency of the disease, there is an epidemic of exposure to AIDS in progress ([Hersch, 1988](#)). In some inner city populations of runaway adolescents, the human immunodeficiency virus (HIV) seropositive rate may approach 10% with much of the exposure occurring through heterosexual contacts ([Hein, 1987, 1989](#)).

Prostitution (male and female) and pregnancy present other risks to runaways ([Brown, 1979](#)). As many as 900,000 adolescents are involved in prostitution each year; many, but not all of them, are runaways. Adolescent male prostitution is common, but female activity predominates. The average age of first intercourse for these girls is approximately 12 to 13, whereas the average age of beginning prostitution is 14 to 15. Prior traumatic sexual experiences are the norm: Many of these adolescent girls have been molested; half have been raped. Although some hard-core runaways prostitute for the money and glamour, most are trying to survive. With this group of runaways in particular, street drug use is extensive and other physical risks excessive ([Yates et al., 1991a](#)).

Teenagers pay a severe psychological price for life on the street; those who successfully adapt are usually the worse for it. Many of these youths are intensely lonely, fearful, and unhappy ([Kufeldt and Nimmo, 1987](#)). The longer they are on the street, the greater the number of demoralizing experiences they will have had. In fact, life on the streets itself can produce all of the symptoms usually associated with runaway adolescents. Running away often has forced them into a life they did not expect and do not want; however, they frequently have few options. Only 50% of chronic runaway teenagers have any possibility of returning home. As time goes by the consequences of running become long lasting; they have effectively excluded themselves from an education and a career. Determination to succeed flags, and many of these youths become permanent members of the underclass.

## TREATMENT

Runaway adolescents can be both difficult to treat as well as desperately in need of treatment. Perhaps the most formidable obstacle to treating them is that they rarely seek help ([Brennan, 1978](#)). Even those in medical need will frequently suffer rather than look for aid from adults, agencies, or shelters. In addition, they are frightened, defensive, hypersensitive, embittered, rebellious, and mobile—they do not stay in treatment long; they run away. Keeping them engaged requires tact, a nonjudgmental attitude, the development of a personal relationship (with someone), and, most frequently, patience. They are present oriented; because of the intensity of their feelings, they tolerate review of their past poorly. However, it is possible to have considerable impact if the child (and his or her family) is engaged skillfully at the right moment.

Most commonly runaways are reported missing by their parents and are brought to clinics or inpatient facilities by the parents, police, a relative, or a mental health worker. Occasionally, their absence from the home goes unreported, and their status only comes to attention when they appear at a shelter or on the street. These "forgotten" adolescents are typically the most impaired. The Juvenile Justice and Delinquency Prevention Act of 1974 prevents the long-term incarceration of these youths, yet their treatment in the eyes of the law reflects state statute: Some states consider runaways to be juvenile delinquents and send them through the courts, whereas other states consider them status offenders and send them home or to treatment facilities.

Once identified, the first order of business is to provide a safe environment. This usually involves a rapid assessment of the home and perhaps a return there, but may mean finding a shelter, group home, or other social service facility as an alternate placement until an appropriate long-term setting can be found. It helps to have an assessment unit as part of the clinic or shelter and to have ready access to medical care, because these youths may be in poor health and need prompt attention. Although their skittishness and lack of cooperation may interrupt treatment, immediate provision of welcome medical care can entice them into a treatment-receptive stance. Although some professionals worry about it, providing medical and psychotherapeutic aid to runaway adolescents in need without parental consent is generally acceptable in the eyes of the law ([Croxtton, 1988](#); [English, 1991](#)).

Appropriate treatment usually depends on the type of runaway and the length of time the teenager has been gone. Usually, however, the earlier the intervention, the better, although simply returning the child home rarely works. An effort at family therapy is essential for the "running from" youth ([Ostensen, 1981](#)). Such therapy is often effective, particularly if the running episode has been brief and if the family is basically stable but in acute crisis. More severely disabled families may respond to intervention; the focus needs to be on family stress rather than on the child's problems, education in parenting skills, and interpersonal skills training for all members. The parents need to learn to listen, show affection, develop consistency and parenting effectiveness, and care. They need to be alerted to and correct interpersonal distortions when they occur, and avoid scapegoating the child in service of their own marital disputes. They often need to develop more realistic expectations for their child, and this typically requires a careful assessment of the child's capabilities.

Like the teenagers, the parents are also often resistant to treatment. They may consider their problems so serious that a bad result is inevitable or too confidential to talk about. They may be defensive or demoralized and without confidence. It is essential to engage them in therapy before they become hardened to their youngster's problems or disenchanted by any treatment efforts. Some families will not follow through in spite of the best efforts.

In general, the more chronic and complex the family's problems, the more broad-based the interventions needed. If the child has been out of the home for a long period, however, the family ties may be so weakened that returning home is unrealistic and formal family therapy of little value. Family therapy is generally not useful for chronic street kids.

"Running to" adolescents, particularly if they are moderately antisocial and enjoying their time away from home, are resistant to treatment. Often the most that can be accomplished is to help them find acceptable, legal, and even constructive outlets for their energies and enthusiasms. Throwaway adolescents typically are the most traumatized of all and need support and stable placement, if they will accept such help. They also occasionally respond to intensive individual psychotherapy, but owing to their sensitivity and lack of trust, group therapy with peers is often a necessary and acceptable alternative.

Runaway adolescents are often difficult to engage in individual therapy, but when a therapeutic alliance develops, such treatment can be very effective. Many of these youngsters want to feel better and do better. Many want to return to school and be reintegrated into their community, only the hurdles seem overwhelming to them. The therapist must recognize their heightened defensiveness, anxiety, and impulsivity—it is impossible to be too gentle and supportive to many of these youths. If they are abusing drugs, every effort must be made to detoxify them. Issues around sexual abuse need to be addressed; nonetheless, the patient may respond with withdrawal, denial, cockiness, anger, or verbal abuse if the pace is too rapid. At least initially, the child needs to feel in control of the interviews. Many (most) of these youths can benefit from training in specific coping skills, well received often through role-playing exercises with peers. Of course, identifying and treating specific psychiatric disorders such as depression, substance abuse, and psychosis is essential, as is the recognition of specific deficiencies such as learning disabilities. Perhaps even more than in most psychotherapy, however, success depends on developing a personal relationship with the youngster that will weather the inevitable storms to follow.

Public and private resources of all types are inadequate for runaway adolescents. Some agencies avoid dealing with these teenagers in part because they can be difficult (Kufeldt, 1991). Comprehensive services with a continuum of care are needed but unavailable in most communities. This continuum should include not only medical care and individual psychotherapy but also runaway shelters for brief but safe stays, small group homes for longer stays, hostels and supervised but independent living apartments for selected older adolescents, carefully chosen foster homes, and secure facilities for very disturbed youths. However, some youths have trouble in any structured setting and may need to be treated for a while on the street (Kufeldt et al., 1992; Smart, 1991; Yates et al., 1991b). Emergency hotlines are available and advertised in some locations, and there are at least three runaway hotlines that serve a national or regional audience: National Runaway Switchboard (1-800-621-4000 [HIT-HOME]), Covenant House (New York) hotline (1-800-999-9999 ["nine-line"]), and National Center for Missing and Exploited Children (1-800-843-5678).

## OUTCOME

Careful outcome studies are rare (Olson, 1980; Robins, 1958), based on few patients, and dated. Only limited conclusions can be drawn. Runaways, as a group, are failures in later life. They never make up for lost schooling or missed occupational opportunities. They tend to slip to the lowest SES group and frequently become dependent on others (ironically, often their families) for support. Adult interpersonal relations are typically poor, and their sense of self remains low. The more significant their runaway activities as an adolescent (i.e., chronic or repeated versus brief and nonrepetitive), the more likely they are to fail as an adult. On the other hand, teenagers with brief, one-time runaway episodes may be indistinguishable from a normal group later in life.

There is insufficient information at this time to either go beyond these tentative conclusions or explain them. It is not clear, for example, how much of runaway behavior or outcome is owing to innate temperament and abilities and how much to parent-child conflicts and experience. It is clear, however, that the runaway adolescent is an individual deserving clinical and research attention.

## RESEARCH DIRECTIONS

The research base with this population is inadequate. Even fundamental clinical questions go unanswered: How diversified or uniform are the personality characteristics of these children? Is drug use etiologic or secondary? What are the features that determine a priori whether a child will engage in a brief or a sustained runaway? What personal characteristics allow a child to succeed as a runaway? Which interventions are effective, if any, and with which populations (Podschun, 1993)? Numerous interwoven factors have made this a difficult group to study; they need to be specifically identified and teased apart.

Any research must be broad-based, or at least must recognize its limitations. Results differ depending on the cultural and socioeconomic group studied, location of the study, and time of the study. Inner city runaways differ from suburban runaways; summer runaways may differ from those gone year-round. Outcome may vary with family structure, drug use, degree of criminality, and interventions available. All results may vary with the generation studied; studies during the restless 1960s do not necessarily apply today. Serious hope of influencing the runaway problem awaits clarification of many of these basic issues and questions.

[Summary](#)  
[Chapter References](#)

The functioning of any individual child is conditioned by the interaction between the child's innate, structural capacities, his physiology, cognition, and developmental status, and the ecologic systems in which he functions. The family system is the earliest and arguably the most significant influence affecting the child; its functional capacity is central to the child's ability to adapt to and cope with the vicissitudes of his or her life. Although family-focused interventions have been used to augment individual mental health treatment for disturbed children for some time, it was not until the final decades of the 20th century that the child's home and family became an essential focus of interventions designed to prevent negative parent and child behaviors in at-risk populations, or to ameliorate problems of serious emotional disturbance, inadequate or abusive parenting, or delinquent behaviors that placed children at risk for placement outside of their own homes ( [Lindblad-Goldberg et al., 1998](#)). The realization that many families in need of service were unable or unwilling to access traditional treatment programs, which, in turn, placed children at even greater risk for removal to more restrictive environments or prevented them from receiving assistance, made the home an important alternative service delivery site. Although scientifically derived evidence of their efficacy and effectiveness has been slow to accumulate, home-based services based on principles first articulated in by the Child and Adolescent Service System Program (CASSP) and further codified in Public Law 94-142, The Education for All Handicapped Children Act, and Public Law 96-272, The Family Preservation and Support Act ( [Solnit et al., 1997](#)), have proliferated across America. Home visiting does not represent a single treatment modality; rather, it describes a systematic mechanism for the delivery of preventive or interventive services ( [Olds et al., 2000](#)), even though the rhetoric of home-based services is similar across a broad range of programs.

This chapter describes the events leading to the current interest of health, mental health, juvenile justice, and child welfare systems in supporting the delivery of services in the home; reviews some of the home-based programs that have been reported in the literature, ranging from preventive, educational, and support models to intensive, focused interventions with delinquent adolescents and dysfunctional families; and presents an example of a program for children and adolescents with serious emotional disturbances.

## THE CHILD AND THE FAMILY

Although foster care or other residential treatment facilities are likely to be available in most communities to provide 24-hour care for those children for whom it is required, few resources are able to replace the family as the most effective, long-term institution for raising children. Adequately functioning families provide safe and secure environments in which the normal developmental processes of childhood and adolescence can unfold predictably. In such environments, children are likely to feel nurtured, cherished, protected, and secure. Consistent relationships with their adult caregivers support the positive use of curiosity and imagination and empower children to explore their world and move toward eventual independence and self-sufficiency. [Solnit \(1976\)](#) has described the family as "the bridge from the past to the future" that provides continuity and a sense of being rooted in time, place, history, and culture. Families socialize children, transmit intergenerational values and beliefs, and provide a place of respite from the challenges of the outside world.

Although most children in the United States live in families able to offer adequate care, society remains challenged by the substantial numbers of families unable to provide stable, consistent, and caring relationships for their offspring. As the United States moves into the 21st century, the country is faced by a crisis in the care of its children, much of which can be associated with inconsistent, inadequate family functioning. Harrison and others found that risk and protective factors associated with child and adolescent problems were determined primarily by parenting and family functioning ( [Harrison et al., 1999](#); [Najman, 1997](#)). Harrison found that children in unstable families with high levels of partner conflict demonstrate higher rates of both internalizing and externalizing behaviors; negative family functioning also has been highly correlated with adolescent substance abuse ( [Harrison et al., 1999](#); [Rhodes and Jason, 1990](#)).

Although the federal government has made serious attempts to assist states to provide services and community supports to preserve families for children ( [Solnit et al., 1997](#)), foster and institutional placements remain overused treatment options for troubled children and families in communities where there are few less restrictive alternatives. In 1998, approximately 500,000 children in the United States were in out-of-home, nonrelative placements ( [Nelson, 1996](#)); estimates of children in the United States living with relatives range from 4.3 million children living with mothers in the homes of other relatives ( [U.S. Bureau of the Census, 1992](#)) to an estimated one-half million children in kinship care arrangements ( [Scannapieco and Jackson, 1996](#)). Even though the effects of multiple caregiving disruptions on child development have been well documented ( [Goldstein et al., 1996](#); [Rosenfeld et al., 1998](#); [Solnit, 1980](#)), the incidence of out-of-home placements has more than doubled since the mid-1980s. This marked change in removals and placements may be associated with an increase in both the severity of symptomatology and the numbers of children being referred for intervention and child protection ( [Child Welfare League of America, 1994](#)). However, moving children in and out of placement in an attempt to address their needs for treatment or safety and protection may, in fact, foster even more severe disturbances by heightening their anxieties and fixing their self-destructive, negative internal representations. Children who are denied consistent, long-term relationships may be compromised developmentally and intellectually and be unable to form positive, intimate attachments as adults ( [Goldstein et al., 1996](#)). The zeal of society to protect and treat children by removing them from their families and placing them in other caregiving arrangements, including institutions and foster homes, in reality may be putting them in harm's way.

## ROOTS OF OUT-OF-HOME CHILD CARE

Community responsibility for the care of inadequately parented children and identification of alternative caregivers has been recognized for centuries. In the Judeo-Christian tradition, childless foster caregivers, extended family members as well as nonrelatives, were among the first adults willing to take on the care of children who were orphaned, abandoned, or beyond the control of their parents ( [Youcha, 1995](#)). As opportunities for work outside of the home developed, uncared-for children were enlisted as apprentices to tradesmen with whose families they lived, providing cheap labor in return for basic necessities. Historically, attempts to provide care for the ever-increasing numbers of destitute or insufficiently cared-for children were guided by altruism and religiosity, but children did not always fare well. Reports of exploitation, cruel treatment, and substandard living conditions challenged the widespread assumption that the family was the ideal place in which to raise children. For a time, orphanages replaced the family as the option of choice; institutional care was thought to be safer, more reliable, and more easily regulated. However, by the end of the 19th century it became evident that institutions were not effective as parental substitutes. Children in institutions evidenced signs of increased physical illness, loneliness, and apathy to their surroundings, reactions attributed by many to the loss of consistent adult relationships and their forced separation from extended families and familiar environments ( [Adnopo, 1998](#)).

One of the best-known interventions for the street children of the rapidly growing urban centers were the Orphan Trains conceived by the Minister Charles Loring Brace in the second half of the 19th century ( [Youcha, 1995](#)). Between 1854 and 1929, approximately 150,000 children were transported by train from the burgeoning cities of the East Coast to the Midwest ( [Rosenfeld et al., 1998](#)). Brace believed earnestly that by placing children with hard-working farm families he would rescue them from their poor, urban conditions and provide them with a more healthy lifestyle. In return, they would provide an important source of farm labor. However, the yearning to maintain their relationships with their families of origin made it difficult for some children to adjust to life thousands of miles away from parents and

siblings. As a consequence, many children made their way back to the communities from which they had come.

The antidote to the failure of the widely publicized Orphan Train movement was the idealization of the family. In 1909, a White House Conference on the Care of Dependent Children ended with the strong endorsement of foster families as the most promising alternative for children whose parents were unable to care for them. The conference did little to settle the controversy. The question of who should care for children when parents appear unable to do so has continued to be a subject of intense debate to the present time, even though for more than 30 years federal child welfare policy has been designed to reduce the numbers of children placed outside of their homes by encouraging states to provide a range of community-based services to maintain children with their families.

In the 1970s, the adoption of state and national child abuse and neglect statutes codified child protection policies and practices concerning the removal of abused, neglected, and at-risk children in all 50 states. The passage of the Adoption Assistance and Child Welfare Act of 1980 (Public Law 96-272) ([Hegar, 1993](#)) was designed to assist families to improve their parenting capacity. Although the act made permanence a central goal for all children entering the child welfare system ([Wells and Tracy, 1996](#)), policies that address the most appropriate means of ensuring permanency for vulnerable children continue to evolve. The Adoption Assistance and Safe Families Act of 1997 provided financial incentives to states to discourage foster care drift and ensure stability, safety, and permanence for high-risk children who often were without long-term plans. During the 1990s, several pronounced and disturbing trends emerged concerning children involved in the foster care system that raised questions about its efficacy as an intervention and treatment option for high-risk children. Over this period, the age of children in out-of-home care has decreased; one-fourth of all children entering the foster care system in the five largest states were younger than 6 years of age ([Berrick et al., 1997](#)). In addition, children entering foster care were more likely to be victims of trauma and to have chronic medical conditions and mental health disorders (Brereton, 2001, unpublished Master's thesis), and they often failed to receive the health care necessary to mitigate these problems while they were in care. Children placed in foster care also were likely to experience more than one placement; for example, in Connecticut, the average number of placements for every child who enters the system is 3.5 (Martin S, personal communication, 1999). Child Welfare data released in 1998 found that 66% of the children in the child welfare system who were placed outside of their homes were eventually reunited with a family member; however, their families may not have received any services while they were in placement or been provided any assistance in preparing for the child's return (Adnopoz and Ezepchick). Disturbingly, the care that was available while the child was out of the home was likely to be fragmented and episodic. As children moved from place to place, their social and medical histories often were left behind, leaving the new caregivers unprepared, uninformed, and at a loss to cope with behavioral or medical problems as they arose.

At the same time that children have been placed out of their homes, only to be returned to an unchanged home environment, many states have been faced with both a shortage of institutional beds and an inadequate supply of licensed foster homes into which children could be placed. The combined weight of these factors increased the interest in and support of child-centered, family-focused interventions as important alternatives for children for whom out-of-home placement was seriously considered. Traditional outpatient mental health resources, such as office- or clinic-based treatment, did not prove to be a good fit for work with chaotic, distrustful, multiproblem families in which children and parents have multiple, competing problems, including serious mental health disorders, many of which are reactive and cannot be relieved without concurrent changes in the environment.

With the support of advocates such as The Edna McConnell Clark Foundation, states were encouraged and funded to implement programs that could maintain children in their own homes and communities, promote permanency for the child, reduce the probability of placement outside of the home, and prevent the inevitable problems associated with foster care drift ([Nelson, 1996](#)). Homebuilders, a model-intensive, home-based intervention developed in Tacoma, Washington, was prized and endorsed by funders and policy makers because the program developers attempted to address the complexity of the interactions between the child, family, and environment and, as a result, demonstrated the ability to reduce placements. The belief that children who were maintained in their own homes would represent cost savings to taxpayers also supported the popularization of family preservation services.

## INTERVENTIONS THAT SERVE THE CHILD AND FAMILY IN THE HOME

Home-based services had their origins in the 19th century, when friendly visitors representing charitable organizations called on families to determine their needs and to work with them to increase their self-sufficiency. Many of these methods were adapted by social workers in the early years of the 20th century who recognized the advantages of entering and observing the family's environment at first hand and mobilizing natural, community-based networks ([Wells, 1995](#); [Woodford, 1999](#)). When clinicians enter the diagnostically rich, textured, and highly personal environment of the home, they are able to step directly into the family's own ecosystem. With their observations, they can piece together a tapestry of knowledge about the real-world experiences of the child and family that not only may facilitate treatment, but is likely to be unavailable to those working in traditional examining rooms (Adnopoz and Culler). The process of working in the home enhances the clinician's ability to understand and address the complexity of the dynamic reality that constitutes the everyday world of both child and parents.

Although the families in which children are at high risk for out-of-home care may be difficult to engage, distrustful of the traditional, clinic-based mental health system, and often unable to maintain regular appointment schedules, clinicians have found that they are more likely to become supportive of and consistently involved in their child's treatment and recovery when clinically informed and appropriate mental health services are delivered directly in the home and community (Adnopoz and Ezepchick, 2000; [Woodford, 1999](#)). Evidence supports in-home, family-focused intervention as a necessary component of comprehensive services developed for children and youth with problems of mental health, substance abuse, and delinquency ([Fraser et al., 1988](#); [Harrison et al., 1999](#); [Henggeler and Borduin, 1990](#); [Kaufman and Kaufman, 1992](#)). Many of the programs that have been studied offer sustained, relationship-based services that usually address three domains: parent–child, and child functioning ([Heinicke and Ponce, 1999](#)). Their success has enabled in-home intervention and treatment to emerge as an effective means of engaging difficult-to-reach families and preparing them to make better use of more traditional treatment modalities.

## IN-HOME PREVENTION AND EARLY INTERVENTION PROGRAMS

Provence ([Provence et al., 1983](#)), a pioneer in the use of home visitation as part of a comprehensive intervention for single, poor, inner-city mothers, was among the first researchers to find that mothers and children who received sustained services from a consistent group of providers through the child's first 30 months of life had positive, long-term outcomes in several domains compared with nonintervention control subjects. At the end of the intervention, children in the experimental group scored higher in language development; at the time of the 5-year follow-up, these children demonstrated higher school achievement and better school attendance, and were more task oriented. At the 5-year follow-up, mothers had fewer additional pregnancies, were more likely to be employed, had improved their socioeconomic status, and had made better use of community support resources. After 7½ years, mothers had completed more years of education, were more likely to be self-supporting, had more satisfying personal relationships, and had waited longer to have a second child. Mothers who received the intervention were more responsive to the needs of their children and reported a more pleasing relationship with them. ([Provence et al., 1983](#))

David Olds ([Olds et al., 1999a](#)), who began his work in Elmira, New York, continues to test his model of nurse-delivered in-home visitation for pregnant and parenting, single, poor, primiparous mothers with few social supports in multiple settings throughout the United States. Designed as a preventive public health intervention to affect the quality of parenting, prevent abuse, and improve maternal and infant health, Olds' initial randomized study in Elmira found that after 2 years of a structured, curriculum-driven home visitation program that included parent education, mothers had fewer preterm deliveries, smoked less, and had fewer kidney infections compared with community control subjects. Infants had higher birth weights and a 4.86-point increase in IQ at 3 and 4 years of age. The quality of the mother–child relationship was enhanced, and mothers provided more play material and used punishment less. In addition, the mothers in the Olds study were also able to make better use of their own partners as well as community supports. Children also were seen in the emergency department less frequently and had fewer accidents than the control group. These findings were sustained at the time of follow-up when the children were 15 years of age. Reduced incidences of child abuse and neglect also were found at 2 and 15 years of age. At the time of the 15-year follow-up, children in the experimental group were considerably less likely to have been arrested, use alcohol, smoke cigarettes, or have multiple sex partners ([Olds et al., 1999b](#)). When the children were 15 years of age, mothers in the intervention group were reported as less impaired by drug and alcohol since the birth of the index child ([Olds and Kitzman, 2000](#)). The initial study was replicated in Memphis, Tennessee with a primarily urban, African-American population, where many of the effects of the Elmira study were replicated, although the effect size was somewhat smaller. The number of health care encounters for injuries and injections was 23% lower than in the control group, and the number of hospital days required for serious injuries was significantly less. Olds reports that there were no differences in parents' reports of child behavior problems in either study. An economic analysis conducted by the Rand Corporation found that real economic benefits were accrued by the fourth year of life for low-income children; this finding did not hold for families of higher socioeconomic status and married women ([Olds and Kitzman, 1993](#)).

[Heinicke and Ponce \(1999\)](#), in a careful review of numerous early intervention studies, find considerable evidence to support the effectiveness of home visitors in improving maternal self-concept and satisfaction and enhancing the responsiveness of the mother to the needs of her infant ([Cicchetti and Toth, 1998](#)). One comprehensive program studied by [Lally et al. \(1988\)](#) used a home visitor, child development centers, and parent associations to address parent–child and partner relationships and child development. The intervention began in the prenatal period and continued until the child's fifth birthday. Children in the program scored higher on the Binet IQ at 36 months, although there were no cognitive or intellectual differences at 60 months. At a 10-year follow-up, program parents had a more positive capacity for relationships and more positive self-development. They reported feeling proud of their children's accomplishments and encouraged by their autonomy and

achievements. The girls in the program were more successful in school; boys and girls had lower rates and less severe forms of delinquency. Parents of premature infants in two separate studies by [Nurcome et al. \(1984\)](#) and [Minde et al. \(2001\)](#) received in-home and in-hospital services targeting parent–child interaction and mastery of parental tasks. They found that mothers demonstrated better relationships with their infants, were more responsive to them, and fostered the child's autonomy at 1-year follow-up.

The UCLA Family Development Project ([Heinicke et al., 1999](#)) demonstrated that a randomized home visiting relationship–based intervention for pregnant women in their third trimester who were classified as at high risk for inadequate parenting was able to effect experienced partner and family support by infant age 12 months compared with control subjects. In addition to home visiting, the experimental group participated in a weekly mother–infant group; the control subjects received regular pediatric follow-up. Children in the intervention group were more securely attached and more autonomous at 1 year and were encouraged by their mothers to be more task oriented. The intervention did not affect maternal depression or anxiety, although continued follow-up at year 2 may reveal statistically significant between-group differences. Heinicke and colleagues point out that the ability to achieve sustained effects with inadequately functioning families depends on the capacity of the intervention to address the adaptation needs of the parents ([Heinicke et al., 1999](#)). Although several programs cited by Heinicke and Ponce (1998) found that positive early cognitive differences between experimental and control groups tend to disappear by 36 months, other child differences remain over time. Studies of an intervention in Houston found that program boys had better peer relationships as preschoolers and were less impulsive, obstinate, and restless as elementary school students. An intervention for pregnant African-American teenagers that lasted until the infant's third birthday found that the children were in better health and were more socially adept and self-confident. Mothers used more appropriate discipline and means of control and in general were more responsive to the needs of their children ([Black et al., 1994](#)).

These studies demonstrate that sustained, relationship-based, in-home visitation can be effective in improving maternal competence and enhancing maternal capacity to enter into positive relationships, use partner and community supports, and attend to issues of self-development. In addition, preventive in-home services encourage more effective maternal responses to limit setting and the use of appropriate controls, as well as to the promotion of the child's autonomy, capacity for exploration, task orientation, and cognition. These studies also have demonstrated the centrality of the sustained relationship between the mother and the intervener in achieving the desired outcomes. The development of a trusting, accepting alliance provides the means through which behavioral changes can occur. The process variables associated with positive outcomes are the duration of the contact between mother and home visitor, the extent of the focus on issues of parenting, the mother's attitude, her willingness to work with the visitor, and her view of the visitor as helpful ([Korfmacher et al., 1998](#)).

## TARGETED IN-HOME INTERVENTIONS FOR HIGH-RISK CHILDREN

### Family Preservation

Family preservation and support services for families in which children are at high risk of out-of-home placement for reasons of abuse or neglect have been available for more than a decade. The Homebuilders program serves as a well replicated prototype, although variations on the model have proliferated across the United States ([Lindblad-Goldberg et al., 1998](#)). Family preservation programs are time limited (approximately 12 to 16 weeks), relationship-based, family-focused, child-centered, small-caseload, flexible services that are available to families 24 hours a day, 7 days a week. They are designed to prevent unnecessary out-of-home placements or promote family reunification by assisting parents to address their own needs and those of their children (see [Chapter 122](#)). Although most studies have shown that placement is prevented for 75% to 90% of the children receiving services, attempts to determine the effectiveness of family preservation programs have been limited by small effect sizes, the lack of randomized, controlled studies, and inadequate program standardization, all of which call into question the adequacy of both the programs and the research methodologies that have been used to evaluate them ([Burns et al., 2000](#)).

### Multisystemic Therapy

Since the early 1990s, family-focused, in-home services have been specifically tailored to meet the needs of children and adolescents with problems of mental health, delinquency, or substance abuse. Several randomized clinical trials have tested these models and found them to be effective in decreasing problem behaviors, improving family functioning, promoting the recovery of the index child, and reducing the need for more costly out-of-home placements, either in hospitals or residential programs. [Henggeler and Borduin \(1990\)](#) have developed a curriculum-driven, home-based therapeutic approach they call *multisystemic therapy* (MST), which has demonstrated its effectiveness with chronic juvenile offenders, adolescent sex offenders, and substance-abusing delinquents. MST directly addresses the interpersonal and systemic factors that are associated with adolescent antisocial behavior ([Henggeler and Borduin, 1990](#)) and considers the child's view of his or her world as well as the direct and persistent influence of family, peer, and school environments. Sessions are held frequently in the child's home and in the community; services are time limited and are designed to empower parents to understand and manage behavioral crises as they may arise after the intervention. The Missouri Delinquency Project examined the long-term effects of MST on the prevention of criminal activity in a sample of predominantly serious juvenile offenders by comparing MST with individual therapy, and demonstrated positive effects on perceived family relations, family interactions, parental symptomology, interfamilial conflict, and the youths' behavioral problems. The intervention also produced long-term changes in the youths' criminal behaviors. MST's focus on the child's ecology differentiates its approach from more traditional interventions with children in the juvenile justice system. Central to the success of Henggeler's programs has been an understanding of the familial and social contexts in which children function and by which they are strongly influenced, and a willingness to address the contextual issues in a structured curriculum. [Borduin et al. \(1995\)](#) suggest that improved family functioning, a result of in-home and community services, was the primary influence on the reduction of criminal behavior in the Missouri study.

[Henggeler and colleagues \(1999\)](#) have reported on a study to determine whether MST could be modified effectively for use with children presenting with psychiatric emergencies and used as an alternative to psychiatric hospitalization. Based on the hypothesis that the child's family plays a central role in predicting and preventing the need for hospitalization, and that behaviors are socially and ecologically influenced, Henggeler and colleagues designed and tested an intervention for children 10 to 17 years of age who were approved for emergency psychiatric hospitalization at the Medical University of South Carolina. These youths were randomly assigned to either an MST experimental condition or to hospitalization and aftercare. To serve this population more effectively, one child and adolescent psychiatry resident and several crisis caseworkers were added to the usual MST treatment team of master's-level clinicians and a single supervisor to provide coverage 24 hours a day, 7 days a week. Services were provided in the homes of family, relatives, or friends, and in community shelters, respite beds, or hospital. Caseloads were reduced from the MST standard of five families per clinician to three. In the beginning of the project, all cases were supervised daily by a child and adolescent psychiatrist; this was reduced later to three times weekly. Children in the experimental group had judicious and controlled access to community resources, including hospitalization and therapeutic foster care. Children in the control group received treatment as usual, often using some of the same resources.

[Henggeler et al. \(1999\)](#) report that MST was at least as effective, and in some cases more effective than emergency psychiatric hospitalization at decreasing child symptomology. Rates of decreased internalizing problems were similar across the two conditions; MST was more effective in decreasing rates of externalizing symptoms. Youths in the control condition reported increased self-esteem, whereas families in the experimental condition showed improved cohesion and increased structure. The researchers note that youth with serious psychiatric problems and their families presented with greater complexity and problem severity than they had expected based on their previous work. Further study, some of which already is in progress, is needed to address the issues raised by this evaluation ([Henggeler et al., 1999](#)).

### Wraparound

The concept of wraparound services that place the child in the context of the family as well as his or her broader social ecology emerged from the CASSP, which was dedicated to the creation of interagency collaborations, community-based, advocacy-oriented systems of care, and the expansion of parental decision making and involvement to meet the multisystemic needs of children with serious emotional disturbances ([Woolston and Berkowitz, 1998](#)). Theoretically based in environmental ecology, wraparound stresses unconditional care and the belief that changes in the environment will foster changes that persist over time for children, families, and communities ([Burns et al., 2000](#)). Wraparound is a strength-based process of intervention that values parental empowerment, culturally competent providers, and the use of natural supports to augment professional involvement. Outcomes are measured against goals established by the family. Unlike MST, wraparound teams are led by a bachelor's-level resource coordinator who does not provide clinical care; the quality of clinical care depends on the resources of the local system of care. Leadership in the MST model is provided by a master's- or doctoral-level clinician who acts as a family therapist. Wraparound services have no time limit, are available 24 hours a day, 7 days a week, and are provided in home, school, clinic, and community. In comparing the effects of MST and wraparound, [Burns et al. \(2000\)](#) found a need for randomized effectiveness trials to demonstrate the effectiveness of wraparound in light of the speed of its national replication, the observable variations in its implementation, its potential for cost savings, and the increasing availability of standards and measures of fidelity.

## IN-HOME SERVICES FOR CHILDREN WITH PSYCHIATRIC DISTURBANCES

Although research on the effectiveness of home-based intensive clinical services for children with serious emotional disturbances is limited, there is some indication that these services can enhance child and family functioning and prevent crisis-driven hospitalization of children. ( [Lindblad-Goldberg et al., 1998](#) ). As a result, programs incorporating elements of family preservation, MST, and wraparound have attracted interest as potentially useful alternatives to more restrictive and expensive out-of-home treatment facilities. Many state agencies, managed care companies, and private payers have endorsed home-based psychiatric services as effective both clinically and fiscally, and have added them to the existing local continuum of care.

## THE YALE IN-HOME CHILD AND ADOLESCENT PSYCHIATRIC SERVICE

The Yale In-Home Child and Adolescent Psychiatric Service (YICAPS), an intensive, in-home, goal-oriented intervention for children with serious emotional disturbance, represents an integration of theory and clinical practice that is guided by principles of developmental psychopathology, attachment, object relations, cognitive-behavioral, and family systems theory, and the process of wraparound. Children referred to YICAPS may be in the process of discharge from hospitals or residential treatment facilities, or their admission to such institutions may be preventable as a result of the intervention. It is funded both by managed care, as a strategy for reducing the need for more costly treatments, and by the state agency responsible for children's mental health services. The basic tenets of a medical model are essential to the program's design. Services are provided by teams consisting of a master's-level clinician (social worker, nurse, or psychologist) and a mental health counselor, who may have a nonclinical degree, both of whom work under the direct, weekly supervision of a child and adolescent psychiatrist or experienced clinician. A child psychiatrist assumes medical responsibility for the care of all patients and presides at weekly rounds. Treatment is focused on specific, defined problems that are viewed as amenable to measurable amelioration.

### Principles of Intervention

The unfolding interaction between the child and his or her psychosocial environment is seen as comparable in importance with any of the child's individual characteristics. As a result, all evaluations and assessments are considered simultaneously at the level of (a) individual child and family functioning, (b) the child's home and community environment, and (c) the child's and family's social networks. Human relationships are viewed as the mediating agents for behavioral and environmental change. Critical relationships exist on multiple levels: between the child and the family, between the team and the child and family, between the family and its physical environment, and between the child, the family, and the community. The ability to understand and address the complexity of the interactions among these levels is central to the success of the child's treatment.

The approach to the work is child centered and home and family based, relying on the development of a therapeutic alliance between the family members and the team to ensure progress toward the established goals. Goals common to all cases include stabilization, improved child and family functioning, and preparation for entry into more traditional, less intensive forms of community-based outpatient treatment. Each treatment plan respects the individuality of the child and family and is developed in partnership with them. The team works with the family to achieve the lowest level of change necessary to improve and sustain the child's more adaptive functioning and ensure his ability to remain in his or her home and community.

With the engagement and support of the managed care coordinator or the state agency staff member, each of whom are enlisted as collaborators in the work, the program is sufficiently flexible to allow for a titration of intensity from 3 to 20 contacts per week and to maintain involvement with the child and family for as long as clinically appropriate. In some rare instances, contact with the family has continued for upward of 18 months. However, the overarching YICAPS aim is to move the child and family to self-sufficiency with deliberate speed so that their need for intervention is as short and at the lowest level of intensity possible ( [Woolston and Berkowitz, 1998](#) ).

The Yale Children's Psychiatric Inpatient Service (YCPIS) has been an important collaborator with and contributor to the development of YICAPS, and the principles that guide the work on the unit have been applied successfully to the work in the child's and family's home. Because the child's behavior and long-term developmental course are recognized as context dependent, understanding and addressing the "goodness of fit" between the child's needs and his or her environment is a central task of staff in both institutional and home settings. While in hospital, the child can be helped to shift to a more functional developmental trajectory through the engagement of his or her family, school, and other treatment providers. During the period of the child's hospitalization, the family also is engaged in therapy and presented with opportunities to alter dysfunctional behavioral interactions with the patient and other family members. In addition, school personnel and outpatient providers are asked to participate in treatment planning so that they can be informed of the insights and information acquired by unit staff during the child's hospitalization. Similar strategies are used by YICAPS either after discharge or while the child remains in the home. The result is a program that integrates a well defined medical model with an ecologically oriented and family-focused approach to meeting the needs of seriously emotionally disturbed children and adolescents.

### Program Elements

The YICAPS program is characterized by six basic elements that can be augmented by others services as deemed necessary in each child's and family's individualized plan of care:

1. The core services, including home-based evaluation, individual and family psychotherapy, parent guidance, case management, crisis intervention, and medication management, are provided consistently by the two-person clinical team with the guidance and support of a child and adolescent psychiatrist.
2. In partnership with the family, the team assesses the strengths and the risk factors present in the home and in the environment to bring to light the factors that may influence the treatment.
3. The tasks of the team include developing collaborations and linkages with the resources and systems in the community with which the child is involved, including but not limited to the extended family system, health and mental health care providers, schools, and faith-based organizations, and assisting the family to advocate for their own interests with these systems and institutions.
4. The team joins with the child and family to develop and implement a treatment plan that meets with the approval of the managed care company or state funding agency and addresses the therapeutic, environmental, and concrete needs identified in the initial assessment.
5. Services are titrated in both intensity and duration to be responsive to the needs of the child and family.
6. The team is available 24 hours a day, 7 days a week to respond to child and family crises. Response may range from telephone consultation to in-home services.

### Who Benefits

The primary beneficiaries of the YICAPS approach are three distinct groups of children. The first group consists of children who are being discharged from psychiatric hospitalization and may require temporary but intensive services to sustain the behavioral and emotional gains they have made as inpatients. These children may have successfully negotiated the crisis that necessitated their hospitalization, but are returning to unaltered environments that may not promote their continued recovery. In these cases, the primary goal of the in-home treatment is to continue and expand the treatment begun on the hospital unit and to engage the child's school and other community resources more intensively. The longer-term goal is the prevention of rehospitalization or placement in a residential treatment facility. A second group of children are those whose behavior is so seriously out of control that they become candidates for acute hospitalization. These children may be referred to YICAPS from home, school, clinic, or emergency department. The immediate goal of the home-based team is to join with the family and the source of the referral to assess the family's capacity to work with the team and ensure the safety of the child in the home. If the family is able and willing to maintain the child at home, the team and the family develop a crisis intervention plan that will lead to the establishment of more distal goals as the therapeutic alliance deepens and the underlying psychodynamic and individual issues come into view. The third group of children for whom home-based services are a particularly viable option are those with serious emotional or behavioral disorders for whom traditional outpatient treatment or partial hospitalization has been insufficient or unsuccessful. Services delivered in the home to both the child and family augment these out-of-home services rather than supplant them, and, in fact, may enhance their use and effectiveness. By entering the family's psychosocial environment, the in-home team is presented with an invaluable opportunity to identify and address the issues and concerns of the child and the adults that serve as latent barriers to the appropriate use of community resources. When these obstacles are overcome, the child and family can return to more traditional treatment modalities.

### Outcomes

Outcome data from a sample of 138 successive cases indicate that the program has been particularly effective for youth who present with diagnostic comorbidity, severe impairment, and extensive psychosocial adversity and are in greatest need of acute psychiatric stabilization. YICAPS intervention for a mean of 19.25 weeks resulted in successful diversion from psychiatric hospitalization for 42% of the children served, and a reduced length of stay among the 26% of children who required

rehospitalization. Clinical improvement over the course of home-based treatment was evident in statistically significant changes in psychosocial functioning. Most children attained stability during the course of treatment. A small proportion experienced decreased levels of functioning, whereas a somewhat larger minority experience functional improvements. The most common admitting diagnoses among the 108 children served in fiscal year 1999 to 2000 included disruptive disorders such as attention deficit/hyperactivity disorder and oppositional defiant disorder (ODD), depressive disorders, parent-child relational problems, and posttraumatic stress disorder. Children also have been referred to YICAPS with diagnoses ranging from anxiety to pervasive developmental spectrum disorders. Patients were more likely to be male (58.3% to 41.7%), live in a one-parent families (64.8%), and be white (59.2%). African-American children comprised 16.6% of the 108 children served in 1999 to 2000, whereas 21.2% were Latino. Forty-eight percent of the children were between 6 and 11 years of age; 38% were between 12 and 19 years, and 3.8% ranged from 0 to 5 years of age. A study of 97 cases in which data were available revealed that 69% of the cases were significant for history of abuse, and 65% for parental psychiatric history. Parental substance abuse and domestic violence were present in 44% and 37% of the cases, respectively.

---

#### CASE ILLUSTRATION: JORGE

*History:* At the time of his referral to YICAPS, Jorge was a 15-year-old Hispanic boy who lived with his adoptive mother, her biological daughter, age 10 years, and a brother, age 22 years, also adopted. His biological mother, a woman with a psychotic disorder and known to abuse substances, placed him at the age of 6 years with a family friend who became his adoptive mother. Jorge's primary symptoms were paranoid and aggressive behaviors, particularly directed toward his adoptive mother. Before the YICAPS referral, Jorge been had hospitalized nine times in a period of 3 years, often after acts of violence toward his adoptive mother. In addition, he had been in several partial hospital programs and had been enrolled in a therapeutic school for the past 18 months. His hospitalizations always were preceded by a period of noncompliance with his medication regimen. Without his medication, Jorge evidenced a mixed manic state characterized by out-of-control behavior. Jorge entered the mental health system at 7 years of age, shortly after his mother had placed him out of her home. At 12 years, he was diagnosed with bipolar disorder after a psychotic episode. At that time, Jorge accused his older brother of sexually molesting him and a restraining order subsequently was put into place. As a result, the brother moved to a nearby apartment; although the two saw each other daily, they did not speak.

*Assessment and Goals:* A YICAPS assessment found that although Jorge was being seen in weekly supportive therapy with his adoptive mother, the sessions were focused on her descriptions of Jorge's bad behaviors. Jorge was intermittently compliant with a medication regimen that consisted of 600 mg of valproate orally twice a day and risperidone, 2 mg orally twice a day. He did not have a treating psychiatrist at that time. The YICAPS team learned that Jorge was not taking his medication, which appeared to be linked to both his mother's anxiety and her controlling and intrusive behavior. In addition, he was attending school only intermittently, no more than three times weekly. The clinical formulation recognized that Jorge was becoming increasingly frustrated and angered by his mother's intrusiveness and retaliated by not taking his medication and not attending school regularly.

With Jorge and his mother, the YICAPS team set the following goals for the intervention: (a) establish consistent psychiatric care, (b) ensure compliance with medication, and (c) decrease truancy. The development of the therapeutic alliance that would be of singular importance to the success of the work required that the team join individually with Jorge and his mother. The team agreed with Jorge that he could give up his valproate if he would continue to take his risperidone and would agree to see a child psychiatrist consistently for medication monitoring. The team agreed with Jorge's mother that a meeting between Jorge and his brother, when the patient was ready to do so, might be a long-term family goal.

*Treatment and Outcome:* In recognition of the treatment needs of both the patient and his mother, one member of the YICAPS team was assigned to provide individual psychotherapy for Jorge, while another provided both individual treatment and parental guidance for his mother. Although it was difficult for his mother to give up control, she was able to accept Jorge's age-appropriate need for independence and autonomy and agreed to help him to find less self-destructive pathways for the discharge of his anger and feelings of inadequacy, powerlessness, and victimization. At the time of discharge from YICAPS, all of the goals established with the family had been met. Jorge had not been rehospitalized, he was meeting with his treating psychiatrist regularly, was compliant with his medication regimen and was attending school daily. At a 3-month follow-up, he had not been hospitalized and was still attending school daily. His mother had joined a long-term parent support group for parents of adopted children and was attending a NAMI (National Alliance for the Mentally Ill) group. Jorge and his brother had not yet spoken to each other.

---

---

## SUMMARY

The YICAPS treatment model derives from a strongly held belief that the most promising approach to children with serious emotional disturbances lies in illuminating, understanding, and addressing the complex set of internal, familial, peer, and social interactions that characterize each child's ecology. The YICAPS approach promotes the development of a supportive relationship with the child and family and recognizes that behavioral changes are most likely to be mediated through the ensuing therapeutic alliance. Although YICAPS has begun to demonstrate that good treatment outcomes are associated with the capacity to sustain the intervention as long as clinically necessary, randomized studies of interventions such as YICAPS are required if their value to children with serious emotional disturbances is to be understood. There is a developing literature that provides evidence of the benefits of home- and community-based interventions for dealing with high-risk, vulnerable children and that speaks to the importance of providing carefully constructed and standardized programs that are monitored for treatment fidelity. The future support of effective, home-based mental health services such as YICAPS depends on the ability of program planners to develop and test interventions that demand specific, quantifiable standards while allowing for the clinical flexibility that defines the work.

[Conclusions](#)  
[Chapter References](#)

The continuum of services offered by child welfare programs presents a challenge to mental health professionals. Services have been developed to serve a diverse group of children and adolescents with multiple and varied needs. The sheer numbers of children needing assistance and the needs of those children at times overwhelm the system that is designed to serve and protect children. The number of children in foster care peaked in the 1970s, declined through the early 1980s, and rose sharply from the late 1980s until leveling off at about half a million children in out-of-home care in the mid-1990s. This represents growth in federal foster care expenditures from \$309 million to \$3.13 billion during the same period. By 1999, federal foster care expenditures were expected to have increased by 1,300% from the 1981 level ([Courtney, 1997](#)).

Children who present with problems that require more than minimal services contribute to the problem of too few services for too many children in the present child welfare system ([Lifting the Veil, 2000](#)). Child-serving agencies often turn to child mental health professionals for consultations or technical assistance as they try to serve children presenting with severe emotional problems. This chapter offers practical advice to the mental health clinician who is called on to provide consultation to child-serving agencies such as foster care homes, residential group homes, emergency youth shelters, domestic violence shelters, and Big Brothers and Big Sisters programs.

## THE CONTINUUM OF SERVICES IN CHILD WELFARE

The child welfare field has evolved into a complex, multidimensional matrix of services and programs since the early 20th century. A continuum of services has developed that vary in level of intensity although these programs and services may vary from community to community and state to state ([McCroskey and Meezan, 1998](#)). In the least intense mode, child advocates lobby for and support policy initiatives that seek to improve or maintain children's rights. Services include community-based emotionally supportive programs offered to children and their families, such as family-centered childcare facilities, school-based health clinics, and support groups. In a moderately intense mode, home-based intensive family preservation services are offered to at-risk families in need of specialized assistance such as respite childcare, services for developmentally disabled children, or adolescent pregnancy/parenting services. Families in crisis or at risk of dissolution may be in need of family-centered services designed to preserve families through intensive home- and community-based intervention. More intensive services may use out-of-home placement of children to provide for the care of children whose parents cannot or have not provided those children with an adequate level of care ([Berrick, 1998](#)). Out-of-home placement varies in intensity in that children may be placed into a foster care setting with relatives (kinship care), licensed foster parents, an emergency youth shelter, a group home, or a more institutional setting such as a residential treatment center.

Youth shelters, group homes, and foster homes are representative of a portion of the child welfare service continuum. Various providers of these services may call on mental health professionals for assistance, because these programs typically do not include mental health professionals as staff members. Even so, many of the children and youth that they serve present with a wide range of problems, including behavior commonly dealt with by mental health providers in more intensive programs, such as community mental health centers, residential treatment centers, and hospitals. Children and youth rarely present themselves for emergency psychiatric services ([Halamandaris and Anderson, 1999](#)). It is very likely that child welfare agencies are the referral source of children and youth in need of emergency psychiatric services. There is empiric evidence suggesting that the prevalence of psychopathology among children in family foster care is higher than would be expected in a typical population of children or children from deprived backgrounds ([Pilowsky, 1995](#)). Leon and associates (2000) found that residential treatment centers serving children and youth frequently refer low-risk individuals for psychiatric hospitalization, suggesting that the residences are struggling to meet clients' needs. The findings of a recent study in Britain revealed particularly high levels of serious psychiatric disorder, comorbidity, and a significant number of undetected, potentially treatable psychiatric disorders in 13- to 17-year-old adolescents living in residential or foster care ([McCann et al., 1996](#)). The demand for psychiatric consultation with this population is significant. Continuing trends suggest that demand will not decline in the near future.

## WHAT IS CONSULTATION?

[Kadushin \(1977\)](#) offers a list of representative definitions of *consultation* from the human services literature. For the purpose of this discussion, Boehm's definition appears to be the most useful:

Consultation is an educational process whereby expertness in knowledge or skill is made available for the purposes of help with the solution of a problem by the provider of the consultation to the recipient of consultation, the latter assuming the responsibility for seeking the consultation and the use, nonuse or partial use of the fruits of the consultation ([Boehm, 1956](#), p. 241).

This chapter concerns itself with the "expertness in knowledge and skill" that relates specifically to the area of child and adolescent psychiatry. This is an important distinction, as many times consultation is requested related to agency functions or problems that are not specifically related to the area of knowledge and skill in child psychiatry. For example, the consultant may be asked to offer help regarding dealing with employee absenteeism. Although the consultant may wish to explore the area further in order to clarify clinical issues (are employees not coming to work because they are feeling too frustrated with the clients?), it is important to remember that employee absenteeism may be a problem that requires "expertness in knowledge and skill" that is outside of the realm of child psychiatry. Consequently, the consultant may find himself or herself acting to refer agency personnel to other "experts" (e.g., employee assistance programs) for help. The consultant may spend a great deal of time helping agency personnel refine questions so that the core problems or issues can be addressed.

## TYPES OF CONSULTATION

It is unlikely that the consultant will meet with a specific problem that can be identified easily. If this were the case, the consultant's help probably would not have been requested in the first place. Rather, the consultant may be met by a situation that is uncertain and a group of workers who are very frustrated because their attempts to intervene may have failed. In fact, unsuccessful intervention may have worsened the situation. The first task of the consultant is to ascertain the type of help that is needed; it can be categorized into one of two types: (a) *clinical* consultation and (b) *programmatic* consultation.

Clinical consultation is usually related to an individual person, family, or group. By and large, the consultant is asked to "reveal" information about the person, family, or group that will somehow improve the agency's ability to serve that particular "unit of intervention." Quite often, clinical consultation takes place on the "turf" of the consultant. For example, a foster mother may be having a difficult time dealing with the behavior of a child and may ask the child welfare worker to arrange for a meeting with the consultant to discuss alternatives for dealing with the child's behavior. The foster mother then meets with the psychiatric consultant at the local child guidance clinic for several sessions in order to make use of the clinician's insight and recommendations related to the foster child.

Programmatic consultation usually relates to groups or classes of persons who are served by the provider. This type of consultation may be offered on the consultant's "turf," but it is usually offered on-site through actual observation or participation by the consultant. Both types of consultation are directed toward

improving services, but the goals may differ significantly in that clinical consultation is directed toward smaller, specially identified units of intervention. Programmatic consultation is directed toward broader organizational change with the goal of improving the care provided or services rendered.

Types of consultation closely related to programmatic consultation are training, education, and supervision of agency volunteers and employees. These types of consultation are covered in more depth elsewhere in the literature but are discussed briefly because they pertain to the programs in the child welfare continuum.

## COMMON THEMES IN CONSULTATION

The mental health consultant should be able to address five closely related themes in most situations. The themes of separation, loss, identity, continuity, and crisis are common to all children who are placed in youth shelters, foster homes, and group homes ([Siu and Hogan, 1989](#)). Children involved in support programs like Big Brothers and Big Sisters programs may have had to deal with some of these issues, although the degree of intensity may be less as they have not necessarily had an out-of-home placement ([Big Brothers and Big Sisters, 2000](#)). A common quirk in the referral process is that the consultant never may be asked directly about any of these themes by the agency or persons asking for help. It is imperative, however, that the consultant be cognizant of the importance of these issues to the children involved in the programs. Further, the consultant should use his or her status as an expert to raise the consciousness of the agency or program staff to the need for consideration of these factors in the day-to-day operation of the program.

A common area of consultation is related to the understanding and management of "acting-out behavior." The consultant should recognize that agency and program staff might often use this term incorrectly; however, that is usually of little consequence. Rather, it is important to recognize that when program personnel describe behavior as "acting out," they may be indicating that they do not have an understanding of this child, or of the child's behavior. This is a cue that the program personnel may be asking the consultant to make use of his or her "expertness" in order to help them understand and deal with the problem child or behavior on both the individual and programmatic level. Helping the program personnel know which behaviors are beyond their scope of intervention also is important. For example, a youth shelter program may not be able to offer shelter to a child who is actively setting fires. Most shelters do not offer the necessary close behavioral monitoring that is imperative in serving children with histories of setting fires. A referral to a more intensive program may be necessary. Shelter personnel may need to be supported in their refusal to admit the child who sets fires. Advocacy for the child may be necessary to assure placement in a program equipped to serve children with histories of fire setting.

In general, the common themes addressed in dealing with children who are being served by these programs are not so different from those themes that are dealt with in evaluating or treating children and youth in the child guidance clinic. One difference is that the consultant is one step removed from the child as the agency or program personnel are assisted through consultation. Another difference is that collateral information, although indispensable, may come from a multitude of sources ([Halamandaris and Anderson, 1999](#)). Deciphering this morass of information may require an inordinate amount of time when scarcely enough time is available to actually examine the child.

## CONSULTATION WITH FOSTER HOMES

Children in out-of-home care have been placed into a variety of settings, including youth shelters, group homes, or foster homes. When children can not be placed with a parent, foster homes are the "placement of choice" whenever possible, because it is felt that they offer the most home-like environment for children who have often experienced significant turmoil in their lives and required protective service intervention. Foster homes offer latency-age and younger children an environment that is temporary in nature and that offers the child the care and nurturance that is needed at the time of placement. Persons who become foster parents must go through a procedure of licensing, but they usually do not have any special training in dealing with children, except for their own life experiences. In recent years, therapeutic foster homes and "special" foster homes (e.g., homes specifically designed for HIV-infected children) have been developed, which make use of foster parents who have a high degree of training. The exact number of licensed foster homes in the United States is difficult to determine, because there is no uniform data set collected by states. The Child Welfare League of America (2000) estimates that there were approximately 300,000 children in foster homes in 1996. This figure is the latest year of a complete data set and does not include children living in residential group care.

Foster parents often are in need of help in order to understand and manage the behavior of children placed into care in the foster home. For example, foster parents may approach the mental health consultant for help with a specific problem they are experiencing with a child, such as nocturnal enuresis. Usually, the foster family has attempted to deal with the problem by making use of their own resources and understanding. If this has failed, they may then approach the consultant for help. It is important, however, that the consultant recognize that the foster parents may also need help with feelings of frustration or failure that they may have because they were unable to deal with the problem on their own. The consultant must consider this as he or she helps the foster family to understand the problem through the use of the knowledge base of child psychiatry. In a sense, the consultant must move through a series of roles as educator, clinician, and "coach" as he or she helps the foster family to deal with the problem at hand.

Child welfare workers may need assistance in understanding the nature of parent-child, sibling-sibling, and grandparent-child attachment relationships and the importance of supporting attachment relationships. Too often, workers underestimate the need for visitation and are not "cognizant of the importance of encouraging and maintaining attachments between children in foster care and persons to whom they are attached" ([Grigsby, 1994](#)). The mental health consultant must remember to advocate for the child's best interest, even if arranging visitation requires a great deal of effort on the part of the child welfare worker.

In some cases, programmatic consultation is requested with regard to the operation of foster homes. The mental health consultant may be asked to train a group of foster parents around some issue or issues pertinent to caring for foster children. For example, a group of foster parents who are providing foster care for adolescents may ask for help with trying to deal with the behavior of these foster children. A time-limited, group-oriented training module for these foster parents on understanding adolescents is one possible option. Information should be presented in such a way that it is specifically related to the children that the foster parents have in their homes. Child psychiatric knowledge should be applied to both the generic and unique situations encountered by these parents. Additionally, the consultant should be prepared to offer consultation to foster parents that is child specific. This may need to be done outside of the group situation, however.

## CONSULTATION WITH GROUP HOMES

Community-based living facilities for youth have come into wide use over the past several years. The Child Welfare League of America (2000) estimates that approximately 48,000 children were living in residential group care in 1996. This figure does not include children in therapeutic settings.

Although group homes have been used for various categories of persons (mentally ill, physically handicapped, recovering substance abusers), this discussion is limited to group homes for clients who are dependent youths, emotionally disturbed youths, and/or socially maladjusted youths ([Shostak, 1987](#)). Group homes of these types usually serve children who have reached adolescence. These facilities are different from residential treatment centers. Their small size, reliance on other community resources such as public schools, and lack of treatment plans indicates that they are more accurately defined as a congregate living facility rather than a therapeutic environment. Between 1965 and 1981 there was a sizable increase in the number of residential group care facilities of this type. Even so, there was a "decrease in the relative proportion of residential group care for dependent, neglected, or abused children and youth" ([Dore et al., 1984](#), p. 493). This was accompanied by a reduction in facility size ([Dore et al., 1984](#)), which suggests that a change in the orientation of services may have taken place during the period of 1966 to 1981. [Dore and Kennedy \(1981\)](#) argued that three major principles affected the delivery of services between 1960 and 1980. The movement toward deinstitutionalization, normalization, and the right to treatment has caused changes to take place within the child welfare system that have greatly affected the clientele and programs at group homes. In a sense, there has been an impetus to improve the services offered in order to meet more effectively the needs of the population served at these facilities. Group home administrators often request consultation to help them:

1. Obtain, retain, and train childcare personnel.
2. Prevent premature discharge or termination.
3. Evaluate and briefly intervene with problem residents.
4. Develop treatment plans and strategies for dealing with seriously disturbed or maladjusted youth placed in the group homes.

The mental health consultant can be most helpful to these programs by focusing on the unique situation of each facility while promoting the generic knowledge offered by the theory base of child psychiatry. In other words, the application of clinical knowledge acts as a guide to help the group home personnel understand the needs and behavior of residents and, to some degree, of staff themselves. The consultant can then guide the program personnel to better serve the group home residents.

The mental health consultant also can be helpful in advocating for these programs. Too often, community members presume that locating a group home in their

neighborhood will have a negative effect. Research indicates that the expectations of negative effects are much greater than what is experienced by neighbors ( [Cook, 1997](#)). Advocating for the establishment of group homes in residential neighborhoods allows for creating a living situation that is more typical of family life and less like life in institutional care.

## CONSULTATION WITH YOUTH SHELTERS

Youth shelters traditionally have been called on to provide safe haven for runaway and homeless youth. The problems of this population group are complex and include severe aggression, conduct problems, and use of alcohol and other drugs at rates substantially higher than nonrunaway and nonhomeless youth ( [Booth and Zhang, 1996](#); [Green et al., 1997](#)). The complexity of presenting problems has created greater pressure on both shelters and the state child welfare agencies to adequately serve youth. Programs designed to shelter children and youth should be equipped to serve children with serious problems, including suicidal behavior and histories of sexual and physical abuse ( [Molnar et al., 1998](#)).

Another complexity in serving runaway and homeless youth in shelters is the difficulty in tracking them to provide follow-up care ( [Pollio et al., 2000](#)). This is typical of children who are commonly referred to as “street youth” (USDHHS, 1998). Many of these children and youth become involved in the sex industry as they struggle to survive on the streets. High-risk sexual behaviors ( [Forst, 1994](#)), substance abuse ( [Greene et al., 1997](#)), and episodic primary health care, if any, are chronic problems of many homeless and runaway youth. Typically, resolution of these problems requires an extended period of contact. Many children and youth will be suspicious of any offer of support or attempt to help. Adults offering help and support to many of these children and youth are likely to have been pimps or pedophiles they met on the streets. Although the initial involvement with those adults may have been positive, it is likely that exploitation was quick to follow because sex and prostitution were expected as “payback.”

Although many of the youth entering shelters have lived with a parent or relative within the past year ( [General Accounting Office, 1989](#)), family life is likely to have been marked by sexual exploitation, mutual aggression, and violence. Simply returning children and youth to parental custody is a naive solution to a terribly complex situation ( [Whitbeck et al., 1997](#)). Many youth entering shelters may have left foster or substitute care situations. A Canadian study found that a significant portion of youth living “on the street” (46%) had left a foster home or other form of government sponsored care ( [Kufeldt et al., 1992](#)).

In spite of the high level of need, service delivery to this population historically has been difficult, and services that are available often have been fragmented or distant. Although some shelters provided basic mental health services long ago ( [Gordon, 1978](#)), many are not equipped to provide these services on site. Mental health consultants may be asked to provide service either on or off site. A model for mental health consultation at shelters for homeless and runaway youth has been developed that makes use of naturalistic methods to provide mental health consultation that is both clinical and programmatic in nature ( [Grigsby, 1993](#)). This model assumes that there is not only a need to understand the individuals who are placed in the shelter, but also a need to understand the “culture” of the shelter environment, if the consultant is to be successful in both the clinical and programmatic senses. This model allows the consultant to enter the “culture” of the shelter in a way similar to that of the field researcher or ethnographer entering a foreign culture and attempting to study that culture as a participant observer. Schein explicates the “clinical perspective” as being different from that of ethnography in that “clinicians enter an organization if they are requested to do so by someone in the organization or someone acting on the organization’s behalf seeking some kind of help” ( [Schein, 1987](#), p. 24). An understanding of the shelter is necessary before any meaningful programmatic consultation can take place. The behaviors of both residents and staff may be better understood as the consultant begins to understand the shelter. Shelter staff begins to accept the consultant as someone who “has been there” and who has an understanding of the day-to-day operations of the shelter. On-site involvement also leads to the formation of relationships between the consultant and residents and between the consultant and shelter staff. The staff and residents will begin to approach the consultant for help as the consultant is accepted as a person who has an understanding of the situation. In order to get to this point, however, many weeks of on-site participant observation may be necessary. Eventually, the consultant will be able to gain enough trust that he or she will be able to offer consultation about residents without waiting to be solicited for advice. As clinical consultation regarding individual residents becomes routine, programmatic consultation can then begin to take place. In one consultation effort at a shelter in New Haven, CT, the rate of unplanned discharge was reduced from 43.5% to 18% within a 6-month period through the use of this model ( [Grigsby, 1993](#)). By taking the clinician out of the clinic and placing him or her in the community, the work of both the mental health professional and the community staff can be enhanced as trust is built. The gulf between the mental health professional and the community staff is reduced, and a statement of the value of the shelter program and its staff is made.

This consultation is not treatment. Rather, it is the use of clinical skills, insight, and knowledge to support those who work on the front line with homeless youth. The consultation helps them to understand the strengths as well as pathology of the individual clients and helps them to gain insight into the group dynamics within the shelter facility itself.

In providing programmatic consultation to emergency youth shelters, the limitations of the facilities and programs may require that the consultant advocate for major change in programming so that the facilities are better able to meet the needs of the children who are referred. In a less sophisticated sense, a consultant may become aware that modifying or altering the present program may still fall far short of what is needed. In these cases, the consultant may need to work toward developing a model or prototype program that will better serve the needs of clients. Advocacy is needed for the creation of shelter care programs for homeless, at-risk youth that are designed to accommodate those with histories of psychiatric problems in need of mental health evaluation and intervention. In order to insure that shelter programs serve the best interests of children, shelters should promote a nonjudgmental philosophy that encourages the admission of children in need while considering the limitations of the emergency youth shelter. Specific recommendations about the types of clients who *cannot* be appropriately served in a shelter care setting may need to be made.

## CONSULTATION WITH DOMESTIC VIOLENCE SHELTERS

Domestic violence is a frequent theme in the families of children being served in the child welfare continuum ( [Findlater and Kelly, 1999](#)). Mothers with children may seek refuge from abuse by entering domestic violence shelters. Since the early 1970s, community-based domestic violence services have grown in size and scope, with the total number of shelters exceeding 1,300 by 1997 ( [National Coalition Against Domestic Violence, 1997](#)). Approximately one-half of the residents in battered women’s shelters are children.

Dealing with “crisis” is common when working with children referred by domestic violence shelters, especially those witnessing interpersonal violence between adult caregivers. Intrafamilial domestic violence can have serious negative effects on children who witness it ( [Edelson, 1999](#); [Fantuzzo and Mohr, 1999](#)). Public awareness of the negative effects of domestic violence on women is growing, and mental health professionals have begun to recognize the needs of children witnessing domestic violence ( [Groves, 1999](#)). Mental health consultants may be asked to evaluate children referred by domestic violence shelter personnel. The impetus for referral may result from to a mother’s request or shelter staff’s expressions of concern about a child’s behavior. Although many children are legitimately traumatized by domestic violence and in need of mental health intervention, shelter staff may attribute children’s behaviors to witnessing violence when the behaviors were present long before any abuse was witnessed. For example, children may lack social skills and appear to be withdrawn as a result. The behavior may be attributed to the child experience of domestic violence when a lack of social skills is the real issue. Consultants can assist shelter staff and, at times, parents in understanding the child’s behavior and intervening when appropriate.

Mental health consultants can be helpful to the shelter staff and the family by providing clinical consultation that allows children to appropriately express their feelings related to witnessing intrafamilial violence and subsequent separation from familiar persons, places (especially school), and pets. Because shelter placement is typically short-term, the mental health consultant can assist with planning for long-term mental health intervention, if necessary, after the family leaves shelter care.

Programmatic consultation helps shelter staff to learn about interventions with children accompanying their mothers. Many domestic violence shelters are part of community-based agencies serving battered women. Some programs may be staffed entirely by volunteers, whereas others may employ social services professionals. Typically, caseloads are high and the focus of the services is on the battered woman, leaving little time to offer child-specific services. Mental health consultants can be helpful in linking these programs with other community-based services for children, including programs oriented toward preventing victimization of children ( [Wolfe and Jaffe, 1999](#)). Advocating for school-based services and other developmentally appropriate intervention strategies can help community-based agencies to better serve children.

## CONSULTATION WITH BIG BROTHERS AND BIG SISTERS PROGRAMS

Big Brothers and Big Sisters of America is the nation’s oldest youth mentoring organization, with programs in all 50 states that match kids with mentors. Founded in 1904, adult volunteer mentors help children “to reach their full potential and fulfill their dreams” ( [Big Brothers and Big Sisters, 2000](#)). Typically, adult mentors are matched with a child from a single-parent home. Mentors and children are usually of the same gender. The programs make use of adult volunteers who have limited

training in working with children but who receive supervision and support from professionally trained social workers employed by the local Big Brothers and Big Sisters programs. These programs may request consultation related to helping volunteers have a better understanding of the needs and behavior of the children that they serve. At times, these programs may request training workshops that are intended to help volunteers have a better understanding of the children who are involved. Training related to the five common themes of separation, loss, identity, continuity, and crisis ( [Siu and Hogan, 1989](#)) may be of value to volunteer mentors as many of these children may have life experiences related to one or more of these themes, especially themes of separation and loss. Consultation also may be requested on a specific child or a specific problem area, such as thumb sucking or fighting with siblings. It is important to remember that the consultant is asked to bring "expertise" on the subject, and that a better understanding of the subject area can be reached if the consultant is able to present the material in a manner that is relevant. In the case of Big Brothers and Big Sisters programs, the presentation should be case specific if possible, as volunteers are likely to be more accepting of the consultation if they feel that the issues are personally relevant. Although a discussion of theory may be fruitful when working with group home or youth shelter personnel, it may not be as useful when consulting with volunteer foster parents or Big Brothers and Big Sisters. Behaviorally explicit, personally relevant, and practical information is most helpful.

## THE LIMITS OF CONSULTATION

As Boehm relates in his definition of consultation, the recipient of the consultation is responsible for the "use, nonuse or partial use of the fruits of the consultation" ([Boehm, 1956](#), p. 241). It is the nature of the consultant's role to have little control over the operation of the consultee's program. In the hospital or clinic setting, the mental health professional has a great deal of responsibility, and to a degree, the concomitant control. The lack of control that is inherent in the consultant's role is at times frustrating to mental health professionals. Even though the consultant may offer concrete advice relating to a situation in a program, the program personnel may choose to disregard the consultant's advice, or to make only partial use of the consultant's advice. A situation may get worse by not using the consultant's advice. The consultant may be sought out for further help at that point, and it may be difficult for the consultant to refrain from expressing his or her displeasure that the initial advice was disregarded or modified. This is the nature of consultation. The consultant may experience a great deal of frustration and at times may be tempted to "take over" as the agency director, supervisor, or foster parent. It is obvious that this is not helpful. Therefore, the consultant must be cognizant of and agree to the limitations of the consultant role from the outset of the consultant–consultee relationship.

## CONCLUSIONS

Child-serving agencies must deal with many children whose needs are varied and broad. Although these agencies are charged with meeting the needs of children, they are at times ill-equipped to do this. When these agencies are overwhelmed or faced with situations of crisis, they may call on mental health professionals for help. Quite often, these agencies have difficulty in articulating the type or degree of problem that they are having. First, the mental health consultant must help the requesting person or persons to define the problem and refine the questions that they wish to have addressed. Second, the consultant must be clear about his or her role as a helper in the problem-solving process. The consultant must recognize the limits of his or her knowledge and power and must be ready to assist in locating an appropriate source of help if the problem or problems encountered fall outside of the scope of the consultant's knowledge base in child psychiatry. Consultants should recognize that issues related to insight, unconscious motivation, and acting out may be encountered and dealt with in the consultation process. Even though these issues are well within the scope of the consultant's knowledge base in child psychiatry, "the consultant's function is essentially educational, that learning develops out of a relationship, but that this relationship need not be therapeutic" ( [Stein, 1956](#), p. 249). Finally, by taking the time to understand the culture of the consultation site through a naturalistic or ethnographic intervention; the consultant is better able to understand the point of view of the client. This allows the mental health consultant's knowledge of child psychiatry to be most useful to agency personnel, volunteers, and the children who are served by these programs.

Collaboration between pediatricians and child psychiatrists not only makes intuitive sense, but is a necessity in providing children with responsible, comprehensive health care. Nevertheless, numerous obstacles have interfered with meeting this goal. Differences in training philosophies and experiences, time pressures, managed care policies that discourage the integration of mental health services, and limited access to services all have contributed to difficulties in implementing effective collaboration.

Haggerty and colleagues first described psychosocial concerns as the “new morbidity” of pediatrics more than 25 years ago ([Haggerty et al., 1975](#)). Today, psychosocial problems are the leading cause of disability in childhood ([Costello and Pantino, 1987](#); [Costello et al., 1988a, 1988b](#)). Conservative epidemiologic data indicate that 12% to 20% of children have a psychiatric disorder ([Bernal et al., 2000](#); [Brandenburg et al., 1990](#); [Institute of Medicine, 1989](#); [U.S. Congress, Office of Technological Assessment, 1986](#)), with prevalence rates rising ([Achenbach and Howell, 1993](#)). The rates of childhood psychosocial problems recognized by primary care clinicians more than doubled between 1979 and 1996 ([Kelleher et al., 2000](#)); still, less than half of children with psychiatric disorders are identified in primary care settings, and only a fraction of these children are referred for mental health services ([Bernal et al., 2000](#); [Brandenburg et al., 1990](#); [Costello, 1986](#); [Costello et al., 1996](#); [Lavigne et al., 1993](#)). Pediatricians are being asked by families to deal with psychiatric disorders and are being encouraged if not required to limit their use of mental health, especially child psychiatric, referrals. The frequency with which primary care clinicians are prescribing psychotropic medications for children, including preschoolers, has increased significantly in recent years ([Kelleher et al., 2000](#); [Pincus et al., 1998](#); [Zito et al., 2000](#)). These statistics highlight not only the need for skilled assessment and treatment of psychiatric difficulties in children, but the need for early recognition and intervention in an effort to prevent more lasting suffering and impairment.

In 1996 there were over 53,000 practicing pediatricians in the United States ([American Medical Association 1997–1998](#)). In 1990, there were only 4,212 child psychiatrists, with 5 states having less than 2 child psychiatrists/100,000 youth. Regions with the highest rates of poverty (and thus the highest prevalence of psychosocial concerns) also had the fewest number of child psychiatrists ([Thomas and Holzer, 1999](#)). Even with the overwhelming need identified, a perception of competition between behavioral pediatrics and child psychiatry also has been a barrier to care.

The relationship between pediatrics and child psychiatry has been marked by both tension and cooperation. Although some psychiatrists have voiced concerns that the growing field of behavioral pediatrics may encroach on their “turf,” others have been actively involved in collaborative projects with pediatrics, such as development of the *Diagnostic and Statistical Manual for Primary Care* (DSM-PC). DSM-PC was published in 1996 as a joint effort between the American Academy of Pediatrics and the American Psychiatric Association ([Wolraich et al., 1996](#)) to improve the classification, recognition, and diagnosis of childhood mental disorders in pediatric primary care. DSM-PC provides a descriptive classification system for a continuum of psychosocial situations and symptoms that range from normal developmental variations, to problems, to psychiatric disorders as defined by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). Specific codes were added to encourage appropriate billing for time devoted to psychosocial concerns. By recognizing that primary care clinicians often are faced with assessing and managing psychosocial issues that may or may not meet full criteria for a specific disorder, it is hoped that DSM-PC will contribute to better identification, treatment, and reimbursement of a spectrum of psychosocial concerns. [Table 126.1](#) is a modified sample page from DSM-PC highlighting its structure and congruence with pediatric primary care practice.

**Table 126.1. Sample Page from the Diagnostic and Statistical Manual for Primary Care.**

The *Bright Futures* initiative, sponsored by the Maternal and Child Health Bureau, has been another valuable tool in addressing psychosocial issues in primary care. *Bright Futures in Practice: Mental Health* ([Jellinek et al., 2002](#)) was recently published as a guide that will help implement primary care goals set forth in *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents* ([Green and Palfrey, 2000](#)). *Bright Futures in Practice: Mental Health* focuses on mental health promotion and early recognition of emotional difficulties by providing primary care clinicians with developmental information, tips for addressing areas of concern, and guidelines for assessment of and interventions for emotional problems and disorders. Recognizing that no minimum standards currently exist for the provision of mental health services in primary care, *Bright Futures* serves as a guide for Medicaid programs and a potential quality assurance standard for all insurers and providers. A compendium of teaching cases for pediatric residents on psychosocial issues also has been developed by [Emans et al. \(2000\)](#), as a teaching initiative consistent with the goals of *Bright Futures* and DSM-PC.

Additional efforts to identify and treat emotional and behavioral problems in children include the development of specialty board certification requirements for behavioral pediatrics by the American Board of Pediatrics, as well as increased training requirements for ambulatory and behavioral pediatrics for pediatric residency programs. The American Academy of Pediatrics (2000) also published practice guidelines for the diagnosis and evaluation of children with attention deficit/hyperactivity disorder (ADHD), for use by primary care practitioners.

Although these initiatives have a well accepted structure to support the mental health of children and adolescents in primary care settings, difficulties remain. This chapter discusses these difficulties and reviews strategies to address them. Topics that present particular challenges to the pediatric clinician, such as psychosomatic disorders, Munchausen syndrome by proxy, and the use of psychotropic medications, also are covered.

### SCREENING

Primary care providers are under increasing pressure today to see a higher volume of patients in shorter amounts of time. Given this productivity expectation, many

pediatricians feel not only that they do not have enough time to ask about psychosocial issues, but overwhelmed and at a loss to address the problems that they might discover. Patients and families are aware of these pressures. In a survey of mothers coming to private pediatric offices, less than a third reported that they were planning or able to discuss significant psychosocial concerns with their child's physician, even when these issues were the main questions on their mind ( [Hickson et al., 1983](#)). Focused interviewing and screening questionnaires can aid primary care clinicians in gathering important psychosocial information in an efficient manner.

The information gathered during a pediatric visit can be highly variable depending on who is providing the information, the pediatrician's receptivity, and the environmental context ( [Hack and Jellinek, 1998b](#)). [Wisow et al. \(1994\)](#) described three simple communication skills used by pediatricians that were associated with disclosure of sensitive information during pediatric visits: asking about psychosocial issues, making supportive statements, and listening attentively. A framework for asking psychosocial questions throughout development is available in the [American Academy of Pediatrics Guidelines for Health Supervisor \(1997\)](#), [Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents \(Green and Palfrey, 2000\)](#), and [Bright Futures in Practice: Mental Health \(Jellinek et al., 2002\)](#). [Hack and Jellinek \(1998b\)](#) have suggested specific questions, based on a review of the literature, that are most likely to provide pediatricians with enough information to identify children and families in need of further evaluation (see [Appendix 1](#)).

Screening questionnaires that can be completed by parents in the waiting room are another useful approach in identifying potential areas of concern. Any problem areas noted on screening can then be followed by more focused interviewing to assess the nature and severity of the problem. To be useful in a primary care setting, a screening questionnaire needs to be easy to administer and interpret, and needs to be well validated in differentiating children who are most likely to be symptomatic. The Pediatric Symptom Checklist (PSC) is one instrument that has been designed specifically for use in a pediatric waiting room (see [Appendix 2](#)). The PSC has been validated for use in children from 4 to 16 years of age, in a variety of settings and among various populations. It is a 35-item questionnaire, focused on assessing a child's major areas of functioning, that most parents can complete in under 5 minutes without assistance. A single score is calculated by the addition of numeric responses to each question, ranging from 0 to 2 as a symptom is rated as being "never," "sometimes," or "often" present. If the score is 28 or higher (24 or higher for preschoolers), there is a 70% likelihood that the child is experiencing significant dysfunction. For children who score below this cutoff, there is a 95% likelihood that they do not have serious difficulties. In previous validity studies, the PSC matched national estimates of psychosocial problems in children and performed comparably with the longer Children's Behavior Checklist (CBCL) ( [Cassidy and Jellinek, 1998](#); [Hack and Jellinek, 1998a](#); [Jellinek, 1998](#); [Jellinek et al., 1999](#)). If a child's PSC score is above the cutoff score, the primary care physician can then spend more time reviewing specific symptoms and assessing severity to determine the next course of action. Although the CBCL ( [Achenbach, 1991](#)) is the most validated psychiatric screening instrument for children, its length and more complex interpretation make it better suited to specialty psychiatric practice and research, or as a follow-up assessment measure of children identified as being at risk ( [Hack and Jellinek, 1998a](#)).

Screening questionnaires that focus on specific symptoms also can be useful in primary care practice when a particular area of concern has been identified. For ADHD, the Conners Parent and Teacher Rating Scales are helpful in assessing the presence and severity of symptoms, and in providing objective measures of treatment response ( [Cassidy and Jellinek, 1998](#)). DSM-IV criteria for ADHD also have been formatted into a checklist questionnaire that can be used for assessing and tracking symptoms.

For mood disorders, children are the best source of information regarding their own emotional states ( [Costello et al., 1988a](#)). Several self-report measures to evaluate depressive symptoms in children and adolescents are available, including the Beck Depression Inventory (BDI), the Children's Depression Inventory (CDI), and the Center for Epidemiological Studies Depression Scale (CES-D). Of these measures, the BDI has been the most widely used and tested. It is written at a fifth grade reading level, and therefore may be more appropriate for use with adolescents ( [Roberts et al., 1991](#)). The CDI was derived from the BDI, and can be used for children 7 to 17 years of age, although it is written at a first grade reading level. All of these measures are brief and easy to use and interpret ( [Hack and Jellinek, 1998a](#)). However, screening for depressive symptoms is a complex matter, with most available rating scales having a relatively low specificity ( [Eisert et al., 1991](#)) and many youth falling within the "at risk" or mild/moderate category. Rating scales for depression in children and adolescents cannot take the place of a careful clinical interview; they may be most useful in helping clinicians assess severity of symptoms and in tracking the progress of symptoms over time.

Focused interviewing and screening measures can help primary care clinicians with the first step of recognizing psychosocial problems. After recognition and assessment of severity of symptoms, clinicians are faced with the even more complex task of determining a course of action. Options for interventions are guided by the nature and severity of impairment. The range of potential interventions may include any of the following (see DSM-PC, pp. 23–27):

- For a concern that appears to be a normal developmental variation or is resolving: routine follow-up or monitoring of symptoms
- For a problem: further evaluation at the primary care level, regular follow-up visits, consideration of mental health consultation or referral, comanagement with mental health clinician(s)
- For a disorder: mental health consultation, mental health referral for a comprehensive evaluation, emergency referral, comanagement and ongoing collaboration with mental health clinician(s) ( [Jellinek, 1998](#))

## COLLABORATION

Many factors affect how effectively pediatricians and child psychiatrists can work together in meeting the needs of children and families. Differences in training, philosophy, approaches, and skill sets offer opportunities for each field to complement the other's efforts, yet also can lead to differing expectations and goals. Pediatricians typically see hundreds of children for short visits, whereas child psychiatrists see fewer children more intensively. Pediatricians gain a broad view of the variations in normal development, whereas child psychiatrists have the opportunity to understand more fully the depth of an individual child's experience or distress. Without open communication, stereotyped perceptions can interfere with providing comprehensive care. Psychiatrists may view pediatricians as more concrete, action oriented, and less able to tolerate slow progress or appreciate subtle dynamics. Pediatricians expect that psychiatrists will be less available and communicative than other specialists, more likely to see pathology instead of strengths, working at too slow a pace, and unhelpful in providing practical and useful interventions ( [Granger and Stone, 1996](#); [Lewis, 1994](#)).

These stereotypes do each field a disservice by depriving both of essential information that the other can provide, and by failing to recognize that within specialties there are wide variations in personalities, approaches, and skills. Collaboration is most effective when it based on a foundation of mutual respect. Primary care providers often have known a child or family over a period of time, and can offer insights into medical, developmental, and family history that are invaluable in treating emotional and behavioral difficulties. Psychiatrists can support medical care in a variety of ways, including providing a fuller picture of how a child is functioning in important areas (e.g., school, family), understanding the impact of physical symptoms or illness on a child's emotional development, and appreciating dynamic factors that may affect compliance with medical care.

Even when primary care providers and psychiatrists approach each other with respect and appreciation for the other's skills, other obstacles may interfere with collaboration. Pediatricians may be reluctant to refer a child or family for mental health services because of worries about stigma or how the referral will be viewed by the family and if it will jeopardize their alliance. Psychiatrists may limit communication with primary care providers because of concerns about maintaining patient confidentiality. Time pressures also interfere with efforts to maintain ongoing communication between providers. Financial considerations may decrease the number of referrals made when managed care plans require that mental health visits be paid for out of the general pediatric budget or offer incentives for limiting referrals; when preferred mental health colleagues are not in the panel of or credentialed (accepted) under a particular insurance plan; and when utilization review decisions are made by managers, not the clinicians involved. Last, in many parts of the country, primary care providers face a real shortage of child psychiatric colleagues ( [Thomas and Holzer, 1999](#)).

Various approaches can be used to address these obstacles. Pediatricians can decrease the stigma that families may associate with mental health services by establishing a practice in which psychosocial issues are routinely assessed and discussed. Families are more likely to follow through with a mental health referral if they understand the reason for the referral (e.g., patterns such as a child with too few friends or intense sibling rivalry) and if their pediatrician conveys that he or she knows and has confidence in the mental health clinician. Pediatricians also can clarify with both families and psychiatric colleagues what their goals are for the referral (e.g., assessment of depressive symptoms in a child with a chronic illness; parent guidance for managing separation anxiety) and how they plan to remain involved in the child's care. In situations where a pediatrician is unsure of how to broach a mental health referral with a child or family, discussing possible approaches with a psychiatric colleague often is helpful.

Child psychiatrists may receive referrals directly from a pediatrician, or from families or outside agencies with or without the knowledge of the child's pediatrician. In all of these situations, care is optimized by the psychiatrist conveying that he or she views the pediatrician as providing a crucial role in supporting the child's well-being. When a psychiatrist meets with a child or family for the first time, discussing how information will be shared with the pediatrician and obtaining signed releases are important in addressing any potential concerns about confidentiality. This process also can underscore to families that the child psychiatrist is committed to taking a comprehensive view of their child's health. For families that may be reluctant initially to allow the psychiatrist to communicate with their pediatrician, clarifying the type

of information that will be shared and the why this information is important to the child's care usually is sufficient to reassure most families.

Other obstacles, such as time pressures and limited access to child psychiatric services, necessitate more creative and flexible approaches. Each clinician needs to develop his or her own system of maintaining communication with other care providers, through scheduled phone calls, letters, e-mail, or regular meetings. When feasible, the inclusion of a mental health clinician in a pediatric practice provides a streamlined and built-in mechanism for meeting the mental health needs of children in the practice. Pediatricians may consider teaming with a mental health colleague in providing educational services for patients and families such as newsletters, parent groups, or informational Web sites. Economic factors and limited access to psychiatric services have led to the development of innovative models of collaboration. Child psychiatrists may consider approaching pediatric colleagues to endorse their application to insurance panels. Pediatric practices can develop an ongoing relationship with a child psychiatrist in the community for informal "curb-side" consultations, or more formalized meetings in which the psychiatrist may meet with a group of pediatricians for case discussions. Technologies such as telemedicine also have made it possible for primary care providers in more remote areas to have access to specialized consultation.

## PSYCHOSOMATIC DISORDERS

The assessment and treatment of psychosomatic disorders in childhood is an area that truly reflects the interface between pediatrics and child psychiatry. Traditionally, the term *psychosomatic* has been used to describe illnesses in which a loss or change in physical functioning appears to be due to psychological factors ([Graham, 1985](#)). Psychosomatic symptoms may range from frequent somatic complaints to more dramatic conversion disorders. Pediatricians often feel frustrated by children who have no organic findings or spurious findings, yet continue to be symptomatic despite their best treatment efforts. Despite this frustration, pediatricians may be reluctant to make a psychiatric referral because of concerns that the child or family will be angered at the suggestion of an emotional component to the physical symptoms. In many of these families, the child's symptoms are presented as the "problem" when in fact they are a defensive solution that avoids confronting emotionally charged family issues. Parents also may communicate their resistance to psychological interventions or they may "doctor shop" to avoid psychiatric referral. As a result, these children typically have been referred to multiple specialists in ongoing efforts to find a specific cause for their symptoms.

[Jellinek and Herzog \(1991\)](#) have suggested a framework that child psychiatrists can use to guide pediatric colleagues in broaching the need for psychiatric consultation in psychosomatic cases:

1. Avoid coming to a final etiologic diagnosis. Suggest that both physical and psychological avenues require further exploration.
2. Have the pediatrician gather information about psychosocial history, family psychiatric history, sources of stress, and emotional consequences of the child's dysfunction. This assessment may identify psychological needs that are quite separate from the child's physical symptoms.
3. Suggest that a psychiatric evaluation is needed to address the child's dysfunction rather than only to pursue a diagnosis.
4. Recommend that the pediatrician be patient with the family, allowing enough time to foster a sufficient alliance with the family.
5. Recommend an "if . . . , then" approach. The pediatrician should discuss with a reluctant or resistant family that if the last round of appropriate diagnostic tests is negative, then a psychiatric consult is warranted.
6. If pediatric hospitalization is necessary, initiate the child psychiatric consult on the first day. This conveys to the family that the psychiatric evaluation is an important part of the child's work-up.
7. Some families will continue to refuse a psychiatric referral. Support the pediatrician in recognizing this refusal as a family problem and not as a reflection of the pediatrician's competency.
8. If the family continues to pursue high-risk, invasive procedures, alert the pediatrician that the child may be at risk for abuse. In extreme cases, referral to social service agencies may be required to protect the child.

Once the family agrees to accept a psychiatric referral, the child psychiatrist can proceed with careful evaluation. This evaluation often is done in the midst of tension and concern on the family's part that they will be told that the problem is "all in your child's head." By adopting a gentle, nonconfrontational approach, the psychiatric consultant can reduce the family's anxiety. Framing the absence of findings in a positive manner is helpful ("The good news is that your child does not appear to have a long-term, irreversible illness"). Explaining that pain, physical disability, or depressed mood in childhood can interfere with developmental tasks encourages the family to focus on ways to increase the child's functioning. Acknowledging the family's frustration at not having a definite etiology for their child's symptoms is important. Providing specific interventions, such as nutritional plans and physical therapy, helps the child and family feel more in control and may gradually allow the child to give up the physical symptoms in a dignified manner.

As the child psychiatrist earns the family's trust, a more comprehensive understanding of the child's and family's psychosocial functioning can be developed. In addition to physical symptomatology, does the child have evidence of further psychiatric dysfunction, such as anxiety or depressive symptoms ([Livingston, 1993](#))? Is there a family history of somatic presentations? Is this a child with a history of traumatic life events, school problems, or poor social competence ([Walker et al., 1994](#))? Are there family stressors such as marital tension, divorce, or parental substance abuse? Is the child unable to tolerate any awareness of unpleasant, angry affects, or internal conflicts ([Campo and Fritsch, 1994](#)), or is the child a symptom bearer for the family? Each of these areas potentially may become a focus for treatment independent of the presenting physical symptoms ([Campo et al., 1999](#); [Fritz et al., 1997](#)).

## MUNCHAUSEN SYNDROME BY PROXY

Munchausen syndrome by proxy [factitious disorder by proxy (FDP)] is an extreme form of child abuse in which a parent's psychopathology is manifested in the pediatric arena. Its key feature is the repeated, intentional production or feigning of symptoms in a child by a caretaker. The motivation for this behavior is thought to be a complex psychological need by the caretaker to assume the sick role by proxy. This syndrome is particularly difficult to diagnose and treat. Because of its potentially lethal outcome and high risk of long-term physical and psychological morbidity, recognition and close collaboration between pediatrics and child psychiatry is critical. The following features may initially alert the pediatrician to suspect a case of FDP ([Schreier and Libow, 1993, 1994](#)) (see also [Chapter 102](#)):

- The child most commonly is of preschool age.
- The perpetrator is usually the child's mother, and often has had some degree of medical training.
- Most symptoms involve the gastrointestinal, the genitourinary, or the central nervous system.
- The child's signs and symptoms may be incongruous with the presented history or usual clinical course of illness.
- Signs and symptoms may occur only when the caretaker is present, or do not seem to respond to prescribed treatments.
- The caretaker may report that the child is allergic to a wide variety of foods or drugs.
- Laboratory results often are inconsistent.
- The caretaker may report that commonly accepted treatments have not been effective or have been poorly tolerated.
- The caretaker may remain constantly at the child's bedside, but may not appear appropriately worried about the child's illness.

Because of the difficulty in diagnosing and addressing this disorder, a supportive team approach between medical and psychiatric, nursing, and social work staff is essential. If a case of FDP is suspected, the following interventions should be pursued ([Sugar, 1990](#)):

- Ensure the child's safety while a confirmatory work-up is being completed. If the child is hospitalized, he or she should be under constant observation by medical staff. If the child is not hospitalized, or if the caretaker insists on taking the child home before the work-up is complete, medical staff need to decide if the child is in sufficient danger to seek legal custody through the courts or child protective services.
- Inform hospital attorneys that a case of FDP is suspected.
- Attempt to form an alliance with family members while obtaining as much medical and psychosocial history from all available sources.
- Initiate child psychiatric consultation for assessment, treatment planning, and support for the child, family, and staff.
- Encourage all staff involved to communicate openly about all aspects of the child's care, to reduce the possibility of the perpetrator "splitting" members of the team.
- Carefully discuss with all staff involved how to present the conclusion to the family, once enough evidence has been obtained to make the diagnosis. Follow-up with needed services (child protective agencies, mental health services for the child and family) should be in place when presenting diagnosis and treatment options to the family.
- Carefully document all treatment and interventions, as repeat offense is common and definitive diagnosis is often difficult to make.

Adapted from *Bright Futures in Practice: Mental Health* ([Jellinek et al., 2002](#)).

## PRESCRIPTION OF PSYCHOTROPIC MEDICATIONS

The use of psychotropic medication in the treatment of children and adolescents has increased significantly since the mid-1980s. Primary care providers, with varying levels of training in and comfort with psychopharmacology, are prescribing a large proportion of these medications ( [Kelleher et al., 2000](#); [Pincus et al., 1998](#); [Zito et al., 2000](#)). Stimulants have long been used in pediatrics for the treatment of ADHD, and the use of selective serotonin reuptake inhibitors (SSRIs) in primary care pediatrics is now commonplace. [Rushton et al. \(2000\)](#) reported that in a survey of over 1,100 pediatricians and family physicians in North Carolina, 72% had prescribed an SSRI for a child or adolescent, yet only 8% of these physicians felt that they had adequate training in the treatment of childhood depression. Recognizing the widespread prescriptions of stimulants and SSRIs by pediatricians, *Bright Futures in Practice: Mental Health* ([Jellinek et al., 2002](#)) has suggested a framework for the use of these medications in primary care (see [Appendix 3](#) and [Appendix 4](#)). The American Academy of Pediatrics has developed its own set of guidelines for the treatment of ADHD in primary care practice. Primary care providers who do prescribe psychotropic medications to children often require guidance from psychiatric colleagues to clarify diagnosis and offer input regarding medication dosage and combination, and duration of treatment.

## OTHER AREAS OF COLLABORATION

The previous sections describe a few of the common areas of interaction between pediatrics and child psychiatry. Other areas include supporting children with chronic illness, children whose parents are coping with medical illness or other difficulties, children who have experienced physical trauma, and children who are coping with more common stressors (e.g., parental divorce). Although these topics are not covered here (see also [Chapter 33](#), [Chapter 103](#), [Chapter 109](#)), they also offer rich opportunities for collaboration.

## ECONOMIC CONCERNS

In the face of increasing psychosocial dysfunction in children and adolescents, pediatricians and child psychiatrists grapple with economic and market forces that have affected provision of high-quality care and have created barriers to effective collaboration between pediatrics and child psychiatry. Managed care practices have resulted in carve-outs of mental health benefits from general pediatric care, lower reimbursement rates for mental health services, and cost shifting for mental health services to general pediatrics and the public sector. Findings released by the federal Substance Abuse and Mental Health Services Administration in July 2000 reported that two-thirds of substance abuse treatment and over half of mental health treatment is paid for by the public sector ( [Jellinek and Little, 1998](#); [Substance Abuse and Mental Health Services Administration, 1997](#)).

Data are emerging that untreated mental health problems in children lead to chronic psychosocial morbidity, and that children with psychosocial dysfunction have higher costs of health care use ( [Bernal et al., 2000](#); [Kelleher and Starfield, 1990](#)). Noncompliance with medical care also increases health care costs. Unfortunately, these data have not yet significantly affected medical practice or market forces because the financial "payback" for the early detection and treatment of psychiatric problems in children is not evident in the time frame that matters to the carve-out company.

Addressing these barriers will require ongoing efforts in many arenas. Pediatricians and child psychiatrists both need to play critical roles in advocating for the inclusion of mental health care benefits as an integral part of general pediatric care, in negotiating contracts that allow for quality services, and in appealing denials of needed care from insurers. By implementing quality assurance efforts such as screening and tracking measures for children at risk, both disciplines also can contribute to databases with the potential to shape health care policy and managed care practices.

## CONCLUSIONS

This chapter has focused on the interactions between child psychiatrists and pediatricians in managing and treating psychosocial problems in children and adolescents. Pediatricians see many more children than child psychiatrists; they often are the first point of contact for psychiatric concerns ranging from common disorders such as ADHD, learning disorders, and substance abuse, to rarer problems such as psychosis. Currently, the system as a whole functions short of the sum of its parts. Children's needs are viewed in a narrow context, depending on the arena in which a child is seen. Medical care is separated from academic services, which in turn often are segregated from a child's family and community experiences. In a system this fragmented, thoughtful assessment and treatment of children's psychiatric needs is a daunting task.

Models do exist for the provision of more seamless and comprehensive care for children. State agencies, school-based health clinics, and community partnerships with schools can be integrated to provide high-quality care. In an ideal system, the roles of pediatricians and child psychiatrists would be established within this network of care. As a first step toward this goal, both fields need to work together in identifying children at risk, determining when and how to refer, understanding the obstacles to effective collaboration, and advocating for their patients' care.

## Appendix 126.1 / Psychosocial Questions for Use in Clinical Pediatric Office Practice

---

### FAMILY

1. Who is in your family and who lives with you in your home?

### Household Stability

2. How many times has your family moved?
3. Have there been any changes in your family or life style since the last time we met?
4. How are you and your child coping with this change?

### Marital Conflict and Divorce

5. Are you and your spouse able to work together in raising your child?
6. How do you handle disagreements in raising your children or between yourselves?
7. When things get out of hand, how far do they go?

### Crisis

8. Has your family ever been through a major crisis?
9. How did you all deal with that crisis?

### Parental Mental Health

10. Have you or any of the members of your family ever suffered from a mental illness or substance abuse problem?
11. Are you aware of any effects that this problem may have had on your child or his or her care?

### SCHOOL

12. How does your child like school and his or her teachers? *How do you like school and your teachers?*
13. How did your child do in first grade?

#### Academic Achievement

14. What grades does your child get on his or her report card? *What grades do you get on your report card?*
15. Has your child ever stayed back a grade?
16. Has your child ever been in special education classes?

#### School Attendance

17. Have you ever had difficulty getting your child to go to preschool or school?
18. Has your child ever missed more than 10 days of school in 1 year? What was the reason?
19. Has your child ever cut school? How often?  
*Have you ever cut school? How often?*

#### PEER RELATIONSHIPS

20. How does your child get along with peers?

#### Friends

21. Does your child have a best friend? (In adolescence . . . a group of good friends?)  
*Do you have a best friend?*

#### Bullies and Victims

22. Does your child seem to enjoy picking on, bothering, or bullying weaker children?  
*Did you ever like to pick on or bother another kid?*
23. Does your child always seem to get picked on?  
*Are you a kid who always gets picked on?*

#### ACTIVITY

24. What does your child like to do?  
*What do you like to do?*
25. Is there something your child is really good at doing?  
*Is there something you are really good at doing?*

#### EMOTIONAL HEALTH

26. What emotions do you see in your child these days?  
*Everyone feels sad or angry at times. How about you?*
27. Has your child suffered the loss of someone important to him or her?
28. Has your child ever been treated for an emotional or school problem?

#### MISCELLANEOUS TOPICS

#### Poverty

29. Have you ever been on welfare or been unable financially to support your family?

#### Injury

30. Has your child ever had to go to the emergency room for treatment of an injury? How many times?

#### Substance Abuse

31. Do you ever drink alcohol? If yes, then . . .
  - C Have you ever felt the need to **cut down** on your drinking?
  - A Have people ever **annoyed** you by criticism of your drinking?
  - G Have you ever felt **guilty** about your drinking?
  - E Have you ever taken a morning **eye opener** to steady your nerves or get rid of a hangover?
32. Do you think your child is drinking alcohol or using drugs?  
*Have you ever tasted beer, wine, or alcohol?*  
*How old were you when you began to drink alcohol?*

#### Risk-Taking Behavior

33. Is there anything that your adolescent is doing or has done to himself or herself that has you really concerned?

#### Suicide

34. Has your teenager ever tried to intentionally hurt himself or herself?  
*Did you ever feel so upset that you wished you were not alive or that you wanted to die?*  
*Did you ever do something that you knew was so dangerous that you could have gotten hurt or killed?*  
*Did you ever intentionally try to kill yourself?*

### Appendix 126.2 / The Pediatric Symptom Checklist

---

Please mark under the heading that best fits your child

	Never	Sometimes	Often
1. Complain of aches or pains	___	___	___
2. Spends more time alone	___	___	___
3. Tire easily, little energy	___	___	___
4. Fidgety, unable to sit still	___	___	___
5. Has trouble with teacher	___	___	___
6. Less interested in school.	___	___	___
7. Acts as if driven by a motor	___	___	___
8. Daydreams too much	___	___	___
9. Distracted easily	___	___	___
10. Is afraid of new situations	___	___	___
11. Feels sad, unhappy	___	___	___
12. Is irritable, angry	___	___	___
13. Feels hopeless	___	___	___
14. Has trouble concentrating	___	___	___
15. Less interested in friends	___	___	___
16. Fights with other children	___	___	___
17. Absent from school	___	___	___
18. School grades dropping	___	___	___
19. Is down on himself or herself	___	___	___
20. Visits doctor with doctor finding nothing wrong	___	___	___
21. Has trouble sleeping	___	___	___
22. Worries a lot	___	___	___
23. Wants to be with parent more than before	___	___	___
24. Feels that he or she is bad	___	___	___
25. Takes unnecessary risks	___	___	___
26. Gets hurt frequently	___	___	___
27. Seems to be having less fun	___	___	___
28. Acts younger than children his or her age	___	___	___
29. Does not listen to rules	___	___	___
30. Does not show feelings	___	___	___
31. Does not understand other people's feelings	___	___	___
32. Teases others	___	___	___
33. Blames others for his or her troubles	___	___	___
34. Takes things that do not belong to him or her	___	___	___
35. Refuses to share	___	___	___

### Appendix 126.3 / Use of Stimulants in Pediatric Primary Care Practice

Children and adolescents with attention deficit/hyperactivity disorder (ADHD) usually require multiple interventions to address their difficulties. In addition to behavioral treatment and collaboration with the family and school, pharmacologic interventions have been shown to be effective in improving functioning in children and adolescents with ADHD. Guidelines for considering a medication trial are offered in the following.

- Given the prevalence of ADHD and its responsiveness to stimulant medication, many primary care clinicians may feel comfortable considering a medication trial in children and adolescents who have good family support and no significant coexisting disorders. Ongoing communication with the child's family and school (following guidelines for confidentiality) through mechanisms such as rating scales is essential in monitoring a child's response to medications.
- Children and adolescents who do not respond to a stimulant trial, who experience adverse effects, or who show evidence of depressive or anxiety symptoms, substance abuse, developmental delays, history of tic disorders, or significant family stress may be more complicated to treat. Although some primary care clinicians have experience in treating ADHD symptoms along with these associated problems, other providers may wish to obtain psychiatric consultation.

Adapted from Jellinek M, Patel B, Froehle M: *Bright Futures in Practice: Mental Health*. Arlington, VA, National Center for Education in Maternal and Child Health, 2002.

### Appendix 126.4 / Use of Antidepressants in Pediatric Primary Care Practice

In addition to interventions such as individual therapy and work with the child's family, school, and peers, medications may be helpful to some children and adolescents with depressive symptoms. In prepubertal children with depression, the diagnostic process, treatment planning, and medication management issues are sufficiently complex to warrant a referral to a child psychiatrist. For older adolescents, primary care clinicians may choose to treat moderate depressive symptoms with medication. In these cases, periodic consultation with a child psychiatrist colleague regarding medication selection, dosing, duration of treatment, and management of adverse effects is highly recommended. Guidelines for considering antidepressant treatment for childhood and adolescent depression are offered in the following.

- Clinicians should be aware that bipolar disorder will develop in 20% to 40% of children and adolescents with a major depressive episode. Therefore, any child or adolescent who undergoes a trial of an antidepressant should be closely monitored for signs of increased agitation or irritability.
- Children and adolescents with coexisting difficulties such as suicidal ideation, significant irritability or impulsivity, anxiety, attention deficit/hyperactivity disorder, substance abuse, or significant conduct problems are likely to present diagnostic and treatment challenges that ideally are managed by a child psychiatrist.
- Although the safety and efficacy of selective serotonin reuptake inhibitor (SSRI) antidepressants has not been as well established for children and adolescents as for adults, available data indicate that the short-term use of SSRIs appears to be safe and potentially useful in the treatment of childhood and adolescent depression.
- In moderately depressed older adolescents with good family support, primary care providers may consider using an SSRI in certain situations:
  - In adolescents with a clear family history of depressive disorders that have responded well to medication treatment
  - In adolescents who had previously been functioning well, with acute impairment due to depressive symptoms
  - In adolescents whose depressive symptoms have continued despite individual, group, or family therapy
- An adolescent who does not respond to an initial trial of an SSRI or who experiences adverse effects with a medication trial should be referred for further psychiatric evaluation.

# 127 POLICE–MENTAL HEALTH RESPONSES TO CHILDREN EXPOSED TO VIOLENCE

## The Child Development-Community Policing Program

Steven Marans, Ph.D., Robert A. Murphy, Ph.D., and Steven J. Berkowitz, M.D.

- [Chapter References](#)

### THE SCOPE OF VIOLENCE

It is well established that exposure to interpersonal violence disrupts the basic preconditions for optimal child development. Children may be traumatized in the face of stabbings, beatings, and shootings, because they are unable to contain the stimulation within existing mental and neurophysiologic structures that enable accommodation and assimilation. When systems are immobilized, a cascade of psychological and neurophysiologic processes ensues. The disruption of psychological and biological systems may lead to symptoms of hyperarousal, withdrawal, and re-experiencing of traumatic events; other children may develop specific, circumscribed symptoms, such as disruptions in sleeping, eating, and toileting ( [Boney-McCoy and Finkelhor, 1996](#); [Foy and Goguen, 1998](#); [Gorman-Smith and Tolan, 1998](#); [Marans and Adelman, 1997](#); [McCloskey and Walker, 2000](#); [Pfefferbaum, 1997](#); [Pynoos, 1993](#); [Terr, 1991](#)). As a result, they may become distracted, unable to concentrate or pay attention in school or at home. Transient oppositional behavior also may emerge and represent both an attempt to reassert power in the face of feeling vulnerable and an effort to cope with the anxiety and hyperarousal caused by the dysregulation of the stress response systems. When children are exposed to the dangers of violence on a chronic basis, however, symptoms may no longer serve the function of restitution and recovery. Rather, symptoms become chronic and maladaptive such that physiologic, cognitive, and emotional capacities are severely impaired. Exposure to chronic violence, which is often punctuated by further acute episodes, is associated with increased depression and anxiety, alcohol use, and lower school achievement ( [Garbarino et al., 1992](#); [Martinez and Richters, 1993](#); [Pfefferbaum, 1997](#); [Widom, 1999](#)). A summary of children's responses to traumatic events is presented in [Table 127.1](#).

Type of Reaction	Clinical Manifestations
Affective distress	Irritability, aggressive behavior, angry outbursts, lethargy, difficulty being soothed, tearfulness, sadness, crying, fearfulness
Cognitive changes	Difficulty concentrating, inattention
Reexperiencing	Reoccupation with frightening thoughts and feelings, increased day dreaming, sudden changes in quality of play, repetitive play related to violence and other traumatic experiences, decreased creativity and spontaneity of play
Regression	Loss of previously obtained developmental skills, acting immature or "babyish"
Regulatory disruption	Hyperarousal, exaggerated startle response, distress in response to traumatic cues or reminders (direct and indirect), lability of mood and behavior
Separation anxiety	Substantial difficulty with separations, complaints of loneliness, increased dependence on caregivers
Sleep disturbance	Nightmares, difficulty falling asleep, waking during the night, enuresis
Somatic complaints	Headaches, stomachaches, aches and pains without medical etiology
Withdrawal	Loss of interest in games, school, or pleasurable activities, social withdrawal, reduced spontaneity, display of range of affect, lack of appropriate affect, dissociation, avoidance of traumatic cues or reminders

**Table 127.1. Summary of Children's Responses to Traumatic Events.**

Most tragically for children and society, another long-term adaptation to ongoing violence is the perpetration of violence. There may be a common progression from witnessing to being the victim of and then to engaging in violence in densely populated, impoverished urban areas where the prevalence of violence is especially high (Marans et al., [1996a,b](#)). The children who shoot and stab other children all too often have been exposed to the abusive relationships of family members, and have themselves been at the receiving end of beatings and neglect ( [Kaufman and Henrich, 1999](#)). Frightened victims become frightening assailants. A longitudinal study by [Thornberry and colleagues \(1994\)](#) demonstrated this pathway. Children who had been victims of violence within their families were 24% more likely to report engaging in violent behavior as adolescents than those who had not been maltreated in childhood. Adolescents who were not directly victimized, but who had grown up in families in which partner violence occurred, were 21% more likely to report violent delinquency than those not so exposed. Finally, children exposed to multiple forms of family violence reported twice the rate of youth violence relative to those from nonviolent families.

In spite of the significant decreases in juvenile crime rates since the early 1990s ( [Snyder and Sickmund, 1999](#)), far too many children living in the United States experience acts of violence that leave them vulnerable to the psychological trauma associated with their exposure:

- In 1998 more than 2.7 million youth between the ages of 12 and 19 years were victims of violent crime, including simple and aggravated assault, rape and robbery ( [Rennison, 1999](#)).
- Children and adolescents are 4.5 times more likely to be the victims of serious crime than are adults ( [Centers for Disease Control and Prevention, 1997](#)).
- In a given year, 1 million children are substantiated victims of abuse or neglect. At least 130,000 children are sexually abused, and 2,000 children die as a result of abuse or neglect ( [Bash, 1997](#)).
- Each year more than 10 million American children witness a physical assault between their parents. There is repeated violence between the parents in two-thirds of these cases ( [Straus and Gelles, 1990](#)).
- Child abuse occurs in 50% of families where domestic violence also occurs ( [Centers for Disease Control and Prevention, 1999](#)).

In light of our current knowledge about the complex interplay of psychological and neurobiologic responses to overwhelming events, ample reason exists for concern about the enduring consequences for children's maturation and development when potentially traumatic responses to violence exposure go unrecognized. Although essential, primary prevention programs alone are unlikely to avert the acute and chronic symptomatic sequelae of children's exposure to violence. Early intervention immediately following a serious violent or traumatic event is both possible and desirable. Psychological and pharmacologic interventions may prevent the acute stress response from becoming permanently dysregulated. By intervening immediately after the event, children and families may be more able to integrate their experiences in a manner that ameliorates the fear and stress that in turn exacerbates and perpetuates acute biologic and maladaptive coping responses.

Children and families who are most vulnerable to the deleterious effects of violence may also lack access to sufficient mental health care. In addition to constraints on overall resources, families who simultaneously contend with the chronic and acute effects of violence, poverty, social disadvantage, and individual and family psychopathology may be unable to access traditional clinic- or office-based services when they are available. In essence, those with the greatest need may receive the least care. In response to these concerns, there has been a proliferation of community-based services where mental health care is provided in homes, schools, and community settings, with an emphasis on acute stabilization of individual and family psychopathology and collaboration with other community providers ( [Aber et](#)

al., 1998; Woolston et al., 1998).

### Community Policing and Effective Partnerships

Beginning in the 1970s and gathering momentum in the latter 1980s, community leaders began to recognize that the academic, social, and emotional health of youth could not be separated from their feelings of safety and security in their schools and neighborhoods. Leaders in law enforcement recognized the need for a change in traditional policing as youth violence peaked. Many departments began a critical transition from a crisis-oriented and response-driven system to one reflecting the principles of problem-oriented community policing (Thurman, 1995), and many of these departments adopted a specific emphasis on the concerns of children and youth. In contrast to a reactive, crime-fighting response, community policing adopts a “proactive, solution-based, and community driven” perspective on policing in which the need to arrest offenders is integrated with a preventive approach based on relationships and problem-solving efforts with a range of community constituencies.

Despite variation across communities, departments that have embraced community policing emphasize accessibility of police to the citizens they serve through problem solving and preventive approaches to policing, proactive order maintenance designed to diffuse situations prior to an emergency complaint, collaboration with community agencies, neighborhood involvement in policing, and sponsorship of community-based crime prevention initiatives (Goldstein, 1987; Thurman, 1995). Community-based policing integrates police officers within the community, where they are known as individuals rather than only by role, and they come to know the people they serve as individuals. Because the model brings police officers into regular, ongoing contact with children and families within a given neighborhood, it requires a new type of police officer with specialized training, supervision, and support.

In a comprehensive review of crime prevention programs, the Office of Justice Programs (Sherman et al., 1998) outlined a range of effective crime and violence prevention programs, yet few feature direct collaboration and integration of psychiatric and law enforcement services. Nonetheless, police can be effective in their efforts to decrease criminal and violent activity among youth. For example, intensified monitoring of repeat offenders by community police and probation officers, as well as additional patrols in areas with high rates of youth crime can ameliorate recidivism. Presumably, these approaches reduce anonymity through supervision and the development of relationships with youth, enhance a sense of security among residents, and foster proactive intervention by police officers.

### Police Officers, Mental Health, and Specialized Training

Police routinely confront the psychological sequelae of violence and psychiatric illness during their patrols. Despite decades of practical experience in responding to psychiatric crises, few police departments provide extensive training in the identification and management of acute mental health problems. Traditionally, their options have been limited to an evaluation of an individual's danger to self or others with resultant alternatives of involuntary psychiatric commitment or arrest (Teplin, 2000). In her recent review, Teplin (2000) noted that the likelihood of arrest was 67% greater for criminal suspects with signs of mental disorder relative to other nondisordered suspects. Two explanations for these findings arise, although neither is exclusive of the other. Police may lack sufficient training in effective responses to psychiatrically disturbed citizens and may rely on arrest in the absence of effective training and awareness of alternative responses. Alternately, they may resort to arrest to secure services in the context of diminished access to behavioral health care in the public mental health sector. Officers may recognize the complex risks and needs among this population that has not been adequately served by mental health or law enforcement alone. From this latter perspective, arrest may serve a therapeutic function through the application of police authority toward the goal of securing necessary mental health care.

The training needs of police departments were highlighted in a survey of mental health crisis responses among 174 urban police departments. More than half (55%) lacked specialized response procedures for mental health crises, despite such incidents comprising a significant proportion of all service calls (Deane et al., 1999). Within the remaining 45% of departments, 3% (six departments) relied on specific officers with crisis intervention training to act as liaisons with mental health providers. Another 12% (20 departments) retained civilians as mental health consultants or providers. The remaining 30% of departments (52) relied on referral to non-police-affiliated mental health professionals. Although most departments, including those lacking a specialized response, perceived their efforts on behalf of psychologically impaired citizens as effective, none were able to point to specific outcomes or benefits that accrued to the individuals in question.

No department specifically addressed the mental health concerns of children, suggesting that the relative paucity of organized police responses to psychiatric concerns is more widespread in regard to children whose difficulties may go unrecognized by officers who lack training and resources for responding to the psychiatric needs of children and adolescents. Training officers to identify psychiatric disorders and symptoms, conduct mental status evaluations, recognize medical syndromes that may cause psychiatric symptoms, understand legal and ethical aspects of involuntary commitment, and utilize interpersonal and communication strategies for interacting with seriously disturbed individuals has improved officers' ability to respond to psychiatric disturbances (Borum, 1999). The effectiveness of police responses to children has not been specifically addressed, despite the ubiquity of children at many of the scenes to which officers respond.

In one of the few evaluations to directly address police and mental health collaboration, the conjoint identification of youth psychopathology by mental health clinicians and police detectives resulted in enhanced treatment access and intervention within an urban European police department (Scholte, 1992). After training juvenile detectives to recognize risk factors for psychopathology among adolescents, detectives began daily rounds with clinicians to discuss juvenile cases from the previous day and develop appropriate treatment recommendations. Programmatic analysis revealed a 74% concordance between youth identified as at risk for serious psychopathology by police and a standardized clinical screening instrument. Although subsequent interventions were not well operationalized, post hoc analyses suggested that a greater number of youth about whom detectives and clinicians consulted engaged in treatment more readily and experienced fewer psychiatric symptoms in the 6 months following referral.

The limited research to date suggests that community policing may be particularly effective at improving residents' satisfaction with police services and subjective feelings of neighborhood safety and security (Catalano et al., 1999; Zhao and Thurman, 1997). In a study of two New York City police precincts that experienced a large drop in civilian complaints, police officers' responsiveness toward citizenry resulted in more positive views of police, as well as fewer complaints about their conduct (Davis and Mateu-Gelabert, 2000). Residents cited a respectful approach by police officers, as well as involvement of patrol and supervisory officers in community initiatives as central to their positive relationship with local police.

As one might expect, adolescents tend to be more ambivalent than children or adults in their views of police. Beyond the expectable reactions of adolescents to figures of authority, a history of criminal victimization, arrest, or questioning by police officers has been associated with negative attitudes toward police among youth (Hurst and Frank, 2000). These findings of ambivalent views toward police should come as no surprise to the developmentally informed officer or clinician who recognizes the significance of adults in positions of authority as figures to be both emulated and defied in the service of identity formation. Comparisons based on types of policing strategies—for example, community policing versus response driven approaches—have not been conducted, but it appears that the attitudes of adolescents toward police vary, depending on individual factors and their previous experiences of victimization, neighborhood crime, and contact with other officers.

### Changing Mental Health and Policing Systems of Care

Despite progress in the development and implementation of community-based mental health interventions, as well as increased attention to the mental health needs of youth in the juvenile justice system, the potential for police officers to exert a specific influence on the mental health of acutely traumatized children and adolescents has been neglected. Unlike the majority of mental health and juvenile justice providers, police officers are, by definition, constantly available to intervene in instances of acute childhood distress and traumatization. Police officers are the first to respond to scenes in which children may be in acute distress, yet they typically lack the resources, in terms of their own training in child-oriented policing and the availability of adequately responsive mental health colleagues, to effect change at the crucial time of their response. Although mental health providers, particularly those working in trauma-related fields, have extolled the importance of acute intervention and its catalytic effects, few have taken advantage of the reality that police officers respond at precisely the moment when previous defenses and ways of coping have faltered, and perhaps, children and families are both more needy and more responsive to intervention.

### The Child Development Community Policing Program

The Child Development-Community Policing Program (CDCP) (Marans et al., 1995; Marans and Cohen, 1993) has capitalized on the shared expertise of police officers and mental health professionals in intervening with children and their families who have been exposed to violence and may be experiencing its posttraumatic effects. The development of the program has been closely allied with research related to children's mental health systems of care (Bickman et al., 1995; Friedman and Burns, 1996), where multiple systems converge in an integrated manner to maximize quality and continuity of care. The Child Development-Community Policing Program extends work related to mental health care systems that have been focused on psychiatric and community support services to encompass law enforcement,

juvenile justice, and domestic violence personnel in an effort to correct the historical isolation of mental health providers from law enforcement and justice personnel.

The Child Development-Community Policing Program was initiated by the Yale Child Study Center and the New Haven Connecticut Department of Police Service in response to shared concerns about the paucity of policing and clinical responses to children and families at greatest psychological risk because of involvement with violence in their homes, neighborhoods, and schools ([Marans and Cohen, 1993](#)). It was recognized that although police officers come in daily contact with children who are victims, witnesses, and perpetrators of violence, they generally did not have the professional expertise, the time, or the other resources necessary to meet these children's psychological needs. Conversely, clinic-based mental health professionals might have been professionally equipped to respond to children's psychological distress following episodes of violence, but these acutely traumatized children were rarely seen in existing outpatient facilities until months or years later, when chronic symptoms or maladaptive behaviors brought them to the attention of parents, teachers, or juvenile court personnel. When there were no collaborative responses immediately following violent incidents, valuable opportunities to intervene were lost at precisely the moment when concerted police and mental health contact could provide both immediate stabilization and bridges to a variety of ongoing services to address their trauma and maladaptive symptomatology. The CDCP program placed mental health professionals in the community, with the police, to develop collaborative strategies for intervening early when violence occurs. The program alters the ways in which policing, mental health, and now other related services are delivered to children and families who are regularly exposed to community violence ([Marans and Adelman, 1997](#); Marans et al., [1995, 1998](#); [Marans and Schaefer, 1998](#)).

The CDCP program involves five central components:

1. **Seminars in Child Development:** The course constitutes approximately 24 hours of seminars and observations in clinical settings (e.g., a child psychiatric inpatient unit, a pediatric emergency room, and a psychiatric clinic in a juvenile detention center) for officers, new clinicians, juvenile probation officers, domestic violence advocates, and child protective service workers. Reflecting the collaborative nature of the CDCP program, the seminars are co-led by a team consisting of a senior/supervisory police officer and an experienced clinician. Seminars focus on principles of child development, human behavior, and trauma as they apply to community policing.
2. **Clinical Fellowships for Police Officers:** Officers who have completed the seminars continue to participate in the program by attending weekly CDCP case conferences, supervising rank and file officers who respond to calls of acute episodes of violence that involve children and families, and coordinating follow-up services for victims, witnesses, and perpetrators. These officers become local and national leaders in the CDCP program and become centrally involved in program dissemination and replication through teaching, presenting, and developing educational curricula.
3. **Police Fellowships for Clinicians:** As police become familiar with aspects of child development, clinicians learn about basic police practices through their attendance at CDCP case conferences, completion of 20 hours of seminars in police practices and protocols, participation in a minimum of 40 hours accompanying officers on patrol, and involvement as an on-call clinician for the acute consultation service.
4. **The Acute Consultation Service:** Clinicians are available by pager 24-hours a day, 7 days a week to the police department for consultation involving children, adolescents, and families who have been involved in violence or other situations that arouse officers' concerns about their psychological/psychiatric status and well-being. Clinicians respond acutely to incidents in which children are affected by violence as witnesses, victims, and perpetrators. Clinicians meet with children in police stations and substations, schools, homes, and emergency rooms and arrange necessary clinic or hospital-based outpatient and inpatient care in the immediate aftermath of violence and trauma.
5. **Program Case Conferences:** Law enforcement officers, clinicians, juvenile probation officers, domestic violence advocates, and child protective service providers meet weekly to discuss and plan coordinated interventions for cases that have been generated through the acute consultation service, as well as through subacute referrals from patrol officers, specialty police investigative units, child protective services, schools, and juvenile probation officers. Discussion at the case conference might involve the potential for clinical engagement and the role of a patrol officer in assuring future safety. For example, clinicians and officers may arrange for a joint follow-up visit to the home of a child who was recently the victim of a neighborhood assault, as the combined police and clinical presence communicates a shared commitment to security and psychiatric intervention.

### **The Child Development-Community Policing Program Principles of Collaboration**

The CDCP program relies on a process of learning about the perspectives and experiences of the other professional as a basis for considering the developmental implications of their respective observations and actions. Clinicians have learned that to be useful to police officers they first must see the clinical phenomena from the officer's point of view. This has been accomplished through the development of fellowships for clinicians and supervisory officers. In the Police Fellowship, clinicians learn about the tasks, demands, and professional needs of officers and move into police settings through spending time with officers during routine patrol, collaborating with police at crime scenes, and sitting in on discussions of case investigations. At the same time, through the Clinical Fellowship, officers become familiar with mental health settings and psychodynamic and developmental perspectives on psychopathology and treatment through observations of clinical activities and consultations.

Although the coordinated police-mental health response remains at the core of the program, the range of additional partners has expanded to include domestic violence advocates, juvenile probation officers, child protective workers, school personnel, clergy, and community members. Wherever the CDCP program has been implemented, innovations have been developed to meet the specific needs and characteristics of each of the local communities. For example, in Charlotte, North Carolina, the early involvement of the county child welfare agency in the CDCP program originated from a preexisting, informal relationship between the police department and child protective services based on their history of collaboration around childhood abuse and neglect cases. In Baltimore's Eastern District, CDCP was implemented with community members and clergy as full partners who are designated as Community Fellows. They are involved in cross-training, acute response, and follow-up activities of the Baltimore program. In Nashville, police department interests in developing new ways of responding to children and adolescents converged with the efforts of the Mental Health Center for Children and Families to better address the psychological needs of battered women. The Nashville CDCP program forged new partnerships that coordinated and expanded services available to all of those affected by domestic violence and introduced acute and longer-term interventions for children and families affected by other forms of violence and related trauma. In Newark, the CDCP collaboration between the Newark police department and the University of Medicine and Dentistry of New Jersey worked closely with the Catholic church and public housing authority to develop additional services in an area of the city with a dense population of families exposed to high rates of poverty and violent crime. Whatever innovations have developed with regard to additional partners or areas of emphasis, the five central program components serve as a basis for the continued development of the Child Development partnerships.

### **Seminars in Child Development**

Child development seminars provide an initial opportunity for participants with diverse backgrounds and professional experiences to develop a common language from which to consider the needs of children and families ([Berkowitz and Murphy, 2000](#); [Marans et al., 1998](#)). The central task of the seminars is to engage officers and other partners in examining how an understanding of emotional, interpersonal, cognitive, and motor development can enhance law enforcement responses to children and families. Particular attention is paid to the ways in which traumatization may be experienced and demonstrated by children at different phases of development, who invariably present with varied histories, family circumstances, and ecologic disadvantage. (See [Table 127.1](#) for a summary of children's responses to trauma and violence.) Exploring the range of psychological and physiologic responses to overwhelming, traumatic events prepares officers to recognize those situations that may place children at the greatest risk for acute and long-term consequences were their exposure to violence goes unnoticed.

Proceeding along a developmental sequence, the seminars highlight the ways in which phenomena originating in an earlier phase of development may be observed in various forms throughout the life cycle. Seminar leaders rely on scenarios encountered in police work, films, and videotapes about children, and cases histories from the acute consultation service to demonstrate that a greater understanding of human functioning need not portend inaction or decreased vigilance with regard to personal safety. Rather, the goal of the seminars is to help officers and others (e.g., juvenile probation officers, child protective workers, educators) discover new ways of observing and formulating responses to children that are informed by an understanding of their development. In addition, officers have the opportunity to establish a more realistic appreciation of the impact they can have on the lives of children and families with whom they interact.

### **INFANCY**

Discussions begin about early development following a first meeting in which seminar members introduce themselves and talk about their expectations of the course. The supervisory officer, who coleads the seminar with a clinician, introduces the topic of infancy by describing the following scene:

You have responded to a complaint of breach of the peace and arrive at an apartment where music is blaring. An angry young mother greets you. The apartment is disheveled and dirty, and three children, ranging from several months to four years of age, are in similar disarray. Diaper changes for two of the children appear long overdue. What is your reaction?

The officers often begin the discussion by expressing their feelings of despair and anger about a scene that is all too familiar. As the instructors probe the nature of

these reactions, the class begins to identify concerns about the babies who are unable to fend for themselves, about the children's physical discomfort, and about the notion that the mother doesn't care enough about them. What emerges from the discussion is the group's awareness of an infant's physical and emotional needs and the role of the mother in mediating distress and providing crucial care and affection. The seminar leaders inquire, "What happens to the infant if those basic needs aren't met?" The answers suggest that the baby will be overwhelmed with pain, discomfort, and despair because the baby is not yet equipped to feed, clothe, comfort itself, or satisfy the demands of its feelings on its own. The leaders ask for more details, and the class responds by identifying developmental capacities and vulnerabilities—the absence of verbal language, motor maturation and coordination, cognitive processes for problem solving, and finally, the utter reliance of the infant on the mother for the experience of physical and emotional well being.

Attention is then focused on the young mother. "How," the leaders ask, "Do we understand this mother's apparent insensitivity or incompetence?" The discussion must first address the mother's surly response to the officers and their subsequent indignation. Seminar leaders introduce clinical phenomena that underlie presenting behavior, and participants begin to discuss symptoms that they quickly recognize but have not necessarily associated with depression and stress. Invariably the discussion turns to examples of irritability and substance abuse, which becomes an opportunity to discuss the complex biological and psychological relationship among stress, anxiety, depression, and substance abuse.

In addition, the concept of transference is introduced. The seminar leaders expand the discussion of a young woman apparently unable to look after her children, let alone herself. They ask, "How might she feel about herself?" The answers vary. "Like a failure? . . . Maybe she just doesn't care!" The seminar leaders ask, "Given either of those possibilities, how might she feel when two police officers come to her door?" The officers respond, "Like we're going to tell her off, tell her what she should be doing, how she should behave." "Who are you to her at that moment? Who tells you you're not getting it right, messing up? Parents? Teachers? A critical boss or colleague?" In one session, an officer interjected, "Right, and then when she feels criticized, she takes on an obnoxious attitude and treats us like dirt." Another officer added, "As though she already knows who you are."

In this particular discussion, the clinical coleader suggested that perhaps from the moment of their arrival, the officers represented something very familiar to the young woman. The clinician added, "Before you open your mouth, you may be the critical voice, the presentation of authority that agrees with her own self-criticism and assessment of personal incompetence. What is it like to feel inadequate and to have someone who, by their very presence on your doorstep, points out your own shortcomings, real and imagined? Is it possible that her surly and combative response serves a defensive function that is triggered by you but is not about you personally?" The discussion culminates with greater appreciation for the complexity of the scene, its interactions, and potential points for response.

#### ATTACHMENT

The Robertsons' film *John* ([Robertson and Robertson, 1969](#)) is shown in the following session. In the discussion that follows, seminar members describe their responses to viewing this film of a 17-month-old child's efforts to soothe himself in the midst of a 9-day separation from his parents. They note John's attempts to reach out to childcare nurses, cuddly toys, and the observer, and his utter despair when these efforts fail. The discussion compares John with the other children who have spent their entire lives in the residential nursery. Seminar members observe that although seeming unfazed by the limited attention and multiple changes of nursing staff, in contrast to John, these children appear dominated by aggressive, driven, and need-satisfying behavior. In an attempt to understand why John may be so vulnerable to the disruption in care, the participants begin to consider individual differences and the transaction among genetics, temperament, and environment. Who John is as a synthesis of his biology and psychology becomes a central topic for conversation. Slowly and often painfully, as the discussion continues, the simple solution of removal from care when parenting seems inadequate fades along with increased recognition of the central importance of a child's attachment to parents or other primary caregivers. The idea that removal always represents rescue is replaced by a growing appreciation for the complexity of the child-parent relationship. Officers recognize the importance of maintaining consistent and continuous relationships between parents and children and the damage that can occur when that relationship is disrupted. In addition, seminar members have a fuller understanding of the balance between the child's physical and emotional needs, the developing capacities to respond to them and the distress that follows when children's needs are persistently unmet.

#### TODDLERHOOD

The link between psychological processes, overt behavior, and the observers' responses is pursued as the seminar moves into the next session in which the hallmarks of the toddler phase are introduced. Focusing on issues of power, size, and capacities, officers discuss the ways in which the challenges and conflicts of early childhood are repeated later in life. This is most evident in situations where police authority is required to contain the impulses and actions of people who are not able to contain them. When they intervene in fights, civil disorders, drug raids, traffic stops, and the like, officers may often feel like parents attempting to set limits on behavior and the intensity of toddlers' demands. It is often at these moments that, in their positions of authority, the police may easily become the lightning rod for the explosive feelings individuals may have when they feel that their power and capacities are challenged or curtailed. Officers report that appreciating the dynamics and earliest origins of these encounters helps them to respond with greater emotional distance and calm. Like parents of young children, the ability of police to maintain professional distance may spell the difference between a short-lived tantrum and a protracted and dangerous battle.

#### PRESCHOOL

As officers participating in the seminars view videotapes of 4- to 6-year-old children engaged in imaginative play, they are able to consider the preschool child's use of fantasy, identifications, and burgeoning cognitive and physical resources to master new demands. In the process, officers appreciate the fact that children's perception of, and communications about, real events often reflect the interplay of fact and fantasy. For example, in one sequence a 5-year-old boy is seen introducing a play scenario in which puppets designated as a mother and father, kiss, fall down covered in blood, and are then taken to the hospital by ambulance. Appearing in the context of other play sequences that depict family life, the officers in the seminar often assume that the child has been exposed to domestic violence or has been abused himself. Officers then learn about the boy's stable home life and overall developmental health and that he had recently been in a minor traffic accident with his mother, who sustained a small cut that required only a single bandage. The boy's "factual" account of the accident was far more elaborate, involving a description of his mother's copious bleeding and serious damage to the car, when neither actually had occurred. From this example, seminar participants reflect on the interplay between the boy's experience of the accident and developmentally expectable concerns about aggression, bodily damage, and intimacy between parents. As a result, they acquire greater appreciation for the multiple ways in which young children tell their stories about life events. From this perspective, previous assumptions about children's testimony during police interviews and courtroom proceedings can be evaluated from an informed and critical developmental perspective, as officers recognize that children may invest their versions of events with more than the simple facts needed for police investigations ( [Portwood et al., 2000](#); [Wells et al., 2000](#) ).

#### LATENCY AND ADOLESCENCE

Subsequent seminars provide a similar level of detail in examining the developmental tasks of the latency and adolescent stages of development. Failures in negotiating oedipal conflicts over competition, envy, love, and hate and the often unstable, overstimulating home situations in which children reside are explored in discussions of latency age children who come to the attention of police because of their antisocial activities. Similarly, puberty is discussed in terms of the intensification of struggles over sexual and aggressive urges. Discussion of each phase of development is used as another opportunity to consider the impact of violent traumatization and the ways in which individual history and normative tasks and challenges shape the child's experience of events and the extent of symptomatic responses to them.

Seminar leaders introduce phases of development by asking officers to describe the most salient aspects either observed or assumed to play a part in a given period of life. As the discussion evolves, officers invoke their own memories as a vehicle for understanding the behaviors they observe and encounter on the street and as a way of becoming conscious of the complicated identifications that these interactions may evoke. For example, when discussing puberty and early adolescence, officers may describe their concerns about provocative, tough, drug-involved, or pregnant teens and the frustration they experience when logic and warnings about consequences seem to have no impact on behavior. As they begin to talk about their own experiences of this phase of development, however, their frustration and angry dismissal are substantially altered. Officers may describe memories from their own lives or about particular children whom they have met over the course of their work and have been unable to forget. Stories of fighting, social isolation, school difficulties, and losses alternate with the ones about best friends, romantic relationships, team sports, and the like. The discussions inevitably focus on concern about body image, group acceptance, struggles with parents, losses, and the overarching experience of embarrassment and urgency in the competing wishes for competent, independent functioning and continued reliance on parents for direction and security. All of the accounts speak to the vulnerability, anxiety, and loneliness so common in this period of development and the various means used to defend against these feelings.

John Singleton's film, *Boyz n' the Hood* ([Singleton, 1991](#)), and Michael King's award-winning documentary film, *Bangin* ([King, 1999](#)), are used as the "texts" for seminars that address adolescence. Each of the films is used to initiate discussion about development in an especially familiar territory: the challenges, hopes, and

dilemmas inherent in adolescence. The discussion of *Boyz n' the Hood* moves from issues of race and inner city socioeconomics to a focus on the internal and external contributions to the fate of the two brothers in the film. One becomes a gun-toting drug dealer and the other a high-school football star bound for college, until he is shot dead by gang members. *Bangin'* follows two cases involving the death of adolescents who were victims of violence and uses interviews with their peers and other adolescents who have been incarcerated because of their involvement in violent crimes. Both films provide an opportunity to focus on the interplay between early development, trauma, the presence or absence of intervention, and the positive and tragic outcomes seen in adolescence ( [Marans and Adelman, 1997](#)).

As the seminars conclude, officers increasingly refer to their reactions to the scenes of violence and suffering they confront on a daily basis. From the perspective of their internal experience they may speak of sealing over and minimizing their emotions, "getting used to it," and distancing themselves as best they can from their troubling experiences. Others describe displacing their frustration onto citizens with whom they interact or family members, which may engender a dichotomous world view (i.e., an "us versus them" approach to their most difficult assignments), and a heightened sense of vigilance to real and imagined danger. The range of officers' responses are discussed in terms of the defensive functions they may serve in warding off unwanted feelings of fear, inadequacy, sadness, despair, and anger, as well as the potential interference they may pose in achieving the desired goals of their interventions.

### Changes in Police Responses

Regardless of the setting, the aim of the seminar discussions for both officers and clinicians is to adopt, to the extent possible, the unique perspectives of individual children, to place themselves in the position of children of different ages, developmental phases, and backgrounds ( [Goldstein, Solnit et al., 1996](#)). For the officers, the opportunity to reflect on what they observe, have a framework for ordering what might have otherwise been too overwhelming to notice, and have colleagues with whom to share the burden of responding at any hour has led to dramatic changes in police practices regarding children. These changes are reflected in officers regularly referring children who have witnessed and experienced violence and, increasingly, children who have committed serious violent offenses, for clinical evaluation and treatment.

Similarly, officers have become more attentive to the potential for dangerous confrontation when they deal with adolescents, especially juvenile offenders, in a harsh manner that may evoke feelings of humiliation and undermine nascent feelings of independence and autonomy. As officers have become regular fixtures in neighborhoods, they have replaced anonymous responses to the groups of youth who congregate on street corners with interactions that are informed by familiarity and individual relationships. From the seminars to the streets, this contact is enhanced by officers' increased appreciation of normative adolescent upheaval that is so often compounded by the despair and impotence associated with severe social adversity. As a result, wholesale condemnation, frustration, and anger are not the only responses to the provocative or illegal behavior with which adolescents confront them on a daily basis. Officers recognize that by dint of their authority and uniformed presence, they will often bear the brunt of powerful emotions that are displaced onto them by the people with whom they find it most difficult to work. Knowing that the origins of such an intense, emotional response is not personal, even when it feels that way, has led to a more judicious and strategic use of police authority. This has been especially true with regard to police-adolescent interactions on the street. In New Haven for example, police report that the sometimes necessary imposition of authority (e.g., clearing a street corner known for drug activity, keeping public noise down, picking up truant students) is more frequently met with compliance rather than an immediate escalation to violent confrontation and arrest because of their ability to assert their authority in a manner that discourages an escalation of conflict and resistance to police authority by the youth who are involved.

Since the inception of the CDCP program, each police officer in New Haven, from line officer to senior supervisory officer, has been trained in the principles of child development and acute traumatic responses. The police have welcomed participation in the program and have believed that it has enhanced their professional functioning as police officers. Collaboration with their mental health colleagues has also helped them deal with the alienation and burnout of their ceaseless confrontation with senseless pain and injury. Working alongside mental health professionals, police officers have been able to respond more humanely and effectively to thousands of children in New Haven and other CDCP sites who have witnessed and experienced violence, as well as hundreds of children who have committed violent crimes ( [Child Development Community Policing Program, 1998](#)).

Many of these children and adolescents have received psychological intervention within minutes of being exposed to murders, shootings, stabbings, beatings, fires, drownings, and other forms of violence. A clinical team composed of child and adolescent psychiatrists, psychologists, and social workers provides immediate and extended clinical assessment and intervention to children who come to the attention and concern of police officers. Together with pediatricians, primary care providers, and other nonmental health colleagues, the clinical team addresses neurophysiologic processes and psychiatric, psychosocial, and environmental concerns, and then attempts to develop the most effective and useful range and type of interventions. Children have been cared for employing many different modalities and have been treated individually and as part of larger groups in their homes, at police substations, within schools, in their neighborhoods, and in traditional clinic settings. A major result of the police-mental health collaboration has been the expansion of the clinical field of observation. Officers and mental health professionals now initiate therapeutic contact on the scene. Whereas the application of developmental principles has affected police approaches to routine interactions with youth on the streets and in the schools, it also has led to interventions that are anything but standard in the traditional approach to law enforcement.

---

#### CASE ILLUSTRATION

Following the shooting death of a 17-year-old gang member, there was ample reason for concern about retaliation and further bloodshed. In the days that followed the death, grieving gang members congregated on the corner where the shooting had taken place. The effort at increased presence and removal and containment of violence was in the form of police, neighborhood-based probation officers, and clinicians spending time on the corner listening to gang members express their grief. As one senior police officer put it, "We could show our concern for their trauma by being with them, lending an adult ear to their misery. Alternatively, we could put more officers on the street, show them who's boss and, with a show of force, sweep them off the corner as often as necessary. We could then offer them an additional enemy and wait for them to explode." At the crucial moment, however, the police did not assume the role of enemy. They did not serve as the target for displaced rage or, in confrontation, offer an easy antidote to sadness and helplessness. Rather than exacting payback in blood, the common gang pathway for turning grief into action, the gang discretely assisted the police in making a swift arrest in the shooting. As the brother of the victim put it to a neighborhood cop, "You were there for us; that helped . . . and we were there for you."

---

### Collaborative Responses to Trauma: The Child Development-Community Policing Program Acute Response

Police requests for mental health services on behalf of children whom they have identified as "at risk" results in the provision of a collaborative response for hundreds of cases each year; in calendar year 2000, CDCP clinicians were consulted on 250 cases involving more than 440 children. The largest proportion of police referrals, approaching 50%, results in an immediate clinical response, usually within minutes of the occurrence of a violent event (CDCP, 1998). Clinicians contact the remaining cases within several days of the referral, typically within 24 hours. Although an immediate response is often preferable from a clinical standpoint, initial contact may be delayed for a range of reasons, including concerns about the safety or placement of children, the status of ongoing criminal investigations, or the availability of caregivers to avail themselves to a clinical meeting. The CDCP response ( [Fig. 127.1](#)) ranges from a simple request for consultation from a clinician to a police officer about a child with whom they have had contact to an acute response involving a child and their family who have witnessed or been victimized by violence within the home or community.

**Figure 127.1.** Child Development-Community Policing Program acute response sequences.

## THE CHILD DEVELOPMENT-COMMUNITY POLICING PROGRAM ACUTE RESPONSE

The acute police–mental health response to children and families exposed to violence represents the foundation of the CDCP intervention for potentially traumatized children. The CDCP acute response is initiated by police officers. (See [Table 127.2](#) for a summary.) As they develop concerns about children and families following a violent event, they may contact the clinician by pager directly at any time of day or night. Alternately, they may choose to consult with their immediate supervisor, who typically has received more extensive training through the child development seminars and fellowship, about the utility of a CDCP referral. As a police initiated referral, it is essential that all officers in a department are oriented to the CDCP program and know how access the clinical team. After consultation with the parent or guardian about their concerns for the child and discussing the availability of clinicians, the police officer seeks verbal consent for an acute clinical response. When the officers contact clinicians, they discuss the nature of the event that has led to referral, including who is present, their involvement and relationship to one another, and their specific concerns about the children. Clinicians are informed of any logistical details, as well as any specific issues related to the safety and security of the proposed meeting site. Together the officer and clinician decide if an immediate clinical response is required or if a next day follow-up would be a more appropriate and useful response, although those children and families who receive an immediate response appear more likely to maintain a therapeutic relationship beyond the acute event (CDCP, 1998).

---

Officer reports violent or potential traumatic incident involving children or victims whose presence is requested.  
Officer discusses concerns about welfare of children with adult caregiver(s).  
Parent/caregiver acceptable to contact CDCP clinician.  
Officer shares CDCP clinician's name.  
Officer and clinician discuss case circumstances, history, and location of incident response site if police case or neighborhood, and safety concerns.  
Officer provides name and contact information to supervisor/officer.  
Officer provides name of service and location of incident (location of incident to children's location).  
Officer meets with adult caregiver to collect history and discuss concerns.  
Officer adopts a child-centered approach using drawing and conversation to focus on child's predictability and comfort response to trauma.  
Officer provides psychoeducational information to parent/caregiver about response to traumatic events.  
Officer offers additional services to caregiver for child.  
Officer and clinician meet case to review CDCP form at weekly program conference.  
CDCP form develops and implements conditions for a history police and mental health.

---

**Table 127.2. Summary of Child Development Community Policing Program (CDCP) Acute Response Sequence.**

The primary goals of the acute clinical intervention are to initiate a process of psychological stabilization following a violent event and to allow the child to gain a sense of control in the face of a potentially traumatizing experience. In the face of the ongoing realistic concerns about danger that may result from interpersonal violence, a psychotherapeutic intervention alone will be both naive and counterproductive. Therefore, it is essential that the lead officer and clinician discuss all pertinent aspects of the case together on the clinician's arrival and decide on the best intervention process together. For instance, the timing of a clinical response may be dependent on issues of safety that require leaving the crime scene and relocating the children to another home or a police substation. In other instances, the involvement of child protective services becomes a prerequisite to any clinical intervention, as children whose safety cannot be assured will not benefit from a therapeutic encounter. These questions and decisions may be made prior to the clinician's arrival during the telephone consultation, but should be revisited when the clinician arrives at the incident location. Without attention to concerns about physical and psychological safety, the potential therapeutic effects of the police–mental health response are fatally compromised. Conversely, attention to these matters advances the initial clinical goal of restoring a fledgling sense of safety and predictability in the wake of violence or trauma.

After the child and family's safety is discussed and assessed, the officer serves as the conduit in establishing the initial relationship between the clinician and the family. This allows for the police and clinician to be viewed as a team who together promote both psychological and physical security and expands the role of police beyond their traditional law enforcement response to include recognition of children's mental health needs in the wake of violence. Often, the children ask for the officer to remain present during the clinical consultation, and this request is best honored whenever possible. It sends a message that their physical safety is assured, allowing them the opportunity to feel and express what may be dangerous or overwhelming emotions.

Clinicians may meet with children individually or in small groups depending on the wishes of the family, availability of additional clinicians, and developmental and psychological characteristics of the children themselves (e.g., age range, cognitive development, status as victim, witness, or offender). Multiple clinicians allow in depth assessment of individual children, although when groups of similarly aged children share a common experience, small group meetings may foster expression and mutual support. Concurrent preliminary discussions with adult caregivers focus on gathering relevant history about prior child and family psychosocial functioning and trauma history, as well as providing developmentally informed education and guidance about children's responses to trauma and violence.

In order to help the child gain a sense of control in the face of potentially traumatic violence, the clinician typically follows the child's lead as expressed in words, play, or drawing and through these media helps the child elaborate his or her concerns. Associations to other events or internal psychological dangers are frequently more pressing or prominent than those related to the event that precipitated the intervention. The clinician's ability to listen quietly and empathetically, without telling or cuing the child about what the clinician might wish to hear, permits the child to assume control in metabolizing the event into an understanding consonant with their needs. Rather than becoming a passive recipient of generic strategies for coping with potentially traumatic events or following a proscribed sequence for responding to traumatic experiences, children are encouraged to adopt an active role in communicating their unique concerns, which may or may not resemble the factual events to which they have been witness. Although child-centered, the clinician becomes an active listener, asking for pertinent clarification, and by the meeting's conclusion, providing the child and the family with their knowledge and expertise about a range of potential interventions and expectable responses to violence and trauma.

Clinicians provide psychoeducational information in verbal and written forms about possible traumatic responses and possible mechanisms to cope with them. The former facilitates the burgeoning clinical relationship; the latter provides a concrete reference that can be returned to at times of heightened concern or distress. At the conclusion of the meeting, the clinician provides the family with contact information, asks to follow-up with a visit or phone call (at the family's discretion), and provides information about longer-term consultation and treatment. Specific information, along with the connection to a clinical expert, normalizes the child and family's response to their experience, provides them with support and the security in the knowledge that help is available and accessible, and facilitates a clinical relationship at a time when defenses are more malleable and receptiveness to intervention is accentuated.

The CDCP Acute Response is the clearest manifestation of the police–mental health partnership and the clearest departure from the traditional activities of both police officers and mental health clinicians: the former as purveyors of punishment and reproach and the latter as office-based theorists with scant awareness of the daily adversity with which their youngest patients must contend. The CDCP Acute Response not only provides intervention to children and families sorely in need, but also changes the paradigm by which police and mental health professionals respond to these needs and concerns. Whereas officers have an opportunity to expand their knowledge and repertoire of interventions within a model of youth-oriented community policing, the collaboration with the police has allowed child therapists a new setting in which to increase their understanding of the impact of violence and trauma and provide clinical care to youth prior to the point at which symptoms crystallize into serious psychiatric disorders.

Collaborative discussions about consultation service referrals focus on the extent to which children describe the violent events they have witnessed in terms of the developmental phase-specific anxieties that are aroused. By following the unfolding stories of children exposed to violence, child therapists come to understand the specific features of a violent event and its sequelae that individual children experience as exceptional, overwhelming, and therefore traumatizing. All too often, clinical assumptions and notions about the nature of a child's traumatization seem to be determined by observable features of the violence as it occurred, yet these assumptions may have little to do with the child's experience of violence or the attributions generated in its aftermath. In turn, there may be little attention paid to learning about the child and his or her previous psychological functioning as a basis for understanding his or her unique responses to an experience of violence, which can only be understood in this context of life history, temperament, family constellation, phase development, and defense configuration. Without awareness of basic historical material and child specific response to violence, the clinician has scant data from which to develop recommendations for police and psychiatric intervention. For clinicians and officers alike, closer attention to the details of the individual child's experience has prompted changes in their responses and allowed them to move beyond proscribed responses, which may not adequately address the child's distress.

## CASE ILLUSTRATION

Sergeant G described an incident in which a 7-year-old girl witnessed a beloved neighbor bleed to death after being fatally stabbed by another neighbor. Believing he was protecting her from the gore of the crime scene, Sergeant G had the child wait on the porch outside while officers conducted their investigation. He was haunted by the intense gaze, a mixture of despair and rage, that the girl fixed on him when he finally invited her back into the apartment as the officers were leaving. The next day the sergeant went back to the house and spoke with the girl and her grandmother and understood that his attempt at being helpful had been without the benefit of considering what this girl was experiencing, what was needed, and from whom.

As he explained in the case conference, "Especially in the midst of so much blood and terror, what she needed was to be close to her grandmother, the most stable figure in her life, not to be stranded alone with images of the scene." Both the girl and her grandmother eagerly accepted his offer of a referral for clinical services. As it emerged in her treatment, being alone with frightening ideas and fantasies involving extremes of love and hate was common for this young girl. Her heroin-addicted mother capriciously appeared in and disappeared from her life, and she was additionally burdened by her realistic uncertainty about her grandmother's health and longevity. Both internalized and external conflicts were boldly underlined by her confusion of loyalties in the stabbing. Although she mourned the death of one beloved and idealized maternal substitute, she anxiously told her therapist about the love letters she was writing to the assailant, now in jail on murder charges, but whom she viewed as safer and more available than her inconsistent and absent mother.

---

## CASE ILLUSTRATION

The therapist's focus on helping to integrate a teen's detailed description of violent events with phase-appropriate concerns and past conflicts is illustrated again in this second case.

Mark, 15 years of age, was robbed at gunpoint on a Friday evening. He'd been walking with friends when two men put a reportedly large-caliber semiautomatic weapon in his face and demanded all of his money and gold jewelry. Mark had been walking behind several friends and they were unaware of what was occurring in an alleyway off of the main sidewalk. Mark later reported that the men repeatedly shoved the weapon in his face and told him they would shoot him. After taking his valuables the assailants fled, and Mark ran home. He ran to his room crying uncontrollably, hid on the floor of his closet, and, in spite of his mother's urging, refused to come out. After a while, through sobs Mark told his mother what had occurred, and she phoned the police.

Each of the three officers who responded had been trained through the child development seminars; the supervisory officer had completed the intensive fellowship. As one of the officers approached the bedroom, Mark began to scream. The officer told him that he had heard what had happened to him and realized the hold-up was a terrifying experience. Mark would not look at the officer and yelled at him to leave the room. The officer was about to leave when the supervisor pointed to his gun and utility belt. With this the officer removed his holster and weapon, explaining to Mark that he would leave them outside of the room because he understood how frightening guns might be to him. Mark continued to sob and shake uncontrollably but allowed the officer to help him out of the room and accepted the suggestion that he go to the emergency room for treatment. The acute consultation service clinician was called and met Mark at the hospital.

During the course of the interview, Mark was able to look at the clinician only after a comment was made about "how feeling very frightened could make a guy feel small and helpless," a particularly undesirable feeling for a 15-year-old boy. Mark began to talk about the events, repeating the same scene and assailants' commands to him over and over. The repetition gradually began to include some slight alterations in the facts, and Mark protested that he should have "grabbed the gun and kicked each of the [attackers] in the balls." He described the size of the gun muzzle as huge and insisted that he thought they would kill him with this huge weapon. As his shaking, hyperventilation, and sobbing subsided, Mark began to talk about the earlier part of the evening. He explained that before being robbed he had been "hanging back from his homeboys because they were with their ladies" and he wanted to "give them space." He shyly told the clinician that he didn't have a girlfriend and then quickly exploded with rage and then tears. He wanted to get a gun and kill the guys who "messed with him." He protested that he didn't deserve what had happened to him—he was a good student in school and had just completed an important history paper. He explained that he'd bought all of the thin gold chains he wore for himself, clarifying that he was not to be lumped together with "low-life drug dealers." Mark began to cry again, as he swore revenge. The clinician commented that it felt humiliating to have to feel so terrified and that Mark was wishing that he could undo his experience. Mark replied that if he had a gun or had disarmed his attackers, he wouldn't have to feel as though he'd "wimped out." The clinician agreed that feeling powerful would certainly be the opposite of what he had experienced with a gun in his face. Mark brightened and looked up suddenly, exclaiming that he now remembered the gun more clearly—it wasn't a 9-mm semiautomatic; it was a BB gun. As the acute terror diminished, he was also able to remember the make of the car the assailants took off in and provide clear descriptions of the two men. His restitution fantasies of revenge began to take another form as Mark talked about helping the police make an arrest. On his request, Mark spoke with the detective involved in the case to offer the information he had recovered in the course of the interview. Two hours after the admission to the emergency room, Mark was discharged.

Mark was seen in outpatient sessions during which he continued to go over the events of that Friday evening as well as exploring equally disturbing lifetime events. The fantasies of what he should have done in both domains were intermingled with talk of the mortification of feeling helpless and the increasing recognition that, in fact, there was nothing he could have done to alter what had occurred. In addition to his hard work in psychotherapy and his enrollment in a special academic program, another ingredient played a crucial role in Mark's improved adaptation. In the months that followed the robbery, the officer who had unhitched his utility belt began stopping in on him regularly for brief chats during the course of his usual beat patrol. The officer's friendship and authoritative monitoring played an essential role in deterring Mark from what emerged as his beginning involvement with drug dealing and engaged him in an after-school activities group. Eighteen months after the incident, Mark has still not "scored" a gun, and instead of continuing to recite numerous violent revenge fantasies, he spoke of the latest academic demands at school and his friendships with the cops on his beat. Although he has not forgotten the terror or rage associated with his experience, Mark knew that his good memory had been instrumental in the arrest and later conviction of the two men who had attacked him. And, as he said, "That feels really good."

---

## Extending the Model

Recognizing the ubiquity of domestic violence in the lives of children, CDCP officers, clinicians, outreach workers, and domestic violence court advocates have implemented a specialized protocol designed to reduce the incidence and severity of domestic violence. In two pilot districts, domestic 911 calls to police result in a CDCP referral and subsequent coordinated intervention involving police, clinical, and court personnel. Initial strategies focus on the safety of mothers and their affected children. Neighborhood police officers and clinical outreach workers conduct follow-up visits to victims' homes where they address pressing concerns about safety. This outreach team ensures appropriate linkage to advocates based in a specialized domestic violence court and assists with communication about protective orders. Mothers who may have difficulty engaging law enforcement or clinical services for their own benefit may respond more readily to these professionals' concerns about the welfare of their children. In the best of circumstances, the neighborhood officer and clinical outreach worker become increasingly familiar to the family, heightening the likelihood of an earlier response should future instances of violence occur and forging an improved sense of safety and security through benign relationships with police authorities and community-based clinical providers that are based on mutual concern for the effects of witnessing domestic violence on children's development.

Preliminary impressions suggest a decrease in recidivism for those domestic violence cases that have received intensive police and clinical follow-up ( [Akiyama and Nolan, 1999](#); [New Haven Department of Police Service, 2001](#) ). In some instances, police follow-up visits have resulted in additional charges being filed against the perpetrator, primarily for violations of court orders. Increased referrals to the CDCP clinical team have provided additional support and resources to domestic violence victims, including intensive clinical services for children who have been exposed to repeated violence and victims whose sense of safety has been compromised. Officers have reported an increased sense of effectiveness in dealing with domestic violence cases, and victims report satisfaction with the attention and support they have received from officers.

Police, juvenile probation officers, child protective service workers, and mental health professionals have also expanded their collaboration to address the inefficiency and limitations of the juvenile justice system in addressing the needs of children and adolescents involved in violent and other criminal activities. Multiple professionals have known various children arrested for delinquent acts prior to their involvement in the juvenile justice system, yet often they have not benefited from efforts at engagement in mental health treatment. Therefore, arrest can represent an opportunity for collaboration and interdisciplinary problem solving as an alternative to traditional approaches that emphasize the independence of the court and associated agencies and often result in duplication of efforts or court-ordered stipulations that are mismatched to the child's needs.

In the current collaboration police and probation officers have begun to share supervision and monitoring of juvenile offenders by relocating probation officers to community substations and by engaging neighborhood officers in supervising community service projects for youth on probation. Comprehensive clinical evaluations are combined with information contributed by probation, police, child protection, mental health, and education professionals so that interventions can be developed, coordinated, and monitored from multiple dimensions of the child's life. These services include the integration of individual, family, and group psychotherapies; mandated community service; curfews; shared probation and police monitoring and supervision; and special education interventions; some or all of which might comprise the individual treatment package for a specific youth.

## Summary

Coordinating responses through The Child Development-Community Policing Program has led to multiple changes in the delivery of clinical and police services. Mental health clinicians and police officers have developed a common language for assessing and responding to the needs of children and families who have been exposed to or involved in violence. Learning from each other, these unlikely partners have established close working relationships that improve and expand the range of interventions they are able to provide while preserving the areas of expertise and responsibilities of each professional group. The immediate access to witnesses, victims, and perpetrators of violent crimes through the acute consultation service provides a unique opportunity to expand the understanding of clinical phenomena from the acute traumatic moment to longer-term adaptation, symptom formation, and recovery. In turn, the initiative introduces the systematic study of basic psychological and neurobiologic functions involved in traumatization as well as the investigation of psychotherapeutic and pharmacologic therapies. Similarly, program involvement with juvenile offenders has led to a coordinated response from the police, mental health, and juvenile justice systems. This project provides an opportunity to develop detailed psychological profiles of antisocial behavior as well as to determine the characteristics that might predict with whom community-based interventions might be most successful. A recent survey of New Haven public school students has yielded promising evidence that youth-oriented community policing and the CDCP model are having a positive impact on the quality of life through promoting feelings of safety and security among youth, decreasing levels of exposure to domestic and community violence, and enhancing perceptions of police as responsive and benevolent authority figures ( [New Haven Public Schools and Yale University, 2000](#); [Schwab-Stone et al., 1999](#) ).

No single group of professionals is able to address the multiple needs of the children and families subject to massive environmental stress. When professionals attempt to intervene in isolation of one another, the multiple and awesome needs of these profoundly stressed children and families become overwhelming. The collaboration among police, probation officers, child protective service workers, and mental health professionals in New Haven provides a model of interdisciplinary action on behalf of children at great developmental risk owing to their exposure to violence and who would be unlikely to receive effective intervention through traditional models of social service delivery.

Our Humanity shall be judged by how we treat our criminals, our children and our insane.

Oliver Wendell Holmes

The first juvenile court was established approximately 100 years ago. Following in close proximity, the Juvenile Psychopathic Institute, directed by Dr. William Healy, was created to investigate the etiology of delinquency. Early child welfare reformers had the prescience to know that child psychiatrists and child psychologists can contribute to the success of juvenile courts ( [Fox, 1996](#)). Although through the years faith has wavered in the court's ability to reform delinquents and psychiatrists' ability to "solve" delinquency, overall the amiable relationship among the juvenile courts, child psychiatry, and community has remained steadfast.

In the following chapter, we discuss the child psychiatrists' role in delinquency cases. In particular, we focus on the role of psychopathology in the formation and treatment of youthful offenders. After reviewing a brief history of the juvenile court system and the contribution of the child psychiatrist to the juvenile court, we discuss the potential developmental pathways of delinquency. Next, we provide an examination of relevant research findings from our own work and the work of others. Finally, we conclude with a discussion of future research and clinical directions for the child psychiatrist involved in the juvenile justice system.

## A BRIEF HISTORY OF THE JUVENILE COURT

In the late 19th century, a separate justice system was created for juveniles because it was apparent that the system for adults was not suitable for children. Developmental reasons (e.g., immaturity) were now for the first time acknowledged to be sufficient grounds for not holding a youth completely responsible for his or her actions and crimes, standing alongside reason of insanity. In addition, a group, often dubbed "child savers," argued that, in comparison to adult offenders, child offenders are more amenable to rehabilitation, less likely to benefit from punishment, and should be held less responsible for their actions ( [Moon et al., 2000](#)). One major outcome of the child savers' arguments was the creation of the first juvenile justice system in Chicago in 1899.

The legal concept of *parens patriae* served as the foundational basis for the establishment of the juvenile justice system. That is, the State would serve as a surrogate parent for those individuals (i.e., juveniles) who could not care for themselves properly. The original juvenile justice philosophy encompassed five central ideas:

1. A special court was needed for neglected, dependent, or delinquent children under the age of 16.
2. Rehabilitation, not punishment, was the purpose.
3. All records and proceedings were to be confidential.
4. When incarcerated, children were to be separated from the corrupting influence of adult criminals.
5. All proceedings were to be informal ( [Crosby and Reppucci, 1993](#)). For the first half of the 20th century, the unoperationalized term "in the child's best interest" guided the juvenile justice system ( [Grisso et al., 1988](#)).

Because of the juvenile court's intrinsic interest in the welfare of children, psychiatrists and their theories on the development and prevention of delinquency generally have been welcomed. Nearly 50 years ago, Markey and Langsam wrote:

The [juvenile] court's legal responsibility has been influenced by basic psychiatric attitudes without becoming subservient to them. The court is thereby stimulated to learn more about the underlying causes of delinquency. This, in turn, prompts an increasing demand for better trained professionals. The psychiatrist acts as an auxiliary to the judge and does not attempt to point out specifically how the judge shall pass sentence or make plans. It is reasonable to suggest that psychiatry has been accepted because it is helpful and applicable, rather than because it adds prestige to the court program ( [Markey and Langsam, 1957](#), p. 799).

Today, the field of forensic psychiatry continues to grow. For the most part, there appears to be a mutual level of appreciation and respect between the courts and the science of psychiatry. Given our newly acquired knowledge of the prevalence of treatable psychiatric disorders in this population, and the fact that we have at our disposal more efficient and well tested treatments for specific disorders, we are in the position to offer new and helpful interventions that are likely to have an immediate and distal impact on the lives of these children.

## DEFINITIONS OF DELINQUENCY

Any clinician working with delinquent or conduct disordered juveniles needs to differentiate among antisocial acts, delinquency, criminality, conduct disorder, antisocial personality disorder, and psychopathy ( [Steiner and AACAP, 1997](#); [Steiner and Feldman, 1999](#); Steiner et al., 1997b). We have discussed these distinctions repeatedly and refer the reader to these publications for a fuller discussion ( [Steiner, 1999](#); [Steiner and Cauffman 1998](#); [Steiner and Wilson, 1999](#)). Suffice it to say that we believe that only a portion of delinquents exhibit an association between their antisocial acts and psychopathology. Certain forms of psychopathology (e.g., conduct disorder and attention deficit hyperactivity disorder [ADHD]) are overrepresented. It is the task of the psychiatrist to help subcategorize the extremely heterogeneous population of delinquents and see to it that those with diagnosable disorders are appropriately treated. We hope that such treatment will reduce antisocial acts, such as has been shown in the case of treatment of ADHD with stimulants across many different studies ( [Hinshaw et al., 1989](#); [Klein and Abikoff, 1997](#)).

## THE CONTRIBUTION OF THE CHILD PSYCHIATRIST TO THE DEVELOPMENT OF DELINQUENCY THEORIES

Several excellent population-based studies of youth at high risk have shed light on the origins of delinquency ( [Loeber et al., 1999](#)). It has become clear that the model that accounts best for the origins of delinquency is a cumulative risk factor model ( [Loeber, 1990](#)). Each risk factor seems to act in a cumulative fashion ( [Rutter et al., 1999](#)). In most cases of delinquency and conduct disorder, there appears to be a gradual accumulation, during the course of childhood and adolescence, of multiple risk factors that are not offset sufficiently by protective factors and that ultimately result in chronic conduct problems ( [Loeber et al., 1993](#); [Steiner and AACAP, 1997](#)). Delinquency arises from risks that accumulate from birth on, including ecological factors, constitutional factors, parenting and parent-related factors, as well as

internal factors such as personality functions, academic performance, and relationship factors, all of which grow in importance as development unfolds. Some of these risks are genetic or constitutional, others environmental or situational. We have newer studies that seek to estimate the relative contributions of genetic and environmental factors to the problem showing a more balanced contribution of environment and internal factors ([Raine, 1993](#)) when comparing these factors in adult criminals. In their data from the Minnesota Family Twin study, [Taylor and colleagues \(2000\)](#) were able to estimate the respective contributions of genes and shared environmental characteristics between children (e.g., parenting), shared environmental characteristics between parents and children (e.g., socioeconomic status), when accounting for similarities between monozygotic and dizygotic twin pairs. Additionally, they measured and estimated the contributions of nonshared environmental characteristics (e.g., life events, specific treatment by parents, and peer influences). In their model, nonshared environment accounted for 56% of the variance in self-reported mild to moderate delinquent acts; genetic influences accounted for 18%, and shared environmental characteristics for 26% in this sample of 17-year-old boys and girls. It is most likely that many of these factors do not exert their influence in a linear and solitary fashion. An interaction among a significant number of such factors ultimately leads to criminality, as has been shown by [Raine and associates \(1994\)](#). In this study, the constitutional risk of birth complications exerted their maximum risk for future violent behavior in the presence of maternal rejection at age 1 year.

It has become clear that delinquency describes a large and heterogeneous population ([Sholevar, 1995](#); [Steiner and AACAP, 1997](#)). Mapping psychopathology onto these samples may facilitate defining the subcategories and help them to receive appropriate intervention. The utility of the diagnosis of conduct disorder by itself appears to be a highly comorbid condition that only sometimes appears in isolation ([Steiner, 1999](#); [Steiner and AACAP, 1997](#)). Another way of putting this is that in the adolescent age range where antisocial and even delinquent behavior is extremely common, most other psychopathological conditions seem to associate with such behaviors. It is an open question as to whether comorbid conduct problems, especially those that are antedated by the onset of other psychiatric disorders (e.g., depression) show a differential outcome from singly diagnosed conduct disorders. From a criminologic viewpoint, it still remains to be seen as to whether a diagnosis such as conduct disorder offers any additional explanatory force beyond the mere criminologic characterization of an individual. Is it true that the label "conduct disorder" rather than that of "delinquent" helps to better explain his or her current or future status (i.e., somebody whose antisocial acts have led to legal conviction and punishment)? One of the main advantages of this label is the independence of legal status. It thus calls for attention to a problem before in a legal sense; it exists, making it amenable to prevention and intervention. By perhaps looking at conduct disorder from the viewpoint of a clustered disturbance of the aggression system, we might add to the understanding why certain youths persist in criminality even after given chance upon chance to break from a lifetime pattern of crime, whereas others desist from such activities easily and quickly even with the most minor intervention. It will be our task in the near future to assess the differential importance of psychopathologic conditions in this cohort, especially in response to well-designed and delivered multimodal interventions. Such studies currently are not available, because we have just begun to map prevalence rates and understand the importance of psychopathology in the context of delinquency.

## THE CONTRIBUTION OF THE CHILD PSYCHIATRIST DURING ADJUDICATION OF JUVENILE DELINQUENTS

The youthful offender may encounter a child psychiatrist or other mental health expert at one or more phases of the legal process: prior to adjudication, after the youth has been dispositioned to help with treatment options, during probation or incarceration, and while on parole. The child psychiatrist can function as a clinical consultant, an expert, and as a part of the juvenile justice mental health system. In each of these roles, a high diversity of training, command of a wide range of interventions, and ability to shift between multiple roles are assets. Our responsibilities and tasks change, as do our relationships with the patients across the various appointments.

During the adjudication phase of a delinquency case, the child psychiatrist may be asked to comment on a number of issues, such as culpability, future conduct, and extenuating circumstances involved in the commission of a crime. In this role, we often have to abandon our usual privileged relationship with the patient. All of these procedures require a public report, which becomes part of the official crime record and is accessible to staff and judiciary as well as the youth. We function as agents of the legal system. We need to take great pains to make sure that the youth and his or her family understands this situation, because it has important implications for confidentiality. In essence, no confidentiality can be granted; information on new or unreported crimes may lead to further prosecution. In California there is a specific legal requirement that new crimes be reported to authorities so they may decide on the necessity of further prosecution. The psychiatrist cannot protect the youth from this reporting requirement, especially when details of events are given. Any psychiatrist should be well aware of the legal statutes in the state of his or her practice governing this set of circumstances.

Child psychiatrists may also be called on to determine the ability of a minor to waive his or her *Miranda* rights. Like adults, juveniles must be read their *Miranda* rights before being interrogated. The *Miranda* warning is read to suspects to ensure that defendants are aware of their rights to not self-incriminate and have a lawyer present when interrogated. It is sometimes questioned whether juveniles have the ability to understand and appreciate, and therefore competently waive their *Miranda* rights. A competent waiver of *Miranda* rights must be done voluntarily, knowingly, and intelligently. [Grisso \(1980, 1981\)](#) found that juvenile offenders aged 14 years and younger were significantly less likely to be considered competent to waive their *Miranda* rights than 15- and 16-year-old and adult offenders. Moreover, 15- and 16-year-old children of low intelligence were significantly less likely to be considered competent to waive their *Miranda* rights than adults of similar intelligence. And, importantly, Grisso found that over 90% of juveniles waived their rights (all of the participants 14 years and younger did so), compared to about 40% to 60% of adults. [Grisso \(1981\)](#) concluded that juveniles should not be allowed to waive their rights to counsel, and recommended that an attorney's presence be required during interrogation. Although this recommendation was made nearly two decades ago, it is only now that some states (e.g., Illinois) are considering legislation to require the presence of an attorney when a child is questioned and during the videotaping of child suspect interrogations.

Another situation in which a forensic psychiatrist may be called on is to evaluate the suitability of a juvenile for transfer of prosecution to adult criminal court. In the recent past, this has become increasingly important because all but five states have made the transfer process easier ([Bilchik, 1999](#)). The two general standards for juvenile transfers are that: (1) the juvenile is not amenable to treatment; and (2) the community needs protection from the juvenile ([Grisso et al., 1988](#); [Poulos and Orchowsky, 1994](#)). In regard to both standards, the following considerations must be taken into account when deciding to transfer cases: whether the juvenile is a recidivistic offender, whether the juvenile has received and/or responded to prior treatment, and the nature of the present charge (e.g., felony, murder) ([Kruh and Brodsky, 1997](#)). [Poulos and Orchowsky \(1994\)](#) found that prior mental health treatment history was negatively associated with transfer decisions, such that those juveniles who had mental health treatment in the past were less likely to be tried in adult court. Finally, some states require the accused juvenile to demonstrate that he or she will benefit from rehabilitation.

Another major task of the child forensic psychiatrist during the adjudication phase is the evaluation of competency. The questions raised regarding the child's competency have become increasingly important, as juvenile court reforms have resulted in making juvenile court more like adult proceedings and as juveniles are being waived to adult court to stand trial. Much of the research conducted on juveniles' legal competency has focused on decision making in the medical arena, specifically on informed consent and the decision to seek medical treatment. Briefly, earlier studies demonstrated that adolescents did not differ from adults in their cognitive decision-making processes ([Grisso and Vierling, 1978](#); [Mann et al., 1989](#)). However, in terms of competency to stand trial, more recent research has revealed that young offenders typically do not meet legal standards and are not comparable to adults ([Grisso, 1997](#)). [Cowden and McKee \(1995\)](#) examined contributing factors to assessments of incompetence, marginal competence, and competence in a population of juveniles. Among the factors to correlate with group assessment was age. Only 16.7% of juveniles 12 years and younger were considered competent. Similarly, [Cooper \(1997\)](#) examined juvenile offenders' competency to stand trial. Before training, only two out of 112 children aged 13 to 16 years were considered competent. After training (i.e., an educational competency training videotape), only 12 juveniles reached a score indicating competence. These results suggest that juveniles need substantial training to be considered competent, that is, to understand and play a meaningful role in their defense.

To overcome the problems associated with juvenile's lack of knowledge, [Grisso and associates \(1987\)](#) recommended that a hearing to determine a juvenile's competency to partake in delinquency proceedings be required when any *one* of the following criteria is met: (a) the juvenile is 12 years or younger; (b) there is an indication of major mental illness or mental retardation; (c) there is an indication of depressed intellectual functioning (borderline IQ or lower), or learning disability; or (d) there is an indication of deficits in memory, attention, or interpretation of reality. Although a majority of juvenile offenders have low intelligence, and many have diagnosable disorders, only one state (Virginia) requires competency hearings for transferred juveniles ([Redding, 1997](#)).

## THE CONTRIBUTION OF THE CHILD PSYCHIATRIST DURING INCARCERATION OF JUVENILE DELINQUENTS

Child psychiatrists are usually employed by the probation or prison system or the judiciary when functioning as consultants when juveniles are incarcerated. The juvenile justice system is charged with the appropriate rehabilitation of the juvenile offender; hence, the questions asked usually involve planning of interventions for the patients and recommendations about appropriate settings in which to carry them out (the assessment of "treatment needs"). On an emergent basis, we are often asked to provide assistance in crisis situations that arise during confinement, or to address issues regarding good or bad conduct in the program. Questions arise regarding the appropriateness of release and future potential for violence as confinement time comes to a close. In California, there are two specific requirements that psychiatrists are often asked to comment on: (a) that the youth develop insight into his condition; and (b) that the youth assume full responsibility for his or her actions. In some special cases, when confinement time is expiring, psychiatrists are asked to assist in the determination of whether confinement time should be extended because of further treatment needs of the patient, usually because the child has responded insufficiently. Very often, as part of such an assessment, we are

asked to assess the risk the patient poses to a specific community or person, if released in his or her essentially unrepentant state.

The situation is somewhat different when child psychiatrists function as employees of juvenile justice systems and provide diagnostic and therapeutic services. In such cases, notes need not reflect the treatment process in as great detail as in a legal record, which may be the object of close cross-examination. Information can be somewhat protected, provided that one defines these parameters with the referring staff. The record still needs to be sufficient to support our treatment decisions. However, ultimately even one's treatment record can be made part of the criminal record by order of the parole board or the court, at which point the material is treated as any other criminal record. Again, the youth needs to be made aware of this possibility, because it might have implications on his or her ability to disclose facts in treatment. Generally, we find it sufficient to issue a warning statement at the beginning of treatment. Such warnings frequently make most youths circumspect in their disclosures. We usually find that this way of proceeding does not impede the delicate and complicated work of exploratory and/or supportive psychotherapy indicted in the treatment of these cases.

Surprisingly, it is only in the recent past that researchers have investigated the mental health of youthful offenders. The research that has been conducted has indicated that the frequency of mental health disorders is higher for delinquents than for comparable nondelinquent adolescents. For example, [Cocozza \(1992\)](#) estimated that every year 150,000 juveniles who come into contact with the juvenile justice system meet the diagnostic criteria for at least one mental disorder. Moreover, certain disorders are extremely common, such as alcohol and substance abuse and dependence; estimates have ranged from 30% to 80% in juvenile delinquents ([Steiner and Cauffman, 1998](#)). Another disproportionately high diagnosis among juvenile offenders is posttraumatic stress disorder (PTSD). Steiner and colleagues (1997a) and [Cauffman and coworkers \(1998\)](#) discovered that in a population of juveniles incarcerated in secure facilities, approximately 50% of the females and 30% of the males fulfilled all criteria for current PTSD. Similarly, [Carrion and Steiner \(2000\)](#) found that in their sample of juvenile delinquents, 28% met criteria for a dissociative disorder and nearly all (97%) self-reported a history of traumatic events. Other disorders, such as affective, psychotic, learning, attention, and anxiety have been found with increased frequencies in other states as well ([Atkins et al., 1999](#); [Pumarieqa et al., 1999](#)), at levels comparable to or exceeding those found in youths from community mental health centers and inpatient units. Clearly, this population is psychiatrically highly compromised, justifying the child psychiatrist's involvement and attention.

Another intriguing line of research involves the frequency and type of personality trait disturbances and even personality disorders among youthful offenders. As we know from the path breaking research by [Robins \(1966\)](#) and others ([Rutter et al., 1999](#); [Zoccolillo et al., 1992](#)), such problems deserve special attention, because they predict in many cases transition to antisocial personality disorder and perhaps even psychopathy as defined by [Hare and colleagues \(1991\)](#). These outcomes portend poorly for the future of the child ([Harrington et al., 1991](#)): Lifetime persistent criminality is likely and, to date, interventions have not been successful, and may even worsen the outcome ([Hare, 1999](#)). A cautionary note should be added: (a) only about half of conduct disordered youth show such progressions; and (b) to date there are no studies with biological interventions in this cohort, and we have some reason to think that at least some psychopharmacologic agents might be effective in this population. Still, the presence of these characteristics in a youth must be considered as serious. Not surprisingly, adolescents adjudicated delinquent often meet the criteria for conduct disorder (CD), oppositional defiant disorder (ODD), and ADHD ([Atkins et al., 1999](#); [Steiner, 1999](#)). In some of our earlier research, we have found that delinquents may not have pure conduct disorders, but rather can be diagnosed with conduct disorder and another one or more diagnoses. In a sample of clinically referred delinquents in custody, 38% were found to have conduct disorder and at least one other internalizing diagnosis (e.g., depression, PTSD), 26% had CD and at least one other externalizing diagnosis (e.g., ODD, ADHD), and 22% had CD by itself (Steiner, 1999).

An examination of stable personality traits (i.e. nonsyndromally defined characteristics) of delinquents also offers an interesting portrayal, and these traits may have predictive value in regard to recidivism and lifetime persistent criminality. One research tool that we find very promising in terms of depicting delinquents is the Weinberger Adjustment Inventory (WAI) ([Weinberger and Schwartz, 1990](#)). The WAI assesses broad personality functioning along two major dimensions: distress (e.g., anxiety, depression) and self-restraint (e.g., suppression of aggression, consideration of others). Intersecting the two dimensions at age-appropriate means creates a four-quadrant typology. The four types are: (a) reactive (high distress, low restraint); (b) suppressor (high distress, high restraint); (c) nonreactive (low distress, low restraint); and (d) repressor (low distress, high restraint). [Steiner, Coffman, and Durburg \(1999\)](#) used this typology to predict recidivism rates among serious institutionalized juvenile offenders. Interestingly, nearly 90% of the nonreactives were rearrested in the 4½ years follow-up. In contrast, less than 50% of the suppressors were rearrested. Findings from this study highlight the importance of examining personality traits and the implications for delinquency prevention and treatment.

## A MODEL OF PERSISTENT DELINQUENCY BASED ON PSYCHOPATHOLOGY

Defining psychopathology as a "harmful dysfunction," [Wakefield \(1992\)](#) states that: (a) a condition causes harm or deprivation of benefit as judged by social norms (and evolutionary purpose); (b) results from the failure of some internal mechanism to perform its natural function (an effect that is part of the evolutionary explanation of the mechanism); (c) It results in adaptive failure-lack of progression in stage-salient tasks and competencies. We would like to add to that definition the notion that the condition has become context independent (i.e., mostly internally driven) in two specific ways: It is independent of social context (i.e., it occurs in all different social settings, as benign and supportive as one can imagine). And it is also independent of the developmental phase of the person who is so affected—temporal context no longer defines the person's conduct and thought. Some forms of delinquency, and hopefully most of the ones associated with the label of conduct disorder, may be viewed from this perspective. Such a model, which is compatible with developmental principles, will assist us in identifying causal processes involved and get us beyond the currently descriptive phenomenology, which may or may not offer advantages over simple criminologic classifications. The model should additionally and increasingly provide us with the needed sophistication to discern those who are very likely to persist in patterns of crime despite all kinds of escapes provided, and ultimately lead them to intensive and new forms of treatment, which has a higher chance of being successful than our current rationalistic appeal to their consciences, sense of responsibility, and ability to think things through.

Despite recent advances in reducing crime and especially juvenile crime ([OJJDP, 1999](#)), juvenile delinquency is still a significant problem in the United States. Whether data are obtained from youth self report or from official crime statistics, the same pattern emerges: There is a sharp rise of antisocial activity between early puberty and late adolescence for both genders ([Snyder, 1994](#)). Some studies ([Caspi et al., 1990](#); [Moffitt and Silva, 1988](#)) report that up to 80% of juveniles are involved in delinquent acts. Although the majority of cases involve property-related offenses, it is also true that juveniles are involved in the perpetration of crimes against persons. Most of all of these crimes appear to be perpetrated by a relatively small number of juveniles: Approximately two-thirds of all violent crimes are committed by juveniles with four or more arrests ([Snyder, 1994](#)). On the other hand, it is also true that although antisocial behavior and delinquency are extremely common in the adolescent age range ([Steiner and Feldman, 1999](#)), the predictive validity of such labels is not very strong for lifetime persistent problems: In fact, the majority of delinquents exit from a lifetime career of crime ([Rutter et al., 1999](#)).

The challenge is to introduce new models of taxonomy and observation to more reliably identify those who are at high risk for reoffending ([Steiner, 1999](#); [Steiner and AACAP, 1997](#)). One such model may be based on the study of the prevalence of psychopathology in delinquent youths. Such a model is distinct from delinquency (a criminologic construct) in that the youth's diagnosis does not depend on their legal status ([Steiner and Cauffman, 1998](#)); it is distinct from the study of traits, such as impulsivity and temperament, in that it seeks to establish qualitative taxa that relate to specific and cost-efficient treatments (e.g., depression, mania, and PTSD).

The model we are proposing attempts to do the following in the prescribed sequence.

### Step One: Diagnose Antisocial Acts That Occur as a Function of Psychopathology

See the modified Wakefield proposition given in the preceding. This step delineates coincidental, situational, and ecologically driven antisocial demeanor, which has a high chance of terminating with change of environment, punishment, education about crime and victims, and so on (i.e., the antisocial action that is generally the purview of classic criminology) from antisocial acts that have a high chance of persisting because of an internal harmful dysfunction that makes the behavior context independent and less amenable to simple criminologic interventions.

### Step Two: Establish the Psychopathologic Process That Associates with the Antisocial Behavior

A primary dysfunction of the aggression system in the youth (e.g., in oppositional-defiant disorder, CD, intermittent explosive disorder), or a dysfunction in the aggression system induced by other forms of psychopathology (e.g., disorders of depression, anxiety, or attention), or more serious forms (e.g., psychosis, pervasive developmental disorders) and macroanatomic disorders of the central nervous system (e.g., seizures, chronic head trauma, or frontal lobe dysfunctions). Also consider whether the disturbance reflects a state (a relatively short-lived disturbance, extending from weeks to months), a trait (extending months to years or lifelong) or a combination of both.

### Step Three: Assign a Causal Sequence to the Disturbance

Did oppositional defiant disorder lead to conduct disorder and substance abuse? Oppositional aggression would then be the primary driving force and primary target for intervention. Or did mood problems lead to substance abuse, conduct disorder, and exposure to traumatogenic incidents, later leading to PTSD and further problems with aggression? Such a developmental sequencing should have therapeutic and prognostic implications and preserve a necessary parsimony in designing treatment plans, a highly desirable feature when operating in juvenile justice settings.

The impetus for introducing this model into the study of delinquency derives from two lines of empiric evidence. First is the relative lack of success of purely criminologic approaches to improve outcomes in delinquent youths (Steiner et al., 1999). Usually, juvenile delinquency has been handled by placements outside of parental homes, removal of parental rights, counseling sessions, and supervision of schooling. During confinement, juveniles receive similar services in a more intensive fashion. Such interventions, however, produced few positive results: Several reviews from the past decades end on a very pessimistic note (Bartol and Bartol, 1989). In the state of California alone, the population of incarcerated juveniles has doubled in the last 10 years (Tinklenberg et al., 1996), whereas recidivism rates of 67% within 4.5 years of their release have been reported (Steiner et al., 1999). From our perspective, such lack of response to selective incapacitation, as incarceration is referred to often in the criminologic literature (Haapanen, 1990), or generic treatment suggests the presence of a substantial psychopathologic component in delinquent youths. In many cases, their behavior has become independent of social context—one of our defining criteria for psychopathology (Steiner and Hayward, 2000).

The second impetus for our model is the fact that there is an accumulating body of evidence that prevalence rates of psychopathology, as traditionally defined within psychiatric nomenclatures, are exceedingly high in delinquent populations either on parole or within confinement. Coccozza (1992) first called attention to this fact in the early 1990s. As mentioned, studies of specific diagnoses yielded very high prevalence rates of PTSD (Cauffman et al., 1998; Foy et al., 1996; Steiner, Garua, Matthews, 1997), dissociative disorder (Carrion and Steiner, 2000), and other diverse psychopathology, especially in comparison to nonclinical populations and on par with prevalence rates found in hospitalized clinical populations (Atkins et al., 1999; Pumariega et al., 1999).

In the first results of our own screening study carried out in the California Youth Authority, we found that using standardized measures of psychopathology (Youth Self Report) (Achenbach, 1991) in approximately 3,638 youths (mean age = 16 years, 92% boys), 20% of boys and girls were in the clinical range on internalizing disorders, and 19% of boys and 30% of girls were in the clinical range on externalizing disorders (Table 128.1). More important, these scales correlate very highly with some personality measures, which have been shown to contribute to criminal recidivism, when age at first offending, number of previous convictions, and severity of current offense were held constant (Steiner et al., 1999; Tinklenberg et al., 1996). The variable of restraint, an obverse measure of impulsivity, relates significantly with the total psychopathology score on the Youth Self Report ( $R = -0.64$ ), the Externalizing subscale ( $R = -0.81$ ), and the Internalizing subscale ( $R = -0.33$ ). This suggests that as the youth identifies internalizing problems (e.g., anxiety and depression) or externalizing problems (e.g., aggression and other disturbances of conduct), their self-reported restraint level (i.e., ability to abstain from impulsive action) decreases. This confers on these morbid youth higher likelihood of recidivism 4.5 and 10 years out, as shown in our previous prospective studies (Steiner et al., 1999; Tinklenberg et al., 1996). The relationship between externalizing problem and restraint is much stronger than with internalizing ones, as one would expect, but the correlation with internalizing problems is not inconsequential, indicating that both types of problems can put youths at increased risk for lifetime persistent patterns of crime. Conversely, we would expect that treating some of these underlying conditions successfully will restore or improve restraint, as we have shown in a small randomized controlled clinical trial of an antikindling agent, divalproex sodium, in a sample of severe and violent conduct disorders (Steiner et al., 2000).

	Males		Females	
	Borderline (%)	Clinical (%)	Borderline (%)	Clinical (%)
Total score	14	23	16	22
Internalizing	12	19	9	20
Withdrawn	8	3	6	2
Anxious/depressed	11	7	11	5
Somatic complaints	4	4	6	2
Externalizing	12	19	7	30
Delinquent behavior	27	21	25	24
Aggressive behavior	5	2	6	8
Attention problems	7	5	10	3
Social problems	5	2	4	4
Thought problems	9	8	18	7

**Table 128.1. Percentage of California Youth Authority Youths Who Fall into Clinical and Borderline Ranges on the Youth Self Report by Gender**

These numbers are all the more impressive given the fact that this self report instrument tends to underestimate the rate of psychopathology in this population, when compared to structured interviews, such as the Diagnostic Interview Schedule for Children (DISC) (Atkins et al., 1999) and compared to other screening instruments, such as the Massachusetts Youth Screening Instrument (MAYSI) (Grisso et al., 1996), which are specifically constructed for the delinquent population (Haapanen and Ingram, 2000). We are currently in the process of concluding our own structured interview study in this population, and preliminary results show that these youths suffer from high levels of psychopathology, between one-third and twice as high as estimated by the Youth Self Report (YSR) results.

The presence of such high levels of psychopathology calls for increased child psychiatric involvement in the systems that handle delinquent youths. No longer is it sufficient to provide the occasional consultation, but is necessary to help the juvenile justice system identify unmet needs, existing and lacking resources, and provide this population with the necessary interventions and services to improve their outcomes more dramatically than we have been able to do to date. It is true that conduct problems are extremely common complications and accompaniments of psychopathology in adolescents. One could argue that such a combination should result in the assignment of youths to treatment facilities rather than incarceration. One also will need to examine the failure of the mental health system in providing care sooner prior to the advent of severe conduct complications. However, at the present time it is also clear that the climate of the country is not such that we are looking to exculpate perpetrators; quite the contrary, there are strong voices calling for increased punishment and the death penalty for juveniles. Against such resistance it is unlikely that we will be successful to assign perpetrators to treatment alone. As the debate continues as to how best handle these cases, we need to be prepared to help with an intermediate step of progress: the introduction of modern continua of care into systems of juvenile detention.

Ultimately, we probably need to help the juvenile justice system rethink where the lines of responsibility and culpability should be drawn. At the present time, it is clear that the McNaughton rule applies to only a small fraction of delinquents: Most of them are not *non compos mentis*, as the rule requires. However, as discussed, it is clear that delinquents are encumbered by factors that are not necessarily operative in the general adolescent population. Most likely we will have to make allowances for these special risks in the legal sense. The child psychiatrist must be prepared to lend a helping hand in this debate. The standard of insanity may not be the right one in these cases. To provide an illustrative metaphor, suffering from depression, PTSD, or disruptive behavior disorders and impulsivity may be more akin to having to drive on the wrong side of the road: Although most of us can perform such a feat for prolonged periods of time when visiting Australia, for instance, certain conditions may change our ability to do it well temporarily: anger, intoxication, fatigue, stress, worry, fear, and general distress, to name a few. Given what we know about the lives of children who end up being delinquent, these emotions and states are extremely common occurrences. Such interference may then manifest itself in at least two ways: (a) resorting to poor reflexive action when rapid decision making is called for (i.e., making a left turn in the car and ending up on the wrong side of the road); or (b) significant drifts in time of antisocial behavior as vigilance relaxes, firm guidelines for prosocial behavior are missed, and influences calling for antisocial action increase (i.e., ending up on the wrong side of the road while driving a deserted country lane, only to recognize that a truck is headed straight for us, while we of course think that he is on the wrong side of the road).

Finally, practitioners in this system need to be aware of the fact that delinquent youths often suffer from a wide range of other health problems, such as tuberculosis, HIV, nutritional deficits, seizure disorders, and head trauma, which can contribute to their psychiatric morbidity and possibly their delinquent behavior (Lewis et al., 1994; Needleman et al., 1996; Thompson and Farrow, 1993). Appropriate consultation should be obtained, especially in cases that present with surprising findings and do not respond to standard treatment. Usually, such consultation is readily available in the systems of juvenile justice, although the quality of services tends to vary considerably.

## SETTINGS FOR INTERVENTION

One of the main problems in the successful rehabilitation and treatment of delinquents is the discontinuity of services these youths experience as they become older and their legal status changes. In general, diversion programs are the domain of police services, social services, and sometimes mental health services. Counties run probation programs, whereas youth authorities are state institutions. During parole, the juvenile returns to county jurisdiction as a rule. All of these services are supported by separate tax dollars; each has its own structure and administrative pyramid. Needless to say, from the perspective of the juvenile offender, such a mosaic can be an absolute nightmare and directly stand in conflict with his or her needs. Because the systems are distinct, they do not provide continuity of care. Because they are administered by different professions, they reflect the parochialism of these professions. It is not unusual for a youth to receive shock incarceration, grief counseling, and victims awareness programming while on probation, vocational counseling and special education while incarcerated, and haloperidol while on parole. Coordination of treatment planning and extension of services needed beyond specific settings are the exception, not the rule. Some notable program models serve as exceptions (e.g., Milwaukee Wrap-Around) (Kamradt, 2000). Yet, if we are to be successful with this population, such conjoint management and consultative arrangements should be the rule and not the exception.

### Juvenile Hall

This is an acute detention center, a pretrial detention facility, or a short-term jail. Programs that are provided usually address schooling and mental health evaluation needs. Casework services, and sometimes day treatment facilities, are available. Lengths of stay are usually short (days to weeks).

### Group Homes and Other Residential Settings

These are long-term placements once the court has found that a youth cannot return home. Stays are extensive, and there is usually an attempt to provide suitable outpatient mental health services in conjunction with the programs offered in the placement setting.

Juvenile detention camps are one such form of extended placement (length of stay is several months). Typically county-run, they are similar in character and concept to incarceration. Placements here are a last resort before referring the youth to a state-run youth authority.

### Youth Authorities

These are state-run systems for the rehabilitation of youths. They are usually operated as part of the department of corrections, which confine delinquent youths who have failed all other alternatives or who have committed few but particularly serious crimes. Although these systems vary in character from state to state, most bear a resemblance to prisons. Programs are administered by peace officers, including treatment and parole staff. Psychologists are on staff and help with program planning and evaluations. Schooling is provided, which may even include junior college level courses. In California, the youth can be confined until the end of his or her sentence or until age 25, whichever comes first.

Programs use behavioral principles to reward good behavior and punish bad behavior. Performance in such programs is monitored daily to weekly, and different privilege levels signal the success or failure of the juveniles or wards of the state, as they are known. A variety of specialized programs are offered (alcohol and drug abuse, victim awareness, specialized sex offender needs, and anger and aggression management). These programs differ widely in their quality and quantity.

Periodically, cases are reviewed by the youthful offender parole board, which makes decisions regarding youths' treatment needs and remaining confinement time, in consultation with the staff and mental health professionals involved in each case. Ultimately, referral to parole is made, at which point the youth is transferred back to the county of origin. Any reoffense generally results in further confinement at the youth authority prior to the age of 18. Any later reoffending is usually dealt with by confinement in adult correctional facilities. Following release from the youth authority and successful completion of parole, the youth's record is permanently destroyed, and need never be mentioned, for example, in future job applications.

### Parole

The last part of a youthful offender's formal rehabilitation is usually spent in the community, with weekly or monthly parole supervision provided by a parole agent. This is a system that is severely burdened by extensive caseloads, and realistically can only provide minimal support, supervision, and structure.

## INTERVENTIONS AND OUTCOMES

Older reviews of the success rates of rehabilitation programs for juvenile delinquents usually concluded that nothing worked (Bartol and Bartol, 1989). The most spectacular failure was that of the Cambridge-Summerville program, often cited as a clinical trial of psychotherapy. Delinquents who were randomly assigned to counseling showed worse or no different outcomes than those who received no counseling (McCord and McCord, 1969). By modern standards this would not be considered a clinical trial for a variety of methodologic reasons, the most important of which is that the delivered treatment was not at all standardized. Lipsey's metaanalysis of more than 400 programs in the early 1990s offered a more positive picture of intervention programs (Lipsey, 1992). He found an overall improvement rate of 10%, which, although modest, is still impressive given the high cost of crime and incarceration and the very diverse nature of the programs reviewed. Furthermore, a significant stratification in the programs was effective in this population; successful programs tended to be privately run, were based in the community, provided interventions with a high level of intensity and duration, and used multiple modes of intervention and a great deal of structure. The most successful variant of this type of program is Henggeler and Borduin's Multisystemic Treatment (MST), which has been tested extensively and shown to be superior to many other alternatives (most notably incarceration), in terms of both efficacy and cost (Borduin et al., 1995; Henggeler, 1997). These principles reflect what is currently known of any successful psychotherapeutic intervention, delivered across all ages and in a wide range of diagnoses (Lock et al., 2001; March, 1995).

The literature is quite deficient in controlled clinical trials of psychopharmacology in this population. Table 128.2 provides a tally of all currently available psychopharmacologic agents tested in proper randomized controlled clinical trials. As of this date, we have a total of 12 studies available, with a grand total of 483 subjects involved (Mean age = 9 years). These studies are predominantly with males, are of very short duration average of about 8 weeks. Six agents were tested, in descending order of number of trials in which these medications were employed: lithium carbonate, divalproex sodium, methylphenidate, haloperidol, carbamazepine, and risperidol. Depending on how we count the study by Klein and Abikoff (1997), which produced equivocal results for one, but not the other agent, eight (or seven studies) favored the medication, four (or five) were equivocal. The studies are difficult to compare: Uniform instrumentation measuring aggression that shows age-appropriate sensitivity and specificity does not exist. All studies enrolled very small samples. Very few compared more than one agent; however, a preliminary recommendation can be given: lithium carbonate, methylphenidate, divalproex sodium, and haloperidol as well as Risperidone seem to be effective in the treatment of conduct disorders. It is highly likely that different comorbidities determine responsiveness to intervention: Concomitant attention problems would signal the use of methylphenidate, affective mood and irritability problems call for mood stabilizers, and cognitive deficits and neurologic impairment would most likely support the use of haloperidol and Risperdal. None of these studies tested a comparison behavioral or other psychotherapeutic intervention, and we can say nothing at this point about the augmenting or detrimental effects of such combination treatments. None of these studies extend over sufficient lengths of times to be able to say with confidence that such treatments continue to show effects after the initial period. We cannot comment on the long-term tolerability of and adherence to such regimens in this difficult-to-treat population. All of these questions deserve an answer. Suffice it to say that these initial studies certainly support continued investigation of these compounds in these youths, regardless of the systemic and other impediments we might encounter.

Study	n	Age	Di	Agents	Setting	Measure	Outcomes

Werner et al., 1997	22	8	CD	MPH	2 weeks	Oppositional/Defiant	MPH + placebo
McCauley et al., 1994	22	11	CD	CCO	1	PA Aggression Index	Drug + placebo
Henggeler et al., 1999	22	11-12	CD	MS	12 weeks	Self-Reported Conduct	Drug + placebo
Werner et al., 2002	22	7	CD	MPH	2 weeks	CD, ODD	High-Dose + low-dose
Shaw et al., 2002	22	11-12	CD	MPH	2 weeks	CD, ODD, IQ	Drug + placebo

Notes: Studies are coded as CD = conduct disorder, ODD = oppositional defiant disorder, Opp = oppositional, CD + ODD = conduct disorder and oppositional defiant disorder. Agents: Hal = haloperidol, CCO = carbamazepine, MPH = methylphenidate, CC = carbamazepine. Aggression: ODD = oppositional defiant disorder, ORE = oppositional defiant disorder and aggression.

**Table 128.2. Randomized, Placebo-Controlled Clinical Trials of Medication for the Treatment of Conduct Disorder (CD).**

## AIMING FOR CONTINUA OF CARE

We are able to distill several salient treatment principles that have promise for success, although our current knowledge base is by no means complete ( [Steiner and AACAP, 1997](#)). The nature and degree of psychopathology that associates with delinquency calls for several program characteristics that need to be implemented to increase our chances of success.

1. Because juvenile delinquents are a highly heterogeneous group, with differing needs and levels of accompanying psychopathology, it is unrealistic to expect that any one intervention or even any one program will be equally effective for all members of such a diverse population. Great care therefore must be taken to profile the youths and address their multiple problems and match interventions to the primary problem. Primacy of problem in a highly comorbid picture can be difficult to establish, but an investigation along developmental principles usually is helpful ( [Steiner and Hayward, 2000](#)). If a condition precedes another in time, it is reasonable to assume that there is a causal connection between them. If a youth is depressed at age 9, substance abusing at age 12, and conduct disordered at age 14, then it would be indicated to see his depression as the pathogenetic center for his condition. His antisocial behavior should respond to treatment of his mood and substance problems.
2. There is little room for complacency or therapeutic nihilism. Loeber and Farrington have most succinctly stated the general message of recent investigations of program efficacy in a recent summary of the accumulated wisdom of an expert panel on the issue: It is never too early and it is never too late (Loeber and Farrington, in press). Early intervention is effective and prevention is preferable to treatment if at all possible. It has a higher chance of success when fewer risks have accumulated ([GAP, 1999](#); [Mrazek and Haggerty, 1994](#)). Conversely, it is also important to continue interventions throughout adolescence because there is accumulating evidence that this approach also can be effective ( [Borduin et al., 1995](#)).
3. Multiple treatment targets should be selected, because most of these youths are deficient in many domains of functioning. Their deficits compound each other: Problems with learning lead to lack of academic success, assortative mating, and social isolation.
4. Most experts agree that there is little chance that isolated single interventions will be effective against all forms of delinquency. Interventions need to be multimodal, they need to be applied over sufficient lengths of time (i.e., over the course of months, not weeks). As much as possible, they need to be delivered in settings that retain the child in the social context to which he or she will return.
5. Simple inoculation approaches and interventions based on single-event hypotheses—boot camps, wilderness programs, and shock incarceration—are not successful ([Grizenko et al., 1993](#); [Mulvey et al., 1993](#); [Sholevar, 1995](#)). All of them, whether biologically or psychosocially based, are at best ineffective and at worst injurious, especially when used in isolation ( [Cowles et al., 1995](#); [Kazdin, 1992](#); [Mendel, 1995](#)).

## FUTURE DIRECTIONS

In this chapter we hoped to establish that juveniles in the legal system are in great need of psychiatric assistance. In order to be more effective, we need to tally the areas of research that we will need to pursue to maximize our impact onto this system. Combining our expertise in development and psychopathology we are in a unique position to offer new tools and interventions that should lead to improved diagnosis, management, and treatment of youths in the system. The following are some areas that deserve particular attention in our opinion.

1. Developmental and psychopathological information should inform the routine procedures of the system. [Steinberg and Cauffman \(2000\)](#) delineated four reasons why an understanding of adolescent development is crucial for an understanding of adolescent criminal behavior. First, adolescence is a period of rapid change, changes in physical, intellectual, emotional, and social appearances, as well as actual capabilities. Second, adolescence is a period of great flexibility in which family, peers, school, and the like can all influence development. Third, adolescence is a formative period in which negative behaviors and attitudes become harder to be modified. Finally, adolescence is a period of great variability within and across individuals. Efforts to gather empiric information on the developmental (cognitive and social) differences between adolescents and adults should be continued and ultimately used to shape public policy and legal practices for adolescents involved in our justice systems. Moreover, developmental information should be considered in conjunction with information on psychopathology.
2. Although we are just beginning to view delinquency through the lenses of development and psychopathology, we already have gained a great deal of insight as to why monochrome approaches to these youths fail. A plotting of the developmental trajectories of these illnesses and disorders so prevalent among these youths, their overlap, our ability to identify them well and quickly, and our ability to establish appropriate services for them should be a high priority given the high levels of disturbance found. We anticipate that the establishment of suitable treatment programs will conflict with criminologic necessities, and there will have to be an active discussion on how best to integrate programs. A top priority also should be the establishment of continua of care that provide appropriate services to youths across funding streams. New models of administration will be necessary to accommodate these.
3. We are becoming increasingly aware of the diverse needs of boys and girls in this system ( [Zoccolillo and Rogers, 1991](#)). It is becoming evident that girls have treatment needs that are several orders of magnitude higher than boys. It is not clear that our current systems are suitable to provide appropriate care. This is an issue that needs to be intensively investigated.
4. It is quite evident that we need sophisticated treatment outcome studies to properly evaluate the short- and long-term efficacy of multimodal treatment programs. These youths have disturbances in multiple domains that overlap and augment each other. We have to bring to bear all that is necessary and that we can muster in a rationally integrated fashion. Particularly missing are studies of modern psychopharmacologic agents that hold considerable promise for cost-effective and efficacious treatment. At the present time, youths in these systems receive low doses of medications over short periods of time. Agents chosen are usually prescribed off label, and there are few if any systematic attempts to evaluate their efficacy. This must change, especially as we have some preliminary evidence accumulating that medications are potentially helpful. Clinics need to be established and evaluated, as should sophisticated randomized controlled clinical trials. Legal impediments to these studies will need to be evaluated and reconsidered.
5. Finally, the study of youths who are in the early phases of going on to life time persistent crime patterns needs to be intensified. The unfortunate youngsters who show the early signs and symptoms of psychopathy should be a high priority. Our ignorance about them has not led us to effective interventions. We should learn considerably more about what might aid them in changing their dismal life trajectories through appropriate delineation and study. The focus to do that has been on their deficient arousal system and possibly dysfunctional frontal lobe functioning. These studies need to be repeated in young subjects, along with a clear mapping of their developmental trajectories and psychopathologic disturbances. It is only with better knowledge that we can hope to help them, and such knowledge will have to include the biological underpinnings of their conditions.

## CONCLUSIONS

Juvenile delinquency is likely to remain a serious problem in the United States for the foreseeable future. Our recent insights into the improved delineation of delinquency from psychopathologically driven antisocial behavior provide us with new opportunities to provide useful psychiatric assistance to the juvenile justice system. Delinquency is often accompanied and/or driven by high rates of coincidental and/or causal comorbidities. We have to be ready to import tested methods of intervention into the system, and retest them in cohorts of these youths. Effective treatment programs for delinquency must use multimodal approaches tailored to each youth's particular set of psychopathologies. Child psychiatrists are uniquely qualified to provide assistance and leadership in the treatment of delinquent youths, because a developmental psychopathology model best captures their problems. Successful involvement in the treatment of delinquent youth requires that psychiatrists maintain a diverse set of skills, high level of flexibility in treatment approaches, and special awareness of the legal parameters governing the rehabilitation of these youngsters. We have suggested that the extensive comorbidity observed in cases of delinquent children may provide a convenient subclassification scheme, because many of the comorbid conditions have immediate management and treatment implications ( [Steiner, 1999](#)). However, it is quite likely also that the sheer accumulation of comorbid diagnoses will have prognostic implications, as it becomes more and more difficult to address each illness in an appropriate manner. Highly compounded psychopathology seems likely to affect multiple domains of functioning and make treatment more difficult, but this hypothesis has yet to be appropriately tested.

We hope that this chapter provides an overview for the child psychiatrist to become more effective and helpful in addressing the needs of youthful offenders. In the past, we have repeatedly called for the increased involvement of our profession ( [Steiner and Cauffman, 1998](#); [Steiner and Stone, 1999](#)), yet only a small minority of child psychiatrists are involved in the diagnosis and treatment of delinquent youths ( [Steiner and Stone, 1999](#)). Most intervention programs are planned and implemented by allied health professions, such as social work, psychology, and criminology. It is our hope that we can improve this state of affairs by providing a state-of-the-art summary of relevant psychiatric research and identifying areas in which this research can have a beneficial impact on the effective treatment of

juvenile offenders.

**Acknowledgment:** *This work was supported by a grant of The California Wellness Foundation-Violence Prevention Initiative to Dr. Steiner. We would especially like to thank Melissa Silverman for her help in preparing the manuscript.*

[Background](#)  
[Telepsychiatry with Children and Adolescents](#)  
[Areas of Expansion](#)  
[Other Uses](#)  
[Problems with Telepsychiatry](#)  
[Summary](#)  
[Chapter References](#)

The explosion of advanced telecommunications technology has changed the day-to-day lives of countless people. A range of technological innovations, from the Internet to intercontinental two-way audiovisual teleconferencing, has helped to minimize the barriers that space and time once placed in the process of human communication and interaction. Telemedicine is most generally described as the use of advanced telecommunications technology to deliver health care at a distance. Because it is not within the scope of this article to discuss all of the various nuances of telemedicine, readers are referred to [Bashshur \(1995\)](#) for a more definitive discussion of telemedicine. On the other hand, common sense suggests that innovations on such a large scale will lead to multiple applications in health care and in psychiatry, in particular. In fact, telepsychiatry has been in use for over 40 years ([Baer et al., 1997](#)).

## BACKGROUND

The use of telemedicine first documented in professional literature is the use of closed-circuit television at the Nebraska Psychiatric Institute in the early 1950s ([Wittson and Benschoter, 1972](#)). The first reference to *telepsychiatry* is found in a description of psychiatric consultation at Massachusetts General Hospital that was completed through the use of interactive television ([Dwyer, 1973](#)). Since then, numerous telepsychiatry initiatives have occurred and are documented in the literature ([Baer et al., 1997](#)). However, most efforts in telepsychiatry have not been specific to child and adolescent patients and have been alternatively described as “psychiatry” or as “mental health” in general ([Allen and Wheeler, 1998](#)).

Early references to the use of audiovisual communication technology specific to child and adolescent psychiatry are descriptions of videotaped monologues created by adolescents with drug problems ([Wilmer 1968, 1970](#)). This technique created tapes that could be reviewed by clinicians and patients *ex post facto*. Real-time, interactive audiovisual communication over distance was not yet feasible owing to exorbitant costs of the technology available at the time. In large part, the advances in technology often described as the *digital revolution* provided the impetus for calling the present period the *Information Age*. Technological advances now make it possible for real-time, face-to-face, interactive audiovisual communication to occur at a fraction of the cost of just a few years ago. This has given rise to the creation of “telemedicine” networks allowing the delivery of health care in rural and isolated areas. Whether these networks are created as statewide systems offering a full range of medical specialties ([Adams and Grigsby, 1995](#)), as networks dedicated to state mental health systems ([Graham, 1996](#)), or personal computer-based video conferencing using standard telephone lines (also known as POTS—“plain old telephone system”) ([Ermer, 1997, 1999](#)), they have the common goal of connecting patients and clinicians. Readers with an interest in the technological and operational aspects of telemedicine in general may find additional information in a book by [Rashid Bashshur and colleagues \(1997\)](#), the definitive work on the subject to date.

## TELEPSYCHIATRY WITH CHILDREN AND ADOLESCENTS

The first documented telepsychiatry program specific to children and adolescents involved the establishment of bidirectional video linkage of Mount Sinai School of Medicine in New York with a child health clinic in east Harlem ([Straker et al., 1976](#)). This project preceded the development of digital technology. At the time of the project's inception, analog signals were sent through coaxial cable, which is roughly the equivalent of closed-circuit TV. The authors concluded that the use of this technology was successful as a means of service delivery to inner-city children.

Over the next two decades, child and adolescent telepsychiatry went through a period of slow or no growth. In the early 1990s, improvements in technology allowed for innovative projects in all areas of telemedicine to proliferate. These programs typically were oriented to delivering services in rural and isolated areas. Child telepsychiatry programs were developed in Newfoundland and Labrador, Canada ([Elford, 1998](#)), Australia ([Gelber, 1998](#); [Gelber and Alexander, 1999](#)), and rural Kansas ([Ermer, 1997, 1999](#); [Sargent et al., 1999](#)) and Kentucky ([Blackmon et al., 1997](#)). Descriptions of these programs offer the common feature of linking child and adolescent psychiatrists to patients at a distance. Although rigorous evaluation of these programs only now is beginning to occur, the authors concluded that these programs offered clinical interactions that were comparable with live, face-to-face interaction. Typically, these projects were small in scope and saw limited numbers of patients. Only recently have randomized, controlled trials of child and adolescent telepsychiatric services been published in the professional literature ([Elford et al., 2000](#); [Gelber and Alexander, 1999](#)). Gelber and Alexander conclude that there are “significant benefits in using the technology,” but add, “it is important to keep monitoring the technology's effect to ensure best practice standards are maintained” (p. 22). The authors argue that videoconferencing is not a substitute for face-to-face contact, but is a tool that complements live interaction. [Elford et al. \(2000\)](#) conclude that child psychiatric assessments can be conducted successfully using personal computer-based videoconferencing technology. These findings are consistent with the findings of [Gelber and Alexander \(1999\)](#). The authors argue that no difference was found in the satisfaction levels of patients or parents, mirroring the findings of [Rohland et al. \(2000\)](#) that telepsychiatry is acceptable to rural populations. A high level of consumer satisfaction with telemedicine child psychiatry consultation has been documented by [Blackmon et al. \(1997\)](#) in rural Kentucky. In fact, most of the parents participating in the [Elford et al. \(2000\)](#) project preferred videoconferencing over traveling long distances. [Karp et al. \(2000\)](#) demonstrated that delivery of services by telemedicine not only was acceptable to families of children with special health care needs, but resulted in decreased out-of-pocket patient travel costs. [Ermer \(1997, 1999\)](#) argues that the quality of clinical interactions by telepsychiatry appears to be comparable with live, face-to-face meetings with children in need of psychiatric services.

## AREAS OF EXPANSION

Child and adolescent telepsychiatry is likely to grow in the coming years. Programs specific to child psychiatry as a stand-alone service will continue to offer services. The integration of child and adolescent psychiatry into other areas is beginning to be documented in the literature. School-based mental health services ([Sargent et al., 1999](#)) and integrated school-based mental health and learning evaluations by telepsychiatry have been documented ([Sargent J., 2000](#)). Likewise, psychology and learning evaluations in schools by telepsychiatry demonstrate that other mental health professionals also have begun to use this means of communication ([Sargent M., 2000](#)). Although school-based telemedicine clinics are not typically established for the purpose of dealing with child behavioral/emotional issues, [Whitten and Cook \(1999\)](#) document a number of cases of children seen for this specific purpose in a school-based telemedicine program.

Integration of telepsychiatry into programs for children with other health care needs is a trend that is likely to continue. Integration of mental health services in school-based telemedicine programs has been discussed, but there are many other examples of programs where telepsychiatry may be useful. [Wheeler \(1998\)](#) describes a pediatric telemedicine network for children with special needs in Texas where technologically dependent children can receive a range of services (p. 17). Homeless children are seen through a telemedicine link in Tampa, Florida (p. 18). The only child psychiatrist in South Carolina fluent in American Sign Language uses telemedicine to see deaf clients from the state School for the Deaf and Blind (p. 20).

Other programs incorporating telepsychiatry include a multidisciplinary team consisting of a child psychiatrist, pediatric neurologist, and other health professionals who see children and adolescents by telemedicine in a pediatric multispecialty clinic for children with significant neurologic, psychological, and social problems ([Vought et al., 2000](#)). [Hilty et al. \(2000\)](#) offer a case example of telepsychiatric consultation in a primary care setting where consultation specific to attention deficit/hyperactivity disorder is offered by telemedicine.

## OTHER USES

Use of telemedicine systems for clinical evaluation in child and adolescent psychiatry is not the only way that networks are being used. A telemedicine network used in South Australia and the Northern Territory is used to deliver educational services to child and adolescent mental health workers. [Mitchell et al. \(2000\)](#) document the

benefits of networking and peer support, reduced travel costs, and improved efficiency of health services. At the same time, the costs of the program, the lack of technical support, and the need for staff training (on using the technology) are all problems encountered in using the network. Using telepsychiatry technology for delivering education and training is likely to be an area of growth in coming years.

## PROBLEMS WITH TELEPSYCHIATRY

Adoption of a new idea, even when it has advantages over the status quo, is not easy. [Everett M. Rogers \(1995\)](#) describes the process as “diffusion of innovations” in a classic work of that title. In essence, Rogers offers a model process through which all innovations move, as they become part of the mainstream thinking and practice. Telepsychiatry is no different from any other innovation. As with the adoption of the telephone, it will take some time before telemedicine is part of the mainstream of medical practice. Likewise, the adoption of telepsychiatry will take time and will encounter obstacles on the way. Although patients may be blamed for the lack of acceptance of telepsychiatry, adoption of the technology by child and adolescent psychiatrists may be more of an obstacle. Even successful programs may have unanticipated consequences or problems because of the novelty of telepsychiatry ([Zaylor, 1999](#)).

In July 1998, the American Psychiatric Association Board of Trustees approved a “Resources Document on Telepsychiatry Via Videoconferencing” describing telepsychiatry applications and other issues. Issues related to privacy, confidentiality, informed consent, medical records, and training/licensure/liability are discussed. These areas represent potential problem areas in the adoption and implementation of telepsychiatric programs. For space reasons, it is not possible to provide a thorough description of these problem areas; suffice it to say that the same problems exist in most live, face-to-face practice situations, especially in the evaluation and treatment of persons at a distance. The unique problems of child and adolescent telepsychiatry are those problems that come with the creation of a widely dispersed caseload where communication depends on the telecommunications infrastructure. As such, the variables affecting telecommunications infrastructure (e.g., weather, integrity of the technology, network support, financial support) may directly or indirectly affect the psychiatric intervention.

## SUMMARY

Telepsychiatry is only one of many major changes underway in the delivery of child and adolescent psychiatric services. The proliferation of telemedicine programs and concomitant telepsychiatry programs suggests that service delivery through advanced telecommunications technology is becoming a mainstream activity in both adult and child and adolescent psychiatry. The Committee on Psychotherapy Work Group on Training and Education of the [American Academy of Child and Adolescent Psychiatry \(1998\)](#) recently issued “Recommendations for Psychotherapy Training,” which specifically refers to telemedicine as a means of linking programs strong in psychotherapy training with other training programs. Although this cannot be taken as a full-scale endorsement of telepsychiatry practice, it is an indication that the advantages of telepsychiatry are being recognized and adoption of this innovation is in process. It probably is most accurate to describe the adoption of telepsychiatry as in an early stage. At this point, there are a number of “early adopters” ([Rogers, 1995](#)) using telemedicine, but most child and adolescent psychiatrists are just beginning to learn about its availability and advantages. The adoption or rejection of child and adolescent telepsychiatry really is not in question. What remains to be seen is the degree to which telepsychiatry will be adopted as a part of mainstream child and adolescent psychiatric practice.

---

### CASE ILLUSTRATION

Tina, a 15-year-old, mildly retarded girl, was referred to her primary care physician because of concerns about her angry outbursts at home and school. Tina recently attempted to run away from home but was picked up by the local police and spent the next 24 hours in juvenile detention. Her behavioral changes began after starting special education classes in a new high school 4 months ago. Her parents and teachers described Tina as a polite teenager who previously never got into trouble.

The nearest child psychiatry services were 80 miles away. The nearest child psychiatrist in practice was 30 miles away and did not provide care to Medicaid patients. The Community Health Center where Tina's physician practiced recently had become part of the statewide telemedicine system by initiating a child telepsychiatry clinic. The telepsychiatry system included a T-1 connection with television monitors projecting video images at real time. This allowed the psychiatrist to interview Tina alone, meet with her parents, and consult with her special education teacher, school social worker, and referring physician. An initial diagnosis of major depression was made without evidence of suicidal, delusional thinking or hallucinations. Recommendations included individual therapy with Tina, parent counseling, school consultation, and a trial of medication. Tina's parents refused consideration of medication but were eager to continue seeing the psychiatrist through the telepsychiatry clinic. Although therapy with an adolescent had not been attempted, the psychiatrist agreed to see Tina weekly, as well as provide consultation to her family, school, and local physician. Over the next 6 months there was marked improvement in her mood, as well as adjustment to high school.

The advantages to telepsychiatry in this case were many. Tina herself indicated that she liked talking with the doctor on the television. Communication between all persons involved in her care, including her father, was possible because the father could attend sessions without missing work. The family did not have to travel long distances, the school was able to participate directly in both assessment and treatment, and the local physician was able to receive consultation from the specialist.

---

### CASE ILLUSTRATION

The second case illustrates a different model of child telepsychiatry. Terry is a 24-month-old girl referred to a multidisciplinary neuropsychiatric team at a major medical center in Georgia, 200 miles north of the family's home. Terry presented with delays in speech, social adaptation, and gross motor skills. Her mother was concerned that her daughter was autistic. At the time of the on-site evaluation, the child was fussy and noncompliant, the young mother was uncomfortable, and there was little understanding of the resources available in the home community. Medical records were incomplete, making a definitive diagnosis and treatment recommendations difficult.

The same multidisciplinary team conducted ongoing telepsychiatry consultations at a health clinic not far from Terry's home in south Georgia. Terry was seen within the next month. The local Early Intervention team, a state and federally supported program providing multidisciplinary services to children from birth to age 3 years presenting with developmental problems, was contacted and able to conduct a preliminary developmental assessment of Terry in the home. Terry was seen by telepsychiatry by the specialty team at the medical center. The technology allowed the child neurologist to complete a neurologic examination, the occupational therapist to assess Terry's gross and fine motor movements, and the other specialists to complete their respective diagnostic evaluations. The assessment was facilitated by the information provided by the local team. The diagnosis supported the mother's impression of autism. Local care was able to provide speech therapy, occupational therapy, a social skills group, and in-home parent teaching to help Terry's mother. The team was able to follow Terry through the telepsychiatry clinic every 6 months for reassessment and treatment changes.

The advantage of telepsychiatry in this situation included the ability of multiple disciplines to work as a team providing specialty care. The child and single mother did not have to travel long distances for a comprehensive evaluation and follow-up consultation. The mother expressed satisfaction with telepsychiatry not only because of the decreased need for travel but because of the simplicity of seeing the specialists in one room, thus avoiding the difficulties of moving between different specialty clinics in large medical centers. Local health care providers were enabled to provide care at a critically important age for Terry with the support of distant specialists.

# 130 RECRUITMENT, TRAINING, AND CERTIFICATION IN CHILD AND ADOLESCENT PSYCHIATRY IN THE UNITED STATES

John E. Schowalter, M.D.

---

[The History of Training](#)  
[Program Accreditation](#)  
[Certification of Individuals](#)  
[Recruitment](#)  
[Conclusions](#)  
[Chapter References](#)

As we begin the 21st century, there are differing opinions about the number of recruits into child and adolescent psychiatry that is necessary to fulfill the research, educational, and service needs of the field and of society. Needs assessment studies routinely show that 5% or 6% of children have a severe mental disorder, and another 10% to 15% have a diagnosable disorder ([Costello, 1989](#); [U.S. Department of Health and Human Services, 1999](#)). This indicates that there should be two or three more times the current number of practitioners and researchers, which is approximately 7,000.

## THE HISTORY OF TRAINING

Medicine began by being passed down as an apprentice-taught skill, not as a university-taught education. Even after the advent of schools of medicine, and up until the middle of the 20th century, the science of medicine, learned at the university, was considered far less important than the art of medicine, learned from a more experienced colleague. It is because of this tradition that we still speak of residency training rather than residency education.

Child psychiatry in this country began during the first decade of the 20th century. The state of Illinois established in 1899 the Juvenile Court of Cook County, the first of its kind in the United States. As a means to study and treat delinquents, Dr. William Healy in 1909 formed a child guidance clinic, the Juvenile Psychopathic Institute in Chicago. This became the prototype for future clinics and employed a multidisciplinary staff that consisted of the so-called holy trinity: psychiatry, psychology, and social work. As child guidance clinics grew in numbers and in size during the second quarter of the century, it was increasingly necessary to train personnel for this new type of work. The clinics typically were headed by a psychiatrist, but the tasks accomplished by the staff of the three disciplines, with the exception of prescription writing and psychological testing, became increasingly interchangeable. It soon became clear that psychiatrists who worked with children must have training that was more extensive and specific than that obtained in their general psychiatry residency. Under the auspices of the Commonwealth Fund, a major conference was held in 1944 that provided an agreed-on set of skill areas that should be mastered by psychiatrists who treat children and their families ([Cohen, 1987](#)). These skill areas included growth and development, psychodynamics, work with parents, administration, and community organization. The psychoanalytic viewpoint initially was by far the most prevalent nationally, but the emphasis of any particular clinic's training was unique to the beliefs of the director, the makeup of the staff, and the clinic's setting.

The year 1946 was a watershed one for child psychiatry training. World War II was over, psychiatry had proven itself as a useful medical specialty, and many psychiatrists returned to civilian life. There was a national thrust to do all that could be done to raise children to live in a better world tomorrow. The baby boom generation was born, and an optimistic American society wanted to be assured that this new postwar generation would grow up right. Included in the Mental Health Act of 1946 were monies for the training of child psychiatrists. Also in 1946, the child guidance clinics banded together in a confederation called the American Association of Psychiatric Clinics for Children (AAPCC). The AAPCC set up a training committee. Clinics that wanted to offer approved training had to apply to the committee and be surveyed ([Krug, 1969](#)). This was a rigorous process, and only approximately one-half of the founding clinics were initially approved for training.

Scientific and training articles in the field of child psychiatry during this time tended to be published either in the *American Journal of Psychiatry*, the *American Journal of Orthopsychiatry*, *The Psychoanalytic Study of the Child*, or in pediatric journals. It became clear that child psychiatry needed its own forum, and in 1953 the American Academy of Child Psychiatry was established. This was a by-invitation-only organization for those who had made a "significant" contribution to the field. For the most part, membership in the Academy was synonymous with being a child psychiatry educator. One of the first tasks of the Academy, therefore, was to transfer training accreditation away from the clinic-based and multidisciplinary AAPCC and to an organization that was more medically oriented.

The American Board of Psychiatry and Neurology was established in 1934 and the American Board of Pediatrics in 1933. It was clear that recognition of child psychiatry as a medical subspecialty would better legitimize its status. Many of the early and influential Academy members were pediatricians originally, and there was vigorous debate whether child psychiatry would more appropriately be a subspecialty of pediatrics or of psychiatry. A mail poll was conducted of leading child psychiatrists, and the choice was made for psychiatry. However, the American Board of Pediatrics demanded, and received, the right in perpetuity to appoint a pediatrician member who would be part of the Committee on Certification in Child Psychiatry. With this stipulation, the American Board of Medical Specialties approved the petition, and the first subspecialty candidates in child psychiatry were examined in 1959.

Inextricably linked to subspecialty certification are standardized training criteria formulated through the Accreditation Council of Graduate Medical Education (ACGME). The ACGME Residency Review Committee (RRC) in Psychiatry oversees periodic surveys and decides whether to accredit and reaccredit each program for training ([Schowalter, 1987](#)). This approach was much more medically oriented than the AAPCC reviews. The ACGME demanded that child psychiatry training programs be linked to accredited general psychiatry residency programs and to medical centers approved by the Joint Commission on the Accreditation of Hospitals. These requirements forced the child guidance clinics interested in training to leave, at least somewhat, their community roots and to become more attached to medicine. It also stimulated the development of new child psychiatry training programs that were situated in medical centers rather than freestanding in the community. The relative equality between the "holy trinity" disciplines also shifted because ACGME subspecialty training requirements with each new revision increasingly emphasized the necessity for child psychiatrists to receive the bulk of their training from child psychiatrists.

In 1969, the Academy opened its doors to all child psychiatrists who graduated from or who were in training in ACGME-approved programs. In this same year, the Society of Professors of Child Psychiatry was established. The membership of this organization was limited to chiefs of academic divisions of child psychiatry. Although not every division was accredited for training, the vast majority were, and the Society's relatively small membership made its meetings ideal forums for the discussion of training issues.

The American Association of Directors of Psychiatric Residency Training (AADPRT) and the Association for Academic Psychiatry are more recently formed organizations devoted to education and training. Although they began with an almost exclusive focus on general psychiatry, both organizations in the 1980s deliberately expanded their involvement with child psychiatry training and training directors.

## PROGRAM ACCREDITATION

The ACGME consists of representatives from the American Medical Association (AMA), the American Board of Medical Specialties, the Association of American Medical Colleges, the American Hospital Association, and the Council of Medical Specialty Societies and is responsible for setting training requirements for all specialties and subspecialties approved by the American Board of Medical Specialties. There are two sets of requirements.

The General Requirements are generic and the same regardless of the specialty being reviewed. They are concerned less with the particular training area than with the overall support and surveillance provided by the medical center in which the training program is embedded. These issues include requirements for the selection of trainees and assurance that there are procedures for evaluation, evaluation feedback, grievance reporting, and due process. There also must be adequate compensation, an emphasis on education rather than on service, and acculturation help for those trainees who need it. Until the 1980s, the General Requirements were not stressed nearly as much as the Special Requirements. The ACGME site visitors, who usually survey a program every 3 to 5 years, have recently begun very seriously to query hospital officials about their involvement in and support of the individual program being reviewed. An individual program can be put on probation if the General Requirements are not fulfilled. More often, however, the threat of probation causes the medical center administration to become more forthcoming in its interest in and support of each of its residency training programs. It was the realization that many individual training programs falter because of supervisory or financial neglect by the central administration that caused the ACGME to place increasing emphasis on the General Requirements. Because hospitals and medical

schools do not like to have their programs disaccredited, most program directors have found the General Requirements to be a useful lever whereby to obtain greater institutional support.

The Special Requirements are specific to a particular specialty or subspecialty. They are revised approximately every decade, although discrete changes may be made between revisions. The revisions of the Special Requirements and the evaluation of the ACGME surveys are the responsibility of the Residency Review Committee (RRC). There are RRCs for all accredited specialties, and the RRCs report to the ACGME. RRC members for psychiatry are nominated by three organizations: the AMA, the American Board of Psychiatry and Neurology (ABPN), and the American Psychiatric Association (APA).

According to RRC meeting minutes, the RRC for Psychiatry and Neurology was organized in Chicago in October 1954. Members were chosen by the ABPN and by the AMA Council on Medical Education and Hospitals. At its October 1959 meeting, the RRC noted that the ABPN had developed a "sub-board in child psychiatry," and the question arose whether to review child psychiatry training programs separately or at the same time as the survey of a general psychiatry residency. A decision was made in favor of the former. At the March 1960 meeting, the *Essentials for Child Psychiatry* was reviewed and subsequently approved. At the October 1960 meeting, a child psychiatrist, Dr. William Langford, was invited as a guest. He reviewed 17 programs and approved 11. Dr. Langford's recommendations needed an RRC vote to become official. This format of child psychiatry program review continued until in 1967, the Committee on Certification in Child Psychiatry of the ABPN petitioned for the position of a voting child psychiatrist member on the RRC. The RRC denied this petition at its April meeting, but for the October 1967 meeting listed the child psychiatrist as an "ex-officio member without vote," rather than "guest," as had been done before. This protocol continued unchallenged until the October 1978 meeting, when the RRC expressed concern that child psychiatry program evaluation was in fact decided, if not voted on, by someone not part of the RRC. This seemed suspect functionally and legally, and the RRC requested that an official child psychiatry member be appointed by each of its two parent organizations. The ABPN approved, but the AMA Council on Medical Education refused. At the March 1979 meeting, the lone ex officio child psychiatrist reviewed 28 programs, whereas 6 general psychiatrist members reviewed a total of 30 programs, and 6 neurologist members reviewed only 15 programs. Because it was clear that more child psychiatry reviewers were needed, the RRC repeated even more strongly its request that two child psychiatrists be appointed as full Committee members. This second appeal was approved by both parent organizations, and at the March 1980 meeting two child psychiatrists attended as full Committee members. Two years later, the RRC was restructured so that the neurology and psychiatry components met on separate occasions. It also was decided to include the APA as a third parent organization for the RRC, and as part of its contribution the APA supported a third child psychiatrist member in 1983. Traditionally, the RRC Chair was from the ABPN and the Vice Chair was from the AMA Council on Medical Education. In 1985, the Committee appointed a child psychiatrist as Vice Chair, and this practice has been continued since. In 1989, it was decided to have each program's survey reviewed by two, rather than one, Committee member. This change required enlarging the RRC membership. In 1990, a fourth child psychiatrist was added, and in 1995 a fifth and sixth. In 2002, there were 115 approved residency programs, and 874 approved residency positions in child and adolescent psychiatry.

Although the initial draft of a Special Requirements revision for child and adolescent psychiatry is written by the RRC members, the draft is sent to the program directors of the accredited training sites and to the specialty's foremost national organizations for review. If major changes are made, the second draft is again sent for comment to program directors and to organizations. The revision process usually takes 2 to 3 years. The final approval of Special Requirements comes from the ACGME board. The most recent child and adolescent psychiatry Special Requirements revision went into effect in 2000. Although there are with each revision a greater number of requirements and a stricter enforcement of the requirements, most child and adolescent training directors have historically believed that the quality and quantity of requirements are fair and possible to do in the 2 years allotted ( [Schowalter, 1989](#)). There has not been a comprehensive survey since the late 1980s. At that time, approximately one-fourth of program directors believed that general psychiatry should be reduced to a single year of training, and approximately one-third believed that the child and adolescent psychiatry residency would have to be extended to 3 years before the end of the century. Although this deadline has passed, there is no ground swell for expanding to 3 years. This lack of pressure seems based less on disbelief that expanded knowledge deserves expanded training time, but on practical issues such as resident debt, lack of institutional funding, and fear of a reduction of our applicant pool.

Although there is a continuous debate as to whether child and adolescent psychiatry should, as did pediatrics from internal medicine, split from general psychiatry, the pressure for this is more through rhetoric than action. Most child and adolescent psychiatrists want the ability also to treat adults. And in practical terms, there are very few child and adolescent psychiatry training programs that have a faculty and financial base broad and deep enough to enable them to function as an autonomous department. One commonly raised proposal is to begin subspecialty training in the third postgraduate year and concentrate the next 3 years of residency on work with children and adolescents. This approach has found no support from either Directors of the ABPN or members of the general psychiatry RRC. These two bodies, crucial in the determination of any policy change, believe that less than 2 years of residency with adults is insufficient training to make one board-eligible in general psychiatry.

An innovative 5-year integrated training sequence in pediatrics, general psychiatry, and child and adolescent psychiatry, better known as the Triple Board, began as an experiment in 1985 and was approved nationwide as a combined residency in 1992 ( [Schowalter, 1993](#)). This track is sponsored by the ABPN, the ABPN Committee on Certification in Child and Adolescent Psychiatry, and the American Board of Pediatrics. For trainees in approved programs, the sponsoring bodies waive the usual training periods required for eligibility for their certifying examinations.

## CERTIFICATION OF INDIVIDUALS

Although it is the RRC's responsibility to accredit training programs, the ABPN certifies individuals as competent to practice as specialists. The ABPN determines the accuracy of the applicant's credentials in regard to schooling and residency. To be a candidate for certification in child and adolescent psychiatry, one must have completed at least 3 postgraduate years of ACGME-approved residency in general psychiatry and a 2-year approved residency in child and adolescent psychiatry. One also must have passed the written and oral ABPN examinations in general psychiatry. In 1987, the ABPN approved the expansion of the subspecialty of child psychiatry to child and adolescent psychiatry. This decision was based on the fact that the RRC Special Requirements for child psychiatry already mandated training with adolescents and that more than one-fourth of the content of the written and oral certifying examinations in child psychiatry already were devoted to the adolescent age range. An important impetus for the expansion was administrative. In the late 1980s, there was much interest in forming psychiatric subspecialties. This interest was based both on an expansion of the knowledge base in such areas as geriatric, forensic, and addiction psychiatry, and on a wish for subspecialty recognition for credentialing and differential remuneration. There was at this time also a move to form a separate subspecialty of adolescent psychiatry. By granting this age group to child psychiatry, where it was placed traditionally, the possibility of having a subspecialty of adolescent psychiatry disappeared.

Another major decision in the late 1980s for the ABPN and the Committee on Certification in Child and Adolescent Psychiatry was to move toward time-limited certification. By this is meant that every 10 years the diplomate must meet a set of criteria to remain certified for the next decade. Not only must reassessment be meaningful, but it is important to keep its cost and annoyance to a minimum. In November 1989, the ABPN decided to begin time-limited certification in both general psychiatry and in child and adolescent psychiatry beginning with examinations held after October 1, 1994. There have been many iterations during the past 10 years as to how continuing certification can be best established. The ABPN made a decision in 2000 that beginning in 2002 all recertification examinations would be taken in a secure setting. Although the ABPN originally planned to allow take-home recertification examinations, pressure from the public and from other Boards led to the final decision.

Although there have been increasing numbers of psychiatrists who take the certification examinations, both in general and in child and adolescent psychiatry, certification is technically voluntary. In point of fact, reimbursement and hospital credentialing are increasingly tied to specialty certification. Also, a number of state medical licensing boards have proposed legislation that ties medical relicensure with either the periodic passing of a state examination in general medicine or evidence within the time period of passage of a specialty board licensure or relicensure examination. Therefore, although in psychiatry and in child and adolescent psychiatry there is a "grandfather" clause that exempts anyone certified before the onset of the time-limited certificate to be recertified, hospital credentials boards and state medical license boards may nonetheless require recertification as part of their requirements.

An ongoing challenge for all examining boards is how to provide a truly competence-based examination. It is relatively easy to obtain reliability with a multiple-choice written examination. To show validity (i.e., that the test performance is linked to actual clinical practice) is much more difficult. With any oral examination, the candidate always has the variability of hard or easy graders in the examiners he or she draws. To avoid these variables, the American Board of Internal Medicine dropped its oral examination in 1977, and the American Board of Pediatrics dropped its in 1989. The ABPN is the only board still to use patients with an oral examination. In the child and adolescent psychiatry examination, there is an adolescent patient. With a patient interview, reliability always suffers because the candidate has the luck of the draw for both patient and examiners. Although fairness and reliability are much surer for written examinations, especially with multiple-choice questions, these questions cannot show a candidate's skill level in interacting with a patient. Videotapes of patients, written vignettes, and actors who simulate patients are all possible substitutes for actual patients. Videotapes of patients are used by many boards, but some candidates seem unable to extract material well from a relatively lifeless tape. It seems unfair to fail candidates on video-watching rather than on clinical psychiatry. Written vignettes usually are brief and used more as a stimulus for discussion than as a substitute for a clinical interview. Written patient management problems help keep the focus of the examination on process rather than product ( [Langsley, 1986](#)), but there is little evidence to prove that the ability to answer didactic questions about psychiatry is highly correlated

to practicing well. In the future, there undoubtedly will be an increased use of an examination format that uses computers—for example, with a CD-ROM format. In 1999, the ABPN voted to build a computer center at its headquarters in Deerfield, Illinois. Other Boards have similar facilities in other parts of the country. In time, these centers will allow each other's candidates to take computer examinations in a facility that is geographically close. Although CD-ROMs can present extended video clips of patients and extensive historic, imaging, and laboratory information, they are not able to assess professional demeanor. To measure this most essential psychiatric skill is the main argument for the use of patients or patient simulators. In public opinion surveys, attitudinal qualities are judged to be equal or close to equal to a practitioner's knowledge skills ([Langsley and Yager, 1988](#)). This is even true for much less patient-oriented specialties, such as radiology ([Tarico et al., 1986](#)). In 1999, the ABPN began exploring the use of standardized patients (SP). An SP is an upgraded simulated patient. Psychiatrist experts on various disorders write scripts for what the SP will say and how he or she will act. The SPs are programmed to give the same history and the same responses with every candidate, based on the candidate's ability to elicit them. Standardization eliminates the reliability problems associated with actual patients' vast diversity in severity and in their willingness and ability to cooperate with the candidate. SPs might be belligerent, seductive, or quiet, but it will be enacted the same for every candidate. Although standardization can be presented on a CD-ROM, with the SP, the candidate's personal empathy and professionalism can be measured directly by the SP on a standardized scale. Given the SP, examiners also are standardized to a much greater degree in their question-asking and less able to ride personal hobby-horses. SPs have been used extensively for medical school and licensing examinations ([Hodges et al., 1998, 1999](#)), but never in as high-stakes an examination as Board certification. Some ABPN Directors did not believe SPs could portray mental illness realistically for trained clinicians, but all were convinced after observing SPs in a mock examination. It will be decided in 2003 whether to begin planning to substitute SPs for actual patients in future examinations, including the adolescent section of the child and adolescent examination.

It is clear that a continuum of evaluation is most accurate—a motion picture rather than a snapshot of a candidate's functioning. Program directors can be sources of information to the ABPN about a candidate's clinical and ethical behavior during residency, but the training director's understandable bias often renders such judgments unrealistically positive. There is pressure on the ABPN from the field to have residents take and pass the Part I written examination in the third or fourth postgraduate year. This probably will not much affect child and adolescent psychiatry residencies because many residents take this examination now during their subspecialty years.

Recertification provides an ideal opportunity to create a prospective, longitudinal research component to follow diplomates' careers and to test results over time. Perhaps in this way it can be discovered how to understand better and test for competence as demonstrated in actual clinical performance. The concept of maintenance of certification has become popular with some other Boards. This includes chart audits, as well as periodic examinations. Because of the necessary confidentiality of psychiatric charts, this approach is unlikely to be adopted by the ABPN.

## RECRUITMENT

Child and adolescent psychiatry has a chronic recruitment problem. The Graduate Medical Education National Advisory Committee (GMENAC) Report of 1980 declared child psychiatry the least sufficiently staffed medical specialty and recommended that it triple its numbers from 3,000 to 9,000 in 10 years. The number was not even doubled in the time allotted. Surveys have shown a shortage of child and adolescent psychiatry trainees, faculty, and, especially, researchers ([Beresin and Borus, 1989](#); [Enzer, 1989](#); [Institute of Medicine, 1989](#)).

The last national conference on recruitment for child and adolescent psychiatry was held in 1989. There was consensus that the greatest need was for more researchers and faculty. It also was acknowledged that improvement of the quantity and quality of residents was the best approach to enhance faculty recruitment. Deterrents to recruitment include a relatively long training period coupled with relatively low income. The latter is due to the high-ambulatory, low-procedure nature of work with patients whose families have not yet reached their earning capacity. In addition, researchers' training is extended, and their salaries tend to be lower than those of practitioners and clinically based faculty. The conference participants proposed a great number of suggestions, the foci of which extended from undergraduates and medical students to postfellowship researcher support ([American Academy of Child and Adolescent Psychiatry, 1990](#)). Personal contact is crucial for recruitment. This can be provided through the teaching of child development in college and medical schools, the organization of student child psychiatry clubs, and the provision of individual mentors for interested medical students and general psychiatry residents. Good communication must be established and maintained between child psychiatry and general psychiatry training directors. It is essential that child and adolescent psychiatry rotations be provided to general psychiatry residents before the time at which they must apply for subspecialty training. A greater emphasis on research should be added to the Special Requirements, and the RRC should be more vigorous and eliminate programs that cannot provide comprehensive training. More money is necessary from government, foundation, proprietary hospital, endowment, and other sources to better support child and adolescent researchers through their postresidency fellowships and early faculty years. Without more full-time researchers, there is little likelihood that investigative productivity can be substantially enhanced.

The rise of behavioral managed care organizations and the plummet of the percentage of health care dollars going into psychiatric services ([National Association of Psychiatric Health Systems, 1999](#)) and the federal bias toward primary care training in the 1990s have made a career in psychiatry relatively less appealing. Child psychiatry has suffered proportionally less because for an extra 1 or 2 years of training, residents can be a dual specialist for the rest of their professional careers. Being able to treat, teach about, and supervise for adult, child, and adolescent patients make the subspecialist sought after. In 2000, the American Academy of Child and Adolescent Psychiatry appointed a Task Force on Work Force Needs to update the country's needs for child and adolescent practitioners.

Recruitment into child and adolescent psychiatry varies greatly throughout the world. There are tremendous national differences in the pathways into child psychiatry and in the formal organization of child psychiatry. Therefore, issues for recruitment must be understood in the context of the status of child psychiatry as a profession, the availability of training programs, and the nation's commitments to child and family welfare. In many of the less developed nations, there are few formally trained child psychiatrists. There are nations in which there are fewer than half a dozen individuals who would call themselves child psychiatrists and in which there is not one person who has had training equivalent to that in the United States. Often in such developing nations, child mental health is covered by pediatricians or psychiatrists with special interests in children who may have a rather informal program of practical experience and some specialized tutorials/seminars. The latter focus is on public health and severely disturbed children. In developing nations, including virtually all of Africa and most of the Middle East and Latin America, the field of child psychiatry as a whole is still in early stages of development. There are individuals in these nations who would like to become trained in child psychiatry/child mental health, but there are no or only very limited training opportunities. In these situations, the central issue is not recruitment, but national priorities and availability of academic resources.

In developed countries, the major pathway to child psychiatry usually is through pediatrics or through programs that lead directly to child psychiatry and include training in general psychiatry, pediatrics, and neurology along the way as part of the child psychiatry training. There are few nations such as the United States that require full and prior training in general psychiatry. In many of the developed nations, other than the United States, recruitment into child psychiatry is not a major issue. In some nations, a rate-limiting issue is the number of residency slots that are available (e.g., in the Netherlands, these are limited and individuals may not be able to find residency training in areas of interest). There are no special problems in recruitment in nations such as Germany, Sweden, Israel, the Netherlands, South Korea, or the United Kingdom. These are nations in which child psychiatry is secure as a medical profession. In these nations, child psychiatry usually is a distinct field and not just a subdivision of general psychiatry. There are definite differences in Europe in the nature of what is considered child psychiatry. In Italy, for example, there are literally thousands of child psychiatrists. They are divided into two distinct groups. Most function in community settings and are essentially social advocates/facilitators/family guides; a smaller number are more closely related to neurology; and some are devoted to psychoanalysis. On the other hand, child psychiatrists in Germany and the Netherlands are very similar in orientation and function to those in the United States, although they tend to serve much more as specialists and consultants. Those in Sweden usually are trained in pediatrics and function as pediatric subspecialists. In all of these nations, child psychiatrists usually are not trained in adult psychiatry. Because of the possibility of physicians moving across national borders in the European Union, the European nations have adopted a uniform set of recommendations for the scope of training in child psychiatry. In content, these are similar to those in the United States.

## CONCLUSIONS

Child and adolescent psychiatry is the first subspecialty of psychiatry, but subspecialty training continues to struggle with the field's level of interdependence with general psychiatry. This has been true for time allotment, faculty duties, standards, and recruitment. How best to train and certify child and adolescent psychiatrists is an ongoing task made more complicated by the burgeoning of research and clinical data, coupled during the 1990s with daunting cutbacks in training and clinical monies. Answers will arise only through a constant dialogue between the members of the American Academy of Child and Adolescent Psychiatry, the Society of Professors of Child and Adolescent Psychiatry, the Residency Review Committee, and the American Board of Psychiatry and Neurology. A permanent structure for this ongoing debate is necessary and should be developed.

*Editor's Note:* For discussion of antecedents of child and adolescent psychiatry found in historical accounts of the discovery of the child, see [Chapter 133](#). For further

discussion of the history of mental health delivery systems in the United States, see [Chapter 133](#).

“So act as to treat humanity, whether in thine own person or in that of any other, in every case as an end withal, never as a means only.” The German philosopher Immanuel Kant provided this formal statement of the ethical principle of respect for persons. Persons are to be regarded as ultimate values in and of themselves; they are not to be used merely as means to another’s goals.

Those who conduct research involving human subjects first define their goals and then identify persons whom they use as means to accomplish these goals. This is not unethical. What is proscribed is the use of persons merely as means—“as means only.” To avoid this, researchers are required both ethically and legally to secure the approval of persons to be used as research subjects through a process called informed consent. If this approval entails acceptance of the researcher’s goals, then the subject is not used merely as a means. Rather, the subject freely chooses to embrace the goals as his or her own and thus remains an end.

This chapter is concerned with informed consent and other issues related to the principle of respect for persons (e.g., privacy and confidentiality) as they relate to the involvement as research subjects of adolescents and children of various ages.

## ETHICAL PRINCIPLES

The basic ethical principles identified by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research ( [National Commission, 1978](#)) as those that should underlie the conduct of research involving human subjects are “respect for persons,” “beneficence,” and “justice.” These principles were endorsed subsequently by the President’s Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research ( [President’s Commission, 1983](#)) as “basic values” for medical practice as well as for biomedical and behavioral research, calling them by somewhat different names: “respect,” “well-being,” and “equity.” According to these authoritative commissions, research involving human subjects should be conducted in accord with norms or rules designed to uphold and embody these basic principles or values. These rules are assembled in federal regulations for the “protection of human research subjects”; most relevant to the present concerns are those of the Department of Health and Human Services (Code of Federal Regulations, Title 45, Part 46; hereafter abbreviated as 45 CFR 46) and the Food and Drug Administration (Code of Federal Regulations, Title 21, Parts 50 and 56; hereafter abbreviated as 21 CFR 50 and 21 CFR 56).

In this chapter there are frequent references to federal regulations. This is not intended to suggest that all ethical considerations are reflected adequately in the law. Rather, the regulations in this field generally represent a broad social consensus about what ought and ought not to be done. Even for research not covered by the regulations, they have come to be regarded as establishing a community standard, departures from which require justification ( [Levine, 1988](#)). The regulations include both substantive and procedural rules (norms). A substantive rule specifies behaviors that are required (or forbidden) because they are morally right (or wrong). Some procedural rules specify procedures that should be performed to determine the most appropriate behavior when the behavior has not been specified by a substantive rule. Other procedural rules are designed to provide documentary evidence that research has been conducted in accord with the relevant substantive rules ( [Levine, 1988](#)).

### An Illustration

The principle of respect for persons requires that human persons must be treated as autonomous agents. The substantive norm that requires informed consent is a specification of one way in which this principle is to be made operational in the conduct of research involving human subjects. The procedural norm that requires review and approval by an institutional review board affords a method for determining what specific bits of information must be divulged to prospective subjects in a particular research protocol. Another procedural norm that requires the signing of a consent form provides documentary evidence that the behavior required by the substantive norm has been accomplished.

According to the National Commission:

Respect for persons incorporates at least two basic ethical convictions: First, that individuals should be treated as autonomous agents, and second, that persons with diminished autonomy and thus in need of protection are entitled to such protections.

An autonomous person is . . . an individual capable of deliberation about personal goals and of acting under the direction of such deliberation ( [National Commission, 1978](#)).

To show respect for autonomous persons requires that we leave them alone, ven to the point of allowing them to choose activities that might be harmful (e.g., hang gliding), unless they agree or consent that we may do otherwise. We are not to touch them or encroach on their private spaces unless such touching or encroachment is in accord with their wishes. Our actions should be designed to affirm their authority and enhance their capacity to be self-determining; we are not to obstruct their actions unless they are clearly detrimental to others. We show disrespect for autonomous persons when we either repudiate their considered judgments or deny them the freedom to act on those judgments in the absence of compelling reasons to do so.

Clearly, not every human being is capable of self-determination. The capacity for self-determination matures during a person’s life; some lose this capacity partially or completely, owing to illness or mental disability or in situations that severely restrict liberty, such as prisons. Respect for the immature or incapacitated may require one to offer protection to them as they mature or while they are incapacitated.

Because the central focus of this chapter is on respect for persons, it is necessary to emphasize that the other two principles are of equal importance in the sense that they have equal moral force. Research involving human subjects can be considered ethically justified if, and only if, it is adequately responsive to each of the three basic ethical principles ( [Levine, 1988](#)). As we shall see, considerations of justice and beneficence place constraints on, for example, whom we can ask to serve as research subjects and how much risk we may ask them to accept in the interests of research.

## INFORMED CONSENT

Principle I of the [Nuremberg Code \(1949\)](#) provides the definition of consent from which definitions supplied in all subsequent codes and regulations are derived:

The *voluntary* consent of the human subject is absolutely essential.

This means that the person involved should have *legal capacity* to give consent; should be so situated as to be able to exercise *free power of choice*, without the intervention of any element of force, fraud, deceit, duress, over-reaching or other ulterior form of constraint or coercion; and should have sufficient *knowledge* and *comprehension* of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision. (emphasis supplied)

Thus, consent is recognized as valid if it has each of these four essential attributes: It must be competent (legally), voluntary, informed, and comprehending (or understanding).

It is through informed consent that the investigator and subject enter into a relationship, defining mutual expectations and their limits. This relationship differs from ordinary commercial transactions in which each party is responsible for informing himself or herself of the terms and implications of any of their agreements. Professionals who intervene in the lives of others are held to higher standards. They are obligated to inform the layperson of the consequences of their mutual agreements.

It is worth noticing that the Nuremberg Code defines and requires “voluntary consent.” Since 1957 this term has been replaced by “informed consent,” a term that reflects an idealized vision of the person as a rational, self-determining agent ( [Katz, 1984](#)).

Federal regulations identify “elements” of information that must be transmitted during the negotiations for informed consent (45 CFR 46.116a); these are:

1. A statement that the study involves research, an explanation of the purposes of the research, and the expected duration of the subject's participation, a description of the procedures to be followed, and identification of any procedures that are experimental
2. A description of any reasonably foreseeable risks or discomforts to the subject
3. A description of any benefits to the subject or others that may reasonably be expected from the research
4. A disclosure of appropriate alternative procedures or courses of treatment, if any, which might be advantageous to the subject
5. A statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained
6. For research involving more than minimal risk, an explanation as to whether any compensation and an explanation as to whether any medical treatments are available if injury occurs and, if so, what they may consist of or where further information may be obtained
7. An explanation of whom to contact for answers to pertinent questions about the research and research subjects' rights, and whom to contact in the event of a research-related injury to the subject
8. A statement that participation is voluntary, refusal to participate will involve no penalty or loss of benefits to which the subject is otherwise entitled, and the subject may discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled

In addition, according to the regulations, the following elements must be provided “when appropriate”(45 CFR 46.116b):

1. A statement that the particular treatment or procedure may involve risks to the subject (or to the embryo or fetus, if the subject is or may become pregnant) that are currently unforeseeable
2. Anticipated circumstances under which the subject's participation may be terminated by the investigator without regard to the subject's consent
3. Any additional costs to the subject that may result from participation in research
4. The consequences of a subject's decision to withdraw from the research and procedures for orderly termination of participation by the subject
5. A statement that significant new findings developed during the course of the research that may relate to the subject's willingness to continue participation will be provided to the subject
6. The approximate number of subjects involved in the study

The regulations define only minimum standards for informed consent. In most cases it seems appropriate to supplement these basic requirements with additional elements of information ( [Levine, 1988](#)). For example, prospective subjects should be told why they have been selected as invitees to participate in the research; ordinarily, this consists of a statement of the major inclusion and exclusion criteria for the protocol. In addition to the statement of “additional costs to the subject” required by the regulations, there should also be accurate statements of any cash payments or other economic advantages associated with participation in the research as a subject.

How does one determine whether any particular fact (e.g., any particular risk of injury) must be disclosed? The legal criterion for disclosure in the context of medical practice is “material risk”; that is, any fact that is material to the patient's decision must be disclosed ( [Holder, 1978](#); [Levine, 1988](#)). The determination of which risks are material in that they must be disclosed may be accomplished according to three different standards or tests ( [Curran, 1974](#); [Levine, 1988](#)). Until recently, the prevailing standard was that of the “reasonable physician”; the determination of whether any particular risk or other fact should be disclosed was made on the basis of whether it was customary to do so in the community of practicing physicians.

The standard that is applied most commonly is the “reasonable person” or “prudent patient” test. In the case of [Canterbury v. Spence \(1972\)](#), the court held that the disclosure required was determined by the “patient's right of self-decision,” a right that can be effectively exercised only if the patient possesses enough information to enable an intelligent choice. A risk is thus material when a reasonable person, in what the physician knows or should know to be the patient's position, would be likely to attach significance to the risks or cluster of risks in deciding whether or not to forego the proposed therapy.

Some courts have adopted the rule that a risk is material if the particular patient making the choice or decision considers it material. Of the three standards, this rule, which some call the “idiosyncratic person” standard, is most responsive to the requirements of the ethical principle of respect for persons ( [Levine, 1988](#)). It is, however, a highly impractical standard.

In the author's view, the reasonable person standard should determine the minimum amount of information that should be imparted by the researcher to each and every prospective subject. Then, in the course of the consent discussions, the researcher should attempt to learn from each prospective subject what more he or she would like to know.

Federal regulations permit “a consent procedure which does not include, or which alters, some or all of the elements of informed consent” or, in some cases, waiver of the entire requirement for informed consent, if:

[a] The research involves no more than minimal risk to the subjects, [b] The waiver or alteration will not adversely affect the rights and welfare of the subjects, [c] The research could not practicably be carried out without the waiver or alteration, and [d] Whenever appropriate, the subjects will be provided with additional pertinent information after participation (45 CFR 46.11 6d).

Implicit in these conditions—particularly second condition—is recognition of the standard of materiality. One may not withhold any material information without adversely affecting the rights of subjects. Waivers and alterations are commonly used in research involving medical records, “leftover” specimens of tissues and body fluids from which personal identifying information has been removed, survey research, and so on. It is more problematic when researchers propose to alter information for purposes of deceiving prospective research subjects ( [Levine, 1988](#)).

The Department of Health and Human Services (DHHS) makes it clear that, “Nothing in these regulations is intended to limit the authority of a physician to provide emergency medical care, to the extent the physician is permitted to do so under applicable federal, state, or local law” (45 CFR 46.116f). Implicit in this rule is a recognition of two exceptions to the legal requirement for informed consent: the emergency exception and therapeutic privilege. <sup>1</sup>

The Food and Drug Administration (FDA) permits waiver of the consent requirement for the use of investigational new drugs (or other regulated “test articles”) in the treatment of individuals in “life-threatening situations” in which “informed consent cannot be obtained . . . because of an inability to communicate with, or obtain legally effective consent from, the subject” (21 CFR 50.23). There is also a provision in FDA regulations for an exception from informed consent requirements for emergency research; this exception is designed for research activities in which most or all of the prospective subject population will be unable to consent and it will not be feasible

(usually owing to lack of time) to get consent from a legally authorized representative (21 CFR 50.24).<sup>2</sup>

## Consent Forms

Thus far we have been considering informed consent, a process designed to show respect for subjects, fostering their interests by empowering them to pursue and protect their own interests. The consent form, by contrast, is an instrument designed to protect the interests of researchers and their institutions by defending them against civil or criminal liability. I believe that one of the reasons there has been so little successful litigation against investigators, as compared with practicing physicians, is the very formal and thorough documentation of informed consent on consent forms. Consent forms may be detrimental to the subject's interests not only in adversary proceedings; signed consent forms in institutional records may lead to violations of privacy and confidentiality ( [Levine, 1988](#)).

DHHS regulations require that:

A written consent document that embodies the elements of informed consent. . . . This form may be read to the subject or the subject's legally authorized representative, but, in any event, the investigator shall give either the subject or the representative adequate opportunity to read it before it is signed (45 CFR 46.117).<sup>3</sup>

Although the primary purpose of the consent form is to protect the interests of researchers and their institutions, it is forbidden by federal regulations to:

include any exculpatory language through which the subject or the representative is made to waive or appear to waive any of the subject's legal rights, or releases or appears to release the investigator, the sponsor, the institution or its agents from liability for negligence.<sup>4</sup>

DHHS requires that "[a] copy shall be given to the person signing the form" (45 CFR 46.117). The primary purpose of the form notwithstanding, it can and should be designed to be helpful to the subjects. Having a copy of the form will afford them an opportunity to continue to get more information as additional questions occur to them. It can also serve as a reminder of the plans they must follow in order to accomplish the purposes of research, of the symptoms they should watch for to protect their own safety, of the perils of omitting doses of drugs, and so on. It can serve as a guide to conversations they might choose to have with family, friends, personal doctors, and other trusted advisors about whether they should consent; in some cases such conversations should be recommended during the consent negotiations. In the use of these forms, however, the researcher should heed the words of the [President's Commission \(1982\)](#): "Ethically valid consent is a process of shared decision-making based upon mutual respect and participation, not a ritual to be equated with reciting the contents of a form that details the risks of particular treatments."

No consent form can be designed so as to anticipate all of any particular prospective subject's wishes to be informed. The consent form is most effective when it is viewed by the researcher as a guide to the negotiations with the prospective subject. The consent form should contain at least the minimum amount of information and advice that should be presented during the negotiations. If any substantive new understandings are developed in the process of negotiations that have any bearing on the prospective subject's willingness to participate, these should be added to the consent form signed by that individual.

DHHS regulations (45 CFR 46.117) permit waiver of the requirement for documentation of informed consent if:

1. The only record linking the subject and the research would be the consent document and the principal risk would be potential harm resulting from a breach of confidentiality.
2. The research presents no more than minimal risk of harm to subjects and involves no procedures for which written consent is normally required outside of the research context.

In some cases in which the regulations permit waiver of the requirements for documentation, it may be advisable to provide subjects with information sheets. These documents provide a written account of all information that could serve subjects' interests in ways suggested earlier. They differ from consent forms primarily in that they are not signed by subjects and retained by researchers. Thus, they afford limited protection to the researcher and the institution.

## JUSTIFICATION OF RESEARCH INVOLVING CHILDREN

Children, as a class of persons, lack the legal capacity to consent. Moreover, many of them, particularly the younger ones, are not only incapable of sufficient comprehension to meet the Nuremberg Code's standard but are also not "so situated as to be able to exercise free power of choice." It is necessary to rely on other devices to show respect for children because they cannot consent. Two of these devices are permission and assent.

Permission of one or both parents or of the legal guardian is closely related to what was formerly called "proxy consent." With few exceptions, federal regulators regard permission as a necessary condition for authorizing the involvement of a child as a research subject; for children who cannot assent, it is usually a sufficient condition as well. The transactions involved in negotiating a valid permission are in all respects identical to those of informed consent.

Assent by the child should be as close an approximation of consent as the child's capabilities permit.

Before proceeding with our discussion of permission and assent, it is necessary to return to a consideration of the basic ethical principles.

Respect for persons requires that we treat individuals as autonomous agents only to the extent that they are autonomous. As noted earlier, "[p]ersons with diminished autonomy and thus in need of protection are entitled to such protections" ( [National Commission, 1978](#)). In response to this ethical conviction, there is established in federal regulations a standard called "minimal risk," which "means that the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests" (45 CFR 46).<sup>5</sup> Minimal risk serves as a threshold standard in that plans to involve children in research that presents more than minimal risk require special justification and procedural protections.

But many therapeutic procedures present far more than minimal risk, and it is not customary to obstruct children's access to them by calling for special procedural protections. The regulations make it clear that the minimal risk standard is applicable only to procedures that do not "hold out the prospect of direct benefit for the individual subjects" (45 CFR 46.405). Therapeutic procedures, by contrast, are to be authorized and justified precisely as they are in the practice of medicine. That is to say, the risk of any procedure is justified in terms of the benefit expected for the individual child-subject who will bear that risk. Also, as in medical practice, the relationship of anticipated benefit to the risk presented by the procedure must be at least as advantageous to the subject as that presented by any available alternative, unless, of course, the subject (or his or her parents) has considered and refused to accept a superior alternative. These rules are responsive to the ethical principle of beneficence, which as articulated by the [National Commission \(1978\)](#) is expressed in the form of two general rules: " (1) Do no harm; and (2) maximize possible benefits and minimize possible harms."

Justice, as envisioned by the National Commission, requires a fair sharing of the burdens and benefits of society ( [Levine, 1988](#); [National Commission, 1978](#)). In the distribution of these burdens and benefits, special consideration is to be given to those who are vulnerable or disadvantaged. Children are considered vulnerable and are to be protected from exploitation because they lack the capacity to consent. They are not to be involved in research that is irrelevant to the class of person of which they are representative. When appropriate, research should be done first on adults and then on older children before involving younger children and infants ([Levine, 1988](#)).

In summary, children and their parents are not completely free to do their own thing. There are constraints grounded in ethical considerations and enforced by regulations on whom researchers may invite to serve as subjects and how much risk they may be asked to assume for research purposes. With these constraints in mind, we now turn to further consideration of assent and permission.

## Assent

Respect for children does not require that we leave them alone even to the point of allowing them to choose dangerous activities unless they agree that we may do otherwise. Young children have no such liberty rights. What they have instead is a right to custody ( [Freedman, 1975](#)). We show respect for them by fostering their

well being, protecting them from harm, and guiding them to become “the right kind of people.”

As we have already noticed, federal regulations reflect the obligation to protect children from harm and to secure their well being. Let us now consider the obligation to guide their moral and social development—an obligation not recognized explicitly in the regulations.

In the 1970s there was a spirited debate over the legitimacy of using persons who are incapable of consent (“unconsenting subjects”) as research subjects. [Paul Ramsey \(1976\)](#) argued that it is always morally wrong. [Richard McCormick \(1974\)](#), arguing the opposing viewpoint, pointed out that members of a moral community have certain obligations. One of these is to contribute to the general welfare when to do so requires little or no sacrifice. In the case of children, one may presume that they would consent if they could; he calls this a “correctly construed consent.” In his view, when supplemented with parental permission, correctly construed consent authorized the use of children as subjects in research that fulfilled an important social need and involved “no discernible risk.”

At this point, [Terrence Ackerman \(1979\)](#) entered the debate, arguing that we tend to fool ourselves with procedures designed to show respect for the child's very limited autonomy. He claims that the child tends to follow “the course of action that is recommended overtly or covertly by the adults who are responsible for the child's well-being.” He further contends that, in general, this is as it ought to be. “Once we recognize our duty to guide the child and his inclination to be guided the task becomes that of guiding him in ways which will involve his well-being and contribute to his becoming the right kind of person.”

[Willard Gaylin \(1982\)](#) tells the story of a man who acted in accord with Ackerman's position. After directing his 10-year-old son to cooperate with a venipuncture for research purposes, he explained that his direction arose from his perceived moral obligation to teach his child that there are certain things one does to serve the interests of others even if it does cause a bit of pain:

This is my child. I was less concerned with the research involved than with the kind of boy I was raising. I'll be damned if I was going to allow my child, because of some idiotic concept of children's rights, to assume that he was entitled to be a selfish, narcissistic little bastard.

Parenthetically, while it is appropriate to guide and persuade a 10-year-old boy to submit to a venipuncture for research purposes, it is not ethically defensible to command him to do so against his will; it is also contrary to the requirements of federal regulations. Guiding children to become the “right kind of persons” entails teaching them about and encouraging them to embrace the sense of obligation to the moral community discussed in the preceding. It further entails showing respect for their maturing capacities for self-determination; one hopes the child will learn to choose to do unto others as the child would wish them to do unto her or him.

At what age does a child become capable of assent? Federal regulations specify no age, leaving it to the discretion of the Institutional Review Board (IRB), taking into account not only the age but also the maturity and psychological state of the children involved.

As the assent regulation is written, it seems to reflect a presumption that the capability to assent is an all-or-none phenomenon; the child is either capable or incapable of assent. This presumption is incorrect ([Weithorn, 1983a, b](#)) and, the author believes, unintended by the regulation writers. In the author's view the regulations are intended to be interpreted to permit a determination that prospective child-subjects may be capable of understanding some but not all of the elements of informed consent. Thus, for example, it may be appropriate to provide some children with “a description of any reasonably foreseeable risks or discomforts,” without providing “an explanation as to whether any compensation [is] available if injury occurs.”

It is possible to make some general comments on the capabilities to assent of children having normal cognitive development in various age groups. According to [Lois Weithorn \(1983a\)](#), who relates her empirical findings to Piaget's concepts of cognitive development:

in general, developmental research suggests that most school-aged children are capable of meaningful assent for participation in most types of research studies. This means that the children probably are capable of comprehending the nature of the proposed procedures, the general purpose of the research, and of expressing a preference regarding participation. Research suggests that normal children ages 6 and older are quite capable of thoughtful and reasoned consideration of the types of information that investigators may provide.

Typically, at about age 11, children's cognitive development enters the “stage of formal operations,” during which they become increasingly sophisticated in their capacities to reason about “possibility” and other abstract concepts. From ages 7 to 11, in the “stage of concrete operations,” the child is more or less limited to thinking about matters that are not too far removed from concrete reality. Thus, there are those who argue that the “age of assent” should be around 6 or 7, and others who say it should be around 11 or 12.<sup>6</sup>

[Weithorn \(1983a\)](#) continues:

Early empirical findings also suggest that, although they may not be legally authorized to provide independent consent for treatment or research in most jurisdictions, normal adolescents age 14 and older may be as capable as adults of making competent decisions about such participation, according to the more stringent legal standards of competency.

The authority of mature and emancipated minors to consent is discussed subsequently in this chapter. (See [Chapter 113](#) for definitions of “mature minors” and “emancipated minors.”)

## Permission

Parental permission is envisioned by the National Commission as a reflection of the collective judgment of the family that an infant or child may participate in research ([Levine, 1988](#); [National Commission, 1977](#)). In most cases the permission of one parent is sufficient; one may assume that he or she will represent the family's wishes satisfactorily.

When more than minimal risk is presented by a nontherapeutic procedure, the permission of both parents is required unless one is “deceased, unknown, incompetent, or not reasonably available, or when only one person has legal responsibility for the care or custody of the child” (45 CFR 46.408).

There are three additional criteria for justification of nontherapeutic procedures that present more than minimal risk (45 CFR 46.406): First, the degree of risk is limited to “a minor increase over minimal risk.” Second, the procedure or intervention must be “likely to yield generalizable knowledge which is of vital importance for the understanding or amelioration of the subject's disorder or condition.”<sup>7</sup> Third, the procedure or intervention must present “experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social or educational situations.” This means that the procedures must be ones that they or others with the specific disorder or condition under study will ordinarily experience by virtue of their having or being treated for that disorder or condition. Thus, it might be appropriate to invite a child with leukemia who has had several bone marrow examinations to consider having another for research purposes.

The requirement of commensurability reflects the National Commission's judgment that children who have had a procedure performed on them might be more capable than are those who are not so experienced of basing their assent on some familiarity with the procedure and its attendant discomforts; thus their decision to participate will be more knowledgeable.

Even though the parent gives permission, the child's refusal to assent to nontherapeutic interventions should be respected. Those who are incapable of assent may have some capacity to make their wishes known. The term *deliberate objection* is used to recognize that some children who are incapable of meaningful assent are able to communicate their disapproval or refusal of a proposed procedure. A 4-year-old may protest, “No, I don't want to be stuck with a needle.” However, an infant who might in certain circumstances cry or withdraw in response to almost any stimulus is not regarded as capable of deliberate objection. A child's deliberate objection usually should be regarded as a veto to his or her involvement in research ([Levine, 1988](#); [National Commission, 1977](#)).

In the case of therapeutic interventions or procedures, the situation is much different. Federal regulations state simply, the assent of children is not a necessary condition (45 CFR 46.408). Parents have both the right and responsibility to override the objection of school-age children to necessary therapy. With regard to teenagers, decisions regarding authorization of investigational therapies are about as complicated as they are in the practice of medicine. The law recognizes the authority of emancipated and some mature minors to consent to or refuse standard or accepted therapy; these rules are not recognized explicitly in federal regulations

regarding investigational therapies.

In the practical world of decision making about who can authorize a therapeutic procedure, whether it is investigational or accepted, it rarely suffices to point to the law and thereby identify the person who has the legal right to make the decision. Many factors must be taken into account in reaching judgments about the capability of various persons to participate in and, in the event of irreconcilable disputes, prevail in such choices. In general, these judgments become more complicated as the child gets older or the stakes get higher ( [Gaylin, 1982](#); [Thomasma and Mauer, 1982](#)).

IRBs have the authority to waive the requirement for permission when "it is not a reasonable requirement . . . provided an appropriate mechanism for protecting the children is substituted" (45 CFR 46.408). The regulations suggest as an example of research in which a requirement for parental permission might not be reasonable is that on "neglected or abused children." The [National Commission \(1977\)](#) specified several other examples:

Research designed to identify factors related to the incidence or treatment of certain conditions in adolescents for which, in certain jurisdictions, they may legally receive treatment without parental consent; research in which the subjects are "mature minors" and the procedures involved entail essentially no more than minimal risk that such individuals might reasonably assume on their own; research designed to meet the needs of children designated by their parents as "in need of supervision," and research involving children whose parents are legally or functionally incompetent.

The [National Commission \(1977\)](#) further elaborates:

There is no single mechanism that can be substituted for parental permission in every instance. In some cases the consent of mature minors should be sufficient. In other cases court approval may be required. The mechanism involved will vary with the research and the age, status and condition of the prospective subject. . . .

Assent of . . . mature minors should be considered sufficient with respect to research about conditions for which they have the legal authority to consent on their own to treatment. An appropriate mechanism for protecting such subjects might be to require that a clinic nurse or physician, unrelated to the research, explain the nature and the purpose of the research . . . emphasizing that participation is unrelated to provision of care.

Another alternative might be to appoint a social worker, pediatric nurse, or physician to act as surrogate parent when the research is designed, for example, to study neglected or battered children. Such surrogate parents would be expected to participate not only in the process of soliciting the children's cooperation but also in the conduct of the research, in order to provide reassurance for the subject and to intervene or support their desires to withdraw if participation becomes too stressful.

The recommendations of the National Commission reflected their assumption that the "normal" family is one in which the members stand in a loving relationship to one another and that the parents in such a family will strive to protect the interests and welfare of their children. This point notwithstanding, they were aware of the fact that there are exceptions. In obvious cases (e.g., neglected or abused children) they recommended that the IRB should have the authority to waive the requirement for parental permission. In the less obvious cases, of which there may be many, decisions as to whether the parents are loyal to their children and welfare require sophisticated professional judgment. The National Commission wisely refrained from recommending that IRBs engage in micromanagement of such cases. Implicitly, the responsibility for such judgments is assigned to the investigator. The National Commission provided a margin of safety by recommending special substantive and procedural protections in cases in which more than minimal risk is presented by interventions that do not hold out the prospect of direct benefit for the individual child-subject.

In recent years there has been increasing interest in giving mature minors independent authority to authorize their own participation in certain types of research without requiring permission of their parents or guardians. To some extent this interest reflects a general trend in public policy toward facilitating inclusion as research subjects members of groups who were previously excluded ([Levine, 1994](#)). This interest also represents a pragmatic response to problems presented by the AIDS pandemic; specifically, many, and perhaps most, adolescents will not enroll as research subjects if this necessarily entails allowing their parents or guardians to learn or even suspect certain details of their sexual or drug-taking experience ( [Rogers et al., 1994](#)).

Most of the current federal regulations for the protection of human subjects reflect the attitude that prevailed in the 1960s and 1970s when they were written, that investigational drugs and participation in research were dangerous and researchers were likely to exploit subjects. Since the mid-1980s, primarily as a consequence of the efforts of AIDS activists, this vision has been largely replaced by one that research participation and access to investigational drugs are both more beneficial than burdensome. As a result of this shift in perception, public policies that were designed to protect persons from harm and exploitation, particularly those persons who are considered vulnerable by reason of limitation in their capacity to give informed consent, are being reinterpreted or rewritten to assure the same classes of persons equitable access to the benefits of investigational drugs as well as to the benefits of participation in research ( [Levine, 1994](#)).

It has long been known that restrictive policies on involvement of children in research have resulted in a class injustice. Children as a class have been deprived of the benefits of the new knowledge that could result from carrying out research involving children as subjects. This deprivation is exemplified by the fact that approximately 80% of the drugs approved by the FDA for commercial distribution are not labeled for use in children, usually because sufficient studies have not been conducted in children ([American Academy of Pediatrics, 1995](#)). In recent years agencies of the federal government have begun to respond to this class injustice. The National Institutes of Health now require that applications for grants or contracts to conduct research involving human subjects must include plans to enroll children unless the applicant can justify their exclusion ( [National Institutes of Health, 1998](#) ). Similarly, the Food and Drug Administration requires inclusion of children in research done to support an application for a marketing permit unless the sponsor can justify their exclusion (Public Law 105-115; Center for Drug Evaluation and Research).

At the time of this writing, federal policies have not been revised to permit involvement of mature minors as research subjects on their own authority except as discussed earlier in this chapter. However, it seems reasonable to predict that in the near future there could be such changes in the relevant policies or their interpretation. [Rogers and associates \(1994\)](#) and [Levine \(1995\)](#) have published examples of specific proposals.

Inclusion of children who are wards (e.g., of the state) in research in which more than minimal risk is presented by nontherapeutic interventions requires special procedural protections that are beyond the scope of this discussion (45 CFR 46.409) ( [Levine, 1988](#) ). Many states and cities have regulations designed to protect the interests of foster children. Concern has been expressed recently that such regulations often create formidable bureaucratic barriers to involving such children in randomized clinical trials or gaining them access to investigational drugs. For two reasons this presents a special problem to children with AIDS: (a) A large percentage of such children are foster children; and (b) Many apparently effective therapies for AIDS and its complications are investigational drugs ( [Secretary's Work Group on Pediatric HIV Infection and Disease, 1988](#) ).

## DOCUMENTATION

The regulatory requirement for documentation of permission is exactly the same as it is for informed consent. In circumstances in which there is no requirement for permission because the minor is authorized to assent for himself or herself the same requirements for documentation obtain. Apart from this, when children are asked to sign forms, as they often and quite properly are, the principal purpose, in the author's view, is to enhance their sense of participation in the process.

### Privacy and Confidentiality

Privacy is, "the freedom of the individual to pick and choose for himself the time and circumstances under which, and most importantly, the extent to which, his attitudes, beliefs, behavior and opinions are to be shared with or withheld from others" ( [Kelman, 1977](#) ). Because this is the definition used in this chapter, some matters considered by the law to fall under the rubric of privacy are excluded (e.g., the right to abortion and contraception). In general, in clinical research, intrusions into individuals' privacy are permitted only with their informed consent. There is no invasion when an informed person allows a researcher into his or her private space.

*Confidentiality* is a term that is all too often used interchangeably with *privacy*. Confidentiality refers to a mode of management of private information; if a subject shares private information with (confides in) a researcher, the researcher is expected to refrain from sharing this information with others without either the subject's authorization or some other justification.

The ethical grounding for the requirement to respect the privacy of persons may be found in the principle of respect for persons. The ethical justification for confidentiality, according to [Sissela Bok \(1982\)](#), is grounded in four premises, three of which support confidentiality in general; the fourth supports professional

confidentiality in particular.

First and foremost, we must respect the individual's autonomy regarding personal information. To the extent they wish, and to the extent they are capable of doing so, they are entitled to have secrets. This facilitates their ability to live according to their own life plans.

Closely related is the second premise, which recognizes the legitimacy not only of having personal secrets but also of sharing them with whomever one chooses. This premise, which embodies an obligation to show respect for relationships among human beings and respect for intimacy, is exemplified by the marital privilege upheld in American law, according to which one spouse cannot be forced to testify against the other.

The third premise draws on the general requirement to keep promises. A pledge of confidentiality creates an obligation beyond the respect owing to persons and existing relationships. Once we are bound by a promise, we may no longer be fully impartial in our dealings with the promisee.

These three premises, taken together, provide strong prima facie reasons to support confidentiality. That is to say, they are binding on those who have accepted information in confidence unless there are sufficiently powerful reasons to do otherwise—as, for example, when maintaining confidentiality would cause serious harm to innocent third parties.

Bok's fourth premise adds strength to the pledge of silence given by professionals. The professional's duty to maintain confidentiality goes beyond ordinary loyalty, "because of its utility to persons and to society. . . . Individuals benefit from such confidentiality because it allows them to seek help they might otherwise fear to ask for" from doctors or others who can provide it.

Investigators, of course, are not necessarily professionals to whom individuals turn for professional help. Thus, only part of the fourth premise applies to investigators, the part that grounds the justification and requirement for confidentiality in its social utility. If researchers violated the confidence of their subjects, subjects would refuse to cooperate with them. This, in turn, would make it difficult, if not impossible, for researchers to contribute to the development of generalizable knowledge.

Over the millennia, the professions have viewed the obligation to maintain confidentiality as very important. The Hippocratic Oath requires, "What I may see or hear in the course of the treatment or even outside the treatment in regard to the life of men, which on no account one must spread abroad, I will keep to myself holding such things shameful to be spoken about."

[Thomas Percival's Code of Medical Ethics \(1803\)](#), on which was based the first code of ethics of the American Medical Association, incorporated the following exhortation: "Patients should be interrogated concerning their complaints in a tone of voice which cannot be overheard."

In all states, the law not only recognizes the obligation of physicians and many other professionals to maintain confidentiality, it requires it. In many states, there are statutes granting testimonial privilege to information secured by physicians from patients in the course of medical practice ( [Brennan, 1983](#)). Testimonial privilege means that physicians cannot be compelled to disclose such information even under subpoena. Although the United States Supreme Court refused to extend the constitutional protections of privacy to physician–patient communications, the *Federal Rules of Evidence*, promulgated by the Judicial Conference, defer to state law on physician–patient privilege ( [Brennan, 1983](#)).

Most state laws on physician–patient privilege contain various exceptions, including mandatory reporting of information regarding battered and abused children, various communicable diseases, gunshot wounds, and certain proceedings concerned with health issues, including workers' compensation and insurance claims ( [Brennan, 1983](#)).

In 1974, in the case of *Tarasoff v. Board of Regents*, the supreme court of California ruled that a psychiatrist has a duty to protect the intended victim of a patient's threat of violence, if it is likely that such a threat would be carried out ( [Holder, 1985](#)); this often but not always entails a duty to warn the intended victim. Subsequently, this duty has been recognized in many other states. The same principle is often invoked in debates over whether state laws should be changed to either permit or require doctors to warn lovers of persons infected with the HIV virus if they are unwilling to do so themselves ( [Gostin, 1989](#)).

It must be recognized that the right to confidentiality or privilege belongs to the patient. The patient may authorize sharing of private information for whatever purposes he or she chooses. In civil or criminal litigation where the patient makes the information in his or her medical record material to the support of his or her position, as so often happens in child custody cases or malpractice litigation, the court usually requires that the contents of the record be disclosed ( [Holder, 1985](#)).

## Confidentiality in Research

Most direct social injuries to research subjects result from breaches of confidentiality. An investigator may identify a subject as a drug or alcohol abuser, as a participant in various deviant sexual practices, as having any of a variety of diseases that may be deemed unacceptable by his or her family or social or political group, as having a higher or lower income than acquaintances might have predicted, as a felon, and so on. If certain individuals know such information, it might cost the subject his or her reputation, job, social standing, credit, or citizenship.

In recognition of these threats of social injury, federal regulations require the IRB to determine that "Where appropriate, there are adequate provisions to protect the privacy of subjects and to maintain the confidentiality of data" (45 CFR 46.111a).

How does one determine that provisions to maintain confidentiality are "adequate"? The first step is to become aware of the variety of factors that may pose threats to confidentiality in the research context. The second is to become aware of the various devices that are available to secure the confidentiality of research data. <sup>8</sup>

The [National Commission \(1978\)](#) offered some suggestions for safeguards of confidentiality: Depending on the degree of sensitivity of the data, appropriate methods may include coding or removal of individual identifiers as soon as possible, limitation of access to data, or the use of locked file cabinets. Researchers occasionally collect data that, if disclosed, would put subjects in legal jeopardy. Because research records are subject to subpoena, the National Commission suggests that when the identity of subjects who have committed crimes is to be recorded, the study should be conducted under assurances of confidentiality that are available from DHHS as well as the Department of Justice. For detailed information on these assurances of confidentiality, which provide immunity from subpoena, see [Office for Protection from Research Risks \(1993\)](#).

## CONSENT

As mentioned in the preceding, informed consent regulations require "a statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained." Statements about confidentiality of research records should not promise more than the researchers can guarantee. For most studies in which the private information to be collected is not especially sensitive, it suffices to state that the researchers intend to maintain confidentiality, that they will take precautions against violations, and that all reports of the research will be in the form of aggregated data and devoid of identifiers. When dealing with more sensitive information, it may be useful to specify some of the precautions; for example, videotapes will be destroyed within 60 days or, if the subject so requests, earlier; data will be kept in locked files; individuals will be identified by a code and only a small number of researchers will have access to the key that links code numbers to identifiers.

Plans to incorporate data in the subjects' medical record should be made explicit. In general, when these data are relevant to patient management, they should be incorporated unless the subject objects. Incorporation of the results of nonvalidated diagnostic tests may lead to false diagnostic inferences, with adverse consequences to the patient's medical care or insurability. Most people do not understand the full implications of signing forms that release their medical records to insurance companies ( [Siegler, 1982](#)).

It is essential to disclose all serious threats of confidentiality breaches that can be anticipated. One such disclosure was used in a study of devices designed to encourage young children who are thought to have been abused sexually to speak freely of their experiences. A portion of the permission form for the normal control subjects reads as follows ( [Levine, 1988](#)):

Because this study is not intended to be related to either diagnosis or therapy for you or your child, you are entitled to decide whether the information

obtained during this study should be entered into the medical record. If, however, during your child's interview, his or her behavior raises a concern of sexual abuse, a clinical evaluation of your child will be performed. . . . If after that evaluation the suspicion of sexual abuse persists, the case will be reported as mandated by law.

FDA regulations require (21 CFR 50.25a) "a statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained and notes the possibility that the [FDA] may inspect the records."

As noted earlier, federal regulations permit waiver of the informed consent requirement under certain conditions. These conditions are usually but not invariably met in studies of medical records (given adequate safeguards of confidentiality) or of "leftover" specimens obtained at autopsy, surgery, or collection for diagnostic purposes of body fluids such as blood or urine. In general, use of tissues or fluids without consent is justified if two conditions are satisfied ( [Levine, 1988](#)): (a) No more tissue or fluid is removed than the amount needed to accomplish the medically indicated purpose of removal; and (b) the specimens are obtained by the researcher under conditions of anonymity (i.e., the diagnostic laboratory removes all personal identifiers before giving the specimens to the researcher).<sup>9</sup>

The practices just described are invasions of privacy. In such cases, patients are said to have a right of notice, that is, a right to be notified that such practices occur in the institution. These notices, which partially mitigate the invasion, are commonly printed in patient information brochures and on permission forms for surgery or autopsy. Although they are designed to afford patients opportunities to object, objections are rare. For examples of such notices, see [Levine \(1988, pp. 179–180\)](#).

In some cases, with suitable justification, even the right of notice may be waived. Examples of such activities include collections of cord blood from neonates under conditions of anonymity in a nationwide study to determine the prevalence of HIV antibodies ( [Levine, 1988](#)); monitoring for compliance in some randomized clinical trials ( [Levine, 1988](#)); and covert observation or recording of public behavior ( [Levine, 1988](#)). Further discussion of these activities and their justification is beyond the scope of this chapter. It must be noted that covert observation is a mild form of deception. In some cases even stronger forms of deception may be justified ( [American Psychological Association, 1982](#); [Levine, 1988](#)).

Researchers commonly use medical or laboratory records to identify patients who might be suitable subjects for their studies. Having identified them, they then contact them by telephone or mail with invitations to participate in research. Those who are contacted usually do not recall having read notices describing such activities in hospital brochures. Some will wonder why a stranger who knows his or her diagnosis is calling. Careful plans must be made to avoid offending patients in such activities ( [Levine, 1988](#)).

## CHILDREN AND PRIVACY

The concerns of young children about privacy are different from those of older children and adolescents ( [Thompson, 1990](#)). Young children first develop territorial privacy ("This is my room") and possessional privacy ("This is my tricycle") and only later begin to develop informational privacy (concerns about others' knowledge of one's activities, associations, and interests). Thus young children may not know that what they say to others may be detrimental to the privacy interests of their families.

DHHS regulations are responsive to this concern. There are several classes of research that are generally considered so free of complicated ethical problems that they are exempted from coverage by the regulations (45 CFR 46. 101b). Two of these exemptions do not apply to research involving children: (a) research involving survey or interview procedures; (b) research involving observation of public behavior in which the researcher is a participant. These activities are not exempt in cases in which they "could reasonably place the subject at risk of criminal or civil liability or be damaging to the subject's financial standing or employability."

Researchers often must secure the approval of various custodians of children to involve them in research. Such custodians may be teachers, day care workers, camp counselors, and the like. At times it is important to withhold or disguise some of the purposes of the research in order to protect the family's privacy or to avoid prejudicial treatment of children. For example, one would generally avoid telling teachers that the children are selected because they are offspring of parents with emotional disturbances.

As mentioned, informed consent requires "an explanation of the purpose of research." Does this mean that parents must always receive a full disclosure of purposes? Suppose the purpose is—as it was in one study—to determine whether little boys with XYY chromosome patterns are more likely than those with XY patterns to develop violent behavior. Disclosure of such a purpose could become a self-fulfilling prophecy. For further discussion of withholding the purpose of research and its justification, see [Levine \(1988, p. 117\)](#).

As mentioned earlier, the requirement for parental permission may be waived in "research designed to identify factors related to the incidence or treatment of certain conditions in adolescents for which . . . they may legally receive treatment without parental consent." In general, the types of activities contemplated by this rule are treatment of sexually transmitted diseases, provision of contraceptive advice, and other matters that teenagers consider highly sensitive. We recognize the teenager's right to privacy, but how far should we go to protect it? Some of the factors that require consideration are illustrated in the following exchange.

[Herceg-Baron \(1981\)](#) published a case study in which she detailed some of the special problems involved in research in the field of family planning involving minors as subjects. Many adolescents wish to seek advice about such matters as contraception without the awareness of such others as their parents. She details her institution's policy for protecting the minors' confidentiality. For instance, with regard to follow-up, investigators are required to offer various options, for example, telephone calls during certain hours when the minor knows she will be at home alone; contacts through school personnel such as nurses, teachers, or counselors; contacts by mail containing no agency letterhead or other identifying information; or leaving messages with friends.

In commenting on this case study, [Carol Levine \(1981\)](#) raises several concerns. First, she suggests that many adolescents are ambivalent about clandestine sex and would, with some encouragement, welcome open discussion with their parents. The great concern with privacy seems to undermine the possibility for what could be valuable communication within the family. Levine is further concerned about the fact that the institution not only approves deception, it collaborates with the adolescent in deceiving her parents. This, she argues, sets a very poor example for the adolescent.

This brings us back to a point discussed in the preceding. Parents are not the only adults having responsibility for guiding the child to become the "right kind of person." Professionals must be aware of the fact that children see them as models of proper behavior. Consciously or otherwise, they provide examples that children will emulate. Accordingly, they should be especially careful not to suggest by example that promises (e.g., of confidentiality), truthfulness, and other ethical matters discussed in this chapter are to be taken lightly. In short, they should help children understand the importance of showing respect for persons.

Portions of this chapter are excerpted or adapted from [Levine RJ: \*Ethics and Regulation of Clinical Research\*, 2nd ed. New Haven, CT, Yale University Press, 1988.](#) Used with permission of the publisher.

<sup>1</sup>For an authoritative commentary on these two exceptions, the reader is referred to Appendix 1 of the [President's Commission's report, Making Health Care Decisions, 1982](#), pp. 199–201. A more concise discussion may be found in [Levine \(1988, pp. 149–152\)](#).

<sup>2</sup>There are further conditions specified by FDA in its regulations. For further discussion of 21 CFR 50.23, see [Levine \(1988, pp. 150–152\)](#). For 21 CFR 50.24 see [Brody \(2000\)](#).

<sup>3</sup>The Department of Health and Human Services regulations also permit use of a "short form." Use of this form of documentation seems even more complicated and cumbersome than use of the standard consent form. Moreover, its use requires a witness to the consent discussion ( [Levine, 1988, pp. 134–135](#)).

<sup>4</sup>Such language is also forbidden in the consent discussion (45 CFR 46.116).

<sup>5</sup>The term minimal risk presents many problems. As it is defined, it may be interpreted in several different ways. For a discussion of its deficiencies, see [Levine \(1988, p. 65\)](#) and [Kopelman \(1981, 1985\)](#). For an excellent discussion relating the concept of risk to the child's level of development, see [Thompson \(1990\)](#).

<sup>6</sup>According to the [National Commission \(1977\)](#), a child with normal cognitive development becomes capable of meaningful assent at about the age of 7 years, although some may be younger and some older. The Department of Health and Human Services (DHHS) did not accept this recommendation. Rather, at the time the proposed regulations were published, DHHS solicited public comment on which of three options it should adopt for nontherapeutic procedures: either age 7, age 12, or leaving the age to the discretion of the IRB. The final regulations reflect the third of these options.

<sup>7</sup>What constitutes "minor increase" and "vital importance" is not defined in the regulations. Responsibility for deciding such matters in relation to particular research proposals is assigned to the IRB. If the IRB cannot decide or if it does decide that the degree of risk is more than a minor increase over minimal risk, it must refer the judgment to the Secretary of The Department of Health and Human Services ( [Levine, 1988, pp. 247–250](#)).

<sup>8</sup>A full discussion of these threats and devices is beyond the scope of this chapter. A treatment of these topics adequate for the purposes of most clinical researchers is found in [Levine \(1988\)](#). [Boruch and Cecil \(1979\)](#) provide an excellent general overview directed primarily at social scientists, with particular concentration on the development of statistical methods for making the responses of any particular subject uninterpretable even if the research records are subpoenaed.

<sup>9</sup>In some cases it may be impossible to remove identifiers, as when the patient's physician is also the researcher. In such cases the requirement for consent may be waived if the research will not yield any information having diagnostic significance. For further discussion of this point, see [Levine \(1988\)](#), pp. 178–181).

## OVERVIEW

Ethical codes in medicine date back to the fifth century BC, yet they received little attention in our medical literature until the 1990s. Greater awareness and interest in ethics can be attributed to (a) heightened consumerism with increased emphasis on patient rights, (b) high-technology medical developments that offer choices unheard of in the past and in turn introduce the need for health care rationing and decisions about prolonging life, and (c) changes in the delivery of health care that alter physician's autonomy, impose the role of gatekeeper, and challenge our traditional ethical codes.

Ethical codes are not laws but standards of conduct expected from a professional. They exist to help professionals to reconcile providing service while also earning a living from that service. In medicine, these codes define the norms, duties, and virtues expected in our professional work. As noted by [Reiser et al. \(1977\)](#), "Self-conscious reflection on standards of conduct is one of the defining characteristics of a profession." Ethical codes serve to protect the profession and benefit the patient and society as well. In maintaining the image and standard of conduct of the profession, they enable the patient to establish trust in the physician.

The Hippocratic Oath originated in the fifth century BC, but it was not widely applied until the 10th century. It stresses the physician's power to heal and the need to divest this power from killing. In doing so, as noted by Margaret Mead, the code clearly separates the physician from the sorcerer or shaman, who has the power both to harm and to cure ([Mead, 1972](#)). The Hippocratic Oath stresses the physician's obligation to the patient and the duty to keep confidences. It prohibits abortion, euthanasia, and sexual relationships with patients. [Dyer \(1988\)](#) notes that the hippocratic tradition has come under scrutiny by critics who contend that it is anachronistic. Critics argue that it does not deal with the technologic advances in medicine or with problems of cost containment. Many contend that it is too paternalistic and does not adequately address the rights of patients. [Dyer \(1988\)](#) recommends that we accept the oath "symbolically in terms of the intent and the concept of the profession it outlines."

Psychiatrists today follow the *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* (1993). These guidelines provide us with a way of thinking about ethical dilemmas, but they do not necessarily solve them. Often competing ethical principles come in conflict, such as a woman's right to autonomy and to refuse a cesarean section versus her physician's concern for the welfare of her fetus. To understand these ethical guidelines, it is helpful to appreciate the ethical principles that underlie them. The four basic moral principles that guide us in medical research and health care are analyzed in great detail by [Beauchamp and Childress \(1989\)](#) and are briefly summarized here. *Autonomy* comes from the Greek words for self and rule and in medicine refers to the ability to make decisions for oneself without being controlled by others. Autonomy becomes the basis for informed consent and therapeutic privilege. *Nonmaleficence* is a concept derived from the Latin "primum non nocere," or first do no harm, and it stems from the Hippocratic Oath, which states "I will use treatment to help the sick according to my ability and judgment, but I will never use it to injure or wrong them." The principle of *beneficence* refers to the obligation to help others to further their legitimate interests and, more specifically, to promote the welfare of the patient. The principle of *justice* refers to offering fair treatment to all.

## NATURE OF THE DOCTOR–PATIENT RELATIONSHIP

A *fiduciary relationship* is one in which one person receives the trust or confidence of another and is under a duty to act for the benefit of that person. Examples include an attorney–client or broker–client relationship. Trust is the cornerstone of the fiduciary relationship that exists between physician and patient. The physician as fiduciary is expected to act for the benefit of the patient and not exploit that relationship for personal gain. [Simon \(1987\)](#) reminds us that the psychiatrist's main source of gratification should arise from the psychotherapeutic process, and his or her only material reward is payment for service.

*Trust* is essential to both evaluation and treatment. Without trust, patients would be reluctant to divulge the intimate details about their lives that are often necessary to arrive at diagnoses and embark on treatment. The fiduciary relationship is less clear-cut in regard to children. Issues of trust and confidentiality are more complex in child and adolescent psychiatry because we must deal with parents as well as the child. Parents' rights to or need to know certain information about their child need to be balanced with the child's interests. Further, the age and cognitive maturity of the child have a bearing on the child's ability to participate in decisions about treatment or medication, as well as disclosures to others.

Doctor–patient relationships are also defined by *boundaries* that keep us in our professional role and prevent us from exploiting patients. Boundaries provide a sense of security to both physician and patient. They help us to maintain objectivity and allow us to focus on the patient's best interest. Boundaries discourage acting out by both patient and physician and foster respect for the patient's autonomy and dignity. The forces of both transference and countertransference threaten the therapist's neutrality and, if not recognized and resolved, may erode boundaries and undermine therapy. Straying from one's usual practices may be a warning sign of boundary violations. Psychiatrists who begin to see patients at unusual locales or times, who waive usual billing procedures, or who start socializing with patients and their families may be on a slippery slope. They need to reflect on that behavior and to consider the consequences, because seemingly benign boundary violations often lead to more serious ethical violations.

## CONFIDENTIALITY

The terms *confidentiality* and *privilege* are often confused. Privilege, the narrower of the two terms, refers only to the patient's right to bar disclosure of information obtained in treatment in judicial or quasijudicial proceedings. Confidentiality, in contrast, refers to the disclosure of information learned in treatment to third parties. The physician's duty to maintain confidentiality is both a legal and an ethical one that derives from the right to privacy under common law and our ethical codes. [Appelbaum and Gutheil \(1991\)](#) note that the ethical foundations for confidentiality are twofold. First is the concern that without assurance of confidentiality patients would be reluctant to seek treatment. Second is the argument that, having implied that communications are confidential, mental health professionals must keep their implicit or explicit promise.

Privilege and confidentiality can be waived only by the patient, with certain exceptions. Generally, these exceptions include when the patient is in danger of harming himself or herself or others, such as a sexually active patient who is positive for human immunodeficiency virus who refuses to take precautions or to inform sexual partners and state laws mandating reporting of child abuse or impaired physicians. However, exceptions continue to grow and now include insurance company audits, which usually call for blanket rather than informed consent to release records, and insurance fraud investigations involving either the psychiatrist or the patient ([Schetky, 2000](#)).

The psychiatrist may be faced with a moral dilemma when a subpoena demands patient records and their release is not in the best interest of that patient. The

psychiatrist's conscience must guide him or her whether to defy the law or seek to quash the subpoena. For discussion of the legal ramifications of breach of confidentiality and consent issues, see [Chapter 112](#) and [Chapter 113](#).

## Consent

Minors, with some exceptions, are not competent to give *consent* to treatment, to medical research, or for release of medical information, but they may be asked to give their assent in accord with their developmental age. Consent must be obtained from parents or guardians unless state law allows adolescents to consent to treatment or unless they are emancipated. For consent to be informed, parties must know the nature of the condition treated, the risks and benefits of the proposed treatment and their choices, and the risks of no treatment, and they should be free, that is, without undue influence, to agree or disagree. It is advisable to obtain consent in writing for high-risk treatments and for release of records. If parents are separated or divorced, consent must be obtained from the custodial parent. If the child is in a shared custody arrangement, the psychiatrist should attempt to contact the other parent regarding treatment decisions, because joint decision making on medical matters is usually part of shared custody arrangements. If one is in doubt about the terms of parental rights, one can always ask a parent to bring in the divorce decree.

The child and adolescent psychiatrist, perhaps more so than the adult psychiatrist, faces many pressures to violate confidentiality owing to all the collateral contacts that arise during our work with children. These include parents, teachers, guidance counselors, other therapists involved with the family, day care providers, the child's physician, and sometimes personnel from protective services or other agencies. Even when there is consent for release of information, the psychiatrist must delicately balance how much information a school needs to know about a child's turbulent family life to help a child while respecting the family's wish for privacy. The child and adolescent psychiatrist may need to decide when it is necessary to override a child's plea not to disclose certain information such as speaking to a teacher when parents have authorized such communication. The following case illustrates the many levels at which we must weigh decisions about confidentiality.

---

### CASE ILLUSTRATION

Sally Barnes, age 8 years, has been in treatment for an anxiety disorder that waxes and wanes. She lives with her recently widowed mother and younger sister. One day, she is brought to her weekly appointment by her grandmother and tells her therapist, Dr. Coles, that her mother is home sick with the flu. Sally then reveals that her mother was drinking excessively the night before at a friend's house and drove Sally and her sister home while under the influence of alcohol. Sally heard her mother vomiting during the night, and in the morning her mother was so sick that she asked Sally to stay home to care for her little sister. Dr. Coles is faced with the issues of (a) using Sally's disclosures to confront Mrs. Barnes, (b) whether to share concerns with Sally's grandmother, (c) whether to contact Mrs. Barnes' therapist, and (d) whether to involve protective services. She chooses to say nothing to the grandmother because she does not have the mother's permission to speak with her. Sally is eager for her therapist to talk to her mother. Dr. Coles calls Mrs. Barnes, who initially denies the allegations made by Sally but who then backs down and agrees to allow Dr. Coles to contact her therapist. Later, she admits that things are very out of control in her life, agrees to an inpatient admission, and approaches her mother to help care for the children. Dr. Coles does not feel the need to involve protective services at this juncture. The question of how much to tell the school and day care is discussed with Mrs. Barnes and is left to her discretion. Sally may have been afraid that Dr. Coles would speak to her mother about her drinking problem. In that case, she would have had to deal with Sally's fear around disclosing this secret and her rationale for overriding Sally's objections in taking the steps she did to ensure her welfare.

---

## Limits of Confidentiality

Child psychiatrists need to define to both patient and parents the *limits of confidentiality* at the onset of evaluation and treatment. The extent to which communications from parent to therapist will be shared with the child should be discussed. If the psychiatrist needs to share the child's confidences with the parents, there are several options. The first is to urge the child to do so or to meet jointly and discuss the issues. If this fails, the psychiatrist may then tell the child why he or she needs to share the information with the parents and what will be told.

In small, underserved communities, the psychiatrist may, like it or not, have to medicate and sometimes treat more than one family member or friends of patients. This poses a challenge to the psychiatrist in terms of double bookkeeping, that is, remembering what information was heard from whom and storing away what may have been heard but cannot be used because it was shared in confidence. Additional problems may arise around advocacy and issues of countertransference. In general, dual agency such as this is best avoided. If no alternatives exist, the psychiatrist should at least make each patient from the same family aware that he or she is seeing the other.

## Double Agency

*Double agency* is a term that refers to serving two masters simultaneously. This is a potential problem that may arise from consultants when they are not clear about their roles. For instance, an adolescent may reveal to a consulting psychiatrist that he or she is dealing drugs in school. If the psychiatrist shares this information with the school, the student is likely to be expelled. If he or she conceals this information, other students are at risk. The consultant needs to be clear that his or her duty is to the school, which hired him or her. The dilemma could be minimized by informing the student at the onset of the evaluation about the limits of confidentiality.

Double agency may also arise when a therapist pursues the parents' agenda without regard to the child's best interests. For instance, Mr. and Mrs. Black seek help from Dr. White in regard to their 14-year-old son, Tom. They complain that he is defiant, questions his father, talks back, and refuses to attend services at their fundamentalist church. They hope that Dr. White will render Tom more compliant and will bring back their "good little boy." If Dr. White colludes with their agenda, he risks becoming their agent. Tom, conversely, does not see that he needs help other than using Dr. White's authority to get his parents off his back so he can gain more freedom. An overidentified therapist could be tempted to collude with Tom's agenda. Dr. White empathizes with Tom's plight but views his role as helping Tom to separate and individuate from his family and to develop responsible autonomy. Unless he spells out where he stands with the family, therapy is not likely to succeed.

## Media

Child and adolescent psychiatrists need to be on guard against violating confidences when giving press interviews. It is usually prudent to be circumspect and to limit comments to what is already public knowledge and to comment on issues rather than specifics of a case. Parents may give consent for a therapist to talk with the media about their children in high-profile custody and abuse cases. There is an unfortunate trend to try these cases in the media. Parents who are caught up in the heat of litigation are not always the best judges about whether media attention will be harmful to their children.

The psychiatrist needs to guard against exploiting high-profile cases for his or her own personal gain. Occasionally, psychiatrists may be tempted to go above the law and try to justify rash actions such as releasing confidential reports to the media as being in the child's best interests. Rarely can such actions be justified, and when closely examined they usually represent grandiosity, narcissism, and unchecked countertransference on the part of the psychiatrist.

## Professional Presentations and Publications

Confidentiality must be preserved when psychiatrists write about patients or present them or their artwork at conferences. One has the choice of disguising material sufficiently to preserve the patient's identity or seeking permission from the child and his or her parents to use the material. Therapists may be tempted to write books about their patients. It is difficult to reconcile this with keeping the patient's interests foremost, and such an agenda is likely to derail therapy. Literary exploitation of therapy in the mass media is unsettling to the public and does not promote trust in our profession. Even if this occurs with the patient's consent, questions may be raised about how informed the consent was, as in the case of author, Anne Sexton, whose psychiatrist released therapy tapes to her biographer after Sexton's death.

## Dual Relationships

*Dual relationships* pose a challenge to maintaining confidentiality. Anyone practicing near where they live or whose children attend the same school as their patients do is bound to encounter awkward situations. The child psychiatrist's children are unaware of who is or is not a patient of their parent. They may wish to invite patients to birthday parties, play at their homes, or share car pools. As the child psychiatrist's children grow older, attend larger schools, and engage in more extracurricular activities, it becomes increasingly difficult to screen patients for their potential ties to one's children. In small towns, one may end up evaluating or treating children of one's colleagues or one's children's teachers or future teachers. If there are no other resources, turning down requests for help in times of crises may be viewed as inhumane and does not help one's image. How well these dual relationships work often depends on the nature of the patient's disorder, the extent of family psychopathology, and the therapist's ability to maintain boundaries. Each new adult patient or parent of a child patient should be viewed as one less potential friend. The two-way give and take of friendships cannot exist in therapy, because the therapist may not use the relationship for his or her own personal needs. It may be necessary to explain this to certain families at the onset of one's professional involvement with them.

The longer one is in practice, the more likely one is to run into patients all over town. The psychiatrist may need to patronize parents of patients, be they shop owners, pharmacists, plumbers, or restaurant owners. Adult patients and patients' parents may be appointed to boards one sits on or may join one's organizations. The child and adolescent psychiatrist either learns to deal with these encounters or retreats to the high ground and becomes a recluse. There is much to be said for patients' seeing their psychiatrists as a real person, whether at the dump on a Saturday morning or at the local high school basketball game. Successfully negotiating these encounters requires that the psychiatrist to be comfortable with his or her public persona, process these encounters, and maintain boundaries and confidentiality. In assessing how to address patients in public, one learns to take cues from patients. Children may be unabashed about seeing their therapist in the supermarket, whereas their parents may be less comfortable. Teenagers may shirk from public contact or may surprise you by wanting to introduce their friends.

### Psychiatrist's Family

One learns to train family members (and friends) not to ask "How do you know so and so?" Some psychiatrists develop nonverbal cues with spouses for handling awkward social situations. Should the psychiatrist's child learn the identity of a patient, he or she must appreciate that it is the patient's choice whether to disclose the psychiatrist-patient relationship. In some communities, children may be quite comfortable telling another child that he or she is a patient of their parent. Conversely, I have had to curb my son's one-time enthusiasm for trying to refer classmates whom he thought were in need of help. Adult patients may deliberately attempt to become friends with their therapist's spouse, and this becomes awkward if the professional relationship is not known to the spouse. The therapist may have to intervene with the patient in such situations.

### FORENSIC ISSUES

*Forensic evaluations* differ from regular diagnostic evaluations in that their intent is not therapeutic. Forensic evaluations are intended to help the court to find the truth and address the legal question at hand. To do so, the forensic psychiatrist must strive for impartiality and must avoid cases in which prior ties, be they social or professional, could tinge objectivity or neutrality. Whenever possible, forensic examinations should be separated from treatment ( [Schetky, 2001](#); [Strasburger et al., 1997](#)). Therapists inevitably become advocates for their patients, and, in doing so, they may be less than objective. Furthermore, they rely on narrative rather than on historical truth and usually do not seek out the type of corroborative material relied on by the forensic psychiatrist. Another reason to avoid such a dual relationship is that confidentiality is compromised once the therapist has to testify in court. Some attorneys may try to draw therapists into child custody battles or may try to persuade them to change their opinions. These issues are discussed extensively by Gutheil and Simon (1999). The forensic psychiatrist needs to be clear from the start with families who have retained him or her and must discuss the limits of confidentiality. It is not an unusual ploy for a parent to attempt to suppress an unfavorable custody report by stating that she went to the psychiatrist for therapy and that the therapist is therefore violating her confidences. When court appointed, the child psychiatrist may operate with quasijudicial immunity, which protects the psychiatrist from liability, whereas protection from liability is less certain in other situations.

The forensic psychiatrist should request payment up front in the form of a retainer. This approach ensures payment, makes clear that one is being paid for one's time rather than for one's opinion, and lessens the possibility of bias. It is customary to charge more for forensic evaluations, because they require more expertise and can be very disruptive to one's practice. It is always unethical to accept a case on a contingency fee because this creates too much vested interest in the outcome of the case.

Psychiatrists who practice forensic psychiatry need to accept the limits of their experience, not inflate credentials, and avoid exceeding data bases and making unsubstantiated statements. For further discussion of the pitfalls in these cases, see Schetky ( [1998](#), [2001](#)).

Forensic psychiatrists who perform assessments out of their own state should be aware that many states now require licensure for this activity. This is a result of the AMA's decision that forensic psychiatry constitutes the practice of medicine. Failure to address local licensure requirements may result in not being allowed to testify, as well as possible civil or criminal liability ( [Simon and Shuman, 1999](#)).

### DEALING WITH THIRD-PARTY PAYERS

The disadvantage of private practice is having to deal with third-party payers and paperwork. With the advent of managed care, telephone trees and voice mail, and the need for prior authorizations and written treatment plans, the task has become even more time consuming and distasteful. Ethical dilemmas arise when the patient's best interests and the psychiatrist's wish to be paid conflict with insurance companies' interest in minimizing cash outflow. This creates temptations on all sides to engage in unethical behaviors.

Insurance companies may deliberately lose or destroy claims, may reject claims for spurious reasons, or may endlessly "research" disputed claims as a delaying tactic. Noncustodial parents may pocket insurance payments. Patients or parents may request that diagnoses or codes be altered out of concerns about confidentiality or so they can receive better reimbursement. The psychiatrist may be tempted to exaggerate the patient's condition to have needed services approved or to obtain higher reimbursement rates. There may be the temptation to alter dates of service, as when Medicaid will not pay for a parent visit on the same day the child is seen, regardless of how far they have traveled. A similar problem arises when only one psychiatric visit is allowed per day, even if the patient needs admission after an outpatient visit. Physicians may be tempted to exaggerate duration of visits to compensate for low rates of reimbursement. Regardless of one's motives, these practices are fraudulent and, as such, are subject to criminal prosecution. The psychiatrist who engages in fraud may also be subject to ethical investigations and sanctions.

With the advent of health care rationing and a profit motive for managed-care companies, serious concerns arise around who is responsible for the patient once a managed-care company decides that it will no longer pay for hospitalization or authorize further outpatient visits ( [Appelbaum, 1997](#)). Little regard is given to the impact on patients of forcing them to change therapists because their managed-care company changes as a result of a job change or a takeover of a managed-care organization. What are the ethics of managed-care companies that direct children of their subscribers to providers who lack adequate training in child therapy? Managed care further disrupts a practitioner's referral patterns if he or she is restricted to obtaining consultations from a list of providers in a particular managed-care company. Additional concerns arise over confidentiality as it becomes necessary to share more and more information about patients to justify ongoing treatment. Of particular concern are the blanket consent forms authorizing release of medical information that subscribers are expected to sign when they become insured by private health care companies, Medicaid, or Medicare. This sort of consent is not informed because the subscriber does not know or cannot anticipate what may be in the records being released. Physicians who refuse to release requested information may be penalized by the withholding of reimbursement or even recoupment notices regarding prior payments.

Managed care pressures physicians to become gatekeepers and to consider not only the patient's needs but society's needs as well when it comes to allocation of health resources. [Levinsky \(1984\)](#) reminds us that this is an untenable position, and "physicians are required to do everything that they believe may benefit each patient without regard to costs or other societal considerations."

### REPORTING ETHICAL VIOLATIONS

The AMA *Principles of Medical Ethics*, section 2, states "A physician shall deal honestly with patients and colleagues and strive to expose those physicians deficient in character or competence, or who engage in fraud or deception." Reporting a colleague is a most unpleasant experience yet necessary to maintain the welfare of patients and the credibility of our profession. Ethical complaints may be filed with the district branch of the American Psychiatric Association (APA), with local medical societies, or with state licensing boards. Complaints are handled confidentially. Where appropriate, the psychiatrist should urge patients to file a complaint. If an ethical violation is confirmed by the APA, there are four possible sanctions, ranging from admonishment or reprimand to suspension or expulsion from the APA. The defendant psychiatrist is entitled to appeal.

Reports of possible ethical violations may be based on our own observations, disclosures from patients, or extrinsic evidence. The psychiatrist may be reluctant to believe allegations by a patient, particularly if they involve sexual misconduct by a colleague known to the psychiatrist. The patient may feel protective of the abusing therapist or fearful of the investigation process and may not wish to disclose. The treating psychiatrist may be reluctant to act contrary to his patient's wishes. Anonymous complaints by therapist or physician usually cannot be investigated. The APA Council on Ethical and Judicial Affairs ( [American Psychiatric Association, 1991](#)) believes that physicians must report sexual misconduct to the appropriate authorities. One should also be aware of state laws regarding the reporting of an impaired physician or one involved in abusive behavior.

Reports based on extrinsic evidence pertain to information a psychiatrist may have read in a newspaper or an event based on a legal fact, such as when a psychiatrist adopts a patient. Filing a complaint allows the ethics committee to further look into the matter. Extrinsic evidence may also be used to bypass an ethics hearing if the facts speak for themselves.

## SUMMARY

Child and adolescent psychiatrists need to familiarize themselves with the ethical codes that govern their practices. They should not be pressured by patients or insurance companies into acting in ways contrary to the patient's interests or our code of ethics, nor should they exploit insurance companies for their own financial gain. If in doubt as to whether a certain behavior is ethical, child and adolescent psychiatrists may refer to AACAP: *Annotations to AACAP Ethics Code* (1995) or consult with the ethics committee of the American Association of Children and Adolescent Psychiatrists or their APA district branch ethics committee.

## Appendix: Principles of Practice of Child Psychiatry

---

A child or adolescent and the family may expect the child psychiatrist to

Have as primary concerns the welfare and the optimal development of the individual child or adolescent assessed in the context of the family, school, and community based on scientific knowledge and collective and personal experience;

Foster the unique and nurturing relationship among the child or adolescent and the parents or caretakers and the family;

Recognize the child's or adolescent's need for the support of adults;

Avoid all actions that may have a detrimental effect on the optimal development of the child;

Use his or her unique relationship with the child or adolescent and family to foster their well-being and optimal development;

Promote, by all appropriate means, the uniqueness of the individual;

Seek to develop with the child or adolescent as thorough an understanding as possible of the child psychiatrist's role, opinions, conclusions, and recommendations;

Protect specific confidences of the child or adolescent and the parents or guardians and others involved, unless this course would involve untenable risks or jeopardize caretaking responsibility;

Seek to develop with those involved in the care or treatment of the child or adolescent (parents or guardians, and, when appropriate, the family, teacher and school, court or correctional agency, physician, and others) as thorough an understanding as possible of the child psychiatrist's role, opinions, conclusions, and recommendations;

Help the child or adolescent to recognize the influence of his or her own relationship with family members and the consequences of his or her decisions;

Help family members to resolve differences in their views of professional judgments or recommendations;

Avoid acting solely as an agent of the parents, guardians, or agencies;

Maintain the integrity of professional judgments and behaviors independent of influence of the source of compensation.

## 133 HISTORY OF CHILD PSYCHIATRY

David F. Musto, M.A., M.D.

---

[Origins of Child Psychiatry in Some Other Nations](#)

[United Kingdom](#)

[Sweden](#)

[Germany](#)

[Conclusion](#)

[Chapter References](#)

In order for the field of child psychiatry to exist, there first had to be the separation of childhood and adolescence from the remainder of the life span. Although infants and toddlers have usually been seen as separate from adults, the appreciation of childhood with characteristic stages emerging into adolescence and youth is a modern achievement. Especially in the 19th and early 20th centuries, the first score years of the life span took on great interest and stimulated extensive study.

Psychiatry itself is a recent profession. From superintendents of mental hospitals and the occasional alienist in private practice in the 19th century, a new medical specialty slowly emerged. In 1934, the American Board of Neurology and Psychiatry began certifying practitioners, and about this time, a few physicians in America and Europe started using the words “child psychiatry” to denote their specialty. Nevertheless, psychiatry remained a small profession through World War II.

Although child psychiatry did not flourish until after World War II, its roots are much more extensive. These fall into two broad categories, study of the normative development of children and investigation of various abnormalities that may affect children. Often, these two streams of research have paid little attention to one another, although in recent decades their topics of study have drawn closer together.

An example of systematic investigation of normal development is the work of G. Stanley Hall (1844–1924), an early psychologist who received his doctorate under William James (1878) and later helped to found the American Psychological Association (1891), for which he served as its first president. Hall's interest was in education and in the nature of the normal child. His leadership among educators led to his selection as the first president of Clark University, in Worcester, Massachusetts (1888). There he immediately created a center for the study of child psychology—said to be the first in the nation—gathered coworkers and instituted intensive surveys of child development. Much of his work was published in journals he had founded: the *American Journal of Psychology*, the *Pedagogical Seminary*, and the *Journal of Applied Psychology*. This whole process was termed the *child study movement* and progressed in part through questionnaires distributed to teachers, students, and parents. From them he sought to learn the characteristics of children at various ages, how they learned, and what they typically knew. The topics ranged from “the teaching instinct” to “anger” ( [Ross, 1972](#)). Out of such studies came ideas that prefigured more recent research such as that on the moral development of children. In 1894, Margaret E. Schallenberger concluded from questionnaires that the child shifts from a morality of consequences to a morality of intention at about age 9, a finding similar to much more recent investigations ( [Siegel and White, 1982](#)).

Perhaps because of Hall's close association with educators, the child study movement had its greatest impact on the teaching profession, not among academics and professional psychologists. The concept of child development with its stages and unfolding competencies enhanced the role of teachers as experts in instruction. Ironically, schools of education pay little attention today to the psychology of child development; its reintroduction through such innovations as the Comer School Project is seen as breaking new ground ( [Comer, 1993](#)).

Hall had what we could now call a romantic view of child development, because he believed that the progression from child to adult recapitulated the history of mankind. Adolescence, for example, represented the “heroic age.” Hall popularized the term *adolescence*, and his fascination with that stage of life is demonstrated by the hefty two-volume work *Adolescence*, published in 1904 ( [Hall, 1904](#)).

Why were the teenage years so important in the late 19th century? Certainly a major reason is that the need for an educated workforce pushed the common endpoint for education from the eighth to the 12th grade. With the proliferation of high schools came a need to direct the legions of nonworking youth into acceptable paths. Where better to turn for advice on rearing this crucial generation than to experts like Hall? Advice and guidance, however, were not aimed solely at adolescents; younger children also could benefit from scientific training. During the first two decades of the 20th century, the Boy Scout and Girl Scout movements took hold, stressing practical and moral education. The child study movement proclaimed an ideal path of development that merged with the “Americanization” campaign directed especially at the growing numbers of new immigrants. In the swirl of this development, the public school was the linchpin that connected the youth movements and the reeducation of the latest Americans.

Sigmund Freud (1856–1939), who influenced child psychiatry profoundly, came from a direction opposite to that of Hall. Unlike Hall, Freud was a physician who studied pathology to illuminate normality, as Virchow had done in the study of organic disease in mid-19th century. Freud postulated certain phases of development from the psychoanalysis of adults. His one case study of a child, *Little Hans* (1909), illustrated the oedipal complex but, because he treated Hans through the father, Freud did not have contact with the boy ( [Freud, 1955–1972](#)). Primary psychoanalytic contact with children rather than adults characterized the career of Freud's daughter Anna, who extended her father's theoretical work. She also established for children a clinic near London that trained child psychiatrists and child psychoanalysts ( [Young-Bruehl, 1988](#)).

The concepts of psychoanalysis reached the United States through several routes. Freud himself was invited to Clark University's 25th anniversary in 1909, when Hall conferred on him an honorary doctorate, the only one he was ever to receive. This brief visit helped to spur an interest in psychoanalysis. Later, Freud's biographer Ernest Jones toured the United States extensively and advocated the new treatment's value. Americans picked up the importance of childhood events in forming adult character and looked to psychoanalysis to undo the damage early experiences may have caused. To estimate the power of psychoanalysis so highly was characteristically American, and it reflected an optimism that any barrier, including the psychological, could be overcome with the right technology ( [Burnham, 1967](#)).

Representative of this sanguine outlook is William Healy, a Chicago neurologist who, in 1909, established the Juvenile Psychopathic Institute to advise the courts on the psychology of arrestees. Healy had been persuaded to undertake this innovative role by several prominent Chicago women: Jane Addams, later awarded the Nobel Prize for Peace; Julia Lathrop, later the first head of the U.S. Children's Bureau (1912); and Ethel S. Dummer, a philanthropic activist. Healy strongly opposed the organic explanation of antisocial behavior; he found the answer in the environment from which the child offender emerged. He was optimistic because he believed the environment could be fixed, whereas biological defects seemed irreversible.

In 1917, Healy and his associate (and later his spouse) Augusta F. Bronner, a psychologist, were lured away from Chicago to Boston where they were given treatment facilities by the new Judge Baker Foundation. The lack of such facilities in Chicago had frustrated Healy, who was not satisfied with just supplying the court with an offender's diagnosis.

Healy was one of several prominent scholars and therapists who believed that the new dynamic psychology, chiefly psychoanalysis, provided a powerful tool for attacking the root causes of criminal behavior. Using the term *orthopsychiatry* to describe what we would now call child psychiatry, Karl H. Menninger brought together in 1923 a group of psychiatrists concerned with youthful offenders. Thus in 1924 was born the American Orthopsychiatric Association, with William Healy as its first president. This association, with annual meetings, a journal, and active representation to other social institutions, further focused attention on treatment of childhood disorders and helped to lead to the separation of child psychiatry from general or adult psychiatry ( [Musto, 1975](#)).

Inspired by Healy's Chicago and Boston clinics, a new kind of institution, the child guidance clinic, came into being in 1921 with the support of the Commonwealth Fund. These clinics had at their core a team approach: a psychiatrist who dealt with the patient, a psychologist who tested the patient, and a social worker who worked with the remainder of the family. The importance attributed to this style of care is shown by the rules for membership in American Orthopsychiatric Association, which by 1930 mandated that a member had to work in a clinic with the team approach.

While the child guidance clinics multiplied in the 1920s, theories of child development, advocated by able partisans on all sides, clashed; parents tried to decide

which philosophy to follow. John B. Watson, a proponent of behaviorism, powerfully influenced the U.S. Children's Bureau which made available millions of pamphlets on child rearing. Parents learned from these publications that rigid feeding schedules conditioned the infants properly and could be part of a larger conditioning program that would bring out the best in the child. Watson had no use for concepts like the unconscious; to him, inculcation of proper behavior would come from unyielding conditioning, with the proper stimulus eliciting the proper response. In other words, the parents' job was to mold the child's malleable mind ( [Kessen, 1965](#)). Rejecting this assumption was Arnold Gesell, a student of G. Stanley Hall who established a psychoclinic at the Yale Dispensary in New Haven, Connecticut in 1911. Like Hall, Gesell saw human life unfolding from inborn biological givens. Parents should be supportive, but the child's development would progress in a regular pattern unless the parents interfered too much. There was no need for rigid conditioning. Elaborate still and motion pictures of infants and children helped Gesell to compile atlases of development. Parents used these guides to assure themselves that their children were progressing normally and to anticipate the next stage of growth ( [Gesell, 1952](#)).

Gesell's psychoclinic grew into the Yale Clinic of Child Development and eventually, under the leadership of Milton Senn, the Yale Child Study Center. The shift from Gesell to Senn, a psychoanalytically inclined pediatrician, illustrates the great change in attitude that followed the era of biological determinism. Senn and many like him stressed a more optimistic faith in environmental causes of childhood disorder. In the tradition of Healy, reform of the child's environment and social improvement generally, including the problems of racism, poverty, and lack of education, became targets. A new emphasis by society on childhood, even if this focus was late and fell short of need, attracted persons who would otherwise have become adult or general psychiatrists.

If one were to search for a key event in the rise of child psychiatry in the United States, it could well be Adolph Meyer's appointment of Leo Kanner to be liaison between pediatrics and psychiatry at the Johns Hopkins Hospital in Baltimore. Meyer's decision had a salutary effect on the attitude of each field toward the other. Kanner termed himself a child psychiatrist and within 5 years published the first American text on child psychiatry ( [Kanner, 1935](#)). He is also the pioneer observer of what he called autism ( [Kanner, 1952](#)).

Pediatrics proved an excellent field from which to draw child psychiatrists. The Commonwealth Fund in 1937 began awarding fellowships to pediatricians for the study of psychiatry. The training program had not been established without debate, but major child guidance clinics and a few medical schools provided what was then available for the new field. The choice of pediatricians followed more than a decade of supporting psychiatrists. In 1922, the Commonwealth Fund and, in 1924, the Rockefeller Foundation had begun providing fellowships for psychiatrists. It was not unusual for psychiatrists to enter psychoanalytic training as well as improve their pediatric skills.

Out of the clinics the first formal training program for child psychiatrists evolved. Clinic directors began discussions in 1940, shortly before the United States entered World War II, that led to a new organization. The war slowed their efforts, but in 1945 they established the American Association of Psychiatric Clinics for Children. In 1947, this association set out formal guidelines for training in child psychiatry. A person could complete the training and could practice as a child psychiatrist, but there was still no accreditation. The physician could be a board certified psychiatrist or pediatrician, but not a certified child psychiatrist. Achieving the high standards of certification became a goal of the slowly growing profession.

In 1953, the American Academy of Child Psychiatry was formed, at first composed of only the highest ranking academics. By 1957, the academy's existence encouraged the American Board of Psychiatry and Neurology to establish child psychiatry as a subspecialty and to establish training standards for child psychiatry ( [Schowalter, 2000](#)). Gradually, the Academy has expanded so now it counts as members most child psychiatrists.

Since the 1970s, child psychiatry has had a burst of accomplishment in epidemiology, genetics, and biochemical studies and the gradual improvement in definition and course of autism, Asperger's syndrome, and attention deficit disorder. An important event that allowed progress in epidemiology was the appearance of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* and the 10th edition of the *International Classification of Diseases*, which established a common international language for child psychiatrists ( [Chapter 39](#)). New publications set forth the explosion in child psychiatric research. The American Academy of Child and Adolescent Psychiatry, for example, in 1962 inaugurated its journal to transmit this current and voluminous research to the profession.

Even, however, as advances in child psychiatry reached unprecedented levels, in the United States the actual delivery of services to child and families in need collided with the cost-cutting restrictions of for-profit health maintenance organizations. Under a managed-care system, these organizations have imposed limitations on the kind and extent of services at the very time that child psychiatry has more to offer than ever before.

## ORIGINS OF CHILD PSYCHIATRY IN SOME OTHER NATIONS

### United Kingdom

Children's psychological abnormalities attracted some attention in 19th-century England. As reflected in Maudsley's 1867 textbook *The Physiology and Pathology of Mind*, which devoted a chapter to "the insanity of early life" ( [Maudsley, 1867](#)), childhood study there grew more intensive and more common around 1900 with child study research similar to Hall's in the United States. With the advent of psychoanalysis, an opportunity arrived when the various strands and professions concerned with children could be drawn together in the Child Guidance Movement. Supported by the Commonwealth Fund, which had underwritten the American clinics, training was made available to British therapists in the 1920s. Emanuel Miller opened the first clinic in East London, and then the London County Council established one. By 1944, there were 95 clinics ( [Wardle, 1991](#)). According to W. Parry-Jones, "Child Guidance Clinics created a model of inter-disciplinary collaboration by psychologists, psychiatric social workers and psychiatrists" ( [Parry-Jones, 1989](#)). One area in which collaboration failed was the creation of a common psychoanalytic training for child therapists: a theoretical split between Anna Freud and Melanie Klein had led to two separate training programs ( [King and Steiner, 1991](#)).

After World War II, the United Kingdom established the National Health Service, which mandated regional planning and the growth of inpatient services for children and adolescents. This system's influence on care was not without controversy. Public pressure mediated through the structures of the National Health System led Wardle to complain that "children and their services have been prey to *causes célèbres*, fashion and exaggerated fads and foibles of the media and politicians" ( [Wardle, 1991](#)). Although service policies may have been controversial, Britain significantly contributed to the understanding of childhood and its vicissitudes through the work of Bowlby, Rutter, Winnicott, and others ( [Bowlby, 1969-1977](#); [Rutter et al., 1970](#); [Winnicott, 1965](#)).

### Sweden

Sweden's early interest in childhood is exemplified by the 1845 appointment of the world's first university chair in pediatrics. During the period from 1900 to 1950, Sweden instituted mental health services for children in hospitals, public schools, and child guidance clinics, although services leaned more toward pediatrics than psychiatry. As early as 1915, prominent pediatricians such as Isak Jundell argued for the creation of a new discipline that would deal with the behavioral and emotional problems of children. In 1951, child and adolescent psychiatry became a separate discipline. Sven Ahnsjö, who came from a background in genetics, held the first chair of child and adolescent psychiatry ( [Rydellius, 1995](#)).

More recently, attention has focused on a program of eugenic sterilization conducted between 1935 and 1975. More than 60,000 Swedes (mostly women) were sterilized to improve the quality of Swedish society. This biological basis for dealing with extreme and condemned behavior had its origins going back as early as 1921, when the Institute of Racial Biology was established. In 2000, one of the physicians who had performed sterilizing operations explained: "We were thinking about the children," a demonstration of childhood's symbolic power to justify extreme measures ( [Boyes, 2000](#)).

### Germany

In general, German approaches toward childhood disorders have been organically based since the 19th century and have never been so widely accepting of psychoanalytic theory as in the United States. Serious attention to what is now embraced in child psychiatry can be found in such pioneering works as *Die Psychischen Störungen des Kindersalters* (Psychic Disturbances in Childhood) by H. Emminghaus in 1887. Perhaps because of the emphasis on organic causation, the eugenics movement, as in Sweden, pre-World War II United States, and other nations, had a great appeal. A desire to improve the quality of citizens stimulated legislation to sterilize criminals, feeble-minded persons, and the insane. U.S. Supreme Court Justice Oliver Wendell Holmes captured the attitude supporting eugenics when he declared, in a decision upholding the state's power to sterilize, "Three generations of imbeciles are enough" (*Buck v. Bell, 1927*) ( [Lewis et al., 1999](#)).

The rise of National Socialism and Adolf Hitler changed the German eugenics program into one that eliminated persons thought to be undesirable. It is estimated that 300,000 psychiatric patients were killed during the Nazi era ( [Peters, 1999](#)). Leading professors of psychiatry were replaced with Nazi adherents; anyone who was Jewish or who had a Jewish spouse was removed. Overall, the Nazi era interfered with investigations and progress in child psychiatry because appointments to head

departments and institutes had as their primary criterion an adherence to the racial ideology of National Socialism. Along with the rise of National Socialism came the exodus of German physicians and scientists, in most cases of Jewish origin, to other nations. In 1921, Prof. Karl Bonhoeffer had opened the Department of Child Neuropsychiatry at Berlin, and it is probably there that the most sustained research continued until his retirement in 1938. Since World War II, German child psychiatrists have formed new societies, reinvigorated research centers, and, once again, have achieved a high international standing.

## CONCLUSION

In many nations during the 20th century, child psychiatry alternated between two major phases: belief in the environment as the crucial determinant for child development and adult maturation, and a faith in an organic or biological basis for behavior. These positions have taken hold with astounding depths of conviction and have led to extreme measures such as massive sterilization and euthanasia in the hope of improving the next generation of children.

Once again, we have entered an era of growing faith in biological determinism. The human genome is in the process of being unraveled and characterized. As we move toward improving life through biological discovery, we must keep in mind the history of exclusive faith in biology and the temptation to act against individuals under the guise of purifying mankind. The early days of a new approach to understanding behavior have always been thrilling and filled with a sense of release from ties and restraints of the past. Such enthusiasm accepts few antidotes, but an appreciation of history tends to temper judgment.
